For an initial length $P - 2$, predict new slots needed after growth by one, three, and $P + 3$ elements in separate replays. Calculate payload initialization bytes and table changes. List which old slots and generations must remain unchanged. Predict peak provisional ownership while preparing a multi-page growth. If the pool cannot supply the complete request, specify the unchanged length, table, and values that rejection must preserve.

Part 4 - Experimental Design and Instrumentation

Use a deterministic append trace crossing multiple boundaries. Record old handles and checksums before each growth, then verify the entire prefix and newly exposed region afterward. Test zero growth, invalid negative growth, integer overflow, tail-only growth, and capacity rejection. Keep a separate reference implementation that reconstructs a dense object on every append, and compare complete cost while acknowledging that the two representations provide different operator interfaces. Do not expose uninitialized tail bytes as valid user data.

Choose newly exposed values from an append counter so tail-only growth cannot accidentally pass using old padding contents. Capture a scalar snapshot of the old mapping handles before preparation. If table growth allocates new metadata storage, report its transient coexistence with the old version. Keep previously issued consumer leases valid or reject concurrent growth under the initial serialized contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
```

```
class GrowablePagedObject:
    def plan_growth(self, new_length):
        # Count tail exposure, new pages, metadata, and provisional capacity.
        ...

    def grow(self, new_length, initialization_policy):
        # Prepare dependencies and publish length/table coherently.
        ...

    def audit_prefix(self, previous_state):
        # Confirm original payload handles and values remain valid.
        ...

def E10(config):
    # Test boundary growth, initialization, and failure atomicity.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report old payload copies separately from new-element initialization and metadata movement. A claim of no copying applies only to preserved payloads, not to all work in the operation. Verify rejection leaves no leaked provisional pages. Benchmark after deliberate CUDA completion and reset peaks for the specified region. If growth shares a tail with another object in later extensions, require copy-on-write before modifying that shared page.

Verify prefix preservation after several growth and shrink cycles, not only a single append. A stable tensor pointer by itself does not prove the prefix was not overwritten; compare both identity and content. For an admission failure, inspect the provisional free list and ensure the next unrelated allocation can still use every legitimately free slot.

Part 7 - Engineering Interpretation and Philosophy

Explain when stable page payloads help incremental workloads and when indirection or a dense materialization remains expensive. State the exact stability guarantee that downstream consumers may rely on, including the conditions that invalidate previously obtained views or table snapshots.

19.35.12 Exercise 11

Exercise Title: Shrink a Logical Tensor and Return Only Its Unused Physical Pages to the Shared Free-Page Pool

Part 1 - Exercise Contract and Why It Matters

Shrink a logical object and return only wholly unused pages to the pool. Preserve retained values and apply explicit lifetime checks before reuse. Define truncation semantics so later regrowth cannot accidentally reveal data that the contract considers discarded or uninitialized.

Part 2 - System and Memory Mental Model

Shrinking changes valid length before it necessarily changes physical backing. The page containing the new final element remains owned even when most of it becomes slack. Removed

mappings release logical ownership, but pending readers, writes, transfers, or shared owners may still prevent slot reuse. Returning a slot to a retained pool does not guarantee a fall in allocator-reserved memory. A slab-backed pool cannot free one slot's backend allocation independently.

Part 3 - Quantitative Prediction Before Execution

For length $3P + 2$, compute retained pages after shrinking to $3P$, $P + 1$, P, and zero in separate trials. Distinguish removable mappings from actually reusable slots. Predict how much assigned slack remains after each shrink and which bytes a later regrowth must initialize. Include a case where a page has no logical mapping but still has an in-flight reader, so immediate reuse would violate correctness.

Part 4 - Experimental Design and Instrumentation

Fill objects with boundary-sensitive values, shrink them, and verify surviving prefixes against a CPU oracle. Test unchanged length, complete destruction, invalid larger target length, and repeated shrink requests. Start with quiescent single-owner objects, then use a controlled completion token to defer one release. Reacquire released slots for a different object and ensure the old object cannot access them through a stale table. Keep physical release policy separate from logical truncation.

Test shrinking by one element when the old final page remains necessary, and shrinking by one element when that change removes an entire page. These nearby lengths expose off-by-one reclamation errors. If readers hold leases to removed mappings, record retired state separately from the current object's table. Later completion must release that retired ownership without restoring the old logical length.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ShrinkResult:
    retained_length: int
    removed_mappings: int
    reusable_slots: int
    deferred_slots: int

def shrink_object(pager, object_id, new_length):
    # Remove only unused mappings and preserve retained tail ownership.
    ...

def reclaim_completed(pool, completion_evidence):
    # Move deferred slots to free state only after all users finish.
    ...
```

```
def E11(config):
    # Validate prefix survival, stale access rejection, and later regrowth.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit free, mapped, and deferred counts after every shrink and completion. Report application-assigned capacity, pool-retained capacity, and backend metrics independently. Check that a truncated region is inaccessible and that regrowth obeys the initialization policy. If data sanitization is part of the chosen contract, measure it explicitly rather than equating release with erasure. Do not infer a leak merely because cached reserved memory stays high.

Destroy an object whose length is already zero and define whether the second destruction is a clear invalid-handle error. Avoid silent counter decrements. Check that a delayed completion for a retired page cannot free its new generation after reuse. This audit requires matching the completion token to the exact slot generation it protects.

Part 7 - Engineering Interpretation and Philosophy

Explain why logical deletion, ownership release, reusable capacity, and backend deallocation are distinct events. Choose a truncation and regrowth policy suitable for the later multi-object manager and document the consumer lifetime conditions required for safe reclamation.

19.35.13 Exercise 12

Exercise Title: Implement Page Reference Counting So Multiple Logical Tensors Can Safely Share Physical Pages

Part 1 - Exercise Contract and Why It Matters

Allow multiple logical objects to share payload pages using explicit mapping reference counts. Deliver checked share, unshare, destruction, and deferred reclamation operations. Keep mutation disabled for shared pages until the copy-on-write exercise defines the required behavior.

Part 2 - System and Memory Mental Model

A mapping reference count measures owning table entries, not arbitrary Python references and not the number of CUDA kernels still reading a page. Maintain in-flight use separately. A page becomes reusable only after its mapping count and outstanding use obligations both reach zero. Internal tensor views exposed outside the pager would create untracked aliases, so disallow them or define an explicit lease. Generation checks remain necessary after a slot is recycled.

Part 3 - Quantitative Prediction Before Execution

Start with two objects sharing three full pages and one object with a private tail. Calculate unique payload slots, total mappings, and counts per slot. Destroy the objects in different orders and predict which slots become reusable at each step. Add a retained read lease to one page and show why count zero alone cannot authorize reuse. Compare logical bytes across objects with unique backing bytes without double-counting shared payload.

Part 4 - Experimental Design and Instrumentation

Create shared objects through a single controlled API rather than copying table dictionaries directly. Verify each count against a recomputation from all live table entries. Test duplicate mappings within one object, partial sharing, complete sharing, destruction order, stale handles, and double unshare. Serialize host ownership changes initially. Record pending leases and their completion boundaries so the reference model can independently predict release. Keep random traces bounded to allow an audit after every event.

Create one object with two logical entries pointing to the same payload and another with one entry to it. Count three mapping references under this model, not two object references. State whether this alias pattern is supported for reads only until copy-on-write behavior is defined. Store mapping identities so repeated attach or detach calls cannot increment or decrement a counter twice without detection.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class SharedPageState:
    mapping_references: int
    inflight_leases: int
    generation: int

class PageOwnership:
    def attach(self, handle, mapping_id):
        # Validate and increment exactly once for a new owning mapping.
        ...

    def detach(self, handle, mapping_id):
        # Remove the mapping and defer reuse while leases remain.
        ...

    def audit(self, all_tables, active_leases):
        # Recompute ownership independently from the maintained counters.
        ...

def E12(config):
    # Exercise sharing and destruction orders against the ownership oracle.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative counts, one ownership contribution per live mapping, and no free slot reachable from a valid mapping or lease. Demonstrate a counterexample where counting logical objects rather than mapping entries is wrong. Measure metadata overhead and avoided payload duplication separately. A reduced unique payload count does not establish total memory reduction if new tables or retained leases dominate the workload.

Use an independently generated multiset of mapping handles to recompute counts. Do not let the audit read the same maintained counters it is supposed to verify. Test a retained lease after all tables disappear, then complete that lease and check reclamation. This distinguishes logical reachability from outstanding execution lifetime.

Part 7 - Engineering Interpretation and Philosophy

Explain how sharing changes memory accounting and reclamation without making writes safe automatically. Define the ownership evidence that copy-on-write will need, and state why ordinary external aliases cannot be inferred completely from the pager's own mapping counters.

19.35.14 Exercise 13

Exercise Title: Implement Copy-on-Write for Shared PyTorch Pages and Allocate New Physical Storage Only When a Shared Page Is Modified

Part 1 - Exercise Contract and Why It Matters

Implement software copy-on-write for shared pages behind the pager's controlled write API. Preserve snapshot values for other logical owners while allowing a writer to modify its private version. Allocate replacement payload only for pages that require separation, and include allocation, copy, and publication costs in the evidence.

Part 2 - System and Memory Mental Model

PyTorch tensor writes do not automatically implement this project's page copy-on-write semantics. The manager must intercept every supported mutation. For a shared page, prepare private backing, copy the values that must survive, apply the update, and publish a coherent replacement mapping with correct ownership. A partial update usually needs the untouched old values. A complete valid-page overwrite may avoid that copy under a declared policy. Keep source pages and old table versions alive until all readers and copies finish.

Part 3 - Quantitative Prediction Before Execution

For two objects sharing four pages, predict new slots and copied bytes for a one-element write, a cross-boundary write, and a complete-page overwrite. Distinguish unique pages touched from number of elements written. Calculate peak ownership while old shared payloads and provisional private pages coexist. Show a pool-full case where copy-on-write must reject or defer the mutation; being able to read shared data does not imply enough space to privatize it.

Part 4 - Experimental Design and Instrumentation

Create two snapshots with identical logical values. Mutate one through only the controlled API and compare both complete objects against independent CPU references. Test repeated writes to an already private page, duplicate logical mappings, partial tail updates, and allocation failure. Serialize writers in the primary version; a concurrent extension requires locking or another defined publication protocol. Reject external writable view access that bypasses the manager. Start with no autograd rather than promising gradient preservation.

Define whether repeated aliases within one logical object belong to a shared mutation group or represent independent snapshot mappings. The selected copy-on-write behavior must preserve that declared relationship. For the primary snapshot model, page replacement affects only the targeted mapping unless the contract says otherwise. Do not infer snapshot semantics from a reference count without defining which mappings a write should update.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class CopyOnWritePager:
    def plan_write(self, object_id, region):
        # Determine touched sharing groups and reserve transition capacity.
        ...

    def prepare_private_pages(self, plan):
        # Copy only required surviving values and retain old ownership.
        ...

    def commit_write(self, plan, values):
        # Apply supported mutation and publish checked mapping replacements.
        ...

def E13(config):
    # Validate snapshot isolation, copy accounting, and failure boundaries.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the unmodified snapshot to remain exactly unchanged and the writer to match its reference. Audit counts and generations after success and rejection. Report copied payload, newly initialized payload, provisional capacity, and steady unique backing. Distinguish admission atomicity from recovery after an unexpected asynchronous execution failure. No general transactional rollback of device faults is required or implied by this exercise.

Inject a failure after one of several replacement pages is prepared but before publication. Require provisional resources to be returned while old snapshots stay readable. On successful publication, preserve the old source until every copy and reader finishes. Record whole-page copy amplification for sparse writes so sharing savings are assessed alongside later mutation cost.

Part 7 - Engineering Interpretation and Philosophy

Explain when snapshot sharing defers rather than eliminates allocation. Recommend a mutation policy from the measured write density and available transition headroom, and identify why a transparent general tensor copy-on-write system would need stronger integration than this restricted manager.

19.35.15 Exercise 14

Exercise Title: Add CPU-Resident Pages and Implement Explicit GPU Page-In and Page-Out Operations Under a Fixed VRAM Page Budget

Part 1 - Exercise Contract and Why It Matters

Extend the pager with CPU backing and explicit GPU page-in and page-out under a fixed application CUDA slot budget. Preserve values across migration and make residency transitions observable. Distinguish the manager's payload budget from total device usage, which also includes outputs, workspaces, metadata, other allocations, and the caching allocator.

Part 2 - System and Memory Mental Model

A nonresident logical page retains an authoritative CPU version or another explicit reconstructible source. Track clean and dirty versions, transfer state, and backing ownership. Do not reuse a GPU slot until its latest values are safely backed and all device users finish. CPU backing consumes RAM; pinned staging consumes additional bounded capacity. Host-to-device submission is not transfer completion, and pinned sources must remain unchanged while transfers still depend on them.

Part 3 - Quantitative Prediction Before Execution

For K GPU payload slots and a larger logical page set, predict residency, CPU backing, dirty writeback bytes, and staging requirements for a short access trace. Count incoming reserved slots and outgoing slots still holding live data against the budget. A full pool may require completing an eviction before admitting a new page. Calculate both logical useful bytes and whole-page transfer amplification for the chosen access pattern.

Part 4 - Experimental Design and Instrumentation

Begin with synchronous migration at deliberate completion boundaries. Test clean eviction, dirty eviction, repeated page-in, a partial final page, and an object destroyed during a deferred transition under a defined cancellation policy. Compare all values with a CPU oracle. Add asynchronous transfers only after defining events, source lifetime, destination readiness, and slot reuse. Bound both host backing and staging. Measure cold population separately from steady migration, including writeback and synchronization cost.

Specify the authority rule for clean CPU-backed pages and dirty GPU pages. An old CPU copy cannot satisfy a fault for a newer version. If CPU backing is pageable, use a synchronous primary path or include a bounded pinned staging step with its own lifetime. Choose whether valid tail elements or full page capacity are transferred, and make the byte ledger follow that choice.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ResidencyRecord:
    backing_version: int
    device_version: object
    state: str
    slot_handle: object
    transfer_token: object

class ExplicitPager:
```

```
    def page_in(self, page_id, consumer_stream):
        # Admit a slot, copy authoritative values, and publish readiness.
        ...

    def page_out(self, page_id):
        # Preserve dirty data and defer slot reuse until all work completes.
        ...

def E14(config):
    # Validate migration, versions, and every budget transition.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export maximum simultaneous slot ownership, CPU backing bytes, pinned staging scope, transfer bytes by direction, and completed latency. Report backend device peaks separately from the application slot budget. Validate a round trip after mutation and demonstrate that a clean backed page can avoid unnecessary writeback. A slot returned to the pool may remain allocated or reserved by PyTorch; this does not invalidate a correctly scoped payload-budget claim.

Test a dirty page with multiple logical mappings under the chosen sharing policy, then verify the authoritative version after eviction and reload. Check both source and destination lifetime during asynchronous copies. A completed host method is insufficient evidence of completed device work; require the correct event or deliberate synchronization before reclaiming staging or payload slots.

Part 7 - Engineering Interpretation and Philosophy

Explain which memory pressure was relieved and which costs moved to CPU RAM, transfer bandwidth, or synchronization. State why explicit paging is a workload management technique rather than transparent CUDA Unified Memory or a hardware page-fault handler.

19.35.16 Exercise 15

Exercise Title: Trigger a Simulated Page Fault When a Required Logical Page Is Not Resident in VRAM and Restore It from CPU Memory

Part 1 - Exercise Contract and Why It Matters

Trigger an application-level simulated page fault when an explicit read or write requests a nonresident logical page. Restore the authoritative values from CPU backing, then resume the supported operation. Deliver fault records, correct retry behavior, and a clear distinction between software miss handling and hardware or operating-system page faults.

Part 2 - System and Memory Mental Model

The access API checks residency before dispatching payload work. A miss enters a controlled state machine rather than dereferencing an invalid CUDA pointer. Possible states include absent, loading, resident, evicting, and failed. A second request for a loading page must wait for the same operation or follow another explicit deduplication policy. Publishing an incomplete destination as resident can expose stale values even when its slot has already been allocated.

Part 3 - Quantitative Prediction Before Execution

For a trace of logical page requests, predict first-touch misses, later hits, repeated misses after eviction, and bytes transferred. Count fault requests separately from unique page-in operations. A range spanning two absent pages may generate two restorations. Derive the latency components of a blocking fault and identify which can overlap only after the later scheduler is added. Include a pool-full miss with no currently evictable victim.

Part 4 - Experimental Design and Instrumentation

Use a tiny bounded GPU slot count and a larger CPU-backed object. Force selected pages nonresident through the manager, then issue boundary reads and writes. Validate fault identity, restored version, resumed output, and unchanged neighbors. Simulate a page-in preparation failure before publication and require a coherent recoverable state. Never provoke an illegal device memory access to represent a software miss. Keep the primary host dispatcher serialized and define a bounded wait or admission failure when no victim can be reclaimed.

Issue two simulated requests for the same absent version before completing the first load in the transition simulator. Expect one page-in reservation and two dependent requests. Then cancel one requester and verify that the remaining requester can still complete. Define how the fault record refers to an object generation so an old request cannot resume against a new object with a recycled numeric identifier.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class FaultRecord:
    request_id: int
    page_id: int
    prior_state: str
    required_version: int
    outcome: str

class FaultDispatcher:
    def ensure_resident(self, page_id, access_mode):
        # Deduplicate transitions and return readiness or an explicit failure.
        ...

    def resume(self, logical_operation, readiness_tokens):
        # Execute only after all required pages are valid and available.
        ...

def E15(config):
    # Predict misses, force software faults, and validate resumed values.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report request misses, unique restorations, wait time, transfer bytes, retries, and failure phase without conflating them with OS fault counters. Check that a failed restoration does not install a valid mapping or leak a slot. Verify repeated requests do not allocate duplicate destinations for one version. Preserve unsupported concurrency cases as explicit limitations instead of assuming a Python dictionary alone implements a safe state machine.

Classify waiting for capacity separately from transferring data and waiting for an already scheduled restoration. These causes have different remedies. A timeout should report its blocked dependencies and preserve coherent state, not install a fabricated zero page. Test explicit failure reporting when the CPU backing version required by the request is unavailable.

Part 7 - Engineering Interpretation and Philosophy

Explain the benefit and overhead of moving residency checks into a controlled API. Identify which future operations can be resumed safely and why arbitrary PyTorch kernels cannot be intercepted by this software fault mechanism without additional integration.

19.35.17 Exercise 16

Exercise Title: Combine Page Prefetching and Page Eviction to Maintain a Dynamic GPU Working Set Without Exceeding the Physical Page Budget

Part 1 - Exercise Contract and Why It Matters

Add bounded prefetch and eviction scheduling while maintaining the declared GPU payload slot budget at every transition. Compare demand-only paging with lookahead policies using the same correct logical workload. Account for useful prefetch, wasted transfers, dirty writeback, waits, and scheduling overhead.

Part 2 - System and Memory Mental Model

Prefetch reserves capacity before use and may evict something needed sooner. An eviction candidate must satisfy ownership and completion rules, not simply have an old timestamp. Protect active leases and incomplete transfers. Maintain an explicit residency state machine and versioned table publication. Logical access order is a policy input; a host timestamp or kernel submission order alone does not establish when a device reader has finished with its payload.

Part 3 - Quantitative Prediction Before Execution

For a small slot budget, hand-simulate demand-only and one-page-lookahead execution on a sequential trace and an alternating working-set trace. Count misses, useful prefetched pages, evictions, writebacks, and peak reserved slots. Show a case where prefetch harms demand admission. Define a useful-prefetch ratio with an explicit lifetime window and leave an empty denominator undefined. Include the transition where an outgoing dirty page still occupies its slot.

Part 4 - Experimental Design and Instrumentation

Implement a conservative eviction baseline and bounded lookahead depth. Keep payload, staging, and outstanding-transfer limits separate. Start with synchronous scheduling, then add a transfer stream and event-based readiness. Require consumers to wait for the correct page generation and writers to respect migration state. Use the same finite trace for correctness and

separate repeated runs for timing. Compare unprofiled complete latency with a short diagnostic timeline; include prefetch setup and drain costs in end-to-end results.

Give demand and speculative work separate admission paths. A prefetched page that has not been consumed may be evicted under a declared policy, but an in-flight destination cannot be overwritten to satisfy demand. For dirty victims, reserve host backing or staging before starting writeback. Bound lookahead metadata and pending requests as well as payload slots so the controller cannot shift unbounded growth into a host queue.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PagerBudgets:
    gpu_slots: int
    cpu_backing_bytes: int
    pinned_staging_bytes: int
    max_transfers: int

class WorkingSetScheduler:
    def plan(self, demand, lookahead, states):
        # Admit demand before speculative work within transition limits.
        ...

    def evictable(self, page_id, completion_evidence):
        # Exclude active, stale, dirty-unbacked, or in-flight dependencies.
        ...

    def advance(self, completed_tokens):
        # Publish finished transitions and reclaim only safe slots.
        ...

def E16(config):
    # Compare policies on sequential and adversarial working sets.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no interval where slot ownership exceeds the bound, including incoming reservations and outgoing live pages. Log a scalar transition ledger and independently audit it. Report wall time, demand stall intervals, useful work, transfer volume, writebacks, and wasted prefetch. Concurrent intervals must not be added as though they were serial. A low fault count can coexist with poor throughput if speculative transfers occupy bandwidth or block demand.

Compare a perfectly predicted sequential trace with a deliberately misleading lookahead trace. Record how often speculation delays demand and whether the fallback policy restores progress. Include a working set one page larger than capacity to expose thrashing. Check that

reported overlap actually shortens completed-work time rather than merely placing transfers on another stream.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest tested prefetch policy that improves useful work without weakening resource or correctness contracts. Explain the difference between hiding latency, reducing transfer volume, and reducing capacity demand; one policy need not improve all three.

19.35.18 Exercise 17

Exercise Title: Build a Multi-Sequence Page Allocator That Serves Many Dynamically Growing Tensor Objects from One Shared CUDA Page Pool

Part 1 - Exercise Contract and Why It Matters

Serve many growing and shrinking sequence objects from one page pool. Add per-object tables, generation-checked identities, lifecycle operations, and fair admission under shared capacity. Support selected shared prefixes and private suffixes only through the ownership and copy-on-write contracts already validated, without assuming a specialized attention kernel.

Part 2 - System and Memory Mental Model

Sequence identity, logical length, page mappings, shared groups, residency, and active leases belong to separate records. A destroyed object's identifier may be reused only with a new generation or another stale-reference defense. One sequence's partial tail remains its own capacity unless explicit sharing permits otherwise. Admission must consider transition headroom as well as steady pages, especially when a shared prefix is about to be modified.

Part 3 - Quantitative Prediction Before Execution

Predict peak unique backing for several sequences with a common full-page prefix and different private suffix lengths. Compare that with the sum of logical lengths and the fully duplicated baseline. Calculate required pages for simultaneous growth and identify an admission order that can starve a small request. Define the chosen fairness or priority rule and state whether it optimizes completed sequences, latency, or another useful-work objective.

Part 4 - Experimental Design and Instrumentation

Replay a bounded multi-sequence trace containing creation, append, read, mutation, shrink, share, and destruction. Preserve stable sequence IDs and expected values in a CPU reference. Compare equal-work isolated pools with the shared pool under equal aggregate payload capacity. Include simultaneous pending growth, cancellation before publication, a shared-tail restriction, and object-ID reuse. Separate allocation service from any model computation; if adding a model consumer, use only the manager's explicitly supported access interface and account for materialized dense inputs.

Use sequences with identical shared prefixes but different final partial pages, and initially permit prefix sharing only at complete-page boundaries. This keeps tail ownership explicit. Later expand sharing only with a reference model for valid lengths and mutation behavior. Label request priorities and record arrival order so a fairness claim can be checked against events rather than inferred from aggregate throughput.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass(frozen=True)
class SequenceHandle:
    sequence_id: int
    generation: int

class MultiSequencePager:
    def create(self, length, shared_prefix=None):
        # Validate sharing boundaries and atomically admit initial mappings.
        ...

    def append(self, sequence, values):
        # Respect fairness, tail ownership, COW, and transition capacity.
        ...

    def destroy(self, sequence):
        # Retire the identity and safely release mappings and pending work.
        ...

def E17(config):
    # Audit the shared pool through mixed sequence lifecycle traces.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report accepted and rejected requests, wait times by sequence, unique payload, mapping count, tail slack, shared capacity saved, and transition peaks. Validate all surviving sequences after every event and ensure a cancelled operation cannot publish into a newly reused identity. A high aggregate throughput can hide starvation; report the worst waiting sequence and the tested fairness contract. Do not claim model-level acceleration from allocator-only timing.

Cancel a waiting sequence, reuse its numeric identifier with a new generation, and then complete the old sequence's outstanding transfer. The old completion must not modify the new sequence. Audit unique backing and reference counts through this interleaving. Check that a large sequence cannot consume all transition reservations indefinitely if the declared policy promises bounded service to smaller requests.

Part 7 - Engineering Interpretation and Philosophy

Explain where shared capacity improves admission and where contention or metadata erodes the benefit. Distinguish a general software sequence allocator from a complete paged attention implementation, and identify the required consumer integration before applying the design to a real model.

19.35.19 Exercise 18

Exercise Title: Stress-Test the Pager with Random Growth, Shrinkage, Sharing, Page Faults, Evictions, and Severe VRAM Pressure

Part 1 - Exercise Contract and Why It Matters

Stress-test the pager with reproducible randomized lifecycle and residency traces, including severe pressure within a small declared slot budget. Find minimal counterexamples to ownership, value, transition, and budget invariants. Separate deterministic fault injection from actual resource exhaustion and keep all real-device allocations bounded.

Part 2 - System and Memory Mental Model

The difficult failures combine individually valid operations: a shared page is being copied while one object shrinks, a dirty victim has pending readers, or a cancelled fault completes after object-ID reuse. A state machine must preserve version and generation identity across these transitions. Resource pressure can mean no admissible slot rather than a CUDA allocation failure. Do not force device-wide exhaustion when a small fixed application budget can exercise the same admission logic safely.

Part 3 - Quantitative Prediction Before Execution

Before execution, define invariants for every state and predict one valid and one invalid short trace. Calculate maximum transition capacity for growth, copy-on-write, page-in, and dirty eviction combinations. Define bounded waiting and progress expectations under a trace that eventually completes outstanding leases. A permanently pinned working set may make admission impossible; the correct result can be an explicit rejection rather than guaranteed progress.

Part 4 - Experimental Design and Instrumentation

Generate traces from a fixed seed with explicit operation probabilities, maximum lengths, page count, host backing limit, and transfer limit. Compare every stable state with a dense CPU oracle and recomputed ownership ledger. Add deterministic scheduler interleavings or completion-token simulation before running actual asynchronous streams. Inject preparation failures at named boundaries. Reduce any failing trace by replaying smaller subsequences while preserving dependencies, then save the smallest reproducible counterexample. Run additional seeds only after the primary trace is auditable.

Separate invalid-operation tests from valid randomized histories. An intentional stale handle should produce the expected rejection without being counted as a pager correctness failure. Save the exact scheduler decisions and completion order for asynchronous reproductions. A random seed alone may not reproduce real timing, so deterministic interleaving simulation is the primary tool for shrinking state-machine failures.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class StressLimits:
    max_objects: int
    max_length: int
    gpu_slots: int
    cpu_bytes: int
```

```
    steps: int

def generate_trace(seed, limits):
    # Produce bounded valid operations and labeled intentional violations.
    ...

def audit_state(pager, oracle, pending_operations):
    # Check values, counts, generations, versions, and all resource states.
    ...

def minimize_failure(trace, replay):
    # Preserve dependencies while finding a smaller reproducible failure.
    ...

def E18(config):
    # Test deterministic interleavings, then supported CUDA executions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, trace IDs, exact failure phase, last valid state, and whether reproduction succeeds. Include stale-handle rejection, double release, leaked provisional pages, invalid tail access, failed copy-on-write, duplicate page-in, and forbidden eviction controls. Distinguish a simulator pass from a CUDA execution pass. Export bounded CPU-only records and never invent hardware results when the execution environment lacks the required device or libraries.

When minimizing a trace, retain object creation, backing availability, and required sharing dependencies. A shortened trace that fails because its setup was removed is a different failure. Report the original and reduced histories with their invariant violations. Track pending work at shutdown so a test cannot appear to pass simply by exiting before delayed corruption becomes observable.

Part 7 - Engineering Interpretation and Philosophy

Explain which invariants survived the tested envelope and which remain unsupported. A randomized run without a failure is evidence about that run, not a proof of correctness under every interleaving. Recommend the next smallest experiment that addresses the most consequential unresolved risk.

19.35.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Virtual Tensor Memory Manager with Logical Addressing, Page Tables, Physical Page Pools, Sharing, Prefetching, and Eviction

Part 1 - Exercise Contract and Why It Matters

Integrate the restricted pager into one benchmarkable virtual tensor memory manager with logical addressing, checked tables, bounded pools, sharing, copy-on-write, CPU backing, explicit faults, prefetch, and eviction. Preserve the distinction between its software interface and

hardware virtual memory. Deliver a support matrix, reproducible traces, correctness evidence, and a workload-specific engineering recommendation.

Part 2 - System and Memory Mental Model

The manager coordinates object identity, mapping ownership, versions, residency, transfer completion, and admission. Use one source of authority for each record and explicit commit boundaries between prepared and published state. Ordinary PyTorch operators do not gain transparent paged access simply because a Python object exposes a familiar method name. The primary version supports a narrow no-autograd flat-value interface; shape metadata can be preserved without promising arbitrary views, gradients, layouts, or kernels.

Part 3 - Quantitative Prediction Before Execution

Predict complete payload residency, CPU backing, pinned staging, table bytes, tail slack, transition headroom, output materialization, and useful-work time for each benchmark trace. Compare dense materialization, a resident-only paged baseline, demand paging, and prefetch with equal useful values and supported semantics. Identify when a model larger than the GPU slot budget can be served and when its active working set or consumer outputs still make admission impossible. No paging policy creates additional bandwidth or physical capacity.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and validate each subsystem before integration. Run short deterministic traces, randomized stress, and held-out sequential, sparse, shared-prefix, write-heavy, and thrashing workloads. Keep the same requests, outputs, and completion boundaries across baselines. Measure cold construction, warmed access, transition costs, and final drain separately. Ablate sharing, copy-on-write, prefetch, and eviction choices to identify mechanisms. Record device and software versions, dtype, page units, budgets, seeds, trace IDs, allocator backend, and initial-state identifiers.

Publish a supported-operation matrix before performance results: creation, range reads, indexed access, mutation, sharing, resizing, migration, and cancellation each need precise semantics. Mark unsupported layouts, external aliases, autograd, graph capture, and concurrent writers explicitly. Preserve one immutable benchmark trace per comparison and use scalar evidence IDs to link outputs, transitions, and resource observations without retaining their payloads.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class VirtualTensorContract:
    device: str
    dtype_name: str
    page_elements: int
    gpu_slots: int
    cpu_backing_bytes: int
    staging_bytes: int
```

```
    max_transfers: int
    supported_operations: tuple

class VirtualTensorMemoryManager:
    def __init__(self, contract):
        # Initialize authority, ownership, state machines, and bounded pools.
        ...

    def access(self, object_handle, request):
        # Validate, restore, translate, and dispatch supported operations.
        ...

    def mutate(self, object_handle, request, values):
        # Respect COW, versions, leases, and coherent publication.
        ...

    def schedule(self, demand, lookahead):
        # Enforce demand priority and every transition resource bound.
        ...

    def audit(self):
        # Recompute mappings, ownership, residency, versions, and budgets.
        ...

    def shutdown(self):
        # Finish or safely cancel owned work and report unreclaimed state.
        ...

def E19(config):
    # Validate the integrated contract before complete-work benchmarking.
    ...
    # Export evidence, counterexamples, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires exact supported values, coherent shared snapshots, checked stale identities, no unsafe reuse, truthful budget accounting, and bounded failure handling. Report useful completed operations, latency spread, slot peaks, host backing, backend allocated and reserved peaks, transfer bytes, faults, evictions, copies, metadata scope, and failure phases. Keep predictions, observations, and interpretations separate. A benchmark with incorrect results or omitted materialization cost cannot qualify as a performance improvement.

Include a workload where dense storage wins and another where the active set is too large for any permitted policy. Report rejection or poor performance honestly. Validate shutdown after normal completion and controlled cancellation, including old mappings and pending transfers. Separate measured delivered features from proposed kernel or VMM extensions so the final engineering recommendation cannot imply capabilities the scaffold leaves to the learner.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest manager justified by the evidence, including a dense baseline when it wins. Explain which benefits came from software placement, sharing, reduced copying, or latency overlap. State what remains necessary for production integration, including supported kernels and stronger concurrency or autograd contracts, without presenting unimplemented extensions as delivered capabilities.

19.36 DMM34

Chapter Title: Paged KV Cache for LLM Inference
Specialization: Dynamic Memory Management and CUDA Systems

19.36.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Transformer KV Cache Growth, Token Residency, Block Allocation, and Why Long-Context Inference Becomes Memory-Bound

Part 1 - Exercise Contract and Why It Matters

Define the lifecycle of attention keys and values during prefill and incremental decoding. Deliver a diagram linking request identity, processed token positions, per-layer KV values, block ownership, and attention reads. Explain capacity pressure and bandwidth pressure separately. This chapter builds a restricted inference cache in PyTorch; its reference attention path may gather blocks into dense tensors and must disclose that materialization cost.

Part 2 - System and Memory Mental Model

For causal self-attention, previously processed tokens supply reusable keys and values at every cached layer. Queries are newly computed for the current positions; caching K and V does not remove attention over their history. A sampled next-token ID normally has no cache entry until its forward execution processes that token. Logical token order is independent of pool slot order. The term physical KV block means application-owned CUDA payload, not a chosen hardware frame or an implicit CUDA virtual-memory mapping.

Part 3 - Quantitative Prediction Before Execution

For homogeneous full-attention layers, predict useful KV payload from layers, KV heads, head dimension, dtype width, and processed token counts. Distinguish query heads from KV heads under grouped-query or multi-query attention. Estimate how much history each decode step reads and why a workload may become bandwidth limited without proving that every long-context run is memory-bound. Separate cache payload from weights, attention outputs, workspaces, metadata, and allocator-reserved memory.

Part 4 - Experimental Design and Instrumentation

Start with one device, deterministic evaluation, no gradients, fixed model weights, unquantized equal K/V dimensions, and full causal attention. Use a tiny explicit decoder as a transparent reference rather than a high-level serving wrapper. State tensor layouts, token-position convention, positional encoding, masks, batch membership, and completion boundaries. Record model configuration, software versions, CUDA device, allocator backend, seed, and initial state. Exclude sliding-window, cross-attention, latent-attention, offloading, and quantization unless separately implemented and validated.

Draw a prefill of several tokens followed by two decode iterations, marking when each token receives its layer-specific cache entries. Include the final sampled token that is never processed because the request stops. Use separate colors or labels for persistent history and one-step temporary tensors. The same diagram must distinguish token positions from pool offsets so a later block permutation cannot change the meaning of attention.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVContract:
    layers: int
    query_heads: int
    kv_heads: int
    head_dim: int
    dtype_name: str
    block_tokens: int
    position_policy: str

def predict_kv_lifecycle(contract, request_trace):
    # Separate processed tokens, sampled tokens, capacity, and read traffic.
    ...

def E00(config):
    # Define the supported decoder and audit its token/cache timeline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require every cached vector to have a request, layer, head, and processed position identity. Keep prediction, observation, and interpretation in separate fields. A lower cache capacity does not prove reduced attention work, and allocator-only timing does not prove model throughput. Export bounded CPU-only evidence without retaining cache tensors in logs. Unsupported GPU measurements remain unmeasured rather than being replaced by synthetic hardware results.

Check the mental model against a small trace before introducing performance claims. A capacity-limited request and a bandwidth-limited decode can have similar latency symptoms but require different evidence. Preserve the distinction between useful KV reads, cache allocation, and model weight traffic. Do not infer the limiting resource solely from context length or an external utilization percentage.

Part 7 - Engineering Interpretation and Philosophy

Explain which benefits require only better allocation and which require an attention implementation that consumes paged storage directly. Paging can improve capacity utilization

without eliminating context reads or guaranteeing lower latency. Use that distinction throughout the chapter's engineering comparisons.

19.36.2 Exercise 01

Exercise Title: Calculate the Exact KV Cache Memory per Token from Layer Count, KV Head Count, Head Dimension, Dtype, and Batch Size

Part 1 - Exercise Contract and Why It Matters

Derive the exact unquantized KV tensor payload for the declared architecture and token population. Produce a calculator that distinguishes one token in one sequence from one decode step across a batch. Validate formulas against small tensor storage allocations and state every excluded source of memory.

Part 2 - System and Memory Mental Model

Ordinary full-attention caching stores a key and a value for each processed position at each layer. Query head count does not determine stored head count when KV heads are shared. Batch size multiplies only when each sequence has the same cached length. Unequal lengths require their sum. Quantization scales, block padding, packed layouts, backend rounding, model weights, and temporary head expansion are outside the simple useful-payload formula.

Part 3 - Quantitative Prediction Before Execution

For L identical layers, H_{kv} KV heads, head dimension D, and s bytes per stored element, derive

$$b_{\text{token}} = 2LH_{kv}Ds, \qquad B_{\text{useful}} = b_{\text{token}} \sum_{j=1}^{B} T_j.$$

For heterogeneous layers, sum their separate K and V widths and element sizes. Calculate an example with 24 layers, eight KV heads, dimension 128, and two-byte elements, then compare query-head counts 8 and 32. Predict bytes added by one processed token per active sequence and distinguish bytes, KiB, and MiB.

Part 4 - Experimental Design and Instrumentation

Implement validation for positive architecture dimensions, supported dtypes, nonnegative lengths, and arithmetic bounds. Use tiny CPU tensors for broad formula checks and bounded CUDA tensors when available. Compare requested payload with actual unique backing for independent K and V arrays; do not sum alias views as independent storage. Test equal lengths, ragged lengths, empty requests, GQA, MQA, and an intentionally incompatible architecture that the simple calculator must reject or route to a generalized formula.

Use independent K and V element-size fields in the generalized calculator, even when the primary model stores them identically. A layer with different value width must not be forced into the homogeneous expression. Include a batch with one empty history and another with a long history. State whether one-token cost refers to adding one position globally or one position to each active request.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LayerKVSpec:
    kv_heads: int
    key_dim: int
    value_dim: int
    key_element_bytes: int
    value_element_bytes: int

def useful_kv_bytes(layer_specs, processed_lengths):
    # Validate the architecture and calculate exact logical payload.
    ...

def compare_with_storage(prediction, key_tensors, value_tensors):
    # Count unique backing separately from views and backend statistics.
    ...

def E01(config):
    # Validate hand calculations and report excluded capacity components.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw layer specifications, lengths, useful elements, requested bytes, unique storage scope, and backend allocated/reserved observations separately. Demonstrate a counterexample to using query heads in the formula and another to multiplying maximum length by batch size for a ragged useful-payload count. An exact tensor formula is not an exact prediction of total process VRAM. Explicitly label padding and alignment when the measured representation adds them.

For a storage check, count each unique backing allocation once and record logical view payload separately. Compare the calculator with a deliberately padded block representation to show why exact useful bytes can be smaller than allocated payload. Keep model-family exclusions explicit: latent or hybrid cache structures require their own architectural accounting rather than a guessed KV-head multiplier.

Part 7 - Engineering Interpretation and Philosophy

Explain how an auditable payload calculation becomes an admission estimate only after adding retained capacity and transient headroom. State which model families invalidate the homogeneous formula and why counting architectural objects must precede optimization.

19.36.3 Exercise 02

Exercise Title: Implement a Conventional Contiguous KV Cache in PyTorch and Measure VRAM Growth During Autoregressive Decoding

Part 1 - Exercise Contract and Why It Matters

Build a conventional contiguous cache and measure its growth during a bounded autoregressive trace. Compare a fixed-capacity in-place baseline with a separately labeled concatenation-based growing baseline. Preserve identical processed positions and numerical outputs while exposing their different capacity and copying behavior.

Part 2 - System and Memory Mental Model

A static cache allocates capacity before valid tokens fill it; allocated payload may stay flat while logical occupancy grows. A concatenation cache creates larger backing and can temporarily retain old and new arrays, copying history repeatedly. Both can be contiguous layouts, so contiguous does not mean one unique growth policy. Cache length is a validity boundary, not the allocated sequence dimension. Record whether stored keys are already positionally transformed and never apply that transformation twice.

Part 3 - Quantitative Prediction Before Execution

Predict static capacity bytes from maximum sequence lengths and useful bytes from current processed lengths. For repeated concatenation, derive the sum of historical elements copied over a chosen decode trace and estimate temporary coexistence. Identify the first step at which a capacity limit is reached. Predict separate curves for useful payload, allocated cache capacity, and backend reserved memory; they need not have the same slope.

Part 4 - Experimental Design and Instrumentation

Use a tiny fixed-weight decoder in evaluation with attention dropout disabled. Compare cached decoding with full-prefix recomputation on the same teacher-forced token trace. Reset cache state between trials. Measure constructor, prefill, warmed decode, and final drain separately. Synchronize at deliberate region boundaries and use device events where suitable. Do not retain every step's logits or KV arrays in Python lists. Treat real generation as a later additional check because token divergence can change the work being compared.

Use a fixed maximum context and a trace that reaches the limit exactly, then attempts one additional append. The failure must leave previously valid cache contents unchanged. Check per-layer valid-write bookkeeping so a failed forward cannot publish a token whose K exists in some layers but whose V or later-layer data is missing. A scalar global length alone cannot describe that preparation state safely.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class ContiguousKVCache:
    def __init__(self, contract, capacities, growth_policy):
        # Define static or concatenating backing and per-request validity.
        ...

    def append_layer(self, request, layer, positions, keys, values):
        # Validate shape, position, capacity, and layer update ownership.
        ...
```

```
    def commit_tokens(self, request, completed_layers):
        # Publish valid lengths only when the required KV writes are ready.
        ...

def E02(config):
    # Compare full recomputation, static cache, and growing cache correctly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require logits and attention outputs within declared dtype-appropriate tolerances before interpreting memory or speed. Check that unwritten capacity is masked out. Record useful tokens, capacity, copy bytes, peak allocated and reserved memory, elapsed time, and failure phase. A flat static-cache allocation curve is expected behavior, not evidence that additional tokens require no KV storage. Unsupported device execution remains explicitly untested.

Compare cached execution with full-prefix recomputation at several positions, not only the final token. A stale prefix can accidentally produce plausible logits while diverging earlier. Report host submission time separately from completed decode time, and record whether model construction, tokenization, transfer, warm-up, and output validation are inside the timed region.

Part 7 - Engineering Interpretation and Philosophy

Explain which cost paging will target in each baseline: reserved unused capacity, repeated growth copies, or placement inflexibility. Keep the baseline policy visible so a later improvement is not attributed to paging when it actually comes from avoiding a particularly inefficient concatenation strategy.

19.36.4 Exercise 03

Exercise Title: Generate Multiple Variable-Length Sequences and Quantify Wasted VRAM Caused by Preallocated Contiguous KV Cache Capacity

Part 1 - Exercise Contract and Why It Matters

Quantify unused KV capacity for variable-length requests under conventional preallocation. Compare per-request capacity and a padded batch layout while holding actual processed token histories fixed. Deliver occupancy timelines and a decomposition of unused capacity rather than one unexplained waste percentage.

Part 2 - System and Memory Mental Model

A request can reserve future decode capacity beyond its current prefix. A padded batch can additionally allocate positions up to the longest capacity for every row. These mechanisms overlap unless the accounting decomposition is carefully defined. Finished requests can leave idle rows in a static batch. None of these unused positions are useful history. The GPU allocator's cached free blocks are a separate layer and must not be added again as cache slack.

Part 3 - Quantitative Prediction Before Execution

For request capacities C_j and current lengths T_j, predict per-request unused payload from the differences. For a batch allocated to a common maximum, separate padding beyond individual capacities from unused positions inside those capacities. Define occupancy with an explicit denominator and leave an empty allocation undefined. Construct two length traces with the same total useful tokens but different arrival, completion, and reservation patterns.

Part 4 - Experimental Design and Instrumentation

Replay bounded short, medium, and long requests with explicit prefill and decode lengths. Compare static per-request arrays with padded batch backing using the same model, dtype, and useful token trace. Preserve masks, row-to-request identity, and completion events. Measure useful payload and capacity after each step, then report temporal peak and average occupancy separately. Add a control whose final lengths fill their reservations to expose how workload knowledge affects the baseline. Avoid device exhaustion by enforcing a small byte budget.

Include a trace where requests reserve generous future output lengths but finish early, and another where they nearly fill capacity. Keep prompt tokens and generated-token accounting separate so the same useful workload is compared. For a padded batch, record row reassignment and active masks explicitly. Do not count a finished row as active merely because its backing tensor still exists.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RequestCapacity:
    request_id: int
    processed_tokens: int
    reserved_tokens: int
    finished: bool

def capacity_decomposition(requests, layout_policy, bytes_per_token):
    # Separate useful history, future reservation, and batch padding.
    ...

def replay_contiguous_requests(trace, cache_contract):
    # Preserve request rows and masks across arrivals and completions.
    ...

def E03(config):
    # Predict and measure occupancy for identical useful histories.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report lengths, reservations, active rows, useful bytes, capacity bytes, allocator observations, and elapsed useful work. Demonstrate why averaging per-request occupancy percentages can disagree with a byte-weighted aggregate. Validate no padding enters attention and no completed row is accidentally reused before pending work ends. A high unused-capacity fraction does not establish slow execution; capacity and throughput require separate evidence.

Recompute useful and unused capacity from scalar request histories independent of cache counters. Compare peak unused bytes with time-averaged unused bytes; the two may rank policies differently. Validate that a static-capacity baseline cannot improve apparent throughput by ignoring long requests, dropping padding checks, or changing output limits relative to the paged workload.

Part 7 - Engineering Interpretation and Philosophy

Explain how reservation policy and batching contribute to apparent waste. Choose a realistic contiguous reference for later comparisons and identify the workload information it legitimately knows, avoiding a comparison against an unnecessarily pessimistic maximum-length allocation.

19.36.5 Exercise 04

Exercise Title: Split Key and Value Storage into Fixed-Token CUDA Blocks and Build a Shared Physical KV Block Pool

Part 1 - Exercise Contract and Why It Matters

Create a shared pool of fixed-token KV block bundles for the supported model. Each bundle holds K and V storage for the same logical token interval across all cached layers. Deliver bounded acquisition, release, initialization, and audit operations with generation-checked handles.

Part 2 - System and Memory Mental Model

Use a documented layout such as $[L, H_{kv}, P, D]$ for each of the K and V arrays, where P is token capacity per block. A bundle may consist of two independent tensors; it is one application allocation unit, not necessarily one backend allocation or hardware page. Retained free blocks remain backed. A slab variant must disclose that slot views retain the slab. Pending CUDA users prevent recycling even when logical mappings have been removed.

Part 3 - Quantitative Prediction Before Execution

Derive bundle payload bytes as Pb_{token} under the homogeneous contract. For K pool slots, predict total backed payload, currently mapped slots, free retained slots, and pending slots. Calculate backend allocation calls for the chosen K/V representation rather than assuming one call per bundle. Include metadata, initialization temporaries, and consumer headroom outside the pool payload budget.

Part 4 - Experimental Design and Instrumentation

Start with one host dispatcher, one CUDA stream, no shared mappings, and a small maximum slot count. Initialize block contents with identifiable layer, head, token, and component values. Test acquire/release cycles, bounded pool exhaustion, double release, stale generations, and wrong-pool handles. Compare cold creation and warmed reuse with separate peak resets. If blocks are allocated lazily, reject requests beyond the declared maximum before attempting unbounded backend allocations. Record both useful and retained capacity.

Choose whether blocks are created lazily or all at pool startup and keep that choice fixed within a comparison. Distinguish a bundle acquisition from a backend tensor allocation, especially when K and V are separate arrays. Include page initialization cost only where the contract requires it, while ensuring invalid bytes are never exposed to attention. Test both zero-capacity admission and an exactly full bounded pool.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass(frozen=True)
class KVBlockHandle:
    slot_id: int
    generation: int

class KVBlockPool:
    def __init__(self, contract, maximum_blocks):
        # Establish bounded K/V bundles and free, mapped, pending states.
        ...

    def acquire(self):
        # Return a valid initialized or explicitly uninitialized bundle.
        ...

    def release(self, handle, completion_token):
        # Recycle only after mappings and device use obligations end.
        ...

    def audit(self):
        # Reconcile unique payload and every slot state.
        ...

def E04(config):
    # Validate layout, cold allocation, reuse, and invalid handles.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check each K and V coordinate against the initialization pattern. Report pool-backed bytes, mapped capacity, free retained capacity, pending capacity, allocation calls, and backend peaks without double-counting shared storage. A returned Python method does not prove that device initialization completed. Evidence logs must store scalar handles and counters rather than references that keep blocks alive. Distinguish pool admission failure from measured CUDA allocation failure.

Audit that K and V bundles share a coherent handle generation even when their tensor pointers differ. A pointer may repeat after backend reuse and cannot identify an old valid request. When a slab variant is explored, count its unique backing once and explain why dropping individual slot views does not return their capacity to the driver.

Part 7 - Engineering Interpretation and Philosophy

Explain the capacity and allocator-traffic objectives of the pool. State why retaining free payload improves reuse while potentially keeping VRAM residency high, and identify the lifetime evidence required before a completed request's blocks become safe inputs for another request.

19.36.6 Exercise 05

Exercise Title: Build a Per-Sequence Block Table That Maps Logical Token Blocks to Noncontiguous Physical KV Cache Blocks

Part 1 - Exercise Contract and Why It Matters

Build a per-request block table mapping logical token blocks to arbitrary pool bundle handles. Preserve request identity, layer correspondence, valid lengths, and generations. Deliver checked lookup, installation, replacement, and destruction operations before using tables in an attention consumer.

Part 2 - System and Memory Mental Model

One logical block covers the same token interval across all layers in the bundle representation. Its table entry must not confuse K from one request with V from another. Committed token length and any layer-write readiness are distinct metadata. The primary table is host-owned Python state; a device kernel does not automatically see it. A future device table requires measured upload, versioning, and publication dependencies. Logical block adjacency does not imply pointer or hardware adjacency.

Part 3 - Quantitative Prediction Before Execution

For positions around $P - 1$, P, and $2P$, predict logical block numbers, within-block offsets, and the handles selected by a deliberately shuffled table. Calculate entry count for a ragged batch. Estimate packed table bytes using a declared entry format, and distinguish that estimate from Python object footprint. Predict stale-handle rejection after a slot is reused with a new generation and a different request owns the same numeric slot ID.

Part 4 - Experimental Design and Instrumentation

Assign distinct values to every layer, head, token, K/V component, and request. Install non-identity permutations in separate request tables. Validate all lookups against an independent CPU oracle. Test missing entries, invalid positions, foreign pool handles, request-ID reuse, and partially written layers. Define admission atomicity for replacements so a failed preparation cannot leave the table pointing to invalid payload. Serialize host updates initially and retain old table versions while supported readers still depend on them.

Give two requests identical logical lengths but different shuffled mappings, and verify that their tables never cross. Add a nonzero absolute position base without changing zero-based table indexing. For each mapping publication, record expected request generation, table version, and slot generation. This makes a stale cached translation detectable without relying on the payload's numeric pattern to reveal the error.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RequestKVState:
    request_generation: int
    committed_length: int
    block_handles: list
    position_base: int

class KVBlockTables:
    def lookup(self, request, logical_block):
        # Validate request generation, bounds, slot generation, and readiness.
        ...

    def install(self, request, logical_block, handle):
        # Publish only a coherent mapping with established ownership.
        ...

    def retire(self, request):
        # Remove mappings without invalidating outstanding device readers.
        ...

def E05(config):
    # Validate shuffled mappings and reject stale request/block identities.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Recompute mapping ownership from all tables and compare it with pool state. Verify exact K/V pair identity independently from lookup success. Report table construction, lookup overhead, metadata scope, and backend payload separately. A coincidentally correct token value cannot establish correct request or layer mapping. Mark unsupported concurrent table access explicitly instead of relying on an unqualified assumption that a Python container makes publication safe.

Test a valid slot index from a different pool and reject it before updating ownership. Then replace a mapping successfully and verify that old readers retain the version they were authorized to consume. If an optional device table is used, include upload bytes and readiness events; a host dictionary update is not evidence that a running kernel sees coherent new entries.

Part 7 - Engineering Interpretation and Philosophy

Explain how table indirection enables independent request growth and block placement. Identify the extra readiness and lifetime guarantees needed before an optimized attention kernel can safely consume the same mapping structure.

19.36.7 Exercise 06

Exercise Title: Append New Tokens by Allocating Additional KV Blocks Without Reallocating or Copying Existing Cache Storage

Part 1 - Exercise Contract and Why It Matters

Append processed-token K and V vectors by filling an existing private tail or acquiring additional blocks. Preserve all earlier cache values and payload handles without copying their history. Commit a new valid length only after every required layer's writes are ready for supported attention consumers.

Part 2 - System and Memory Mental Model

A decode step produces one new K/V pair per layer for each processed token. Unused tail capacity may avoid a new block; crossing a boundary requires another bundle. Table growth can move metadata even when old payload does not move. New token IDs, positions, and layer writes must correspond to the same request generation. Shared-tail mutation is excluded until copy-on-write is implemented. A sampled output token is not committed merely because its ID exists in the scheduler.

Inside a forward operation, layer attention may consume that layer's prepared new KV through the operation plan after its writes are ordered correctly. This internal readiness is distinct from the globally committed length exposed to other operations. Otherwise, waiting for every layer before letting the first layer attend would create an impossible execution order. Do not publish partial per-layer preparation as a reusable complete-prefix cache entry.

Part 3 - Quantitative Prediction Before Execution

Starting with length $P - 1$, predict additional bundles for appends of one, two, and $P + 2$ processed tokens in separate trials. Calculate new K/V write bytes and distinguish them from historical copies and table movement. Predict provisional capacity for a multi-block append and the state preserved when that full request cannot be admitted. Explain the layer at which a partially completed forward must remain uncommitted.

Part 4 - Experimental Design and Instrumentation

Drive the cache with a deterministic teacher-forced trace and explicit per-layer K/V outputs. Check every preserved prefix and newly appended position against the contiguous reference. Test zero-length append, boundary crossing, invalid shapes, inconsistent positions, missing layer writes, and bounded pool exhaustion. Reject the complete invalid request before mutation when possible. Measure allocation, new-value writes, metadata work, and completed append latency separately. Do not describe the whole operation as free of copying when newly produced values still require storage writes.

Make newly appended keys position-sensitive and values token-sensitive so swapped positions or omitted layers cannot pass by coincidence. Preserve the positionally transformed key convention used by the decoder. For a multi-token prefill append, validate all target positions before any publication and state which partial execution states are internal only. Keep growth metadata and payload lifetime records separate.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class KVAppender:
    def plan(self, request, token_positions):
        # Validate positions and reserve complete append capacity.
        ...

    def write_layer(self, plan, layer, keys, values):
        # Fill only the supported tail/new slots and record readiness.
        ...

    def commit(self, plan, completion_evidence):
        # Publish coherent token validity after all required layers.
        ...

def E06(config):
    # Check prefix identity, exact new values, and rejected append cleanup.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report committed lengths, provisional blocks, old payload copies, new K/V writes, table bytes moved, and latency. Verify that a rejected append leaks no slots and exposes no partly valid token. Unexpected asynchronous execution failures are a separate failure phase; admission atomicity does not imply transactional rollback of arbitrary device errors. Preserve a stable prefix handle ledger and value checks rather than using pointer equality alone.

Check several appends after a rejected growth to ensure provisional cleanup did not corrupt the free list. Stable old pointers are only one part of the no-history-copy claim; compare old values and count actual copied payload. If a new table representation is allocated, report that metadata movement rather than describing the entire growth operation as zero allocation.

Part 7 - Engineering Interpretation and Philosophy

Explain the precise no-history-copy guarantee and its measurement boundary. Identify when block growth improves a workload and when attention reads, projection computation, or table dispatch still dominate total decode time.

19.36.8 Exercise 07

Exercise Title: Implement Logical Token-to-Physical Block Translation and Retrieve the Correct Key and Value Vectors for Attention

Part 1 - Exercise Contract and Why It Matters

Implement token-to-block translation and retrieve the correct K and V vectors for selected layers, heads, and positions. Preserve requested order and repeated reads across nonconsecutive payload slots. Deliver a validated retrieval path whose materialization cost is visible before building paged attention.

Part 2 - System and Memory Mental Model

For a zero-based logical token index t, compute block index and token offset using the software token capacity. Absolute model positions may include a separate base and are not interchangeable with table indices. Retrieval must respect valid length and the chosen positional-key representation. A dense gather result usually allocates new storage. Grouping accesses by block can reduce dispatch, but the final result must return to logical request order.

Part 3 - Quantitative Prediction Before Execution

Translate a shuffled request list containing positions P, 0, $P-1$, and a repeated P. Predict touched logical blocks, unique payload bundles, read elements, and output bytes. Repeat for two layers and different requests to expose index-order mistakes. Estimate the difference between retrieving one token and reconstructing its entire block or full history. Account for host index conversion or synchronization if the implementation performs it.

Part 4 - Experimental Design and Instrumentation

Use deterministic coordinate-coded K and V arrays and random nonidentity block placement. Test single positions, boundary ranges, repeated indices, empty reads, final valid positions, invalid tails, and different request bases. Compare with contiguous reference retrieval before invoking any attention. Start with a no-alias copied-output contract so callers cannot bypass cache mutation rules. Benchmark scalar dispatch, grouped retrieval, and full-history materialization separately under the same returned-value contract.

Include a retrieval request that changes both layer and request after every few indices. This exposes implementations that cache the wrong bundle base. Check head order independently from token order, particularly when query heads outnumber KV heads. The retrieval API should return stored KV heads; any query-head expansion belongs to the attention consumer and its own temporary-memory ledger.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TokenLocation:
    handle: object
    token_offset: int
    absolute_position: int

def translate_token(request_state, logical_token, pool):
    # Check identities, validity, and the logical/absolute position mapping.
    ...

def retrieve_kv(cache, request, layer, token_indices):
    # Gather matching K/V vectors and preserve the requested order.
    ...
```

```
def E07(config):
    # Validate translation independently from attention numerics.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact retrieval values for the supported test dtype and initialization. Record requested tokens, unique blocks, output bytes, temporary bytes, dispatch count, and completed time. Validate both K and V and every selected head; checking only final attention output can hide compensating errors. Demonstrate that reading padding or another request's slot is rejected. State which output storage owns returned values and when it can be released.

Use one invalid index late in a read request and define whether validation rejects the whole request before output allocation. Report this boundary. Compare a copied-output path with any leased-view extension under clearly different contracts. A returned internal view can keep a block live and must not silently permit mutation or become stale after recycling.

Part 7 - Engineering Interpretation and Philosophy

Explain when sparse or grouped retrieval is useful and when reconstructing history erases the capacity advantage of paging. Identify the evidence required before replacing this transparent reference with a device kernel that translates block tables directly.

19.36.9 Exercise 08

Exercise Title: Reconstruct Attention over a Paged KV Cache and Verify Numerical Equivalence with a Conventional Contiguous Cache

Part 1 - Exercise Contract and Why It Matters

Compute attention using paged KV and verify numerical equivalence against contiguous caching and full-prefix recomputation. Implement a transparent gather-then-attend reference first. A direct blockwise attention extension is optional and must preserve global normalization rather than independently normalizing each block and averaging its outputs.

Part 2 - System and Memory Mental Model

Attention depends on values, head mapping, scale, valid lengths, positions, and masks. For query at absolute position q, allow only valid keys with positions no greater than q under the full causal contract. A rectangular causal helper may align queries differently from incremental decoding; inspect the API rather than assuming a one-row query sees all past keys. Set attention dropout explicitly to zero for evaluation. GQA expansion or specialized backend support also has numerical and memory consequences.

Part 3 - Quantitative Prediction Before Execution

Write a hand-checkable one-head attention example spanning two blocks and a partial tail. Predict allowed key positions for a single decode query and a multi-token suffix. Compare global softmax with the incorrect average of block-local attention outputs. Estimate dense gather output, attention workspace, and any repeated-head temporary storage. State numerical tolerances by dtype and accumulation/backend policy before comparing results.

Part 4 - Experimental Design and Instrumentation

Use fixed Q/K/V values first, then the tiny decoder with cached positional keys and a fixed teacher-forced token trace. Test unequal request lengths, partial blocks, nonzero position bases, GQA, and multiple new queries. Construct an explicit position-aware mask and validate its boolean or additive semantics. Record attention backend and compare like-for-like paths where possible. Include gather, mask construction, and output storage in end-to-end timing and peak memory. Profile a short diagnostic run separately from throughput runs.

For a single decode query, explicitly list all valid historical keys that should participate, then compare that list with the generated mask. Repeat with a two-query suffix and different request lengths. Test boolean-mask polarity rather than copying a padding mask from another attention API. Where head expansion is necessary, record whether it allocates repeated K/V storage or uses a supported backend path.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.nn.functional as F

def allowed_keys(query_positions, key_positions, valid_lengths):
    # Construct and validate the declared full-causal visibility relation.
    ...

def paged_attention_reference(query, cache, request, layer, mask_policy):
    # Gather valid KV and apply correctly mapped, globally normalized attention.
    ...

def compare_attention_paths(cases, tolerances):
    # Check contiguous, paged, and recomputed outputs before performance.
    ...

def E08(config):
    # Test rectangular masks, GQA mapping, partial tails, and decoder logits.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report maximum and aggregate numerical errors, mask mismatches, backend, dtype, temporary peaks, and complete elapsed time. Use a negative mask control that hides legitimate history and require validation to catch it. Different floating-point reduction orders can prevent bitwise equality while satisfying an explicit tolerance. Greedy token agreement is useful additional evidence, but does not replace direct attention and logit checks.

Use a small high-precision mathematical attention reference to diagnose errors before testing lower precision. Validate normalization over the union of blocks, including a very large score in a later block. If implementing online blockwise softmax, compare its running maxima,

denominators, and weighted sums with the dense result. Exclude fully masked queries or define and test their behavior explicitly.

Part 7 - Engineering Interpretation and Philosophy

Separate representation correctness from attention-kernel efficiency. Explain why a gather-based prototype can validate paged storage yet perform poorly, and what global-softmax, masking, and lifetime guarantees a direct paged kernel must retain.

19.36.10 Exercise 09

Exercise Title: Sweep KV Block Size and Measure Internal Fragmentation, Block-Table Overhead, Allocation Frequency, and Decode Latency

Part 1 - Exercise Contract and Why It Matters

Sweep token capacity per KV block and quantify internal slack, table size, allocation frequency, translation work, and completed decode latency. Choose a tested compromise under explicit payload and total-headroom constraints. Keep the same request trace and attention implementation across candidates.

Part 2 - System and Memory Mental Model

Smaller token blocks can reduce final-block slack and provide finer sharing and recycling granularity. They also increase table entries and dispatch or kernel metadata work. Larger blocks may reduce per-block overhead but retain more unused tail capacity. The software token capacity is not a CUDA hardware page size. Under equal payload bytes, changing capacity changes the number of available bundles and must change the admission calculation accordingly.

Part 3 - Quantitative Prediction Before Execution

For each candidate P, calculate assigned capacity from current request lengths, useful payload, tail slack, and mapping count. Predict new-block acquisitions over a decode trace, distinguishing pool reuse from backend allocation. Include a prefix-sharing trace whose matching prefix ends inside a block. Estimate copy-on-write amplification for later sparse tail writes, and distinguish packed table bytes from measured Python metadata.

Part 4 - Experimental Design and Instrumentation

Run a bounded geometric sweep with fixed dtype, layers, heads, request arrivals, prompt lengths, output lengths, and token values. Rebuild equal-budget state for each trial and separate cold pool creation from warmed reuse. Use deterministic short, long, and mixed request traces, then validate promising settings on held-out traces. Measure useful completed tokens, peak slot ownership, table work, dense gather temporaries, and full latency. Preserve rejected candidates and their failure phases rather than silently dropping them.

Hold the total pool payload budget in bytes constant and derive the maximum bundle count for every candidate block size. Record any unusable budget remainder. Use matching prompts whose common prefix ends just before and just after a block boundary so sharing granularity is observable. Keep attention backend and gather policy stable; otherwise a kernel-selection change may dominate the block-size comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVBlockTrial:
    block_tokens: int
    payload_budget_bytes: int
    trace_id: str

def predict_block_trial(trial, request_trace, kv_contract):
    # Estimate capacity, mappings, allocation events, and sharing boundaries.
    ...

def benchmark_block_trial(trial, validated_runtime):
    # Compare identical useful work with cold and warm costs separated.
    ...

def E09(config):
    # Select a robust feasible block size from auditable measurements.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep raw lengths, capacities, block counts, allocator peaks, error checks, and timing distributions beside summary scores. Require a counterexample to smaller-blocks-always-win and another to larger-blocks-always-run-faster. A lower slack percentage can coexist with higher total peak memory because metadata or gather outputs grow. Report sampling limitations and uncertainty when latency differences are smaller than run-to-run variability.

Show whether the selected block size remains feasible during copy-on-write and request replacement, not only in steady state. Compare calculated slack with direct assigned-capacity accounting at each event. A lower number of bundle acquisitions does not imply fewer backend allocations after warm-up; report these counters separately and preserve uncertainty in unavailable allocator fields.

Part 7 - Engineering Interpretation and Philosophy

Recommend a block size conditional on the tested workload and consumer. Explain whether the limiting mechanism was capacity, metadata, launch overhead, or attention work. Avoid translating a prototype's optimum into a universal recommendation for optimized serving kernels.

19.36.11 Exercise 10

Exercise Title: Free KV Blocks Immediately When a Sequence Finishes and Reuse Them for Newly Arriving Requests

Part 1 - Exercise Contract and Why It Matters

Release a finished request's KV mappings promptly and recycle eligible blocks for later arrivals. Interpret immediately as prompt logical retirement followed by reuse at the earliest safe completion boundary. Deliver lifecycle evidence proving that a new request never receives storage still used by an older request's attention or append operations.

Part 2 - System and Memory Mental Model

Request completion may follow sampling, an EOS decision, a length limit, or cancellation. Previously submitted CUDA work can remain active. Retiring the request prevents new operations but does not make unfinished readers vanish. Keep pending blocks separate from reusable free blocks. Initially there is no prefix-cache retention; later reusable cached blocks require a separate ownership policy. Backend allocated or reserved bytes may remain high while application slots are successfully recycled.

Part 3 - Quantitative Prediction Before Execution

For staggered arrivals and completions, predict mapped, pending, and reusable counts after every event. Include a request that finishes while its last attention read has not completed. Determine which next arrival can be admitted before and after that event. Calculate new backend allocations versus pool reuses. Predict why a pool with unchanged retained payload can serve more total requests without reducing its measured backend residency.

Part 4 - Experimental Design and Instrumentation

Use bounded requests with deterministic output lengths and a separate controlled completion-token model before introducing actual CUDA events. Test EOS, maximum length, cancellation before append publication, and repeated completion notification. Reuse numeric request IDs only with new generations. Fill recycled payload with a new recognizable pattern and verify request isolation. Measure finish-to-logical-retirement and finish-to-safe-reuse delays separately. Include shutdown drain in complete-run throughput and do not abandon outstanding work to make recycling appear instant.

Create a completion event whose request has no remaining scheduler work but still has an outstanding reader lease. Submit a new request before that lease completes. It must use another eligible slot or wait under the declared policy. After completion, verify the old generation is retired and the slot can be reused. Treat cancellation as a lifecycle transition rather than a magic synchronization operation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RetiredRequest:
    request_id: int
    generation: int
    pending_handles: tuple
    completion_tokens: tuple

def finish_request(runtime, request, reason):
```

```
    # Retire identity and detach mappings without premature storage reuse.
    ...

def recycle_completed(pool, completion_evidence):
    # Reconcile exact generations before moving pending slots to free.
    ...

def E10(config):
    # Replay arrivals, completion, cancellation, and delayed reader events.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require every free block to be unreachable from a live mapping or outstanding lease. Audit request tables and pending work independently from the free list. Report admitted requests, reuse count, pending peaks, delays, backend peaks, and rejected stale operations. A completion callback for an old generation must not release a newly reused slot. Report cached reservation separately from a genuine ownership leak.

Record a delayed completion for a block that has already been safely recycled through another path and require generation validation to prevent double free. Check finish notifications for idempotence or a clear duplicate-operation error. Measure application slot reuse independently of backend memory release, which may not occur while the pool intentionally retains free tensors.

Part 7 - Engineering Interpretation and Philosophy

Explain how safe recycling improves sustained capacity without necessarily lowering retained VRAM. Choose a lifecycle policy with explicit cancellation and shutdown behavior, then state the extra ownership rules needed when completed prefixes remain available for reuse.

19.36.12 Exercise 11

Exercise Title: Build Reference Counting for Shared KV Blocks and Prevent Shared Prefix Memory from Being Released While Another Sequence Still Uses It

Part 1 - Exercise Contract and Why It Matters

Track explicit references when requests share complete prefix blocks. Prevent reclamation while any supported owner or in-flight reader remains. Deliver independent reference-count audits and a decomposition of logical mapped capacity versus unique payload backing.

Part 2 - System and Memory Mental Model

Count owning mapping entries rather than only request objects. Separate active request references, optional reusable-prefix retention, and device leases. A zero active-request count can coexist with a valid cached prefix; a zero logical count can coexist with an unfinished reader. Read-only sharing is the initial contract. Arbitrary external writable tensor aliases are not tracked automatically and must be disallowed or represented by explicit leases.

Part 3 - Quantitative Prediction Before Execution

For three requests sharing two full blocks and owning separate tails, calculate total mappings, unique bundles, and counts per bundle. Destroy requests in multiple orders and predict reclaimable capacity. Add a retained prefix-cache owner and a delayed attention lease in separate trials. Compare avoided duplicate payload with added table and ownership metadata. Define whether duplicate entries in one request are supported and how they contribute to the count.

Part 4 - Experimental Design and Instrumentation

Create sharing through one controlled attach operation and detach through one checked lifecycle path. Recompute counts from a multiset of live mapping handles and separately recorded cache owners. Test shared-prefix destruction, request cancellation, duplicate attach, double detach, stale handles, and completion after the last request disappears. Keep host ownership changes serialized initially. Validate the complete K/V identity and immutable content for every sharing request after each event, not just reference-count totals.

Create three mappings to one block, including a controlled duplicate mapping case if supported, and remove them in different orders. Track active mappings, retained prefix ownership, and device leases as separate contributions to release eligibility. Define whether an index entry itself owns payload or only references an independently owned cache record. Never leave this choice implicit in the reference-count implementation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVReferences:
    active_mappings: int
    retained_cache_owners: int
    inflight_leases: int
    generation: int

class KVReferenceTracker:
    def attach(self, handle, mapping_identity):
        # Add exactly one supported ownership contribution.
        ...

    def detach(self, handle, mapping_identity):
        # Remove ownership and defer reuse while other obligations remain.
        ...

    def audit(self, request_tables, prefix_index, active_leases):
        # Recompute counters without trusting maintained reference totals.
        ...

def E11(config):
    # Validate shared prefix lifetime under all request completion orders.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative counts and no reusable block with a valid owner or lease. Record unique payload, mapped capacity, retained reusable prefixes, metadata, and pending reclamation independently. Demonstrate a counterexample to freeing blocks when the original producing request finishes. Also demonstrate why counting references alone is insufficient for safe mutation. Missing external alias tracking must remain an explicit interface restriction.

Use an independently enumerated mapping multiset for the audit rather than reading maintained totals back as their own proof. Verify a page with zero active requests but a retained immutable cache owner remains available for a later hit. Then evict that cache record, invalidate lookup reachability, and reclaim only when the remaining lease obligations have ended.

Part 7 - Engineering Interpretation and Philosophy

Explain when sharing reduces unique storage and when retained cache owners reduce capacity available for active work. State the reference and immutability conditions that copy-on-write must preserve to let requests diverge safely.

19.36.13 Exercise 12

Exercise Title: Implement Copy-on-Write When Two Sequences Share a Prefix Block and One Sequence Extends or Modifies Its Logical Cache

Part 1 - Exercise Contract and Why It Matters

Implement copy-on-write for a shared partial prefix block before a request extends or changes that cache region. Preserve the other request's KV values, valid length, and future outputs. Allocate and copy only the necessary private replacement while accounting for transition headroom and failure behavior.

Part 2 - System and Memory Mental Model

Sharing a complete immutable prefix block does not require copying it when a new token starts a new logical block. Extending a shared partial block requires a private tail under this exercise's immutable-sharing policy. Mutation of an earlier token's KV is not generally an equivalent model edit: subsequent layers or positions may depend on the original history. Restrict the primary workload to append-only branches from identical processed prefixes; label direct KV modifications as storage-isolation tests, not semantic text edits.

Part 3 - Quantitative Prediction Before Execution

For two requests sharing $P-1$ valid tokens in one block, predict private bundles and copied valid K/V bytes when one appends. Contrast with a shared full block followed by a new block. Calculate peak unique payload while old and replacement bundles coexist, including all layers. Predict the pool-full case and the unchanged state required if private capacity cannot be admitted. Separate copied prefix values from newly computed token writes.

Part 4 - Experimental Design and Instrumentation

Create identical deterministic decoder prefixes, branch their teacher-forced suffix tokens, and compare each branch with an independent contiguous reference. Test partial and full

boundaries, repeated private appends, cancellation during preparation, and insufficient transition capacity. Serialize writers initially. Define publication only after the private copy and new writes have the required dependencies. Keep old shared blocks live for other requests and pending readers. Reject writable view access that bypasses copy-on-write interception.

Choose an immutable-sharing rule even for currently unused bytes in a partial block. This conservative policy makes private-tail publication easier to audit. Contrast it with a possible more complex append-sharing policy without claiming that the latter is implemented. For storage-isolation mutation tests, do not present manually edited KV as equivalent to changing the original prompt tokens and rerunning the model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class KVCopyOnWrite:
    def plan_append(self, request, new_positions):
        # Identify immutable shared tails and reserve private capacity.
        ...

    def prepare_tail(self, plan):
        # Preserve valid old KV and establish copy completion dependencies.
        ...

    def publish(self, plan, layer_write_evidence):
        # Replace only the writer's mapping and update reference ownership.
        ...

def E12(config):
    # Compare branching logits and audit full/partial boundary behavior.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require both branches' attention outputs and logits to match their references within declared tolerances. Verify the untouched branch's stored prefix exactly and audit counts after success and admission failure. Report copied bytes, new writes, provisional blocks, steady sharing, and completed latency. Distinguish pre-publication cleanup from arbitrary device-fault recovery; do not claim transactional rollback after a failed asynchronous kernel.

Inject failure after preparing one replacement but before committing a multi-block operation. Old snapshots must remain valid and provisional blocks must become recoverable. Verify that a full shared prefix followed by a private new block incurs no unnecessary copy of completed history. Report copy-on-write latency and peak headroom beside steady shared-memory savings.

Part 7 - Engineering Interpretation and Philosophy

Explain how sharing shifts some allocation to the moment of divergence. Recommend a tail-sharing policy from measured branch frequency and headroom, and preserve the distinction between storage mutation safety and the mathematical validity of editing a Transformer history.

19.36.14 Exercise 13

Exercise Title: Build Prefix KV Cache Sharing for Requests with Identical Prompt Prefixes and Measure the Reduction in KV Memory and Prefill Work

Part 1 - Exercise Contract and Why It Matters

Reuse validated prompt-prefix KV across requests and measure both unique storage savings and avoided prefill computation. Preserve exact model context and output semantics. Distinguish reuse of already computed KV from merely sharing a copied tensor after independently recomputing every request's prefix.

Part 2 - System and Memory Mental Model

A prefix match concerns the complete preceding token context under the same model weights, adapter, positional convention, masks, and other relevant inputs. Matching a middle token block alone is insufficient because its hidden states depend on earlier tokens. Initially share complete immutable blocks and compute partial suffixes privately. Reused KV does not automatically include the final prompt logits or hidden state needed to choose the next token. Define whether a small boundary recomputation or separately retained output state supplies it.

Part 3 - Quantitative Prediction Before Execution

For requests sharing m complete blocks and different suffixes, predict unique backing and token positions whose prefill projections and earlier hidden computations can be skipped. Account for suffix queries still attending to shared history. Calculate matching tokens lost to an incomplete block. Compare first-request cold cost, later hit cost, and retained-prefix capacity. Include lookup and any boundary recomputation in the expected latency savings.

Part 4 - Experimental Design and Instrumentation

Use a fixed tiny decoder and explicit token-ID sequences with identical prefixes but different suffixes. Compare independent prefill, post-compute storage sharing, and actual prefix-skip execution. Validate per-layer KV, attention outputs, and next-token logits. Include nearly matching prompts, different position bases, and an incompatible model-context identifier that must miss. Separate cold population from warmed hits and bound retained prefix ownership so memory savings are not claimed while cached blocks grow without limit.

Keep model weights, adapter, input embeddings, causal policy, and positional configuration fixed during a hit comparison. Context-dependent positional scaling can invalidate an apparently identical prefix, so unsupported changes must force a miss. Establish how a fully reused prompt obtains the final hidden state or logits; recomputing a boundary token requires the corresponding cache validity and overwrite policy to be defined.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PrefixReusePlan:
    matched_full_blocks: int
    resumed_position: int
    boundary_output_policy: str
    context_identity: tuple

def plan_prefix_reuse(request, cache_index, model_context):
    # Validate complete causal prefix identity and output-state availability.
    ...

def resume_prefill(plan, suffix_tokens, decoder):
    # Skip valid reused work and obtain correct boundary/suffix logits.
    ...

def E13(config):
    # Separate storage sharing from actual prefill work avoided.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report matched tokens, skipped computed positions, remaining suffix work, unique payload, retained cache bytes, lookup time, and complete time-to-first-token. Verify a full-prompt hit under the declared boundary-output policy; KV alone must not be mistaken for ready logits. Check numerical parity before reporting speedup. A higher cache hit rate need not improve end-to-end latency if lookup, materialization, or retained-capacity pressure dominates.

Measure skipped prefill positions directly rather than inferring them from shared block counts. Post-compute sharing can save storage without avoiding any projections. Include a long shared prefix with a short suffix and another with a long suffix, since suffix attention still reads the prefix. Report retained cache capacity and additional output-state storage alongside the observed time-to-first-token change.

Part 7 - Engineering Interpretation and Philosophy

Explain the semantic identity required for valid prefix reuse and the workload conditions that amortize retained-prefix storage. State which input families are unsupported instead of generalizing a text-only fixed-context prototype to every model or prompt representation.

19.36.15 Exercise 14

Exercise Title: Hash Complete Prefix Blocks and Build a Global KV Block Lookup Table for Automatic Prefix Cache Reuse

Part 1 - Exercise Contract and Why It Matters

Build a global lookup index for complete immutable prefix blocks using context-aware chained hashes and verified candidate matches. Connect index ownership to block lifetime so cached hits cannot resolve to recycled payload. Deliver collision, invalidation, and stale-generation tests before automatic reuse is enabled.

Part 2 - System and Memory Mental Model

A block key must depend on its preceding prefix, current token IDs, and semantic model context. Identical current tokens after different histories can produce different KV. A hash selects candidates; it is not mathematical proof of equality. Store sufficient identity evidence to verify matches under the chosen threat and correctness model. Do not hash uninitialized partial blocks or mutable payload as stable prefixes. The index's retained ownership and eviction policy are separate from active-request references.

Part 3 - Quantitative Prediction Before Execution

Construct two prompts whose second blocks contain identical tokens after different first blocks and predict a required miss between their second-block identities. Calculate index entry count, retained payload, and host token metadata for a finite prompt set. Predict duplicate-content candidates and lookup behavior after block recycling. Define the expected longest reusable complete-prefix boundary when only some earlier blocks remain cached.

Part 4 - Experimental Design and Instrumentation

Use deterministic canonical key encoding and a documented digest choice. Include model revision, adapter identity, position policy, dtype/layout, and cache namespace as required by the support contract. Force collisions with a deliberately tiny test digest and require full identity verification to reject false hits. Invalidate entries before recycling their blocks and validate generations on every hit. Test duplicate insertion, partial-block rejection, context changes, and a missing earlier block in a prefix chain.

Verify ancestry as well as current-block tokens when resolving a collision. A parent digest can collide too, so a verified chained identity needs sufficient prefix evidence under the selected policy. Canonical encoding must preserve token boundaries and context fields unambiguously. Make the cache namespace part of the allowed reuse contract and keep unsupported multimodal or custom embedding inputs outside the text-only index.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import hashlib

@dataclass
class PrefixCandidate:
    digest: bytes
    parent_identity: object
    block_tokens: tuple
    model_context: tuple
    handle: object

class PrefixBlockIndex:
```

```
    def lookup(self, parent, tokens, context):
        # Hash canonically, then verify semantic identity and generation.
        ...

    def insert(self, candidate, completion_evidence):
        # Publish only immutable complete KV with valid retained ownership.
        ...

    def invalidate(self, handle):
        # Remove reachability before payload recycling.
        ...

def E14(config):
    # Test forced collisions, stale entries, and context-dependent misses.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report hit candidates, verified hits, collisions rejected, stale entries, lookup cost, index bytes, and retained unique payload. A single dictionary entry per digest must not overwrite distinct colliding prefixes without a safe resolution policy. Verify attention and logits after automatic hits. A successful hash test does not establish cross-model compatibility or correct reuse when omitted context changes the cached values.

Populate the index, recycle a candidate's slot, and attempt lookup again. The stale entry must be invalidated or rejected by generation checking. Force two distinct histories into the same digest bucket and verify both remain resolvable without false hits. Record lookup metadata growth and bound it; a compact GPU pool does not justify an unbounded host index.

Part 7 - Engineering Interpretation and Philosophy

Explain why automatic reuse combines content identity, lifetime management, and admission policy. Choose a small auditable index with bounded retention before adding complex eviction heuristics, and identify what evidence makes a reported hit safe for the supported decoder.

19.36.16 Exercise 15

Exercise Title: Serve Continuously Arriving Variable-Length Requests from a Fixed KV Block Pool and Detect Allocation Pressure Before Exhaustion

Part 1 - Exercise Contract and Why It Matters

Serve a replayable stream of variable-length requests from a fixed KV pool. Detect pressure before admitting appends that cannot finish safely. Deliver explicit admit, queue, pause, reject, and completion decisions under a declared policy, preserving useful token histories and bounded host scheduling state.

Part 2 - System and Memory Mental Model

A free-block count is only one admission input. The next step may need new tail blocks, copy-on-write replacements, temporary attention outputs, and pending-reader headroom. Cached

inactive prefixes occupy retained slots and may be reclaimable under their ownership policy; active history is not arbitrarily disposable in this full-context chapter. Offloading and lossy context eviction belong to later chapters. Never silently truncate context to make a request fit.

Part 3 - Quantitative Prediction Before Execution

For each scheduler step, predict active mapped blocks, retained prefix blocks, pending slots, reusable slots, and provisional reservations. Calculate new bundles for the next permitted token quantum. Define a pressure threshold in a named scope and show a case where equal free counts imply different next-step demand. Estimate maximum admitted concurrency for one trace without treating average request length as a hard capacity guarantee.

Part 4 - Experimental Design and Instrumentation

Replay fixed arrival times, prompt lengths, output lengths, and token traces. Start with one host scheduler and explicit microbatch boundaries. Reserve capacity before processing a step and commit only completed supported work. Bound waiting requests and prefix retention. Test a burst of arrivals, many partial tails, a long request, and a temporarily unreclaimable pending block. Compare simple FIFO and a documented fairness policy while reporting rejected and unfinished requests. Include prefill and decode separately in the useful-work ledger rather than mixing all tokens into one ambiguous rate.

Reserve upcoming boundary-crossing and private-tail requirements before launching the next token quantum. Protect active full-context history from reclamation. If retained inactive prefixes are evicted, invalidate their lookup entries and release cache ownership before reuse, while respecting any device leases. Track the temporary headroom required by the selected attention consumer instead of admitting solely from nominal KV payload.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVAdmissionState:
    free_blocks: int
    pending_blocks: int
    retained_prefix_blocks: int
    provisional_blocks: int
    workspace_headroom_bytes: int

class ContinuousKVScheduler:
    def pressure(self, state, next_step_demands):
        # Predict complete supported step demand before exhaustion.
        ...

    def admit(self, arrivals, active_requests, state):
        # Enforce capacity, bounded queues, and the declared fairness policy.
        ...

    def commit_step(self, completed_work):
```

```
        # Advance only coherent processed-token and completion state.
        ...

def E15(config):
    # Replay steady traffic and bursts with exact request accounting.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit every admission and transition against the slot and temporary-memory contracts. Report completed requests, generated tokens, queued/rejected work, time-to-first-token, inter-token gaps, tail latency, and peak state. A scheduler that maximizes token rate by starving long requests has not met an unspecified fairness objective. Do not report success only for admitted survivors while hiding rejected arrivals. Mark unsupported total-VRAM guarantees explicitly.

Replay a pressure burst followed by a recovery period and verify queued requests retain their original identities and histories. Compare admission predictions with observed slot changes at every step. Report waiting time and rejected work alongside throughput; excluding slow or rejected requests from the denominator can make an overloaded policy appear unfairly successful.

Part 7 - Engineering Interpretation and Philosophy

Explain the chosen pressure signal and the response it authorizes. Distinguish predicting block exhaustion from controlling all GPU memory, and identify the workload envelope in which the admission policy preserves full-context semantics and useful progress.

19.36.17 Exercise 16

Exercise Title: Compare Contiguous and Paged KV Cache Designs by Peak VRAM, Memory Waste, Maximum Concurrent Sequences, and Decode Throughput

Part 1 - Exercise Contract and Why It Matters

Compare contiguous and paged cache designs under equal semantics and auditable resource budgets. Report peak memory, unused capacity, maximum tested concurrency, and completed decode throughput. Preserve the cache growth and attention consumer policies so differences can be attributed to actual mechanisms rather than labels.

Part 2 - System and Memory Mental Model

A static contiguous cache, a growing concatenation cache, and a paged cache make different capacity and copying choices. A paged reference that reconstructs dense KV still pays temporary memory and data movement. An optimized paged kernel is a different consumer and must be labeled as such if implemented. Equal pool payload does not imply equal total peak VRAM. Weights, outputs, workspaces, retained prefixes, and table storage need consistent accounting.

Part 3 - Quantitative Prediction Before Execution

Predict memory curves for a fixed batch and for continuously arriving ragged requests. Estimate a concurrency bound from capacity, then add slot rounding, sharing, pending work, and temporary headroom. State whether maximum concurrency means a tested safe admission

count, a measured completed workload, or an analytical estimate. Predict a case where paging admits more sequences but has worse per-step latency because its reference gather dominates.

Part 4 - Experimental Design and Instrumentation

Benchmark equal teacher-forced traces first and separately test deterministic greedy generation. Keep weights, precision, masks, positions, attention backend, arrival trace, and output limits fixed. Report cache-only microbenchmarks separately from complete decoder execution. Reset initial state and peaks for each region, repeat trials, and separate cold prefill from warmed decode. For concurrency sweeps, use bounded admission rather than allocating to uncontrolled device failure. Evaluate sharing disabled and enabled as separate ablations so allocation and prefix benefits are not conflated.

Define prefill-token rate, generated-token rate, and request throughput with separate numerators and complete elapsed-time denominators. A processed prompt token is not a generated output token. For maximum-concurrency tests, include the long-context peak and request replacement transitions. Record whether the baseline knows final output lengths or only receives the same conservative limits available to the paged runtime.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVBenchmarkCase:
    cache_policy: str
    attention_consumer: str
    sharing_enabled: bool
    payload_budget_bytes: int
    request_trace_id: str

def compare_cache_designs(cases, decoder, reference_outputs):
    # Validate equal work and include all consumer/materialization costs.
    ...

def concurrency_sweep(case, tested_limits):
    # Record admission, completed work, and resource evidence per candidate.
    ...

def E16(config):
    # Explain measured capacity and performance differences by mechanism.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report allocated and reserved peaks, useful KV bytes, assigned capacity, tail slack, retained free payload, metadata, temporary peaks, and elapsed completed work. Include error tolerances, failures, admission counts, unfinished requests, and latency spread. Do not infer model throughput from an allocator loop or borrow published optimized-kernel speedups as measurements of this prototype. A negative or inconclusive performance result is valid evidence.

Repeat close comparisons and report uncertainty rather than ranking from one run. Keep failed and unfinished cases in the result table. If actual generation diverges because of floating-point differences, return to equal teacher-forced traces for performance attribution and report generation divergence separately. A change in sampled token histories changes the workload and cannot be ignored.

Part 7 - Engineering Interpretation and Philosophy

Recommend a design for the tested workload and support matrix. Explain when contiguous storage remains preferable and when paging's capacity flexibility outweighs indirection. Preserve uncertainty when close rankings are dominated by measurement noise or a consumer implementation difference.

19.36.18 Exercise 17

Exercise Title: Implement a Dynamic KV Block Allocator That Grows, Shrinks, Shares, and Recycles Physical Blocks Across Concurrent Sequences

Part 1 - Exercise Contract and Why It Matters

Integrate grow, shrink, sharing, copy-on-write, and recycling into a dynamic KV allocator serving multiple live requests. Preserve coherent per-layer validity and checked identities across every operation. Keep allocator service and model execution evidence separate while connecting them through explicit completion and ownership tokens.

Part 2 - System and Memory Mental Model

Growing appends processed tokens. Shrinking may truncate an uncommitted speculative suffix or destroy a completed request, but removing required past history changes the full-context task. Define supported truncation to a retained prefix under the fixed causal positional policy. Later tokens must be recomputed if the continuation changes. A retained partial block can contain invalid old tail bytes; validity and future writes must prevent those bytes from becoming visible accidentally.

Part 3 - Quantitative Prediction Before Execution

Hand-simulate a trace containing two shared prefixes, divergent appends, partial truncation, cancellation, and request-ID reuse. Predict unique blocks, mappings, private replacements, pending blocks, and reusable capacity after each event. Calculate the maximum provisional ownership, not just final live capacity. Show when truncation removes a full block and when it merely increases slack in a retained partial block.

Part 4 - Experimental Design and Instrumentation

Build all operations on one checked ownership authority instead of separate free lists maintained by different subsystems. Compare every stable state against independently reconstructed request histories and reference counts. Test failure before publication, delayed completions,

stale block handles, shared-tail truncation, and duplicate lifecycle notifications. Use one host scheduler initially; concurrency support requires an explicit serialization or synchronization protocol. Bound metadata and pending operation records. Validate the decoder after regrowing a truncated prefix with a different suffix.

Define truncation as retaining a known causal prefix and invalidating only later positions. If the next continuation changes, recompute its K/V through the model rather than reviving old tail bytes. A shared block that remains partially valid must preserve other owners' values and follow the declared copy-on-write rule before new writes. Keep table changes coherent with per-layer valid-write state.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVMutationPlan:
    request_generation: int
    expected_length: int
    target_length: int
    provisional_handles: tuple
    dependencies: tuple

class DynamicKVAllocator:
    def plan_change(self, request, operation):
        # Validate semantics, ownership, and complete transition capacity.
        ...

    def prepare(self, plan):
        # Reserve/copy/initialize while old committed mappings stay valid.
        ...

    def commit(self, plan, readiness):
        # Publish checked length/table changes and retire old obligations.
        ...

    def reclaim(self, completed_tokens):
        # Reuse only exact generations whose obligations have ended.
        ...

def E17(config):
    # Audit mixed lifecycle operations and resumed decoder correctness.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact supported KV values, correct logits within tolerance, count reconciliation, no stale publication, and no capacity violation. Report failed plans and provisional cleanup as well as successful operations. A successful shrink must invalidate removed positions without erasing another request's shared prefix. Distinguish logical allocator rejection from model execution failure and avoid promising rollback after arbitrary CUDA errors.

Exercise a delayed completion after truncation and after request generation reuse. It must retire only the ownership it originally protected. Compare mixed-operation histories with a dense CPU lifecycle oracle and actual decoder checkpoints. State whether failures are rejected before commit or leave the request in an explicit failed state; never silently advance length after incomplete layer execution.

Part 7 - Engineering Interpretation and Philosophy

Explain which semantic operations the allocator genuinely supports and why storage reclamation cannot authorize arbitrary context deletion. Choose a small coherent lifecycle API that later stress tests can exercise completely rather than exposing many loosely synchronized mutation entry points.

19.36.19 Exercise 18

Exercise Title: Stress-Test the Paged KV Runtime with Long Contexts, Shared Prefixes, Random Sequence Completion, Block Exhaustion, and Heavy Request Churn

Part 1 - Exercise Contract and Why It Matters

Stress-test the paged KV runtime with long bounded contexts, shared prefixes, random completion, block exhaustion, and heavy request churn. Search for minimal reproducible failures in values, attention semantics, ownership, identity, and resource bounds. Keep controlled slot pressure separate from uncontrolled hardware exhaustion.

Part 2 - System and Memory Mental Model

Critical failures combine valid operations: a shared tail is copied while a request is cancelled, a prefix index points to a recycled block, or an old attention completion arrives after request-ID reuse. Numerical parity alone cannot detect a leaked slot, and a correct free count cannot detect incorrect masking. Maintain independent semantic, ownership, and resource oracles. Long context is bounded relative to the tested environment, not a requirement to consume all available device memory.

Part 3 - Quantitative Prediction Before Execution

Define expected invariants and calculate worst-case transition demand for an adversarial short trace before random testing. Predict exhaustion where active history consumes every slot and no retained prefix is safely reclaimable. Specify the correct queue or rejection response. Construct one trace that crosses every block boundary and another that repeatedly creates partial shared tails. Define progress only for histories whose dependencies eventually finish and whose resource demand becomes admissible.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, finite request counts, bounded lengths, an explicit arrival trace, and controlled completion order. First run a deterministic transition simulator, then supported actual CUDA execution. Add named preparation failures and forced hash collisions. Compare

stored KV and teacher-forced logits with a contiguous oracle at selected checkpoints and audit ownership after every event. Save failing traces and reduce them while preserving setup and dependencies. Repeat additional seeds after the primary trace is reproducible.

Separate expected invalid-operation rejections from correctness failures in valid traces. Save completion ordering and scheduler decisions as well as the random seed, because actual asynchronous timing may not reproduce from seed alone. Include a deterministic interleaving where a request ends while a shared-tail copy is pending. Keep all payload and metadata bounds small enough for repeated diagnostic replay.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVStressBounds:
    max_requests: int
    max_context_tokens: int
    pool_blocks: int
    steps: int
    max_pending_operations: int

def generate_kv_trace(seed, bounds):
    # Produce supported histories and labeled invalid-operation controls.
    ...

def audit_runtime(runtime, semantic_oracle, lifecycle_oracle):
    # Check KV identity, masks, counts, generations, and capacity separately.
    ...

def minimize_kv_failure(trace, replay):
    # Preserve causal/setup dependencies while reducing a failing history.
    ...

def E18(config):
    # Validate adversarial traces before supported asynchronous stress.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report trace IDs, seeds, exact failure phase, reproducibility, and smallest counterexamples. Include double release, delayed readers, stale prefix hits, partial-block leakage, duplicate append, pool exhaustion, and shutdown with pending work. Mark simulator-only and CUDA-validated outcomes separately. A run without observed failure is not a proof over all

interleavings. Never invent hardware results, memory peaks, or throughput when the required execution was not performed.

When reducing a failure, retain the prefix population, sharing, and request creation needed to reproduce it. A shorter trace with missing setup is a different error. Audit after final drain so corruption cannot hide in pending work. Record when no counterexample is found in the tested range and avoid turning that absence into a universal concurrency proof.

Part 7 - Engineering Interpretation and Philosophy

Identify the remaining highest-impact uncertainty and design its next bounded test. State which contracts survived the tested envelope and which operations remain unsupported. Treat an honest rejected allocation or unreproduced failure as an experimental outcome rather than pressure to fabricate a success story.

19.36.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Paged KV Cache Runtime That Serves Concurrent Autoregressive Sequences Through Dynamic Block Allocation, Prefix Sharing, Copy-on-Write, and Block Recycling

Part 1 - Exercise Contract and Why It Matters

Build and benchmark the integrated PyTorch paged KV runtime with dynamic allocation, validated prefix reuse, copy-on-write, continuous request service, and safe recycling. Deliver a precise support matrix and reproducible evidence for correctness, capacity utilization, and complete useful-work performance. All substantive implementation remains learner work in the scaffold.

Part 2 - System and Memory Mental Model

Coordinate model context, processed positions, per-layer writes, block tables, reference ownership, immutable prefix identity, pending consumers, and scheduler admission. One authority must decide each mapping and lifecycle transition. The reference attention consumer may gather KV and must account for it. No general optimized PagedAttention kernel, transparent arbitrary-model support, offloading, quantization, or distributed execution is implied by this chapter's software interface. Preserve the fixed full-context inference contract.

Part 3 - Quantitative Prediction Before Execution

Predict useful KV, assigned capacity, unique shared backing, retained prefix payload, free pool capacity, metadata, provisional copies, and attention headroom for each benchmark trace. Compare contiguous, paged without sharing, paged with manual sharing, and automatic prefix reuse under equal supported work. Estimate time-to-first-token and decode-rate effects separately. Identify a workload where sharing helps and another where churn or materialization cost overwhelms its benefit.

Part 4 - Experimental Design and Instrumentation

Freeze the supported model and operation matrix. Validate subsystem oracles, then run deterministic and randomized integration traces. Evaluate held-out short, long, shared-prefix, divergent-tail, and high-churn traffic. Record device, PyTorch/CUDA versions, allocator backend, model revision, positional policy, dtype, head counts, page units, budgets, seeds, and

initial-state identifiers. Separate cold construction, prefill, warmed decode, index lookup, lifecycle transitions, and drain. Run ablations for sharing, copy-on-write, and indexing; keep correctness and admission gates unchanged.

Publish supported operations and model assumptions before the benchmark: creation, prefill, append, lookup, sharing, truncation, cancellation, and shutdown need precise semantics. Use scalar IDs to link request traces, output checks, resource observations, and lifecycle events. Bound logs and clear diagnostic tensor references between trials. Keep the final pool budget and consumer headroom identical across integrated ablations.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PagedKVRuntimeContract:
    model_context: tuple
    block_tokens: int
    maximum_blocks: int
    workspace_headroom_bytes: int
    maximum_waiting_requests: int
    attention_consumer: str
    prefix_boundary_output_policy: str
    supported_operations: tuple

class PagedKVRuntime:
    def __init__(self, contract):
        # Establish decoder, tables, ownership, prefix index, and scheduler.
        ...

    def submit(self, request):
        # Validate identity/context and queue or admit within all limits.
        ...

    def step(self):
        # Reserve capacity, compute supported work, and commit coherent KV.
        ...

    def finish(self, request, reason):
        # Retire active ownership while preserving supported prefix retention.
        ...

    def audit(self):
        # Independently reconcile values, masks, references, and budgets.
        ...

    def shutdown(self):
```

```
        # Drain or cancel owned work and report all remaining obligations.
        ...

def E19(config):
    # Validate semantic/lifecycle contracts before complete-work benchmarks.
    ...
    # Export evidence, counterexamples, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires validated KV and logits, correct request boundaries, causal masks, coherent positions, safe sharing, no premature reuse, and truthful resource accounting. Report completed requests, prefill positions computed, decode tokens, latency distributions, rejection/waiting counts, capacity peaks, tail slack, copy bytes, index behavior, and backend allocated/reserved peaks. Keep prediction, observation, and interpretation distinct. Report actual supported execution only; an incomplete scaffold supplies neither benchmark results nor an implemented serving engine.

Include a case where contiguous caching wins, a full-prompt reuse boundary, a forced hash collision, an exhausted pool, and cancellation with delayed readers. Verify complete shutdown after both success and controlled failure. Separate proposed optimized kernels from delivered reference attention paths. The strongest final report explains correct useful work and the resource trade-off without inventing speedups or suppressing unfavorable workloads.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest design justified by the evidence, including contiguous caching when it wins. Explain which benefit came from flexible allocation, shared storage, avoided prefill, or consumer implementation. Identify the next kernel, concurrency, or model integration needed before broader use, and keep proposed extensions separate from measured capabilities.

19.37 DMM35

Chapter Title: KV Cache Offloading Between VRAM and RAM
Specialization: Dynamic Memory Management and CUDA Systems

19.37.1 Exercise 00

Exercise Title: Build a Precise Mental Model of KV Cache Residency, CPU Offloading, Reload Latency, and the VRAM-Bandwidth Trade-Off During LLM Decoding

Part 1 - Exercise Contract and Why It Matters

Model lossless KV movement between CPU and GPU during full-context Transformer inference. Deliver a timeline of per-layer cache use, append, writeback, reload, and reclamation, with explicit value authority and completion boundaries. Separate the capacity benefit from transfer cost and GPU stall cost. Offloading changes residency, not which historical tokens the model is allowed to attend to.

Part 2 - System and Memory Mental Model

Previously processed tokens retain keys and values at each attention layer. CPU backing can preserve that history while GPU slots serve the active layer or blocks. Every valid copy needs a version and an ownership lifetime. A dirty GPU update cannot be replaced by an older CPU copy. A submitted transfer is not necessarily finished, and a free Python reference is not proof that its storage is reusable. Full-context active history is generally revisited each decode step, so cold does not automatically mean irrelevant.

Part 3 - Quantitative Prediction Before Execution

For homogeneous unquantized layers, useful payload is

$$B_{\mathrm{KV}} = 2LH_{kv}Ds\sum_{j} T_j.$$

Predict GPU residency, CPU backing, pinned staging, transition duplicates, and attention temporaries separately. Estimate reload time from measured bytes and effective link bandwidth, then add latency and scheduling overhead. Compare full-layer round trips with a policy retaining an authoritative CPU prefix and writing back only newly appended values. Do not promise the same transfer volume for these different protocols.

Part 4 - Experimental Design and Instrumentation

Use a tiny explicit decoder with fixed weights, evaluation, zero attention dropout, and no autograd. Start with unquantized full causal attention, one device, and a teacher-forced token trace. Preserve GQA head mapping, positions, mask visibility, request identity, and layer order. Keep model weights resident so cache offloading is the controlled variable. Record versions, device, link, dtype, dimensions, seed, trace ID, allocator backend, and initial state. Offloading model weights, lossy KV eviction, and quantization are separate work.

Draw separate CPU and GPU version records for a cache before append, after append, after writeback submission, and after completion. Mark which operations may read each copy in every state. Include the last sampled token that is never processed because a request ends. Its token ID does not create an extra KV position. Keep layer-local prepared values separate from globally committed request progress.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVOffloadContract:
    model_context: tuple
    cache_dtype: str
    gpu_payload_budget_bytes: int
    cpu_backing_budget_bytes: int
    pinned_budget_bytes: int
    authority_policy: str
```

```
def predict_offload_timeline(contract, decode_trace):
    # Track valid versions, residency, transfers, and completion dependencies.
    ...

def E00(config):
    # Define lossless semantics and audit a small layer-by-layer timeline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require separate columns for prediction, observation, and interpretation. Report cache useful bytes, retained capacity, transfer direction, completed latency, and unsupported metrics honestly. A capacity saving is not proof of a throughput gain. Export bounded CPU scalar logs without retaining live KV tensors or graphs. Hardware results must come from actual execution; a simulator can validate protocol transitions but cannot establish PCIe bandwidth.

Compare a model where all active history is revisited every step with a trace containing inactive requests. Explain which apparent cold blocks are merely waiting for their next mandatory use. The residency model should expose both cases without changing attention masks or token histories. A convenient software label cannot establish semantic dispensability or guarantee future reuse timing.

Part 7 - Engineering Interpretation and Philosophy

Explain which limitation moved from VRAM to host capacity or transfer bandwidth. Identify when lossless offloading makes an otherwise inadmissible workload possible and when fully resident execution remains preferable. The objective is correct useful inference within a declared resource envelope.

19.37.2 Exercise 01

Exercise Title: Measure Per-Layer KV Cache Growth During Autoregressive Generation and Determine When KV Memory Begins to Compete with Model Weights for VRAM

Part 1 - Exercise Contract and Why It Matters

Measure cache growth separately for every attention layer and determine when its residency creates pressure alongside fixed model weights. Produce an auditable token-by-layer memory ledger rather than subtracting arbitrary process totals and calling the difference KV memory.

Part 2 - System and Memory Mental Model

Useful per-layer KV payload follows processed lengths, KV heads, dimensions, and dtype. Static capacity can remain flat while valid occupancy grows; concatenation-based growth can temporarily retain old and new arrays. Parameters may share storage and backend memory includes context and workspace costs. There is no universal context length where KV becomes dominant: model layout, concurrency, available headroom, and temporary peaks change the crossover.

Part 3 - Quantitative Prediction Before Execution

Derive each layer's useful bytes and aggregate them across ragged requests. For equal K/V width, calculate $2H_{kv}Ds\sum_j T_j$ per layer. Predict the length where useful KV equals unique

parameter payload under a named model, then explain why actual admission can fail earlier. Estimate static reservation, growth-copy peaks, and the next decode quantum's additional values separately. Keep query head count out of stored-head accounting under GQA.

Part 4 - Experimental Design and Instrumentation

Use bounded contexts and a fixed-weight decoder. Capture scalar observations after prefill and selected completed decode steps, with layer identities and valid lengths preserved. Compare direct cache allocation accounting with CUDA allocated/reserved peaks and driver observations under their separate scopes. Reset peaks around declared regions. Do not synchronize after every layer in the primary throughput run merely to simplify logging; use a separate diagnostic replay for detailed attribution. Validate logits against the same baseline before interpreting resource pressure.

Count parameter storage independently from parameter names because tied weights may expose multiple names for the same backing. Record useful cache values and allocated capacity per layer before aggregation. Include an empty request and a short request beside a longer one to expose incorrect maximum-length multiplication. For heterogeneous layers, preserve their own dimensions and valid lengths rather than forcing a homogeneous shortcut.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LayerKVObservation:
    layer_id: int
    processed_lengths: tuple
    useful_bytes: int
    capacity_bytes: int
    observation_phase: str

def layer_kv_ledger(cache, architecture, phase):
    # Count unique KV storage and preserve each measurement scope.
    ...

def predict_weight_kv_crossover(architecture, parameter_storage):
    # Separate payload equality from actual headroom/admission constraints.
    ...

def E01(config):
    # Compare predictions with bounded per-layer growth observations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw dimensions, dtype widths, lengths, weight payload, useful KV, assigned capacity, temporary peaks, and measurement timestamps. Flag aliases and unsupported storage counters. Demonstrate a static-cache case where allocated bytes do not grow with every token, and a ragged case where maximum length times batch size overestimates useful payload. Do not manufacture an OOM to establish that cache and weights share finite capacity.

Plot or tabulate several checkpoints including prefill, early decode, and near the bounded context limit. A single final measurement cannot reveal a transient growth-copy peak. If measuring detailed layer boundaries changes synchronization and timing, retain those results as a diagnostic replay and use an uninstrumented or minimally instrumented complete run for the performance baseline.

Part 7 - Engineering Interpretation and Philosophy

Explain whether pressure comes from useful history, overreservation, transient copies, or non-cache allocations. Use that diagnosis to define a small offload target and leave a margin for future growth rather than choosing a policy solely from one memory percentage.

19.37.3 Exercise 02

Exercise Title: Build a PyTorch KV Cache That Stores Every Layer on CUDA and Establish Peak VRAM, Decode Latency, and Throughput Baselines

Part 1 - Exercise Contract and Why It Matters

Establish a fully GPU-resident KV baseline with correct prefill and decode. Measure cache capacity, complete peak VRAM, per-token latency, and useful throughput before introducing migration. Preserve enough metadata to reproduce the exact inference workload and compare every later policy fairly.

Part 2 - System and Memory Mental Model

Choose and name the baseline growth policy: bounded static capacity or a separately measured dynamic policy. Committed lengths exclude unwritten tail capacity. Layer attention can consume its own prepared new KV after ordered writes, while global token commit waits for required layer completion. Positionally transformed keys must retain their convention. Attention masks for incremental queries must expose the correct historical positions, including ragged requests.

Part 3 - Quantitative Prediction Before Execution

Predict useful cache growth, backing capacity, headroom for one decode quantum, and relevant attention temporaries. Derive separate prefill and decode token rates with clear numerators. For a static cache, predict a flat capacity curve and increasing occupancy. For a dynamic cache, include historical copy volume if concatenation is used. Define whether constructor, transfers, sampling, validation, and final drain belong to the end-to-end region.

Part 4 - Experimental Design and Instrumentation

Use evaluation with explicit zero dropout and an inference-safe no-gradient boundary. Compare cached outputs with full-prefix recomputation on a fixed teacher-forced trace. Record the attention backend, model revision, positions, GQA mapping, masks, batch shape, and dtype. Warm relevant kernels deliberately and report cold start separately. Use wall-clock completed regions and CUDA events for suitable device intervals. Keep evidence scalar and release intermediate logits between validation points instead of retaining the entire trace on GPU.

Include a rectangular incremental-attention mask test whose query sees every legitimate earlier position. Verify mask polarity and position offsets instead of assuming an API's generic causal flag matches decoding alignment. Preserve the same backend and output-validation policy in all later comparisons. If using GQA expansion in the reference consumer, count any repeated-head temporary storage in the baseline's peak.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class ResidentKVBaseline:
    def initialize(self, architecture, capacities):
        # Establish explicit backing layout and per-layer validity metadata.
        ...

    def prefill(self, requests):
        # Preserve causal positions, masks, and complete cache readiness.
        ...

    def decode_step(self, teacher_forced_tokens):
        # Process tokens, append each layer, and commit coherent state.
        ...

def benchmark_resident_case(runtime, trace, measurement_contract):
    # Check outputs before reporting complete useful-work metrics.
    ...

def E02(config):
    # Produce the auditable all-CUDA correctness and performance baseline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require attention outputs and logits within declared tolerances. Report useful KV, capacity, allocated and reserved peaks, output tokens, processed prompt tokens, latency spread, and failures separately. A short unsynchronized host submission interval is not completed decode latency. If actual generation diverges between variants, return to equal teacher-forced traces for performance attribution and report generation behavior as a separate validation outcome.

Record processed prompt tokens, generated tokens, and completed requests as separate quantities. A prompt-token rate cannot be substituted for decode throughput. Include a final completion boundary so trailing kernels are charged to the run. Release validation tensors between trials and confirm diagnostic logging does not retain whole cache histories whose lifetimes distort later memory measurements.

Part 7 - Engineering Interpretation and Philosophy

Identify the baseline bottleneck and the performance ceiling offloading cannot exceed without another mechanism. Preserve the resident reference as a correctness oracle even when larger future workloads no longer fit it; use smaller matching cases rather than inventing oversized baseline results.

19.37.4 Exercise 03

Exercise Title: Move Selected Layer KV Tensors from GPU to CPU After Attention and Restore Them Before Their Next Decode-Step Use

Part 1 - Exercise Contract and Why It Matters

Move selected layers' KV to CPU after their last supported attention use and restore it before the next use. Begin with a synchronous lossless protocol, then quantify memory relief and round-trip cost. Preserve every historical key and value; migration must not silently truncate context.

Part 2 - System and Memory Mental Model

Each layer requires an authority rule: CPU current, GPU current, or a coherent replicated version. An append makes new GPU values dirty relative to older backing. Writeback must finish before CPU data is authoritative and before the GPU source can be reused. Reload must finish before attention reads the destination. Dropping a CUDA tensor while a view or evidence record retains it does not reduce live cache residency. Backend reservation may remain even after logical offload succeeds.

Part 3 - Quantitative Prediction Before Execution

For a selected layer set, predict GPU bytes removed, CPU bytes added, and H2D/D2H traffic over a finite decode trace. Compare a simple full-history writeback with an append-aware protocol that keeps an unchanged CPU prefix and transfers only dirty new ranges. Include transient old/new coexistence, new-token growth, and any dense reconstruction. Estimate a serialized latency bound using measured effective bandwidth rather than a nominal bus label.

Part 4 - Experimental Design and Instrumentation

Choose one layer first and use deliberate completion boundaries around copies. Validate the entire cache and logits after reload. Expand to several layers only after the basic version protocol is auditable. Test empty history, partial capacity, different lengths, and failure before publishing a new CPU version. Keep weights, model operations, dtype, masks, and token trace fixed. Measure migration, capacity change, and complete decode time separately. Bound CPU backing and reclaim it when its request no longer needs that version.

Define the dirty-range protocol only for append-only fixed causal KV, where older stored values remain unchanged. If the supported operation overwrites earlier KV, expand dirty tracking accordingly or reject it. Compare full-history writeback and suffix-only writeback with identical restored values, not merely the same reported cache length. Record whether CPU backing is persistent or newly allocated on every offload.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LayerResidency:
    cpu_version: object
    gpu_version: object
    valid_tokens: int
    dirty_ranges: tuple
    state: str

def offload_layer(layer_state, cpu_destination):
    # Preserve the latest values and publish authority only after completion.
    ...

def restore_layer(layer_state, gpu_destination):
    # Restore authoritative valid KV before attention can consume it.
    ...

def E03(config):
    # Compare full writeback and supported dirty-range transfer protocols.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful values, stored capacity, transferred bytes by direction, version transitions, peak duplicate residency, and completed latency. Check that the next step does not read a stale CPU prefix or omit newly appended values. A failed migration must remain an explicit state, not a fabricated zero-filled cache. Do not infer total-VRAM reduction from the number of tensors whose device field changed.

Use a failure injector before authority publication to test that an incomplete CPU destination cannot become the next reload source. A cancelled request may make its values unnecessary, but its transfer endpoints still need safe lifetime handling. Report partial-copy state explicitly and keep retry behavior bounded; do not claim recovery from arbitrary device errors solely because preparation failure was handled.

Part 7 - Engineering Interpretation and Philosophy

Explain the capacity gained per transferred byte and why frequent layer reuse can make naive round trips costly. State which data becomes authoritative at each boundary so later asynchronous extensions have a precise protocol to preserve.

19.37.5 Exercise 04

Exercise Title: Verify Exact Numerical Equivalence Between Fully GPU-Resident KV Cache and Lossless CPU-Offloaded KV Cache

Part 1 - Exercise Contract and Why It Matters

Verify that lossless CPU migration preserves stored KV exactly and preserves the intended numerical inference result. Separate byte-preserving transport from attention arithmetic equivalence. Deliver staged comparisons that locate whether an error originates in copying, position mapping, masks, head layout, versioning, or a changed execution backend.

Part 2 - System and Memory Mental Model

A same-dtype copy can preserve cache values without quantization, but changing layout or attention backend can alter floating-point reduction order. Exact stored-value equality and bitwise output equality are therefore different claims. The exercise title's exactness requirement applies to preserved KV representations under the declared copy contract; inference comparisons need explicit numerical tolerances unless identical deterministic arithmetic is actually established. NaNs also require an appropriate comparison convention.

Part 3 - Quantitative Prediction Before Execution

Define expected differences for same-dtype finite-value round trips, selected raw encodings, and intentionally converted values. Predict zero cache corruption under the supported lossless path. State tolerances for attention and logits by dtype and accumulation policy. Construct negative controls for a stale version, swapped K/V, wrong layer, incorrect causal visibility, and an omitted last token. Explain which validation stage should detect each error.

Part 4 - Experimental Design and Instrumentation

First copy coordinate-coded KV through CPU and back without attention. Then compare contiguous resident and offloaded caches at every selected layer and decode position. Use a fixed teacher-forced trace with zero dropout and stable backend selection. Include partial tails, ragged sequences, GQA, nonzero positions, and boundary growth. For raw bit-pattern claims, compare bytes without converting values first. Run greedy generation only as additional evidence after direct cache, attention, and logit validation succeeds.

Create transport tests with finite coordinate-coded values, signed zero, and selected nonfinite encodings under an explicit byte-comparison policy. Keep dtype and layout fixed for the lossless baseline. A separate conversion control should fail the exact-transport criterion when information changes. For model comparisons, record accumulation precision and deterministic settings rather than assuming a fixed random seed controls every backend detail.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def compare_kv_transport(before, after, encoding_policy):
    # Test exact supported values or raw encodings without dtype conversion.
    ...

def compare_inference_paths(resident, offloaded, cases, tolerances):
    # Locate cache, attention, and logit differences separately.
```

```
    ...

def inject_validation_control(case, fault_kind):
    # Produce a labeled semantic or copy error that validation must catch.
    ...

def E04(config):
    # Establish transport exactness and appropriately scoped output parity.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report maximum and aggregate errors, mismatch coordinates, comparison policy, dtype, backend, and token position. A matching sampled token is insufficient: large logit errors can preserve the same argmax. Conversely, a tiny numerical change can alter a near-tied sampled decision without proving a lossy copy. Keep exact-copy tests separate from tolerance-based arithmetic tests and do not weaken tolerances after inspecting failures without documenting why.

Validate at more than one layer and token position so errors cannot compensate in a final output. Report the first mismatch coordinate and whether the copy already differed before attention ran. An intentionally stale version should be rejected by metadata as well as detected numerically. This distinguishes prevention by protocol from accidental detection by favorable test values.

Part 7 - Engineering Interpretation and Philosophy

Explain which equivalence was established and under what assumptions. Lossless offloading preserves the required information; it does not license unqualified claims of universal bitwise-identical outputs across devices, kernels, layouts, or software versions.

19.37.6 Exercise 05

Exercise Title: Compare Pageable and Pinned CPU Memory as KV Offload Destinations by Transfer Latency, RAM Cost, and Decode Throughput

Part 1 - Exercise Contract and Why It Matters

Compare pageable and pinned CPU destinations for KV offload using identical valid values and transfer volume. Measure preparation cost, completed copy latency, host capacity, and end-to-end decode throughput. Do not treat a quickly returned nonblocking call as proof that transfer completed or overlapped.

Part 2 - System and Memory Mental Model

Pinned memory changes host transfer capabilities and consumes a bounded system resource. Pinning a pageable tensor can allocate and copy rather than magically changing all existing references. For asynchronous D2H, the CPU must not consume incomplete destination values. For H2D from pinned memory, the source must remain alive and unchanged until transfer finishes. Reusable host buffers require ownership tracking; allocator caching and logical live pinned payload are different measurement scopes.

Part 3 - Quantitative Prediction Before Execution

Predict valid transfer bytes and destination capacity for both paths, then estimate bandwidth from completed regions. Include initial pinning and any pageable-to-pinned staging copy. Compare steady reuse with pinning on every iteration as separately labeled experiments. Derive host capacity when CPU backing and pinned staging coexist and identify the maximum outstanding slots allowed by the declared host budgets.

Part 4 - Experimental Design and Instrumentation

Preallocate matched CPU destinations and CUDA sources with the same dtype, layout, valid lengths, and values. Verify actual pin status on relevant tensors. Test both directions with explicit completion before CPU validation or source reuse. Warm deliberately, repeat trials, and separate cold allocation from reused buffers. Integrate each path into the same decoder trace after isolated copy checks. Hold stream policy fixed before studying overlap. Record whether pageable copies introduce hidden staging or synchronization only when observed, not by assuming a universal implementation detail.

Use reusable pinned destinations and a separately labeled pin-every-iteration control. Ensure the pageable comparison does equivalent copying and has the same valid capacity. A view retaining a larger host buffer can make logical payload smaller than retained RAM; record unique backing where available. Check that asynchronous D2H output is not inspected by a checksum or logging operation before its completion boundary.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class HostKVBuffer:
    storage: object
    pinned: bool
    capacity_bytes: int
    ownership_state: str
    completion_token: object

def allocate_host_kv(spec, pinned_policy, host_budget):
    # Preallocate within the correct pageable/pinned accounting scopes.
    ...

def transfer_trial(source, destination, completion_policy):
    # Measure completed copies and preserve both endpoint lifetimes.
    ...

def E05(config):
```

```
# Compare isolated transfer and complete decode behavior fairly.
...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report submission time, completed duration, transfer bytes, effective bandwidth, known live pinned payload, CPU backing, and complete throughput. If total OS or allocator pinned-memory usage is unavailable, say so instead of equating it with one tensor's payload. Require exact valid KV recovery. A pinned path that loses after including preparation is a legitimate result, not a reason to omit its allocation and copying cost.

Measure both isolated directional copies and their behavior inside decode. Host preparation or simultaneous link traffic can change effective throughput. Do not reuse a bandwidth number from another transfer size or topology without labeling it as an estimate. Known live pinned payload is an auditable lower-level quantity, not a substitute for an unavailable total OS page-lock measurement.

Part 7 - Engineering Interpretation and Philosophy

Choose host storage and staging from complete measured work and bounded capacity. Explain when pinning enables the intended pipeline and when its preparation cost or retained capacity outweighs the benefit for the tested cache sizes and reuse pattern.

19.37.7 Exercise 06

Exercise Title: Build a Layer-Wise KV Offload Pipeline That Keeps Only the Current Attention Layer Cache Resident in VRAM

Part 1 - Exercise Contract and Why It Matters

Build a serialized layer-wise pipeline that retains only the current layer's active KV payload on GPU. Keep other layer histories in CPU backing and restore them just in time. Establish this conservative capacity reference before introducing prefetch that necessarily adds simultaneous resident payload.

Part 2 - System and Memory Mental Model

Only current-layer cache residency is an application KV scope, not a promise that total VRAM equals one cache. Weights, activations, outputs, masks, workspaces, and allocator retention remain. A previous layer cannot release its source until all attention reads and required writeback finish. The current layer needs prepared new KV before its own attention, while global token commit follows required layer completion. Use reusable bounded storage rather than retaining separate CUDA arrays for every supposedly offloaded layer.

Part 3 - Quantitative Prediction Before Execution

Predict maximum layer-cache capacity for the supported dimensions and request lengths. Add new-token append space and any copy temporaries. Derive serialized H2D, attention, and D2H time over one decode step using separate measured components. Compare full-history writeback with a validated append-only dirty suffix protocol. State whether varying layer sizes require a maximum-sized slot and how much unused slot capacity remains.

Part 4 - Experimental Design and Instrumentation

Use one transfer/compute sequence with explicit completion at handoff boundaries. Process layers in decoder order and validate per-layer outputs against the resident baseline. Test prefill-to-decode transition, multiple decode steps, ragged requests, and maximum bounded length. Measure time waiting for reload and writeback separately from computation. Audit every live GPU KV reference, including views and diagnostic variables. Keep the no-prefetch policy intact in this experiment so its residency bound remains interpretable.

Start with a maximum-sized reusable current-layer slot and charge its full capacity even when a short layer uses fewer valid bytes. Later compare exact-size allocation as a separate policy with its growth and allocator costs. Test the first layer of a new decode step while the previous step's final layer has only just retired, because step boundaries can hide retained references.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class SerialLayerKVOffloader:
    def acquire_layer(self, layer, request_state):
        # Restore authoritative valid history into the bounded active slot.
        ...

    def run_attention(self, layer, prepared_tokens):
        # Order new KV writes and consume the correct full history.
        ...

    def retire_layer(self, layer, update_record):
        # Finish required writeback and readers before releasing the slot.
        ...

def E06(config):
    # Validate the one-active-layer protocol and account for total peaks.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct KV, attention, and logits at selected checkpoints. Report maximum live active cache bytes, actual slot capacity, temporary KV duplicates, host backing, backend peaks, and complete decode latency. If the implementation requires a second full CUDA cache while growing or copying, disclose it and revise the claimed bound. A retained allocator reservation is distinct from a second live active cache.

Audit tensor views and local variables as well as cache dictionaries when checking the one-active-layer claim. A deleted table entry does not prove the payload lost all owners. If appending requires a temporary larger dense cache, count that transient capacity. Preserve a clear distinction between a small live working set and unchanged backend reserved memory after safe reuse.

Part 7 - Engineering Interpretation and Philosophy

Explain the best capacity guarantee achieved by serialization and the stalls it exposes. Use this reference to evaluate later overlap as an explicit exchange of extra simultaneous capacity for reduced wait time.

19.37.8 Exercise 07

Exercise Title: Asynchronously Prefetch the Next Layer KV Cache from Pinned RAM While the Current Layer Performs Attention Computation

Part 1 - Exercise Contract and Why It Matters

Prefetch the next layer's KV from pinned CPU backing while the current layer computes. Preserve correctness with explicit readiness and source-lifetime evidence. Compare complete decode time and peak simultaneous KV residency against the serialized pipeline rather than promising overlap from API flags.

Part 2 - System and Memory Mental Model

Current-layer payload and next-layer destination coexist during useful prefetch. Any outgoing source still in use adds further residency. A transfer stream must wait for the correct CPU-backed version and available destination; the compute stream must wait for its reload-ready event before attention. Pinned source data cannot be rewritten while H2D still reads it. Prefetch crossing the final layer into the next decode step must respect token and version readiness, not merely cyclic layer indices.

Part 3 - Quantitative Prediction Before Execution

For measured next-layer transfer time and current-layer compute time, predict a best-case overlap window and the residual exposed stall. This is a hypothesis, not guaranteed concurrency. Calculate live current and incoming payload, staging, and any retained outgoing source. Construct a small transfer case likely to be hidden and a large case whose copy exceeds the available compute window. Keep host submission and device completion intervals separate.

Part 4 - Experimental Design and Instrumentation

Add one-layer lookahead to the validated serial engine using a dedicated transfer stream and per-generation events. Start with one request and static capacity, then test growth and ragged histories. Validate restored KV before attention in diagnostic replays. Compare blocking restoration, nonblocking submission without overlap, and actual prefetch under identical token traces. Use a short timeline to establish concurrency, then unprofiled repeated runs for throughput. Include pipeline startup and drain in end-to-end time and retain only bounded event records.

Use ticket identities containing layer, step, version, and destination generation. Reusing one event object without a protocol can make old readiness appear to authorize a new payload. Initially allocate a bounded event/ticket set and recycle it only after consumers finish. Include the last-layer-to-first-layer wraparound explicitly in the dependency diagram rather than treating the model as an unversioned ring.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVPrefetchTicket:
    layer_id: int
    decode_step: int
    required_version: int
    destination_generation: int
    ready_event: object

def schedule_kv_prefetch(engine, next_layer, dependency_state):
    # Protect pinned source and reserve a nonconflicting destination.
    ...

def consume_prefetched_layer(ticket, compute_stream):
    # Wait for exact-version readiness before using KV in attention.
    ...

def E07(config):
    # Verify timeline overlap, numerical parity, and extra residency costs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report transfer and compute intervals, residual stall, completed decode time, active/incoming bytes, and backend peaks. A separate stream can still serialize through dependencies or resource contention. Do not infer overlap from a shorter host call. Include a source-mutation negative control in a safe transition simulator and require the lifetime protocol to reject it, rather than deliberately racing real device memory.

Compare the expected overlap window with an observed short timeline and then with complete unprofiled time. Prefetch can overlap attention yet compete for memory bandwidth and slow that attention. Report both effects. Do not add compute time and copy time to calculate wall time when they overlap, and include cold pipeline fill and final drain in end-to-end comparisons.

Part 7 - Engineering Interpretation and Philosophy

Explain whether prefetch reduced the critical path or merely shifted work. Choose a bounded lookahead depth justified by measured benefit and headroom, and state which versions can be prepared before the next token is actually computed.

19.37.9 Exercise 08

Exercise Title: Asynchronously Evict the Previous Layer KV Cache to CPU Without Blocking the Current Attention Layer

Part 1 - Exercise Contract and Why It Matters

Write back the previous layer's dirty KV while the current layer performs attention, without blocking unrelated compute unnecessarily. Preserve source lifetime, CPU destination ownership, and authoritative-version publication. Measure whether asynchronous eviction reduces stalls and what capacity remains occupied until completion.

Part 2 - System and Memory Mental Model

An outgoing GPU cache is still live while D2H reads it. It becomes reusable only after its last device consumer and transfer complete. The CPU destination is not valid backing until the correct event finishes, and cannot simultaneously serve an incompatible reader or writer. With prefetch enabled, outgoing, current, and incoming payloads may coexist. Two staging slots cannot bypass these dependencies; they may force waiting before a slot can be overwritten.

Part 3 - Quantitative Prediction Before Execution

Predict transferred bytes for full-cache and dirty-range writeback protocols. Draw a timeline containing previous-layer D2H, current-layer computation, and next-layer H2D. Count simultaneous source and destination ownership at each boundary. Estimate a best-case hidden interval and exposed writeback tail. Do not assume opposite-direction copies run at independent full bandwidth: copy engines, host memory, and the link can contend.

Part 4 - Experimental Design and Instrumentation

Begin with the verified prefetch engine and introduce a separate eviction stream only where dependencies permit. Order eviction after append completion and the last attention read. Publish CPU backing after transfer completion, then release GPU ownership. Test a layer needed again before its previous writeback finishes, a growing tail, and request cancellation. Compare a serialized writeback control, asynchronous submission, and evidenced overlap. Measure full decode time with final drain and record bounded transition state.

Distinguish writing a dirty suffix into persistent CPU backing from replacing the entire backing tensor. For suffix writeback, preserve the unchanged prefix and publish the combined version only after new values arrive. An H2D reader of an overlapping CPU range can conflict with D2H writes; serialize overlapping ranges or use separate bounded backing versions under an explicit protocol.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVEvictionTicket:
    source_generation: int
    layer_id: int
    version: int
    dirty_ranges: tuple
    complete_event: object
```

```
def schedule_kv_eviction(engine, layer_state, last_reader_event):
    # Protect the source and destination through ordered D2H completion.
    ...

def publish_cpu_backing(ticket, residency_state):
    # Advance authority and release exact-generation GPU ownership safely.
    ...

def E08(config):
    # Validate overlapped writeback and any additional residency or stalls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact backed values and correct next-use logits. Report D2H bytes, writeback delay, pending-source capacity, H2D contention, and completed useful work. Verify that a delayed old event cannot publish over a newer CPU version. A visible overlap interval is not sufficient if total decode becomes slower. Record capacity-induced waits explicitly instead of hiding them as generic attention time.

Inject delayed writeback completion in a simulator and issue the next demand for that layer. The engine must wait, use a valid newer source, or reject according to its contract. It must not restore stale values merely because the older CPU tensor exists. Verify source retirement matches the exact GPU slot generation that the D2H transfer actually read.

Part 7 - Engineering Interpretation and Philosophy

Explain the conditions under which eviction is off the critical path and when it competes with more urgent reloads. Choose a transfer ordering policy that prioritizes correct demand readiness while retaining bounded outgoing work and truthful peak-capacity accounting.

19.37.10 Exercise 09

Exercise Title: Coordinate KV Prefetch, Attention Compute, and KV Eviction with Dedicated CUDA Streams and Events Without Device-Wide Synchronization

Part 1 - Exercise Contract and Why It Matters

Coordinate reload, attention, append, and eviction using explicit CUDA stream dependencies and events. Remove device-wide synchronization from the steady pipeline while preserving meaningful measurement and CPU-consumption boundaries. Deliver a dependency graph and a generation-aware transition audit.

Part 2 - System and Memory Mental Model

Compute must wait for the required KV version; eviction waits for the last reader and new writes; slot reuse waits for all previous users. The host may submit work ahead without making it complete. Events establish ordering, not ownership by themselves. PyTorch allocator

lifetime mechanisms can protect backend deallocation, but do not authorize overwriting a still-live application pool slot. A CPU consumer of D2H output needs actual completion before reading.

Part 3 - Quantitative Prediction Before Execution

Draw the dependency graph for two decode steps and three layers with bounded staging. Predict which waits are necessary and identify a dependency cycle that would deadlock a naive ring schedule. Count pending events and live slot generations. Estimate critical-path time from dependencies and observed intervals; do not add overlapping stream durations as if all operations were serial. State where outer benchmark synchronization remains necessary.

Part 4 - Experimental Design and Instrumentation

Use named compute, reload, and eviction streams with operation IDs tied to request, layer, step, version, and slot generation. Start with deterministic simulated completion orders, then run supported CUDA traces. Audit every wait before optimizing it away. Compare against a fully synchronized correctness control and validate all outputs. Test event reuse, next-step wraparound, cancellation, and shutdown. Keep timing instrumentation separate from dependency events and include its overhead in a control run.

Name every edge in the dependency graph by the value or storage lifetime it protects. Event readiness, allocator deallocation safety, and application overwrite permission are separate obligations. Keep timing events separate from dependency-only events when configuring measurements. A CPU wait for a specific D2H completion can be valid even when the steady compute schedule contains no device-wide barrier.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVDependencyIdentity:
    request_generation: int
    layer_id: int
    decode_step: int
    version: int
    slot_generation: int

class KVStreamCoordinator:
    def reload_dependencies(self, identity):
        # Wait only on required source and destination obligations.
        ...

    def compute_dependencies(self, identity):
        # Order attention after the matching reload and new KV writes.
        ...

    def eviction_dependencies(self, identity):
```

```
        # Order writeback and reclamation after all exact-generation users.
        ...

def E09(config):
    # Validate the dependency graph before measuring asynchronous execution.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require identical valid KV and appropriate numerical output parity with the synchronized control. Report event/wait counts, stage intervals, host submission, completed wall time, and peak pending state. Mark inferred intervals separately from directly observed ones. Absence of device-wide synchronization does not prove absence of stalls. A missing dependency detected by simulation must be repaired before running real asynchronous accesses.

Test an event recorded for an old step against a new step's ticket and require identity validation to reject the mismatch. Check for cycles in the simulated wait graph before launching real CUDA work. At shutdown, account for work submitted on every owned stream so a successful return cannot conceal delayed writes or live sources that outlast their logical request.

Part 7 - Engineering Interpretation and Philosophy

Explain which synchronization was removed and which dependencies remain essential. Recommend the smallest explicit graph that preserves correctness; additional streams are worthwhile only when measured concurrency improves useful work within resource limits.

19.37.11 Exercise 10

Exercise Title: Build Double-Buffered KV Staging Memory So One Layer Cache Transfers While Another Layer Uses GPU-Resident KV Data

Part 1 - Exercise Contract and Why It Matters

Build double-buffered KV staging with explicit per-slot states and generations. Let one layer transfer while another uses its cache where dependencies and capacity permit. Demonstrate when two slots suffice and when pending writeback forces a stall instead of silently allocating an uncounted third buffer.

Part 2 - System and Memory Mental Model

A staging slot has capacity, assigned identity, valid version, readiness, and outstanding users. Alternating index modulo two is not a safe lifecycle protocol. A slot holding previous-layer dirty data cannot receive next-layer H2D until eviction and all readers finish. Host backing and pinned staging have independent lifetimes. Different layer lengths or dimensions can require maximum-sized slots or explicit size classes, whose retained capacity must be included in the budget.

Part 3 - Quantitative Prediction Before Execution

Hand-simulate three layers over two decode steps with H2D, compute, and D2H durations. Predict slot states and the first required reuse wait. Calculate two-slot capacity using the supported maximum layer size and separate valid payload from unused slot capacity. Add a

case where long D2H prevents ideal overlap. Estimate host staging occupancy and event state at startup, steady execution, and final drain.

Part 4 - Experimental Design and Instrumentation

Implement a checked slot state machine before introducing CUDA transfers. Require acquisition to prove all prior-generation obligations ended. Use the same layer trace as the event-coordinated reference. Test odd layer counts, step wraparound, unequal cache sizes, growth, and cancellation. Measure warm steady-state overlap separately from complete latency. Validate contents after every handoff in diagnostic replays and compare model logits. A three-slot variant is an optional separately budgeted control, not an invisible fallback.

Use a schedule where eviction is slower than computation and another where reload dominates. Determine which phase prevents the next slot reuse in each case. For unequal layer sizes, record valid bytes and maximum slot capacity separately. A two-buffer implementation must not quietly allocate a temporary third full-layer tensor when a slot is unavailable; waiting is a valid bounded response.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVStagingSlot:
    slot_id: int
    generation: int
    capacity_bytes: int
    assigned_identity: object
    state: str
    pending_tokens: tuple

class DoubleBufferedKV:
    def acquire_slot(self, identity, required_bytes):
        # Reject or wait until the prior generation is safely reusable.
        ...

    def transition(self, slot, event, new_state):
        # Validate the state graph and exact completion identity.
        ...

    def audit(self):
        # Count all live payload, capacity, and pending obligations.
        ...

def E10(config):
    # Validate two-slot schedules including capacity-induced stalls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual allocated slot capacity, live valid bytes, slot waits, transfer intervals, temporary buffers, and complete throughput. Verify no hidden allocation exceeds the two-slot contract during growth or reconstruction. A stall can be the correct outcome of a safe schedule. Distinguish waiting for buffer availability from waiting for link completion and from attention computation; they suggest different remedies.

Validate slot identity after several odd-length layer cycles and decode-step wraparounds. A simple alternating counter may appear correct in a two-layer toy model while failing later. Include cancellation between transfer submission and consumption, then confirm the cancelled generation's completion cannot release storage assigned to another request. Audit pinned host slots using the same lifetime discipline.

Part 7 - Engineering Interpretation and Philosophy

Explain whether double buffering buys enough overlap for its retained capacity. State the workload and transfer assumptions under which two slots are sufficient and why buffer count must follow lifetime analysis rather than a fixed rule that two always hides all movement.

19.37.12 Exercise 11

Exercise Title: Compare Full KV Offloading Against Selective Layer Offloading and Identify Which Layers Are Worth Keeping Permanently Resident in VRAM

Part 1 - Exercise Contract and Why It Matters

Compare full offloading with selective permanent residency for chosen layers. Determine which retained caches save the most exposed decode cost under a fixed GPU KV budget. Keep the same processed-token trace and distinguish transfer volume saved from actual critical-path latency saved.

Part 2 - System and Memory Mental Model

In a homogeneous full-context decoder, every active layer's history is normally used once per decode step. Early or late layer position alone does not make one intrinsically hotter. Residency value can differ through cache size, transfer time, available overlap windows, and contention. Optional heterogeneous architectures need their own accounting. Retaining one layer uses capacity that could otherwise provide staging or admit another request.

Part 3 - Quantitative Prediction Before Execution

Estimate bytes and exposed stall avoided by retaining each candidate layer. Construct two layers with equal payload but different overlap opportunities, and predict why transfer volume alone gives an incomplete ranking. Calculate resident-layer capacity plus staging and transition headroom for each subset. Compare full offload, no offload, a simple fixed subset, and a measured selective policy under equal useful work.

Part 4 - Experimental Design and Instrumentation

Calibrate copy and compute intervals on separate traces. Evaluate small layer subsets first so exhaustive comparisons remain auditable, then test a simple heuristic. Preserve model weights, dtype, request lengths, mask semantics, and attention backend. Include stable contexts and growth phases. Measure cold population, warmed decode, and request completion separately.

Validate all outputs and report whether staging capacity changed when a layer became permanently resident. Test selected policies on held-out traces rather than choosing and evaluating on the same favorable sequence.

Evaluate whether retaining a layer reduces critical-path reload, dirty writeback, or both under the chosen authority protocol. Saving full writeback bytes in one protocol does not imply the same gain in a suffix-only protocol. Keep CPU-backed copies and initialization costs in the comparison. A permanent resident layer still grows and needs budget admission for later tokens.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class LayerResidencyCost:
    layer_id: int
    resident_bytes: int
    transfer_bytes_avoided: int
    exposed_stall_estimate: float
    uncertainty: object

def rank_resident_layers(measurements, staging_contract, budget):
    # Compare saved exposed cost per constrained capacity, not layer order.
    ...

def evaluate_layer_subset(subset, decoder_trace, resource_contract):
    # Include all retained, staging, and transition memory in the comparison.
    ...

def E11(config):
    # Compare full and selective offload with held-out correctness checks.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report retained layers, payload bytes, staging capacity, transfers by direction, demand stalls, complete latency, and backend peaks. Include a counterexample where the largest cache is not the best retention choice under the measured objective. Do not claim a universal best layer subset from one model or trace. A policy that improves one request's latency but lowers useful concurrency must report that trade-off.

Test the chosen subset on a different context-length and concurrency trace. The best overlap opportunity can change when attention compute grows or copy contention increases. Report a case where the simple fixed subset performs as well as the more complex policy. Prefer the simpler choice when the measured gain is smaller than uncertainty or monitoring overhead.

Part 7 - Engineering Interpretation and Philosophy

Choose a minimal selective policy supported by measurements and explain its workload sensitivity. Distinguish preserving capacity for admission from using that capacity to reduce transfer stalls, and state which objective the experiment actually optimized.

19.37.13 Exercise 12

Exercise Title: Build a VRAM Watermark Policy That Begins KV Offloading Before Cache Growth Reaches the CUDA OOM Boundary

Part 1 - Exercise Contract and Why It Matters

Begin KV demotion before predicted growth and transient work exhaust the declared GPU budget. Implement a watermark policy with explicit metric scope, hysteresis, and next-step admission checks. Avoid treating a sampled free-byte value as an atomic reservation or a guarantee against every CUDA OOM.

Part 2 - System and Memory Mental Model

Application live KV, pool-backed capacity, PyTorch allocated memory, allocator-reserved memory, and driver headroom describe different layers. Offloading can release logical capacity while cached reservations remain. A watermark must name its accounting scope and include staging, provisional copies, output workspace, and pending sources. Other device users and allocator constraints can change real headroom between observation and allocation. The engine can strictly enforce only the resources it actually owns and admits.

Part 3 - Quantitative Prediction Before Execution

Predict the next token quantum's growth and maximum simultaneous transition capacity. Define high and low thresholds in bytes, with a margin and a bounded observation age. Hand-simulate a growth trace that triggers early offload, then stabilizes without repeated promotion/demotion. Construct a transient copy peak that a steady-state-only watermark misses. Leave unsupported or stale headroom evidence unknown rather than silently treating it as zero.

Part 4 - Experimental Design and Instrumentation

Use a small application budget to trigger pressure deterministically before real device exhaustion. Separate a known-valid engine budget from advisory driver observations. Test growth spikes, delayed writeback, retained free pool capacity, and fluctuating synthetic external pressure in a clearly labeled model. Apply actions at coherent operation boundaries and reserve complete transition demand before dispatch. Compare fixed residency, reactive high-water response, and hysteresis with matching useful traces. Record rejected actions and the dependencies that prevent immediate reclamation.

Keep a watermark ledger with measurement layer, timestamp, support status, and proposed capacity relief. Do not subtract planned evictions from current usage until their sources are actually reclaimable. Include retained free pool payload in a backed-capacity scope and distinguish it from driver-visible free bytes. Use an explicit unknown state when a counter is unsupported or too old for the action.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVWatermarkEvidence:
    scope: str
    observed_bytes: object
    sample_age_seconds: float
    high_bytes: int
    low_bytes: int
    next_step_demand_bytes: int

def choose_watermark_action(evidence, ownership_state, budgets):
    # Validate scope/age and account for growth and transition headroom.
    ...

def admit_offload_transition(action, pending_operations):
    # Ensure the proposed relief does not exceed capacity while in flight.
    ...

def E12(config):
    # Replay growth and delayed reclamation without uncontrolled OOM probing.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report thresholds, observed scope, sample age, predicted demand, actual peaks, action count, stalls, and admission failures. A policy must not claim recovered bytes until ownership truly becomes reusable. Record backend OOM separately if encountered; a watermark test can succeed without producing one. Explain any remaining gap between an enforced payload budget and total device usage rather than calling the controller universally OOM-proof.

Validate a sawtooth growth trace and a stable near-threshold trace. Excessive promotion/demotion indicates weak hysteresis or inaccurate demand prediction. A reserved-memory value can stay high after logical pressure falls, so a controller using it needs a justified policy rather than endlessly repeating offload. Report no universal protection against unrelated processes changing the device's available headroom.

Part 7 - Engineering Interpretation and Philosophy

Explain which warning is actionable and which uncertainty remains outside the engine's control. Choose margins and hysteresis from tested growth and transition behavior, while preserving honest limits on prediction under other processes, changing workspaces, or unsupported allocator fields.

19.37.14 Exercise 13

Exercise Title: Implement Hot and Cold KV Block Classification from Access Frequency, Layer Reuse Timing, Sequence Activity, and Reload Cost

Part 1 - Exercise Contract and Why It Matters

Classify KV blocks using declared access, reuse, activity, and reload-cost signals. Deliver a score with evidence age and uncertainty, then test whether it predicts useful residency decisions. Do not confuse cold placement priority with permission to delete required full-context history.

Part 2 - System and Memory Mental Model

For an active full-attention request, historical blocks are usually consumed at each relevant layer on every decode step. Old tokens are not automatically cold merely because they were created long ago. Inactive requests, reusable prefixes, different next-use timing, and scheduling gaps can create residency opportunities. A host method call count may not equal actual attention reads. Access instrumentation must describe which events it observes and how they relate to the consumer.

Part 3 - Quantitative Prediction Before Execution

Define score inputs with units: expected next-use delay, bytes, reload time, observed uses, active-request status, and uncertainty. Predict classifications for an active long history, an inactive retained prefix, and a soon-resuming request. Construct a trace where LRU ranks required old blocks poorly. Calculate the consequences of a false-hot and false-cold prediction without altering attention semantics.

Part 4 - Experimental Design and Instrumentation

Use fixed traces with known future accesses for diagnostic evaluation, but keep the online policy limited to information actually available at decision time. Compare recency, activity-only, and a simple cost-aware score. Record observed reads separately from predicted reuse. Include a homogeneous active decode control where block frequencies are nearly uniform. Measure instrumentation overhead and bound logs. Keep model outputs fixed across classifications; the policy chooses placement only and every required block remains retrievable.

Define observed-use events at the consumer boundary rather than counting only translation calls. One grouped attention operation can read many blocks, while repeated lookup requests may share one pending restoration. Record sequence activity and scheduled next use independently. A hypothetical future trace may evaluate prediction quality, but its oracle timing must remain unavailable to the online classifier.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVHeatEvidence:
    block_identity: tuple
    active_owner_count: int
    observed_uses: int
    predicted_next_use_seconds: object
    reload_seconds: object
    sample_age_seconds: float
```

```
def classify_kv_blocks(evidence_rows, policy, support_contract):
    # Preserve unknowns and rank placement without dropping required history.
    ...

def evaluate_heat_predictions(predictions, later_accesses):
    # Separate predictive quality from complete residency-policy usefulness.
    ...

def E13(config):
    # Test controlled hot/cold examples and full-context counterexamples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report score inputs, classifications, later uses, false predictions, transfer consequences, and complete useful work. A correlation between recency and reuse is not a universal cache law. Mark unavailable timestamps or access counts explicitly. Demonstrate that a semantic attention-importance score is a different mechanism from lossless residency ranking and is outside this chapter unless separately implemented as a changed task.

Use two old blocks with different request activity and two active blocks with equal reuse frequency. Explain why age alone misses the first distinction and provides little information for the second. Evaluate classifications through actual residency outcomes and full-context correctness. A false-cold page must be restored, not omitted from attention to make the classifier's performance appear better.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest classifier justified by the tested scheduling pattern. Explain whether genuine reuse differences exist in the workload and when uniform full-context accesses leave little opportunity for block-level hot/cold optimization beyond scheduling and transfer overlap.

19.37.15 Exercise 14

Exercise Title: Keep Hot KV Blocks in VRAM and Demote Cold Blocks to CPU While Maintaining a Strict GPU KV Cache Budget

Part 1 - Exercise Contract and Why It Matters

Keep preferred blocks on GPU and demote lower-priority blocks to CPU while enforcing a strict named GPU KV payload budget. Preserve lossless full-context attention through explicit restore or a validated streaming consumer. Deliver budget audits covering transitions, staging, and pending users.

Part 2 - System and Memory Mental Model

A block can be absent from VRAM yet still required by the next attention. The consumer must restore it or process it through a correct blockwise method. If attention gathers the complete history into a dense CUDA tensor, that tensor counts toward live KV payload and may exceed the budget. Splitting attention requires global softmax normalization across blocks,

not averaging independent block outputs. A budget below the consumer's minimum feasible working set requires explicit rejection or a different validated consumer.

Part 3 - Quantitative Prediction Before Execution

Predict resident hot bytes, demanded cold bytes, staging capacity, outgoing sources, and provisional copies for a short trace. Calculate peak concurrent ownership rather than subtracting planned evictions immediately. Include a case where the full dense history cannot fit even after all cold blocks are demoted. State whether the strict limit covers valid bytes or allocated payload capacity; the primary contract must charge actual live slot capacity.

Part 4 - Experimental Design and Instrumentation

Start with the validated layer consumer and budgets large enough for its working set. Add block classification and controlled demotion without changing values or masks. Test delayed eviction, demand arrival during reload, unavailable victims, and a too-small budget that must be rejected. An optional streamed attention extension needs independent numerical checks for global normalization, positions, and GQA. Track CPU backing and pinned staging separately. Keep a scalar transition ledger that can be audited independently of policy counters.

Charge all allocated GPU KV slot backing to the strict payload-capacity budget, including free retained pool slots, staging, and independent gather outputs. Views of the same backing contribute once. Moving a mapping to CPU does not reduce backed capacity while its GPU tensor remains retained. Either reuse that fixed capacity within the bound or explicitly destroy eligible independent backing under a separate release policy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVCapacityState:
    free_retained_capacity_bytes: int
    resident_capacity_bytes: int
    staging_capacity_bytes: int
    pending_source_bytes: int
    provisional_bytes: int
    budget_bytes: int

def admit_kv_residency(plan, state, consumer_requirements):
    # Count unique live backing and reject impossible working sets.
    ...

def demote_cold_blocks(engine, candidates, completion_evidence):
    # Preserve authority and defer capacity relief until safe reclamation.
    ...
```

```
def E14(config):
    # Validate strict capacity and full-context outputs through all transitions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no stable or transitional state above the declared live-capacity bound. Report unique backing so a staging view is not double-counted, while independent duplicates are not omitted. Record payload budget, total backend peaks, transfer volume, stalls, and rejected operations separately. A correct budget rejection is preferable to claiming that demotion alone permits an attention consumer whose dense inputs cannot fit.

Test a demand whose pages individually fit but whose full dense materialization would exceed the limit. Require early rejection or the separately validated streaming consumer. For blockwise attention, global normalization and mask positions must match the dense reference. Report total backend reserved memory beside the enforced payload bound so the reader can audit the boundary of the guarantee.

Part 7 - Engineering Interpretation and Philosophy

Explain the budget actually guaranteed and the consumer assumptions behind it. Distinguish lossless movement from context pruning, and state when a streamed attention implementation is required to make a smaller working-set contract achievable.

19.37.16 Exercise 15

Exercise Title: Combine Paged KV Cache with CPU Offloading So Individual Physical KV Blocks Can Be Page-In or Page-Out Independently

Part 1 - Exercise Contract and Why It Matters

Combine paged KV addressing with independent CPU/GPU migration of individual layer blocks. Preserve logical token order, shared-prefix ownership, copy-on-write, and valid versions through page-in and page-out. Make the migration unit explicit when adapting the all-layer bundle representation from the earlier paged-cache chapter.

Part 2 - System and Memory Mental Model

For layer-wise transfer, a page can own K and V for one layer and a fixed token interval. Its identity includes request-sharing group, layer, logical range, and version. An earlier table entry covering all layers must be refined or linked to per-layer residency records; it cannot silently become a one-layer page. Physical means application-owned payload, not a hardware frame. Shared mappings reference one authoritative page version, while residency and active transfer ownership are tracked separately.

Part 3 - Quantitative Prediction Before Execution

Derive per-layer page capacity from token capacity, KV heads, head dimension, and dtype. Calculate touched pages for a range spanning a partial tail, and predict migration bytes versus useful requested elements. Include shared references, clean CPU backing, dirty tail writeback, and provisional private copies. Count duplicate page-in requests separately from actual unique transfers. Predict a full-pool miss with no safely reclaimable victim.

Part 4 - Experimental Design and Instrumentation

Adapt checked logical tables and generation-aware pools rather than bypassing them with raw tensor pointers. Start with synchronous migration and a dense consumer whose working set fits, then use the established stream protocol. Test partial tails, cross-block reads, same-page demand from two requests, shared-prefix destruction, copy-on-write, and stale transfer completion after slot reuse. Compare every restored layer history and decoder output with a resident reference. Bound CPU backing, staging, outstanding operations, and GPU payload separately.

Record the precise page unit in bytes and tokens for each layer. If the previous chapter used all-layer bundles, preserve a parent logical identity while adding checked per-layer backing records. Test two requests sharing one layer page and ensure only one restoration of the required version is scheduled. A page-in operation must not inflate reference ownership merely because multiple requesters await it.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LayerKVPage:
    layer_id: int
    logical_block: int
    valid_tokens: int
    version: int
    gpu_handle: object
    cpu_backing: object
    residency_state: str

class PagedKVOffloader:
    def ensure_resident(self, page_identity, consumer):
        # Deduplicate restoration and return exact-version readiness.
        ...

    def page_out(self, page_identity):
        # Preserve authoritative values and active/shared ownership.
        ...

    def publish_mapping(self, operation, completion_evidence):
        # Validate page and slot generations before publishing residency.
        ...

def E15(config):
    # Validate paged translation and independent layer-page migration.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit mappings, references, versions, residency, transfer state, and capacity independently. Report page-in/out bytes, duplicated backing, pending ownership, cache misses, stalls, and full decode time. A simulated page fault is a software residency miss, not an illegal device pointer access. Rejected demand must remain explicit when the working set is infeasible. Do not claim a transparent general tensor or optimized paged-attention backend from this restricted migration interface.

Cancel one requester while another still needs the shared restoration. The remaining requester must receive correct data and the cancelled one must not publish a stale mapping later. Invalidate any GPU handle before recycling its slot, preserve valid CPU backing, and check partial-tail boundaries after reload. Track per-layer migration bytes independently from global logical token capacity.

Part 7 - Engineering Interpretation and Philosophy

Explain which granularity improves placement flexibility and which overheads it adds. State whether the actual consumer benefits from page-level residency or still reconstructs full layer histories, and use that distinction to frame the measured capacity and performance results.

19.37.17 Exercise 16

Exercise Title: Detect KV Cache Thrashing When Frequently Reused Blocks Are Repeatedly Offloaded and Reloaded Across PCIe

Part 1 - Exercise Contract and Why It Matters

Detect repeatedly moved KV working sets and distinguish unavoidable offload traffic from avoidable policy churn. Deliver a diagnostic that relates repeated migration to exposed stalls and complete useful-work degradation. A large transfer count alone is not sufficient to diagnose an incorrect residency policy.

Part 2 - System and Memory Mental Model

Full-context decoding can require every offloaded layer history again at the next step. Repeated reload is then inherent to the chosen capacity and consumer contract. Additional promotion/demotion before any useful use, misleading prefetch, or preventable eviction of soon-needed pages can be avoidable churn. A detector needs a named comparison policy and a time window. Fault count, bytes moved, stall duration, and missed throughput are related but nonidentical signals.

Part 3 - Quantitative Prediction Before Execution

Construct traces for mandatory layer cycling, a fitting working set with avoidable eviction, and a working set just larger than capacity. Predict reloads per useful access, transfers that produce no use, dirty writeback, and exposed wait intervals. Define ratios with explicit denominators and leave empty cases undefined. Calculate whether a larger retained set or a smaller admitted batch could remove the repeated capacity conflict without changing required attention history.

Part 4 - Experimental Design and Instrumentation

Replay deterministic access traces through demand-only, simple recency, and bounded lookahead policies. Keep model/token semantics and total resource scopes fixed. Record page version and generation so repeated requests for one pending transfer are not counted as multiple completed migrations. Use a counterfactual feasible policy or controlled capacity change to

test attribution. Measure diagnostics overhead separately and retain bounded scalar windows. Validate numerical outputs before comparing transfer and latency patterns.

Label a movement cycle by whether the page was usefully consumed between reload and eviction. This helps separate wasted speculation from mandatory full-context traffic. Compare the same trace with enough capacity to hold its working set and with one fewer slot. Keep the model's required history fixed in both cases, even when the constrained run becomes substantially slower.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVMovementWindow:
    useful_accesses: int
    reload_bytes: int
    writeback_bytes: int
    unused_prefetch_bytes: int
    exposed_wait_seconds: float
    comparison_policy: str

def detect_kv_thrash(window, trace_features, support_contract):
    # Separate mandatory traffic, avoidable churn, and unknown attribution.
    ...

def validate_thrash_diagnosis(trace, controlled_replays):
    # Test a specific mechanism without silently changing the computation.
    ...

def E16(config):
    # Compare migration patterns with useful work and latency consequences.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw movement events and ratios beside the diagnostic label. Include a mandatory round-trip trace that should not be called an avoidable-policy failure and a deliberately poor policy that should be detected. A correlation between reloads and latency does not establish which decision caused the stalls. Preserve unknown attribution when no controlled comparison supports a stronger claim.

Use a controlled policy change to test whether the detector's proposed remedy reduces exposed waits. A larger hit rate can still lose if the policy retains many small cheap pages and repeatedly reloads one large expensive page. Preserve raw bytes, event counts, and latency evidence rather than collapsing every pattern into one unqualified thrashing percentage.

Part 7 - Engineering Interpretation and Philosophy

Recommend an actionable response only when its mechanism is supported: retain a tested working set, reduce speculative movement, alter scheduling, or admit less simultaneous work. Explain when the observed cost is the unavoidable price of the chosen capacity target and consumer.

19.37.18 Exercise 17

Exercise Title: Build a Cost-Aware KV Residency Policy That Balances Available VRAM, Block Size, Expected Reuse, PCIe Bandwidth, and GPU Stall Time

Part 1 - Exercise Contract and Why It Matters

Build a cost-aware residency policy combining constrained GPU capacity, page size, predicted reuse, measured transfer cost, and exposed GPU wait. Compare it with simple baselines under equal lossless inference semantics. Deliver a decision ledger and held-out evaluation rather than claiming a globally optimal policy from one trace.

Part 2 - System and Memory Mental Model

A retention decision saves future reload only if the page is actually reused while resident. Dirty eviction can add writeback and transition headroom. Available overlap changes exposed cost, while shared pages serve multiple owners. Capacity is discrete and current leases can make an attractive victim temporarily unavailable. Future use predictions have uncertainty; offline knowledge may provide a diagnostic bound but must not leak into the online policy's inputs.

Part 3 - Quantitative Prediction Before Execution

Estimate transfer time as measured fixed overhead plus bytes divided by effective bandwidth, then estimate its exposed fraction under the supported schedule. Define retention value per constrained byte using expected reuse and avoided cost, with explicit uncertainty. Account for dirty writeback, shared benefit, and transition feasibility. Construct an example where minimizing bytes moved differs from minimizing latency and another where maximizing hit rate chooses the wrong resident set.

Part 4 - Experimental Design and Instrumentation

Calibrate copy and compute behavior on separate bounded cases, including concurrent H2D/D2H if the engine uses them. Use a small auditable candidate set and feasibility gates before scoring. Compare static layer residency, activity-based placement, recency, and the cost-aware policy on held-out traces. Add hysteresis or minimum residence only when justified by observed churn. Preserve request fairness and output semantics. Include calibration, monitoring, scheduling, and transition costs in complete-run results.

Use measured transfer-size curves instead of a single bandwidth constant when fixed overhead dominates small pages. Include the effect of simultaneous H2D/D2H and pinned staging limits where the schedule permits concurrency. Score only actions whose ownership and transition requirements are currently feasible. Reserve a known-valid fallback so inaccurate predictions cannot force an unsupported mutation or loss of history.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVResidencyDecision:
    page_identity: tuple
    action: str
    predicted_saved_stall_seconds: object
    required_capacity_bytes: int
    uncertainty: object
    reason: str

def score_residency_candidates(evidence, cost_model, budgets):
    # Reject infeasible actions before comparing uncertain expected value.
    ...

def choose_residency_actions(candidates, ownership_state):
    # Preserve demand readiness, fairness, and bounded transition ownership.
    ...

def E17(config):
    # Evaluate held-out useful work and explain every selected action.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predictions, actual later reuse, transferred bytes, stalls, resource peaks, action count, and complete latency. Show sensitivity to inaccurate bandwidth or next-use predictions. A policy that improves an isolated copy metric but worsens decode or starvation must report that outcome. Keep model fit quality distinct from causal proof that a particular decision saved time. Unsupported measurements remain unknown.

Evaluate a stable trace, a phase change, and misleading reuse predictions. Report policy overhead, oscillation, demand waits, and request fairness. A future-aware oracle may establish a diagnostic comparison, but the online policy must use only available evidence. Separate improvements in a fitted cost estimate from improvements in measured completed decode work.

Part 7 - Engineering Interpretation and Philosophy

Choose the simplest policy that improves complete useful work within tested budgets. Explain whether complexity is justified by real heterogeneity and reuse differences, and identify the next measurement needed before extending the policy to another architecture, link, or concurrency pattern.

19.37.19 Exercise 18

Exercise Title: Stress-Test KV Offloading with Long Contexts, Concurrent Sequences, Variable Generation Lengths, Shared Prefixes, and Artificially Restricted VRAM

Part 1 - Exercise Contract and Why It Matters

Stress-test lossless KV offloading under bounded long contexts, concurrent requests, variable completion, shared prefixes, and a deliberately small engine VRAM budget. Find minimal reproducible failures in semantic outputs, version authority, asynchronous lifetime, or resource accounting. Avoid uncontrolled machine-wide exhaustion.

Part 2 - System and Memory Mental Model

Difficult failures combine valid transitions: a shared page is copied while its request ends, a CPU buffer is reused before H2D finishes, or an old D2H completion overwrites a newer backing version. Correct logits alone cannot prove capacity compliance, and correct byte totals cannot prove masking or request isolation. Maintain independent semantic, ownership, residency, and budget oracles. Restrict pressure through admission limits rather than consuming all physical VRAM.

Part 3 - Quantitative Prediction Before Execution

Define invariants and worst-case transition demand before random execution. Predict a trace where no victim is currently safe and the correct response is waiting or rejection. Include long contexts relative to the bounded test model, many partial pages, and shared-tail divergence. State progress assumptions: pending work eventually completes, and the admitted working set is feasible. No policy must promise progress when the consumer's minimum working set exceeds its declared capacity.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, trace IDs, finite arrivals, explicit output lengths, maximum host backing, pinned capacity, GPU payload, and pending-operation limits. Begin with deterministic completion simulation, then run supported CUDA traces. Inject failures before named publication points, not illegal pointer races. Compare selected cache and logit checkpoints with a resident reference on matching smaller cases. Audit every transition and final drain. Save failing histories and reduce them while preserving sharing, allocation, and request creation dependencies.

Save exact scheduler decisions and completion ordering along with random seeds. Real asynchronous timing may not reproduce from a seed alone, so use deterministic transition simulation to shrink state-machine failures. Keep expected rejection controls separate from valid traces that expose bugs. An intentionally too-small working set budget should produce a clear unsupported or inadmissible outcome, not a false correctness failure.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVOffloadStressBounds:
    max_requests: int
    max_context_tokens: int
    gpu_payload_bytes: int
    cpu_backing_bytes: int
    pinned_bytes: int
```

```
    max_pending_operations: int
    steps: int

def generate_offload_trace(seed, bounds):
    # Produce bounded valid operations and labeled rejection controls.
    ...

def audit_offload_state(engine, semantic_oracle, lifecycle_oracle):
    # Check values, masks, versions, ownership, and every resource scope.
    ...

def minimize_offload_failure(trace, replay):
    # Preserve setup and completion dependencies while reducing the failure.
    ...

def E18(config):
    # Validate deterministic interleavings before supported CUDA stress.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, traces, failure phases, last valid states, reproducibility, and smallest counterexamples. Include stale CPU versions, duplicate reload, delayed writeback, cancellation, slot-generation reuse, pinned-buffer reuse, and infeasible working sets. Separate simulator-only and actual CUDA outcomes. A failure that does not reproduce remains an outcome; it is not permission to invent evidence or silently claim the bug is fixed.

Audit after final drain and after controlled cancellation, including CPU backing versions, pinned buffers, retained shared pages, and pending events. A process that exits early can hide delayed corruption. When minimizing a failure, retain the prefix-population and allocation dependencies needed to reproduce it. State when no counterexample was observed rather than claiming a proof over every interleaving.

Part 7 - Engineering Interpretation and Philosophy

State which contracts survived the tested envelope and which concurrency or model patterns remain unsupported. Select the next smallest experiment that addresses the most consequential unresolved risk. A clean random run supports a bounded claim, not correctness under every interleaving.

19.37.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Memory-Aware KV Cache Offload Engine That Dynamically Pages Hot and Cold Cache Blocks Between VRAM and RAM While Minimizing Decode Stalls

Part 1 - Exercise Contract and Why It Matters

Integrate a memory-aware KV offload engine with explicit CPU backing, versioned residency, page pools, bounded staging, stream/event coordination, pressure monitoring, and cost-aware placement. Benchmark correct concurrent autoregressive work while minimizing measured exposed stalls under declared budgets. All substantive implementation remains learner work.

Part 2 - System and Memory Mental Model

One authority must coordinate request identities, layer/token validity, shared page versions, CPU backing, GPU slots, copy-on-write, pending readers, and transfer completion. Hot/cold classification changes placement, not the required full-context computation. The selected attention consumer determines the minimum feasible working set and must include gather or streaming costs. Weights remain fixed for the primary comparison. A software engine does not provide transparent hardware paging or universal OOM prevention.

Part 3 - Quantitative Prediction Before Execution

Predict useful KV, GPU slot capacity, CPU backing, pinned staging, provisional duplicates, attention temporaries, and transfer bytes for each trace. Compare resident, serialized layer offload, overlapped offload, selective residency, and paged cost-aware policies on equal supported workloads. Estimate prefill, time-to-first-token, warmed decode, and request completion separately. Identify a capacity-limited case offloading can admit and a bandwidth-limited case where fully resident execution should win.

Part 4 - Experimental Design and Instrumentation

Freeze the model and operation support matrix. Validate copy exactness, attention/logit parity, lifecycle oracles, and budget checks before performance. Evaluate held-out sequential, mixed-length, shared-prefix, bursty, and high-churn traffic. Record hardware, link topology, software versions, model context, dtype, masks, positions, budgets, page units, seeds, and initial state. Include cold setup, calibration, monitoring, transitions, and drain in complete cost. Run ablations for dirty-range writeback, pinning, overlap, classification, and cost-aware placement without weakening correctness or fairness gates.

Publish a support matrix for prefill, append, page migration, sharing, copy-on-write, truncation, cancellation, and shutdown before benchmarking. State the minimum consumer working set and every resource scope. Use scalar evidence IDs to connect traces, copy validation, policy actions, and outputs. Bound logs and release diagnostic payloads so monitoring cannot become the engine's largest unreported retained allocation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVOffloadEngineContract:
    model_context: tuple
    gpu_payload_bytes: int
    cpu_backing_bytes: int
    pinned_staging_bytes: int
    max_pending_transfers: int
```

```
    attention_consumer: str
    supported_operations: tuple

class MemoryAwareKVOffloadEngine:
    def __init__(self, contract):
        # Establish authority, pools, backing, streams, and bounded policy state.
        ...

    def submit(self, request):
        # Validate semantics and queue or admit within complete resource limits.
        ...

    def step(self):
        # Plan residency, order copies/compute, and commit coherent token state.
        ...

    def finish(self, request, reason):
        # Retire mappings while protecting shared and in-flight obligations.
        ...

    def audit(self):
        # Recompute exact-version authority and unique resource ownership.
        ...

    def shutdown(self):
        # Drain or safely cancel work and report unreclaimed obligations.
        ...

def E19(config):
    # Validate the integrated contract before held-out useful-work benchmarks.
    ...
    # Export evidence, counterexamples, limits, and engineering recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires preserved valid KV, numerical output parity under the stated policy, correct masks/positions, no unsafe reuse, bounded resources, and honest useful-work accounting. Report completed requests, processed prompt positions, generated tokens, latency distributions, rejected/waiting work, transfer bytes, exposed stalls, residency peaks, host capacity, and backend allocated/reserved peaks. Keep predictions, observations, and interpretations separate. An unfinished scaffold supplies no hardware benchmark results.

Include an unfavorable offload case, a strict-budget rejection, a delayed writeback, a shared-page cancellation, and a long growth phase. Report unfinished and rejected requests as well as successful survivors. Distinguish actual CUDA execution from simulation and proposed extensions. The final recommendation must connect correct useful inference to measured capacity relief and its complete transfer, host-memory, and latency cost.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest engine justified by complete measured work, including no offload when the resident baseline wins. Explain the capacity gained and the bandwidth, host memory, or latency paid. Separate delivered supported behavior from proposed kernel, concurrency, quantization, or distributed extensions.

19.38 DMM36

Chapter Title: KV Cache Quantization
Specialization: Dynamic Memory Management and CUDA Systems

19.38.1 Exercise 00

Exercise Title: Build a Precise Mental Model of KV Cache Precision, Quantization Error, Compression Ratio, and Decode-Time Memory Trade-Offs

Part 1 - Exercise Contract and Why It Matters

Define a precise contract for compressing stored attention keys and values while retaining the same token history. Deliver a representation diagram, a byte ledger, and a numerical evaluation plan. Separate lossless integer packing from lossy floating-to-integer quantization, and distinguish compressed storage capacity from the working memory required to consume that storage.

Part 2 - System and Memory Mental Model

The cache contains processed-token K and V at each attention layer, not queries or merely sampled token IDs. Quantization stores codes plus parameters needed to reconstruct approximate values. Keys affect attention scores and values affect weighted outputs, so reconstruction error alone does not establish model quality. A reference consumer can unpack and dequantize before floating attention, creating temporary full-width arrays. This prototype does not imply a fused low-bit attention kernel or universal speedup.

Part 3 - Quantitative Prediction Before Execution

For homogeneous layers, start from useful unquantized KV bytes

$$B_{\mathrm{fp}} = 2LH_{kv}Ds\sum_{j} T_j.$$

Predict code bytes, scales, zero points, padding, recent high-precision values, tables, and dequantization workspace separately. Define compression ratio as named baseline storage divided by complete compared storage. Leave empty denominators undefined. Calculate how an ideal bit-width ratio can overstate usable capacity when metadata and transient float reconstruction remain live.

Part 4 - Experimental Design and Instrumentation

Use a tiny explicit full-causal decoder, fixed weights, zero dropout, no gradients, and teacher-forced token traces. Keep model arithmetic fixed while varying stored KV precision. Declare layout, KV head mapping, scale axes, rounding, clipping, dtype, positional-key convention, masks, and valid lengths. Record software, device, allocator backend, seeds, model context, and

initial state. Use bounded synthetic tensors before integrating model execution. Quantization is intentionally lossy; context pruning and model-weight compression are separate variables.

Draw the lifetime of original KV, codes, metadata, and reconstructed inputs for one attention call. Mark which allocations coexist and which can actually be released. Define the stored representation independently from the arithmetic dtype used by projections and softmax. A storage experiment that also changes weights or attention arithmetic is a different comparison. Include one complete format identity covering grouping, code mapping, parameter dtype, layout, valid length, and positional convention.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVQuantizationContract:
    code_bits: int
    scheme: str
    reduction_axes: tuple
    group_shape: tuple
    scale_dtype: str
    position_policy: str
    quality_thresholds: tuple

def predict_quantized_kv(contract, architecture, trace):
    # Separate codes, metadata, residuals, padding, and consumer workspace.
    ...

def E00(config):
    # Define representation and quality claims before implementing compression.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require separate representation-correctness, arithmetic-parity, model-quality, and resource checks. Preserve prediction, observation, and interpretation as distinct fields. A matching greedy token does not prove matching logits or acceptable long-context quality. Export bounded CPU scalar evidence without retaining full GPU references or original caches that invalidate memory claims. Unperformed hardware experiments remain explicitly unmeasured.

Define quality at three levels: local reconstructed values, fixed-input attention behavior, and integrated decoder behavior on held-out data. State which level a reported metric supports. A tiny synthetic decoder can expose implementation bugs but cannot establish quality for a production model. Research methods can motivate experiments, but their published numerical gains are not results of this learner implementation. Preserve every untested model or hardware condition as an explicit gap.

Part 7 - Engineering Interpretation and Philosophy

Explain the resource purchased by compression and the numerical risk it introduces. The useful outcome is a measured capacity-quality-latency trade-off within a declared model and workload envelope, not the assumption that fewer stored bits automatically improve complete inference.

19.38.2 Exercise 01

Exercise Title: Measure KV Cache Memory in float32, float16, and bfloat16 for the Same Transformer Configuration and Context Length

Part 1 - Exercise Contract and Why It Matters

Measure cache storage for float32, float16, and bfloat16 under identical architecture and logical token lengths. Distinguish element-width savings from numerical range and precision differences. Produce an exact useful-payload calculation and separately measured backing and backend memory observations.

Part 2 - System and Memory Mental Model

float16 and bfloat16 both use two bytes per element but represent numbers differently. float32 uses four bytes. Identical shape and element width do not imply equal numerical behavior or backend support. Keep model weights and attention arithmetic fixed in the storage-only comparison. A dtype conversion can temporarily retain source and destination. Views can share storage, and static reservation can exceed valid token payload. None of these extra costs is represented by element count alone.

Part 3 - Quantitative Prediction Before Execution

Calculate per-token and total useful K/V bytes using KV heads rather than query heads under GQA. Predict ratios for the three storage dtypes and the peak during conversion when both copies coexist. Include ragged lengths, empty history, and static capacity larger than valid lengths. State whether measurements cover only cache payload, unique backing, or total process/device residency, and do not substitute one scope for another.

Part 4 - Experimental Design and Instrumentation

Create bounded coordinate-coded cache tensors with identical valid shapes. Compare storage allocation first, then a separately labeled numerical experiment that stores and reconstructs values in each dtype. Verify hardware and attention backend support before CUDA arithmetic. Reset state and peaks between cases, separate construction from warmed execution, and record conversion temporaries. Test representable finite values, small magnitudes, and large finite ranges without claiming every dtype can hold them equally. Keep alias ownership and padding explicit in the byte ledger.

For storage comparisons, allocate each dtype in an independent replay so source arrays from another case do not inflate the measured peak. If conversion itself is the experiment, retain and charge both sides deliberately. Include views with nonzero storage offsets and count their backing once. Report the valid tensor payload beside maximum reserved cache capacity. Identical useful shapes do not imply identical retained storage when one layout uses padding or a larger base allocation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVDtypeCase:
    storage_dtype: object
    logical_lengths: tuple
    capacity_tokens: tuple
    architecture_identity: tuple

def predict_dtype_payload(case, layer_specs):
    # Validate element widths and distinguish useful values from capacity.
    ...

def measure_dtype_storage(case, measurement_contract):
    # Count unique backing and conversion peaks under explicit boundaries.
    ...

def E01(config):
    # Compare storage costs and separately report numerical/support differences.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report shapes, element sizes, valid lengths, backing capacity, conversion peaks, and allocated/reserved observations. Require the predicted useful bytes to match the supported tensor representation, while explaining backend rounding or retention separately. If bfloat16 arithmetic is unsupported in the tested path, retain its storage calculation but mark execution unsupported. Do not report a numerical result from an unrun fallback.

Use range-sensitive values only in the numerical comparison, not as evidence that byte counts changed. Compare actual element widths rather than inferring them from dtype names. Where arithmetic support differs, distinguish a storage-only pass from an executed attention pass. A bfloat16 storage estimate can remain valid even when the chosen device/backend cannot run the desired consumer; mark that consumer result unsupported rather than substituting a different precision without labeling it.

Part 7 - Engineering Interpretation and Philosophy

Explain why equal storage cost is not interchangeable numerical precision. Choose a justified cache baseline for the remaining exercises and preserve the fixed arithmetic policy so later changes can be attributed to storage quantization.

19.38.3 Exercise 02

Exercise Title: Implement a Baseline float16 KV Cache in PyTorch and Record Peak VRAM, Decode Latency, and Output Logits

Part 1 - Exercise Contract and Why It Matters

Build an explicit float16 KV reference and record complete peak VRAM, decode latency, and selected output logits. Establish semantic correctness before using this cache as the comparison for lossy compression. Preserve a repeatable teacher-forced trace and a documented attention consumer.

Part 2 - System and Memory Mental Model

Choose a bounded static or clearly labeled dynamic growth policy. Valid token length differs from allocated capacity, and per-layer prepared new KV differs from globally committed request progress. Attention must see the correct causal history with consistent GQA heads, positions, and positional-key convention. float16 cache storage does not require changing all model arithmetic to float16. Store reference outputs for evaluation without retaining every live cache version in the measured GPU run.

Part 3 - Quantitative Prediction Before Execution

Predict useful float16 payload, assigned capacity, growth temporaries, masks, and attention workspace. Define prompt processing, decode tokens, and request throughput with separate numerators. State whether constructor, warm-up, sampling, validation, transfer, and final drain are included. Calculate a bounded context limit from the declared budget with headroom rather than finding it by uncontrolled allocation failure.

Part 4 - Experimental Design and Instrumentation

Use fixed weights, evaluation, explicit zero attention dropout, and a no-gradient inference boundary. Compare cached decoding with full-prefix recomputation on small cases. Include ragged requests, partial capacities, multiple layers, and query/KV head differences. Record attention backend and accumulation policy. Use deliberate completion boundaries for wall time and appropriate CUDA events for device intervals. Run detailed validation separately from primary throughput when frequent checks would synchronize every step.

Define how current-layer attention sees prepared new KV before the request's global token length is committed. A partial forward must not become a reusable complete cache snapshot. Verify a one-query decode mask against explicitly listed allowed key positions, then repeat with a multi-query suffix. The reference must establish this before compression, otherwise later numerical differences may be caused by a baseline masking error rather than quantization.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class Float16KVReference:
    def initialize(self, architecture, capacities):
        # Establish explicit cache layout and valid-position metadata.
        ...
```

```
    def prefill(self, token_trace):
        # Preserve positions, causal masks, head mapping, and layer readiness.
        ...

    def decode_step(self, tokens):
        # Process actual tokens and commit coherent new KV across layers.
        ...

def record_reference(runtime, cases, measurement_contract):
    # Export selected outputs without contaminating measured GPU lifetimes.
    ...

def E02(config):
    # Validate and benchmark the reproducible float16 cache baseline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require attention and logit checks within declared reference tolerances. Report processed lengths, useful and capacity bytes, allocated/reserved peaks, completed time, latency variability, and unsupported conditions. An unsynchronized host timer measures submission rather than completed decode. If greedy generation diverges later under quantization, use equal teacher-forced traces to attribute performance and separately evaluate generation quality.

Separate reference capture from measured inference. Saving all logits or all original KV on GPU can erase apparent compression savings in later tests. Use bounded CPU exports with explicit synchronization and record their cost outside or inside the declared region consistently. Count prompt-token processing, newly processed decode tokens, and final sampled outputs separately. A sampled token that is never forwarded contributes no additional cached K/V position.

Part 7 - Engineering Interpretation and Philosophy

Explain which properties of this reference are semantic requirements and which are implementation choices. A poor concatenation baseline must not make compression appear to save work that actually came from changing cache growth or attention backend.

19.38.4 Exercise 03

Exercise Title: Quantize Key and Value Tensors to int8 with a Simple Per-Tensor Scale and Measure the Resulting Memory Reduction

Part 1 - Exercise Contract and Why It Matters

Implement a simple symmetric int8 quantizer with separate per-tensor scales for K and V under a precisely defined tensor scope. Measure actual code and metadata storage after releasing measured-path source copies. Validate quantizer invariants before integrating the compressed representation into decoding.

Part 2 - System and Memory Mental Model

For finite values, choose a declared signed code range such as $[-127, 127]$, leaving the remaining int8 code unused. Scale selection, rounding, clipping, and all-zero handling are part of the format. K and V need not share their scale. A scale spanning a growing history can change when a new outlier arrives; old codes cannot simply be interpreted under a new scale. Quantization parameters must remain associated with the exact values they encode.

Part 3 - Quantitative Prediction Before Execution

With scale $a > 0$, define

$$q = \mathrm{clip}(\mathrm{round}(x/a), q_{\min}, q_{\max}), \qquad \hat{x} = aq.$$

Derive an absmax scale for the declared range and a valid all-zero convention. Predict code bytes, scale bytes, and a round-trip error bound only for unclipped finite inputs under the chosen rounding. Compare nominal float16-to-int8 payload reduction with metadata-inclusive storage and conversion peak.

Part 4 - Experimental Design and Instrumentation

Begin with fixed bounded K and V arrays, including zeros, sign changes, midpoint ties, extreme finite values, and outliers. Specify reduction axes and whether one tensor means one layer and request over a fixed token interval. Use a documented rounding policy. Reject or explicitly handle nonfinite inputs. For append integration, choose frozen calibrated scales with clipping evidence or a correctly accounted rescaling protocol; do not silently change old scales. Measure old/new coexistence and retain originals only outside the production memory path or in a separately charged reference store.

Perform scale estimation in a documented working dtype and validate that stored scales stay finite and positive where required. Small scales can underflow in a narrower metadata dtype; large intermediate values can overflow before clamping if conversion order is wrong. Apply the all-zero convention consistently on encode and decode. Reject nonfinite calibration values under the primary contract instead of allowing an invalid scale to propagate through the cache.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class Int8KVPayload:
    key_codes: object
    value_codes: object
    key_scale: object
    value_scale: object
    valid_tokens: int
    format_identity: tuple
```

```
def quantize_per_tensor(keys, values, format_contract):
    # Select valid scales and apply the declared rounding/clipping policy.
    ...

def int8_storage_ledger(payload, source_lifetimes):
    # Count codes, parameters, padding, and retained originals separately.
    ...

def E03(config):
    # Validate edge cases and truthful steady/transition memory reduction.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report code range, scale values, clipping counts, error distribution, source and destination bytes, and transition peaks. Test a new outlier appended after initial encoding and require the scale policy to preserve format validity. A float tensor containing rounded integers is not compressed int8 storage. A low code-payload total does not establish a lower device peak while full-width sources or dequantized results remain live.

Test midpoint rounding and clipping before casting to int8. An integer cast by itself does not implement the declared round-to-nearest policy and can produce a different quantizer. Compare a frozen-scale append with a full rescale only when their history handling is explicit. If rescaling uses reconstructed rather than original values, label the composed approximation and evaluate its error separately. A metadata change cannot reinterpret existing codes silently.

Part 7 - Engineering Interpretation and Philosophy

Explain what the simple quantizer loses and which uncertainty remains before model use. Keep its format auditable rather than introducing finer groups before per-tensor scale identity, clipping, and byte accounting are correct.

19.38.5 Exercise 04

Exercise Title: Dequantize int8 KV Tensors Back to Floating Point During Attention and Verify End-to-End Numerical Correctness

Part 1 - Exercise Contract and Why It Matters

Dequantize stored int8 KV for attention and validate the complete inference path. Separate correct decoding of the format from acceptable lossy model behavior. Deliver per-layer and token-position evidence for reconstructed KV, attention outputs, logits, and a declared quality metric.

Part 2 - System and Memory Mental Model

Dequantization reconstructs approximate values using the matching scale and format metadata. It does not recover the original float16 values generally. A reference path may build full floating histories before attention, adding workspace and memory traffic. Positions, valid lengths, head mapping, and masks must remain unchanged. Local replay of frozen reference KV

isolates quantizer effects; integrated decoding can produce different later KV because earlier quantized attention changed hidden states.

Part 3 - Quantitative Prediction Before Execution

Predict reconstructed shapes and dtype, code/metadata reads, floating output bytes, and temporary coexistence with compressed storage. Define allowed KV, attention, and logit errors before running comparisons. Construct negative controls for swapped K/V scales, wrong group broadcasting, stale metadata, and invalid tail inclusion. Explain why agreement of one sampled token cannot establish that the format or model-quality contract holds.

Part 4 - Experimental Design and Instrumentation

Validate dequantization on small synthetic arrays first. Then use fixed queries and reference K/V to isolate local arithmetic, followed by integrated teacher-forced decoding with quantized caches. Keep model weights, attention backend, dropout, positions, and masks fixed. Include partial tails, GQA, ragged lengths, and multi-query suffixes with explicitly verified causal visibility. Measure unpack/dequantize, attention, and complete decode separately, but include every temporary in the complete peak. Use independent held-out cases for quality after calibration choices are fixed.

Validate reconstructed K and V independently before invoking attention, including a case where their scales differ strongly. Keep reference queries fixed for the local experiment. In integrated decoding, newly computed queries and later KV can diverge because earlier approximate attention changed hidden states; this is an additional effect to evaluate, not a scale-broadcast bug by definition. Label the two experiment modes in every result row.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.nn.functional as F

def dequantize_int8_kv(payload, compute_dtype):
    # Validate metadata and reconstruct only the supported valid values.
    ...

def quantized_attention_reference(query, payload, attention_contract):
    # Preserve head mapping, masks, positions, and the floating consumer policy.
    ...

def evaluate_quantized_decode(reference, compressed, cases, quality_contract):
    # Distinguish format errors, local distortion, and integrated model effects.
    ...

def E04(config):
    # Validate correctness of the approximation, not lossless equivalence.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Report reconstruction errors, attention/logit deviations, clipping, quality metric, backend, dtype, elapsed time, and complete memory peak. Treat threshold failures as failures even if generation looks plausible. Compare local frozen-KV replay with integrated rollout explicitly. If a higher-precision oracle is unavailable at runtime, do not claim the engine can verify every future token's original-output error automatically.

Include a high-precision mathematical attention control for small cases, then compare the actual reference backend at its declared dtype. Validate boolean mask polarity and rectangular query alignment. If model quality is evaluated with negative log-likelihood, define target-token alignment and evaluation corpus; if using perplexity, derive it from the same token-weighted loss. Do not equate logit similarity on one prompt with a general task-quality guarantee.

Part 7 - Engineering Interpretation and Philosophy

Explain which numerical contract was satisfied and the scope of the evidence. Quantized decoding can be a correct implementation of an approximation while failing an application's accuracy requirement; those outcomes need separate labels and separate engineering decisions.

19.38.6 Exercise 05

Exercise Title: Compare Symmetric and Asymmetric KV Quantization and Measure Error Distribution in Keys, Values, and Attention Outputs

Part 1 - Exercise Contract and Why It Matters

Compare symmetric and affine asymmetric KV quantization at the same stored bit width. Measure error distributions in keys, values, attention, and logits, including metadata and calibration cost. Keep grouping, model arithmetic, inputs, and quality thresholds fixed so the comparison isolates the scheme.

Part 2 - System and Memory Mental Model

A symmetric format uses a zero-centered code interpretation and scale. An affine format adds a zero point and may use an unsigned code range. The reconstruction is $\hat{x} = a(q - z)$ for the declared scale and zero point. Different integer ranges have different endpoint conventions. Range estimation, rounding, clipping, inclusion of zero, and constant-tensor handling must be specified together. An offset distribution can favor affine placement, but that is a hypothesis to test rather than a universal property of KV.

Part 3 - Quantitative Prediction Before Execution

Derive scale and zero-point choices for an affine min/max range that includes zero, with an explicit all-zero fallback. Predict behavior for positive-only, negative-only, centered, constant, and outlier-heavy inputs. Calculate code, scale, and zero-point bytes under actual metadata dtypes. Compare expected unclipped rounding error with clipping error and stored-scale rounding; a simple half-step bound does not cover all three.

Part 4 - Experimental Design and Instrumentation

Use identical synthetic distributions and captured reference KV. Separate calibration from held-out evaluation. Compare local frozen-KV attention before integrated teacher-forced decoding. Preserve scale scope, layout, positional representation, head mapping, and backend. Report both overall and per-head error summaries so a few severe errors are not hidden by a small average. Include a new range-shifting append under the declared update policy. Keep signed int8 and unsigned affine-code interpretations explicit at every boundary.

For affine min/max calibration, explicitly include zero in the represented range and define the constant-input branch. Test zero, positive constants, negative constants, and a narrow offset range. Record actual unsigned versus signed code storage and do not subtract zero points in an unsigned dtype that can wrap. Use a sufficiently wide intermediate before converting to the requested floating reconstruction dtype.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AffineKVParameters:
    scale: object
    zero_point: object
    code_min: int
    code_max: int
    reduction_axes: tuple

def estimate_affine_parameters(tensor, format_contract):
    # Include zero/range conventions and handle constant finite inputs.
    ...

def compare_quantization_schemes(cases, schemes, attention_contract):
    # Preserve equal bits and grouping while counting metadata and errors.
    ...

def E05(config):
    # Test distribution-dependent trade-offs and update behavior.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct code bounds, finite valid scales, valid zero points, and metadata broadcasting. Report clipping, bias, error quantiles, worst coordinates, attention/logit errors, memory, and time. An asymmetric scheme is not guaranteed to beat symmetric under every distribution or quality metric. Keep parameter estimation arithmetic and stored-parameter precision visible when interpreting small differences.

Compare schemes with identical calibration data and grouping, then evaluate a shifted held-out range to reveal clipping sensitivity. Report error bias and tail behavior as well as mean squared error. A stored zero point is part of the interpretation metadata and must follow the same generation as its codes and scale. A deliberate stale-zero-point control should fail even when its tensor shape still broadcasts successfully.

Part 7 - Engineering Interpretation and Philosophy

Choose a scheme from measured data and the application's quality contract. Explain whether the extra parameters buy enough error reduction to justify storage and kernel complexity, and state the conditions under which the simpler symmetric reference remains preferable.

19.38.7 Exercise 06

Exercise Title: Implement Per-Head KV Quantization and Compare It Against Per-Tensor Scaling by Reconstruction Error and Metadata Cost

Part 1 - Exercise Contract and Why It Matters

Implement per-head KV scales and compare them with the per-tensor reference. Measure reconstruction, attention distortion, metadata, and complete decode cost. Define head identity using stored KV heads rather than expanded query heads so GQA does not duplicate the quantizer's ownership.

Part 2 - System and Memory Mental Model

For a documented layout such as $[B, H_{kv}, T, D]$, a per-request per-head scale reduces over the selected token and channel dimensions without mixing requests. K and V retain independent parameters. A per-head scale over an entire growing history still has an update problem when its range changes. Finer grouping can reduce the influence of another head's outlier but cannot remove outliers inside the same group or guarantee lower downstream error.

Part 3 - Quantitative Prediction Before Execution

Predict parameter counts for one scale per tensor versus one per stored head, separately for K and V and each layer/request. Calculate metadata bytes using the actual stored scale dtype and optional zero-point format. Construct two heads with sharply different ranges and another example with equal ranges. Estimate how parameter overhead changes the effective compression ratio for short and long histories.

Part 4 - Experimental Design and Instrumentation

Implement parameter shape and broadcasting assertions before CUDA timing. Test shuffled head values, GQA with multiple query heads per KV head, empty valid histories, partial token intervals, and a new head-local outlier. Use fixed code width, rounding, clipping, and update policy across variants. Compare synthetic reconstruction, frozen-KV attention, and integrated decode on separate held-out traces. Count metadata and any expanded floating heads in the consumer peak. Measure scale estimation and update work rather than assuming per-head metadata is free.

Give different heads easily distinguished amplitudes and reverse their order in one negative control. Use a batch where requests have very different ranges so accidental reduction across the batch dimension is observable. Specify whether empty heads have no parameters or a defined neutral metadata record. A valid broadcast shape is necessary but insufficient: each parameter must describe the correct request, stored KV head, and token interval.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class HeadQuantizationLayout:
    tensor_axes: tuple
    head_axis: int
    reduced_axes: tuple
    request_scope: str
    parameter_shape: tuple

def quantize_per_head(keys, values, layout, format_contract):
    # Validate KV-head identity and retain matching independent parameters.
    ...

def compare_head_granularity(reference_cases, quantizers):
    # Count metadata and trace downstream errors, not only average MSE.
    ...

def E06(config):
    # Validate head broadcasting and measure complete granularity trade-offs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report group count, parameter shape, code bytes, metadata, error distribution, clipping, attention/logit quality, and timing. Use a wrong-head permutation negative control and require detection. A lower KV mean-squared error can coexist with worse logits, so preserve both observations. Reject scale shapes that broadcast numerically but associate parameters with the wrong request or head.

Count scales and zero points separately for K and V at every cached layer. If metadata is stored in a padded tensor, report its capacity rather than only the number of meaningful entries. Compare short and long histories to show amortization. Keep query-head expansion out of stored-parameter counts, while including any expanded floating tensors in the attention consumer's peak. This prevents a GQA layout change from being mistaken for a quantization storage effect.

Part 7 - Engineering Interpretation and Philosophy

Explain where head-level independence helps and where its extra parameters or update work dominate. Recommend a granularity only for the tested model, length distribution, and consumer, preserving the distinction between stored heads and arithmetic head expansion.

19.38.8 Exercise 07

Exercise Title: Implement Per-Channel KV Quantization and Determine Whether Finer-Grained Scaling Improves Attention Accuracy Enough to Justify Extra Metadata

Part 1 - Exercise Contract and Why It Matters

Implement a precisely defined per-channel KV format and determine whether its downstream accuracy benefit justifies added parameters and computation. Compare with per-head and per-tensor formats under equal code width and complete resource accounting.

Part 2 - System and Memory Mental Model

The term channel must name an axis. In the primary layout, define one parameter per KV head and head-dimension coordinate over a bounded token interval, reducing over tokens and preserving channel identity. This differs from a per-token format that reduces over channels. Keys and values can have different distributions, and positional transformations can change those distributions. Keep pre- or post-positional key representation fixed rather than silently adding another optimization.

Part 3 - Quantitative Prediction Before Execution

Derive parameter shapes and counts for the selected layout and interval. Calculate code bytes, scales, zero points, and group padding. Construct a channel-local outlier case and a case where short groups make metadata dominate. Predict differences between reducing over tokens and reducing over channels. Include scale-update costs when a growing interval changes existing channel ranges; old encoded values must remain associated with their original parameters.

Part 4 - Experimental Design and Instrumentation

Use axis-labeled synthetic tensors that expose transposed parameters and head/channel swaps. Compare the same captured K/V under per-tensor, per-head, and per-channel formats, optionally adding a separately labeled per-token control. Keep calibration/evaluation separation and fixed model arithmetic. Test partial groups, empty intervals, large channel ranges, and held-out lengths. Validate reconstruction and attention before integrated decode. Record actual metadata dtypes and any layout-conversion copies required by the implementation.

Write the reduction expression in axis names and tensor indices before coding. In the primary per-channel scheme, one channel coordinate is observed across its chosen token interval within a KV head; it is not a reduction over every channel of one token. Test token/channel transposes with unequal dimensions so an incorrect implementation cannot pass because two axes happen to have the same length.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ChannelQuantizationLayout:
    channel_axis: int
    token_axis: int
```

```
    head_axis: int
    token_group_length: int
    parameter_shape: tuple

def quantize_per_channel(tensor, layout, format_contract):
    # Reduce only declared axes and preserve parameter-to-channel identity.
    ...

def evaluate_channel_format(cases, decoder, quality_contract):
    # Compare metadata-inclusive capacity and downstream numerical effects.
    ...

def E07(config):
    # Validate axis semantics before selecting finer-grained storage.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report reduction axes, groups, parameter counts, metadata bytes, clipping, error quantiles, attention/logit metrics, complete peaks, and latency. Reject an ambiguous axis label as missing format information. Do not transfer published results for a particular model and quantization method to this simpler prototype. A measured benefit must identify the representation, grouping, and positional convention that produced it.

Keep the key positional representation fixed when comparing granularity. Pre-positional and post-positional quantization are different formats requiring different consumer work; published methods using one do not validate the other. Measure scale-update work or sealed-group conversion explicitly. Include one case where parameter overhead dominates a tiny group and another where a channel outlier motivates finer scaling, then assess downstream quality rather than assuming the synthetic advantage transfers unchanged to the model.

Part 7 - Engineering Interpretation and Philosophy

Explain whether finer scale independence improved the application's quality metric enough to pay for its metadata and execution cost. Keep K and V choices independent and resist assuming that one grouping is universally optimal for both components or every positional representation.

19.38.9 Exercise 08

Exercise Title: Sweep KV Quantization Bit Widths and Compare Estimated 16-Bit, 8-Bit, and 4-Bit Cache Capacity Under the Same VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Estimate and compare 16-bit, 8-bit, and packed 4-bit cache capacity under one named GPU budget. Deliver a byte-level capacity model with metadata, tail rounding, recent full-precision storage, and consumer headroom. Distinguish analytical estimates from implemented and measured formats.

Part 2 - System and Memory Mental Model

A bit-width label describes code precision, not necessarily actual tensor storage. Four-bit values stored one per uint8 still consume eight payload bits until packing is implemented. Scales, zero points, per-group alignment, page capacity, and metadata may differ across formats. Dequantization output can dominate peak memory even when persistent codes shrink. Equal nominal bits do not establish equal model quality or maximum safe concurrency.

Part 3 - Quantitative Prediction Before Execution

For N codes at b bits, begin with ideal bytes $\lceil Nb/8 \rceil$, then apply the actual packing boundary for each independently stored group or block. Add parameter and residual bytes and reserve the selected consumer's workspace. Compute a capacity bound using identical model dimensions and ragged request traces. Show a small-block case where metadata invalidates the nominal fourfold float16-to-4-bit gain. Leave measured maximum context undefined until tested.

Part 4 - Experimental Design and Instrumentation

Use a fixed set of lengths and grouping contracts across estimates. Implement real 8-bit storage and label 4-bit as estimated until the next exercise's codec is validated. Keep allocator capacity and total device usage separate from useful code payload. Test empty objects, odd code counts, partial groups, and multiple request tails. Use a bounded admission sweep when validating estimates; never allocate until the workstation becomes unstable. Require each candidate to satisfy the same declared quality gate before ranking usable capacity.

Use per-block packing calculations when blocks are independently allocated. Rounding one global code count can undercount bytes when many odd groups each require their own padding nibble. Add residual-window capacity and metadata alignment for the actual implementation. If pool slots retain the float16 maximum size regardless of code width, record that no physical pool capacity has yet been saved. Distinguish useful code bytes from owned backing bytes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVBitWidthEstimate:
    code_bits: int
    packing_scope: str
    scale_bytes: int
    zero_point_bytes: int
    group_elements: int
    residual_tokens: int
    implementation_status: str

def estimate_quantized_capacity(spec, architecture, lengths, budgets):
    # Count actual packing/metadata rules and complete consumer headroom.
    ...
```

```
def validate_capacity_bound(estimate, bounded_trials, quality_contract):
    # Separate analytical capacity from supported measured execution.
    ...

def E08(config):
    # Compare feasible quality-qualified capacities rather than bit labels.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report every storage component, assumed alignment, budget scope, headroom, quality support, and estimate status. Include counterexamples to both ideal ratio equals total savings and smallest bit width gives highest usable capacity. A format that fails quality or cannot be consumed within the budget is not a valid winner even if its codes alone are smallest.

Build a table showing estimate assumptions, implemented status, tested quality, and measured feasibility for every bit width. A hypothetical packed format may be listed as an estimate but cannot win a measured benchmark. Include consumer reconstruction headroom before converting a byte bound into maximum context or concurrency. A policy that fits persistent codes but cannot perform attention within budget must be rejected or paired with a separately validated streaming consumer.

Part 7 - Engineering Interpretation and Philosophy

Explain how storage accounting becomes a tested capacity decision. Choose which low-bit representation deserves implementation next and identify the largest uncertainty in metadata, working-set feasibility, quality, or execution cost.

19.38.10 Exercise 09

Exercise Title: Build Packed 4-Bit KV Storage in PyTorch and Verify Correct Packing and Unpacking of Quantized Values

Part 1 - Exercise Contract and Why It Matters

Build an exact nibble packing and unpacking codec for four-bit integer codes. Validate it independently from floating quantization, then connect it to a declared KV format. Demonstrate real two-codes-per-byte storage with explicit odd-length handling and group boundaries.

Part 2 - System and Memory Mental Model

The codec maps unsigned codes 0 through 15 to byte nibbles using a specified low/high order. A symmetric signed quantizer needs a separate declared code mapping, such as an offset convention; unpacking alone does not define floating values. Preserve original code count, shape, grouping, and valid tail information. Padding nibbles are not logical cache values. Avoid sign-extension, overflow, and implicit dtype behavior by validating the integer representation used for shifts and masks.

Part 3 - Quantitative Prediction Before Execution

Predict packed byte counts for zero, one, two, three, and several independently stored odd groups. Derive the byte and nibble selected by each logical code index. Specify padding

nibble contents and how they are excluded on decode. Separate the exact invariant unpack(pack(codes)) equals codes from the lossy invariant that reconstructed floats approximate their originals. Calculate complete packed KV storage including parameters and alignment.

Part 4 - Experimental Design and Instrumentation

Exhaustively test all sixteen codes and all two-code pairs on CPU before supported CUDA tests. Add random arrays, odd lengths, empty groups, noncontiguous inputs under an explicit normalization policy, and invalid codes. Test group boundaries with different scales so adjacent packed bytes cannot be decoded using another group's metadata. Validate K and V shape restoration separately. Measure packing/unpacking temporaries and actual uint8 backing bytes rather than counting a logical code list.

Specify the signed-to-unsigned code interpretation separately from nibble packing. For example, an offset-coded symmetric range may leave an unused nibble value; the codec can still test all sixteen bit patterns independently. Define byte order, low/high nibble order, group offsets, and original length in versioned metadata. Keep padding bytes deterministic in diagnostic tests so accidental tail consumption produces a recognizable error.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PackedKV4:
    bytes_payload: object
    logical_code_count: int
    logical_shape: tuple
    group_offsets: tuple
    nibble_order: str
    quantizer_parameters: object

def pack_4bit_codes(codes, packing_contract):
    # Validate range/order and define padding for every independent group.
    ...

def unpack_4bit_codes(payload):
    # Restore exactly the valid integer codes before floating dequantization.
    ...

def E09(config):
    # Exhaustively validate the codec and audit true packed storage.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact integer equality and record the smallest failing code pair or boundary. Verify invalid values are rejected before silently truncating high bits. Report packed bytes, padding, metadata, temporary peaks, and latency. A correct integer codec does not prove acceptable model quality; run the separate quantization and attention validation before using packed KV in decode.

Test every adjacent two-code pair and independent odd groups, then verify that unpacking one group cannot borrow another group's padding nibble. Reject negative or oversized unsigned input codes before masking, since masking can hide invalid values. For noncontiguous inputs, count normalization copies. When integrated with KV, verify exact codes first and approximate floating values second, then assess attention quality under its separate numerical contract.

Part 7 - Engineering Interpretation and Philosophy

Explain which part of compression is lossless representation and which part is lossy approximation. Keep the packing format stable and versioned so later paging, sharing, and offloading can move bytes without guessing their numerical interpretation.

19.38.11 Exercise 10

Exercise Title: Measure Quantize and Dequantize Overhead Separately from Attention Compute and Determine When Compression Becomes Slower Than Full-Precision KV Access

Part 1 - Exercise Contract and Why It Matters

Measure quantization, packing, unpacking, dequantization, and attention costs separately, then compare complete decode against float16 storage. Identify workloads where lower persistent capacity is useful but the reference compressed consumer is slower. Do not infer a fused-kernel speedup from storage reduction.

Part 2 - System and Memory Mental Model

A PyTorch reference often materializes integer intermediates and full floating KV before attention. Quantizing history again on every append can add substantial work beyond encoding newly sealed data. Separate one-time cache conversion, new-token updates, parameter estimation, and repeated consumption. Attention backend selection or layout changes can alter arithmetic cost independently of quantization. Host submission time and completed CUDA time answer different questions.

Part 3 - Quantitative Prediction Before Execution

Predict bytes read and written by every stage and the maximum live intermediate capacity. Compare short and long histories and small and larger batches. Estimate when conversion overhead exceeds any saved memory traffic under the actual consumer, not an imagined direct low-bit kernel. Define an amortization window for one-time compression and account for final drain. Keep concurrent intervals from being summed as if they were serial.

Part 4 - Experimental Design and Instrumentation

Use identical validated code formats, queries, token traces, and model arithmetic across cases. Benchmark isolated stages with appropriate completion, then unprofiled complete decode regions. Record warm-up, repetitions, shapes, backend, and timer semantics. Include per-tensor and grouped formats only after correctness checks pass. Add an ablation that encodes once and reads repeatedly, and another following the real append/update policy. Bound logging and avoid synchronizing every operation in the primary throughput run solely for profiling.

Benchmark update protocols separately: encoding a sealed block once, quantizing only new eligible values, and re-encoding a growing interval. Keep the same valid history and state the source used for every re-encoding. A fast read path does not compensate automatically for expensive updates. Include parameter estimation, packing, layout normalization, and host dispatch in the appropriate stage ledger instead of timing only the final quantized attention call.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVStageMeasurement:
    stage: str
    input_bytes: int
    output_bytes: int
    temporary_bytes: object
    completed_seconds: float
    measurement_scope: str

def benchmark_quantization_stages(cases, completion_contract):
    # Measure real representation work and preserve timing boundaries.
    ...

def compare_complete_decode(reference, compressed, trace):
    # Include updates, materialization, attention, and final drain.
    ...

def E10(config):
    # Explain both favorable capacity cases and slower compressed cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report stage intervals, complete wall time, temporary peaks, useful tokens, and quality gates. Explain differences between isolated sums and measured pipeline time. A reduced cache allocation cannot be presented as reduced decode latency without execution evidence. Preserve negative or inconclusive results, including contexts where metadata and conversion cost dominate.

Use a short profiler trace to attribute work and repeated unprofiled regions for throughput. Profiling or validation synchronization can change the measured schedule. Compare completed wall time with device intervals under named boundaries. Include a negative performance case where compression saves persistent bytes but increases total latency. Explain whether the cause

is temporary bandwidth, small kernels, parameter work, or a changed attention backend rather than assigning every slowdown to low-bit arithmetic.

Part 7 - Engineering Interpretation and Philosophy

Choose the simplest consumer justified by complete measurements. State the additional implementation and validation needed for direct packed attention, and keep that proposal separate from the delivered reference path's measured behavior.

19.38.12 Exercise 11

Exercise Title: Compare Quantizing Keys Only, Values Only, and Both Keys and Values to Determine Which Component Is More Sensitive

Part 1 - Exercise Contract and Why It Matters

Compare keys-only, values-only, and joint KV quantization to diagnose component sensitivity. Hold code width, grouping, calibration, and model arithmetic fixed for the primary comparison. Report error and storage together rather than assuming equal-sized components have equal numerical importance.

Part 2 - System and Memory Mental Model

Key error changes attention scores before softmax; value error changes the vectors combined by those weights. Their effects depend on queries, score margins, outliers, and later layers. The same KV reconstruction MSE can lead to different attention or logit changes. Quantizing only one component retains the other at its actual baseline precision and needs a mixed-format consumer. No universal K-versus-V sensitivity ranking follows from the equations alone.

Part 3 - Quantitative Prediction Before Execution

Construct a small example where key perturbation changes attention weights, and another where similar key errors leave them nearly unchanged. Construct a value perturbation case with fixed attention weights. Calculate mixed-format bytes for keys-only, values-only, and both, including their separate parameters. Define how quality is compared at equal code bits and, in a secondary experiment, at approximately equal complete storage.

Part 4 - Experimental Design and Instrumentation

Use fixed Q/K/V replay to isolate local effects, then integrated teacher-forced decoding on held-out traces. Measure attention weights where the transparent reference exposes them, attention outputs, logits, and the chosen model-quality metric. Preserve positional-key convention and masks. Include different layers, heads, and lengths without selecting only a favorable example. Record separate K and V clipping and reconstruction errors. Keep any attention-weight diagnostic allocation outside the primary throughput measurement.

Preserve the same frozen queries when isolating key and value sensitivity. If queries change in integrated decoding, label the result as a compounded model effect. Compare errors per layer/head and include score distributions with close and widely separated maxima. Softmax can attenuate or amplify the consequence of score perturbation depending on the case. This makes a universal sensitivity ordering an empirical question rather than a property of tensor size.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVComponentPolicy:
    key_format: str
    value_format: str
    key_grouping: tuple
    value_grouping: tuple
    calibration_identity: str

def evaluate_component_policy(policy, frozen_cases, decoder_cases):
    # Separate score/weight effects from value aggregation and rollout drift.
    ...

def compare_component_tradeoffs(results, quality_contract):
    # Compare complete bytes and quality without assuming equal sensitivity.
    ...

def E11(config):
    # Test K-only, V-only, and joint formats under explicit matching rules.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report K/V errors, clipping, weight changes, attention/logit metrics, complete bytes, workspace, and latency. Preserve cases whose component ranking reverses. Equal MSE is not equal model quality and a single prompt is not a model-wide sensitivity study. Distinguish frozen local evidence from integrated cache trajectories that already differ because of earlier quantization.

Compute actual bytes for the untouched component and its compressed counterpart, including separate parameter shapes. At approximately equal storage, document which grouping or bit-width changes were necessary; that is a secondary comparison, not the same controlled experiment as equal bits. Report cases where lower reconstruction MSE fails to improve logits. Keep quality thresholds fixed before observing which component appears more favorable.

Part 7 - Engineering Interpretation and Philosophy

Choose component-specific formats only when the evidence supports the extra complexity. Explain the tested sensitivity mechanism and uncertainty, without turning observations from one model or head into a universal compression rule.

19.38.13 Exercise 12

Exercise Title: Preserve a Recent Full-Precision KV Window While Quantizing Older Tokens and Measure the Memory-Accuracy Trade-Off

Part 1 - Exercise Contract and Why It Matters

Keep a recent high-precision KV window and quantize older processed tokens. Measure persistent bytes, transition peaks, update cost, and quality as window length changes. Preserve exact logical token order and complete causal history across the boundary.

Part 2 - System and Memory Mental Model

Recent refers to processed positions within each request, not wall-clock age or a global batch counter. A token aging out of the window changes format but remains part of attention. Group boundaries can require delaying conversion until a complete block exists or handling a partial group explicitly. The high-precision window is high precision relative to stored codes; it need not be float32. Once original values are discarded, later promotion from low-bit reconstruction does not recover them.

Part 3 - Quantitative Prediction Before Execution

For request length T and nominal window W, predict floating and quantized token counts under the exact boundary policy, including $T < W$ and an empty history. Add scales, packing tails, and possible block rounding. Calculate maximum coexistence while sealing old values into codes. Predict conversion frequency and compare a zero-window policy, several bounded windows, and an all-float reference with the same consumer.

Part 4 - Experimental Design and Instrumentation

Implement explicit region metadata and transition ownership. Test crossing the window boundary by one token, partial quantization groups, multiple requests with different lengths, and shrink/regrowth under a supported prefix policy. Use a fixed teacher-forced trace and independent held-out quality cases. Validate that the mixed consumer neither duplicates nor omits positions and uses matching positional keys. Charge temporary originals, code destinations, and reconstructed attention inputs. Measure update latency as well as steady read latency.

Define the exact processed-position boundary for each request and assert that quantized and floating regions neither overlap logically nor leave a gap. Test several requests aging at different rates in the same batch. If conversion waits for a complete block, report the additional high-precision residual capacity beyond the nominal window. Old floating capacity retained in a reusable buffer still counts even after its logical region becomes quantized.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVPrecisionRegions:
    quantized_stop: int
    floating_start: int
    committed_length: int
    boundary_policy: str
    region_formats: tuple

def advance_recent_window(cache, request, new_length, policy):
```

```
    # Convert eligible old values and publish nonoverlapping valid regions.
    ...

def read_mixed_precision_kv(cache, request, attention_contract):
    # Restore correct logical order without dropping boundary positions.
    ...

def E12(config):
    # Sweep windows with truthful persistent and transition accounting.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual floating token counts, quantized groups, parameters, residual capacity, workspace, and quality. A nominal window can differ from actual retained floating capacity because of grouping and allocator policy; report both. Include a case where a larger window costs more without meaningful quality gain and one where aggressive conversion violates the quality gate. Do not assume recent tokens are always the most important.

Test a token crossing the boundary, a group crossing a page boundary, and a request truncated then regrown under a supported causal-prefix policy. Do not resurrect stale tail values. When a shared prefix ages into a different format, preserve every owner's interpretation through immutable replacement or a coordinated supported policy. Charge any retained originals used for quality comparison outside the measured production path and report their actual storage scope separately.

Part 7 - Engineering Interpretation and Philosophy

Choose a window policy conditional on measured quality and update cost. Explain what information its recency heuristic uses and why retained high precision is a capacity-quality choice rather than a guarantee about every long-range dependency.

19.38.14 Exercise 13

Exercise Title: Build a Block-Wise Quantized KV Cache Where Every Physical KV Block Stores Independent Scale Metadata

Part 1 - Exercise Contract and Why It Matters

Build independently decodable quantized KV blocks with per-block format and scale metadata. Support sealed immutable blocks and a declared writable-tail policy. Deliver checked block encoding, decoding, publication, and byte accounting as the foundation for paged compression.

Part 2 - System and Memory Mental Model

A physical block is application-owned payload for a documented layer and token interval, not a hardware page. Its codes, scale/zero-point arrays, valid length, group shape, format version, and positional convention form one interpretation unit. Independent block parameters avoid changing every historical scale when a new block arrives, but reduce the quantizer's observation scope. A mutable partial block still needs a defined update or residual policy.

Part 3 - Quantitative Prediction Before Execution

For a fixed-token block, derive code bytes and parameter counts under each supported grouping. Include odd packing groups and valid tails. Predict how many complete blocks can be sealed during prefill and one decode step. Calculate transition capacity while source floating data and encoded destination coexist. Compare independent-block storage with whole-history per-tensor scaling at the same code width without assuming equal numerical error.

Part 4 - Experimental Design and Instrumentation

Use coordinate-coded block identities and different value ranges per block. Test shuffled physical placement, partial tails, zero groups, large outliers, and format mismatches. Seal blocks only after required layer writes are ready and validated. Keep a residual floating tail or an explicit frozen-scale policy; do not reassign parameters to old codes. Compare each block's reconstructed values and integrated logits with references. Retain only bounded scalar diagnostics in the measured memory path.

Associate code payload, parameters, shape, and valid length with one block generation. Reject a decoder receiving matching shapes but mismatched format identity. Test blocks with very different scales adjacent in logical order. A sealed block can be immutable while its placement changes; its numerical interpretation must stay attached during migration. State whether one block covers one layer or multiple layers and derive parameter counts accordingly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class QuantizedKVBlock:
    layer_id: int
    valid_tokens: int
    payload: object
    parameters: object
    format_identity: tuple
    generation: int
    sealed: bool

def seal_kv_block(floating_block, quantizer_contract):
    # Encode matching codes/parameters and preserve publication dependencies.
    ...

def decode_kv_block(block, consumer_contract):
    # Validate complete format identity before reconstructing valid KV.
    ...
```

```
def E13(config):
    # Test independent scales, writable tails, and metadata-inclusive costs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact packed-code behavior, valid parameters, correct tail boundaries, and quality thresholds. Report block payload, parameter arrays, alignment, residual storage, temporary coexistence, and completed time. A stale scale from another generation must be rejected, not silently broadcast. Verify failed encoding leaves no published block or leaked provisional allocation.

Compare actual allocated backing with useful code count, especially for partial blocks and independently padded groups. A per-block quantizer changes its calibration scope relative to whole-history scaling, so evaluate quality rather than assuming numerical equivalence. Inject failure after destination allocation but before publication and audit provisional cleanup. Old consumers must retain their original codes and parameters until their leases finish, even after a new block generation is ready.

Part 7 - Engineering Interpretation and Philosophy

Explain how independent interpretation units simplify paging and sharing, and what statistical or metadata cost they introduce. Choose a block/tail contract that remains auditable before adding mixed precision and dynamic re-encoding.

19.38.15 Exercise 14

Exercise Title: Combine Paged KV Cache with Quantized Physical Blocks and Recalculate Maximum Concurrent Sequence Capacity

Part 1 - Exercise Contract and Why It Matters

Combine logical paging with quantized physical blocks and recalculate quality-qualified concurrent-request capacity. Preserve checked tables, generation identity, shared-prefix ownership, and correct attention positions while accounting for representation-dependent allocation sizes.

Part 2 - System and Memory Mental Model

Logical token capacity and physical byte capacity are different. Two blocks covering the same number of tokens can require different bytes because of bit width, grouping, metadata, and residual policy. A pool may use separate size classes or fixed maximum-sized slots; unused slot capacity still counts. Sharing requires compatible format and model context. A float reconstruction of shared codes can create separate temporary payload even when persistent codes are unique.

Compressed prefix reuse also depends on the numerical trajectory that produced the cached values. Identical tokens and weights can yield different later KV after earlier approximate attention differs. Include the relevant precision-policy and canonical prefix-construction identity, or validate a deliberately weaker equivalence contract. Do not assume that matching final code format alone makes prefixes computed under different adaptive histories interchangeable.

Part 3 - Quantitative Prediction Before Execution

Calculate unique encoded backing, logical mappings, table bytes, free retained pool capacity, and consumer workspace for ragged requests. Derive a tested concurrency bound for homogeneous precision, then a mixed-format case. Include partial tails, shared prefixes, and a copy-on-write conversion. Compare nominal payload admission with complete working-set feasibility; packed storage alone does not prove the dense attention reconstruction will fit.

Part 4 - Experimental Design and Instrumentation

Adapt checked block tables with explicit format identifiers and per-layer layout. Start with one precision class, then add another using a documented pool policy. Replay the same bounded request arrivals, lengths, token traces, and completion events as the float reference. Validate table translations and codec correctness before model comparisons. Test stale handles, format-class reuse, shared-prefix destruction, and a budget rejection. Measure complete capacity peaks through request replacement and conversion, not only stable resident codes.

Use separate byte-accounted size classes or explicitly charged maximum-size slots. A free retained slot is still owned GPU backing and must remain in the strict capacity ledger. Test an admission where code bytes fit but metadata, residuals, and the dense consumer do not. Keep logical token mapping independent from physical slot order, and verify GQA head identity after mixed-format block decoding.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class QuantizedBlockMapping:
    logical_block: int
    handle: object
    format_identity: tuple
    valid_tokens: int
    model_context: tuple

def admit_quantized_requests(trace, pools, consumer_requirements, budgets):
    # Count real slot classes, metadata, residuals, and working-set headroom.
    ...

def audit_quantized_tables(tables, pool_state, shared_owners):
    # Verify generation, format, positions, and unique backing ownership.
    ...

def E14(config):
    # Validate paged numerical behavior before reporting concurrent capacity.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report maximum tested admission and completed concurrency separately from analytical bounds. Include useful tokens, unique codes, metadata, padding, retained slots, residuals, workspace, quality, latency, and rejected work. A format stored in oversized fixed slots may save no pool capacity despite smaller logical codes. Do not borrow optimized paged-kernel throughput results as measurements of this reference consumer.

Share only compatible immutable representations under the declared model context. Two requests can share original semantic prefixes but require different precision policies; define whether they share a common supported encoding or receive private replacements. Count unique backing once and every logical mapping separately. Report tested completed concurrency, queued/rejected work, and quality beside analytical capacity so a high admission estimate cannot hide unfinished or invalid inference.

Part 7 - Engineering Interpretation and Philosophy

Explain whether compression improved real admission, only persistent payload, or complete decode. State the pool and consumer assumptions behind the capacity claim, and preserve the separate contributions of paging, sharing, and lossy precision changes.

19.38.16 Exercise 15

Exercise Title: Combine KV Quantization with CPU Offloading and Compare Transfer Volume Against Lossless float16 KV Offloading

Part 1 - Exercise Contract and Why It Matters

Combine compressed KV storage with CPU offloading and compare actual transfer volume, host residency, GPU peaks, quality, and complete decode against lossless float16 offload. Preserve the stream/event and authority protocols established for migration while adding exact format metadata to every transferred block.

Part 2 - System and Memory Mental Model

Transfer savings require packed codes and parameters to cross the link. Dequantizing on CPU and transferring float16 does not provide low-bit link volume merely because CPU storage is compressed. Quantization adds approximation; moving the resulting bytes can still be lossless. Codes and scales must describe the same version, and their sources remain live and unchanged until the transfer completes. CPU backing, pinned staging, decoded GPU values, and retained references all consume separate capacity.

Part 3 - Quantitative Prediction Before Execution

Calculate H2D and D2H bytes for float16 offload versus the implemented compressed protocol, including parameter arrays, padding, and dirty updates. Estimate transfer time from measured size-dependent bandwidth and fixed cost. Add packing/dequantization and attention workspace. Predict a small-page case where metadata and launch overhead erase link savings, and a larger case where bandwidth reduction may matter. Compare model-quality changes separately from transport correctness.

Part 4 - Experimental Design and Instrumentation

Begin with synchronous compressed round trips and exact code/metadata checks. Then reuse bounded pinned buffers and generation-aware CUDA events. Keep weights, positions, masks, token trace, and consumer backend fixed. Test partial blocks, shared pages, cancellation,

and delayed metadata transfer. Validate that a block cannot be published ready until both payload and parameters are ready. Measure complete cold and warmed decode, not only DMA submission. Charge any retained float originals to their real host or GPU scope.

Capture actual transferred payload and metadata bytes by direction. A compressed CPU store followed by float16 H2D should be reported as float16 link traffic. For packed transfers, preserve valid code counts and grouping at the destination. A metadata copy can complete later than its code copy; publish readiness only when both are valid. Use bounded pinned staging and generation-aware identities for every outstanding transfer.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class QuantizedKVTransfer:
    block_generation: int
    format_identity: tuple
    payload_version: int
    parameter_version: int
    ready_events: tuple
    destination_state: str

def transfer_quantized_block(block, destination, transfer_contract):
    # Move matching packed payload/parameters and preserve endpoint lifetimes.
    ...

def publish_transferred_block(ticket, residency_state):
    # Require exact-generation readiness for every interpretation component.
    ...

def E15(config):
    # Compare link bytes, complete cost, and quality against float16 offload.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual direction-specific bytes, payload/metadata sizes, pinned capacity, host backing, GPU workspace, transport mismatches, numerical quality, and complete latency. A bit-width ratio is not a measured PCIe compression ratio. Keep the lossless baseline's semantics visible and do not call a lossy quantized model result numerically identical merely because transferred bytes were preserved exactly.

Test a delayed parameter transfer and reject a consumer that attempts to use newly arrived codes with old scales. Compare codec-preserving round trips independently from model-quality

changes. Include host backing, staging, original-value retention, reconstructed GPU history, and pending sources in the memory ledger. Do not infer link savings from bit width or use nominal PCIe bandwidth as a measured transfer result.

Part 7 - Engineering Interpretation and Philosophy

Explain whether compression relieved link bandwidth, persistent capacity, or neither after conversion costs. Recommend offload only within measured quality and resource limits, preserving the distinction between approximate KV representation and correct migration of that representation.

19.38.17 Exercise 16

Exercise Title: Build a Dynamic Precision Policy That Keeps Important or Recent KV Blocks at Higher Precision and Compresses Older Blocks More Aggressively

Part 1 - Exercise Contract and Why It Matters

Choose higher precision for selected recent or importance-ranked blocks and compress other blocks more aggressively. Deliver an explicit policy, quality evaluation, and byte ledger. Keep importance as a tested predictor, not permission to omit required attention history or claim guaranteed future accuracy.

Part 2 - System and Memory Mental Model

Mixed precision changes representation, not token visibility. Importance may use available recency or measured sensitivity proxies, but a future-aware oracle belongs only to diagnostic evaluation. Attention weights from one step do not universally measure future importance. Promoting a low-bit reconstruction to a wider format does not restore discarded information. Genuine restoration requires retained originals or recomputation under a supported model protocol, whose cost and lifetime must be counted.

Changing historical cache precision does not retroactively recompute later KV or hidden states that were already produced from an earlier approximation. The controller manages that evolving approximate state; its evaluation must follow the actual integrated trajectory rather than substituting freshly quantized reference KV and calling the two histories identical.

Part 3 - Quantitative Prediction Before Execution

For a fixed byte budget, predict code and metadata capacity for a mixed precision assignment, including residuals and size-class slack. Compare a recency-only policy with a simple calibrated sensitivity policy and a uniform format. Construct one trace where recent blocks matter and another requiring older history. Estimate transition capacity and conversion error for proposed format changes rather than treating precision switches as cost-free labels.

Part 4 - Experimental Design and Instrumentation

Calibrate proxies on separate traces and freeze their interpretation before held-out evaluation. Start with one-time assignments to sealed blocks, then add bounded changes with generation-aware publication. Preserve query/head mapping, positional convention, masks, and model weights. Measure task-level quality or a clearly labeled proxy, logits, byte peaks, conversion frequency, and complete latency. If a higher-precision fallback needs originals, store them in an explicitly charged scope. Otherwise allow queuing or rejection instead of pretending lost precision is recoverable.

Specify whether importance is a calibrated sensitivity estimate, a current attention diagnostic, or recency. Do not mix these labels. A future-aware assignment may be a useful offline upper comparison, but it must remain separate from the online controller. Use one stable workload and another with an older critical dependency to expose proxy failure. Preserve full causal visibility for every precision choice.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVPrecisionEvidence:
    block_identity: tuple
    age_tokens: int
    sensitivity_proxy: object
    current_format: tuple
    original_values_available: bool
    uncertainty: object

def choose_block_precisions(evidence, budgets, calibrated_quality_policy):
    # Use available information and reject unsupported restoration promises.
    ...

def apply_precision_assignment(plan, engine):
    # Preserve ownership, interpretation metadata, and transition headroom.
    ...

def E16(config):
    # Compare mixed formats with uniform and recency-only policies honestly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report score inputs, assigned formats, quality gates, predicted and actual bytes, transitions, and latency. Include a proxy misranking and an attempted promotion without originals. Label calibration-based quality estimates as such; a live engine without an oracle cannot certify every unseen token's deviation from original inference. Do not use held-out reference outputs as online policy inputs while claiming an ordinary deployable controller.

Attempt promotion after discarding originals and require the engine to report that reconstruction width is increasing without recovering information. If originals are retained, count their bytes and transfer/recompute cost before claiming a reversible policy. Report every quality failure and policy fallback. An unseen request outside the calibrated envelope may need conservative handling or rejection; it cannot receive an automatic accuracy guarantee from a recency score.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest policy whose quality-capacity benefit exceeds conversion and monitoring cost. Explain uncertainty and reversibility explicitly, especially when the preferred precision would require information already discarded.

19.38.18 Exercise 17

Exercise Title: Select KV Precision from Live VRAM Pressure and Automatically Re-Quantize Existing Cache Blocks When Memory Crosses a High Watermark

Part 1 - Exercise Contract and Why It Matters

React to a named memory watermark by re-quantizing existing blocks when admissible and supported by the quality policy. Preserve valid formats, ownership, and transition capacity. Demonstrate that a pressure response cannot assume old storage is freed before replacement codes and metadata are ready.

Part 2 - System and Memory Mental Model

Re-quantization from reconstructed low-bit data composes approximation error; it is not equivalent to quantizing original values once. A retained original source changes host or GPU memory accounting. Shared blocks may require copy-on-write or a coordinated policy for every owner. Watermarks from live payload, allocator reservation, and driver headroom have different meanings. The controller can enforce its owned-byte admission contract, not guarantee universal freedom from CUDA OOM or unseen quality degradation.

Part 3 - Quantitative Prediction Before Execution

Predict old format, decoded temporary, replacement codes/parameters, and pending-reader coexistence for one conversion. Calculate eventual savings and immediate peak separately. Hand-simulate high/low thresholds with hysteresis and a context-growth spike. Include an action whose final representation fits but whose conversion peak does not. Compare one-shot and repeated conversion errors against the same original reference in an offline diagnostic.

Part 4 - Experimental Design and Instrumentation

Use a small application budget and deterministic pressure traces rather than uncontrolled device exhaustion. Admit complete transition demand before dispatch and publish checked format/version replacements only after readiness. Test missing originals, active readers, shared-prefix ownership, stale completion, and an infeasible conversion. Choose queuing, rejection, or another supported fallback when quality evidence or headroom is insufficient. Keep reference-based quality evaluation outside the online decision unless its availability and cost are explicitly part of the contract. Record sample age and unsupported counters.

Use high and low watermarks with a named byte scope, timestamp, and next-step growth estimate. Before conversion, reserve capacity for decoded intermediates, new codes, new metadata, and old-reader retention. Include a case where the engine has too little headroom to perform its preferred compression. The supported response must be explicit rather than freeing old live storage prematurely or allocating outside the declared budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVRequantizationPlan:
    block_identity: tuple
    source_format: tuple
    target_format: tuple
    source_is_original: bool
    transition_capacity_bytes: int
    expected_final_bytes: int
    quality_evidence: object

def plan_pressure_requantization(engine, watermark_evidence):
    # Admit complete peaks and reject unsupported quality/reversibility claims.
    ...

def commit_requantization(plan, readiness, ownership_state):
    # Publish matching codes/parameters and retire old exact-generation users.
    ...

def E17(config):
    # Test pressure, hysteresis, cumulative error, and failed-action cleanup.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report metric scope, thresholds, age, proposed savings, transition peaks, actual reclaimed capacity, quality, and failures. A fixed oversized pool slot may remain the same capacity after re-encoding, so code-size savings need not relieve pressure. Keep old backing counted until all users finish. A rejected action is correct when conversion or quality prerequisites cannot be satisfied.

Compare repeated conversions with one-shot quantization from the same original cache in an offline diagnostic, while preserving the online source policy. A later wider code format cannot erase earlier error. Test shared-owner disagreement and stale conversion completion after a slot is recycled. Validate hysteresis on a stable near-threshold trace so a precision policy does not oscillate without useful capacity or quality benefit.

Part 7 - Engineering Interpretation and Philosophy

Explain whether reactive compression provides real usable headroom and what approximation risk it purchases. Recommend thresholds and fallbacks from tested behavior while preserving uncertainty about external allocations, future quality, and irreversible repeated compression.

19.38.19 Exercise 18

Exercise Title: Stress-Test Quantized KV Caching with Long Contexts, Variable Sequence Lengths, Shared Prefixes, Paged Blocks, and Aggressive Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Stress-test quantized KV with long bounded contexts, variable lengths, shared prefixes, paged formats, and deliberately tight resource limits. Search for minimal failures in codecs, numerical quality, format identity, lifecycle, and byte accounting. Separate intentional quality rejection from implementation corruption.

Part 2 - System and Memory Mental Model

Critical cases combine valid transitions: a shared block changes precision while a reader uses its old format, an odd packed tail crosses a page boundary, or a stale scale is paired with recycled payload. A byte-perfect codec can still produce unacceptable model error; acceptable logits do not prove safe ownership. Maintain separate format, semantic, resource, and quality oracles. Memory pressure should be bounded by engine admission limits, not machine-wide exhaustion.

Part 3 - Quantitative Prediction Before Execution

Predict complete peaks for residual-window sealing, copy-on-write compression, offload, and repeated re-quantization combinations. Construct short traces that expose zero scales, clipping, odd nibble padding, stale metadata, and shared-format disagreement. Define which quality failures should reject a configuration and which invalid operations should produce explicit errors. State progress assumptions when conversion requires temporary headroom or original values that may not be available.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, trace IDs, finite requests, bounded contexts, host/GPU budgets, and pending-operation limits. Begin with CPU codec and deterministic transition checks, then supported CUDA execution. Evaluate held-out model quality and teacher-forced logits at selected checkpoints. Inject preparation failures before publication and forced stale-handle controls. Audit after every transition and final drain. Save and reduce failing histories while preserving calibration identity, prefix setup, format metadata, and completion order.

Keep exact codec tests, valid approximate inference, intentional quality failure, and unsupported operations as different outcome classes. Save format and calibration identities with seeds and completion order. A seed alone may not reproduce asynchronous behavior. Start from deterministic short traces that expose each invariant before running randomized combinations, and bound pending conversions and diagnostic logs as well as payload storage.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class QuantizedKVStressBounds:
    max_requests: int
    max_context_tokens: int
    gpu_bytes: int
    host_bytes: int
    max_pending_conversions: int
```

```
    steps: int

def generate_quantized_trace(seed, bounds, supported_formats):
    # Mix valid histories with labeled codec/metadata rejection controls.
    ...

def audit_compressed_runtime(engine, format_oracle, semantic_oracle):
    # Separate exact code invariants, approximation quality, and resource state.
    ...

def minimize_compression_failure(trace, replay):
    # Preserve source/calibration and asynchronous setup dependencies.
    ...

def E18(config):
    # Test deterministic failures before bounded supported CUDA stress.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, traces, exact failure phase, quality thresholds, reproducibility, and smallest counterexamples. Distinguish unsupported execution, expected admission rejection, quality failure, and corruption. A run with no observed counterexample is not proof over all inputs or interleavings. Do not fabricate hardware peaks, throughput, or model-quality scores when those experiments were not performed.

Check final drain and cancellation so delayed metadata publication cannot hide after the test appears finished. Reduce a failure only while preserving its source values, grouping, shared-prefix setup, and required lifecycle events. Record both original and reduced traces with their invariant violation. If quality fails without codec corruption, preserve that distinction and reject the tested format/policy rather than silently widening the acceptance threshold after seeing the result.

Part 7 - Engineering Interpretation and Philosophy

Identify the most consequential unresolved numerical or lifecycle risk and its next bounded test. State the supported envelope honestly, keeping exact representation correctness separate from empirical model-quality evidence.

19.38.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Adaptive KV Cache Compression Engine That Dynamically Chooses Precision per Block to Maximize Context Capacity Under Accuracy and VRAM Constraints

Part 1 - Exercise Contract and Why It Matters

Integrate an adaptive per-block KV compression engine with explicit formats, quality policy, byte admission, residual windows, paging, optional offload, and safe re-encoding. Benchmark quality-qualified context and concurrency capacity under named VRAM limits. All substantive implementation remains learner work in the scaffold.

Part 2 - System and Memory Mental Model

One authority coordinates request positions, layer validity, codes, parameters, format generations, shared owners, pending readers, and residency. The attention consumer sets working-set requirements and includes unpack/dequantization or streaming costs. Dynamic precision is an approximation policy, not an online proof of model accuracy. Original-value retention and restoration are supported only when their storage and computation are explicitly budgeted. Keep model weights and required full-context semantics fixed for the primary comparison.

Part 3 - Quantitative Prediction Before Execution

Predict persistent codes, parameters, residuals, page slack, retained free slots, conversion duplicates, decoded workspace, and offload staging. Compare float16, uniform int8, implemented packed 4-bit, fixed mixed precision, and adaptive policies under equal supported token traces. Define quality thresholds and capacity objectives before evaluation. Estimate both steady savings and maximum transition demand. A candidate outside quality or consumer-feasibility constraints is not an admissible capacity improvement.

Part 4 - Experimental Design and Instrumentation

Freeze support for layouts, model context, grouping, sharing, append, truncation, conversion, cancellation, and migration. Validate codecs and metadata, then numerical and lifecycle oracles before benchmarking. Use separate calibration, policy selection, and held-out evaluation traces. Record device, software versions, allocator backend, model revision, dtype, masks, positions, formats, budgets, seeds, and initial state. Include setup, conversion, calibration, monitoring, attention, and drain in complete cost. Run ablations without weakening quality or resource gates.

Publish supported schemes, code mappings, scale axes, parameter dtypes, packing, residuals, sharing, and consumer semantics before the integrated benchmark. Keep model arithmetic and weights fixed for the main comparison. Evaluate a memory-constrained case and a short-context case where compression may lose. Separate estimated maximum context from actually completed inference, and count rejected or unfinished requests in the outcome record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AdaptiveKVCompressionContract:
    model_context: tuple
    supported_formats: tuple
    gpu_capacity_bytes: int
    host_capacity_bytes: int
    attention_consumer: str
```

```
    quality_policy_identity: str
    original_value_policy: str
    maximum_pending_conversions: int

class AdaptiveKVCompressionEngine:
    def __init__(self, contract):
        # Establish formats, tables, ownership, budgets, and calibrated policy.
        ...

    def append(self, request, layer, keys, values):
        # Preserve valid positions and the declared tail/group update policy.
        ...

    def attention(self, query, request, layer):
        # Decode exact format identity and preserve the causal consumer contract.
        ...

    def adapt_precision(self, pressure_evidence):
        # Gate actions by capacity, quality evidence, and reversibility support.
        ...

    def audit(self):
        # Recompute codes/metadata ownership, quality support, and complete bytes.
        ...

    def shutdown(self):
        # Drain or cancel owned work and report outstanding obligations.
        ...

def E19(config):
    # Validate integrated semantics before held-out capacity/quality benchmarks.
    ...
    # Export evidence, counterexamples, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires exact codec behavior, valid parameter association, correct masks/positions, quality within declared tested limits, safe ownership, and truthful complete capacity. Report context/concurrency estimates and tested completed cases separately. Include quality metrics, clipping, code/metadata bytes, temporary peaks, conversion count, transfer volume, latency distributions, and rejected work. Keep prediction, observation, and interpretation separate. An incomplete scaffold supplies no hardware or model-quality results.

Report complete quality-qualified capacity with codes, parameters, residuals, retained free pools, decoded workspace, transitions, and optional host originals. A strict memory gate can be enforced from owned allocations, while an empirical accuracy envelope needs held-out evidence and explicit uncertainty. Do not present a calibration proxy as a guaranteed online oracle.

Conclude with the smallest supported format/policy and the next experiment needed to justify more aggressive adaptation.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest quality-qualified design supported by complete measurements, including float16 when compression does not help. Explain the capacity gained, numerical approximation accepted, and conversion or transfer cost paid. Keep proposed fused kernels, wider model support, and untested accuracy guarantees separate from delivered evidence.

19.39 DMM37

Chapter Title: KV Cache Eviction and Context Retention Policies
Specialization: Dynamic Memory Management and CUDA Systems

19.39.1 Exercise 00

Exercise Title: Build a Precise Mental Model of KV Cache Eviction, Context Retention, Attention Importance, and the Memory-Accuracy Trade-Off

Part 1 - Exercise Contract and Why It Matters

Define the distinct meanings of KV eviction before implementing retention policies. Deliver a lifecycle and semantic diagram separating active-context pruning, CPU demotion, compression, and reclamation of unused reusable prefixes. The first changes the attention inputs; the others can have different numerical, residency, and future-prefill consequences. Keep their outcomes distinguishable throughout the chapter.

Part 2 - System and Memory Mental Model

Removing an active token's KV generally changes attention and renormalizes weights over retained keys. It is not a cache miss that automatically reloads an unchanged computation. Removing an unreferenced prefix-cache entry can leave current inference unchanged and require future recomputation. Physical storage reclamation still waits for every owner and device reader. Retained KV values may already encode information from earlier context; pruning storage is not equivalent to recomputing a model on only the retained text.

Part 3 - Quantitative Prediction Before Execution

Predict useful token entries, unique backing, metadata, score arrays, workspace, and transition copies for a bounded policy. Separate logical token removal from physically reusable bytes. Define accuracy and resource contracts before measurement: retained-position correctness, perplexity protocol, retrieval accuracy, and complete decode cost. Construct a case where memory falls but quality fails and another where prefix hit rate falls without changing a completed request's outputs.

Part 4 - Experimental Design and Instrumentation

Use a transparent tiny decoder for implementation invariants and a fixed supported trained model for meaningful quality evaluation when available. Preserve weights, tokenization, model revision, attention backend, positions, GQA mapping, masks, and precision in the primary comparison. Start with one global retained-position set per request across layers; per-head variants are separate extensions. Keep original absolute positions in the reference policy and

stay within supported positional limits. Record hardware, software, seed, trace ID, budgets, and initial state.

Draw four actions applied to the same logical token: keep on GPU, move an unchanged representation to CPU, store an approximate compressed representation, and remove its direct attention entry. Record what later retrieval requires in each case. Include inactive reusable prefixes as a separate ownership class. A permanent-delete label means no restoration path in the declared runtime; if original input is retained for recomputation, record that recovery capability and its host storage explicitly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class KVRetentionContract:
    eviction_semantics: str
    position_policy: str
    retention_scope: str
    maximum_tokens: int
    physical_budget_bytes: int
    quality_policy_identity: str

def classify_eviction_action(action, ownership, backing_state):
    # Distinguish semantic pruning, movement, compression, and cache reclaim.
    ...

def E00(config):
    # Define the supported task and audit semantic/resource transitions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require separate prediction, observation, and interpretation fields. Report logical retained tokens, real backing capacity, protected owners, quality, and completed time. Do not claim lossless equivalence after active context deletion or universal semantic importance from attention magnitude. Bound scalar evidence and avoid retaining the full cache in diagnostic tensors. Unperformed model or CUDA experiments remain explicitly unmeasured.

Classify every result by semantic correctness, approximation quality, physical reclamation, and complete performance. A policy can pass one and fail another. Do not interpret a good sentence as a resource audit or a low byte count as quality validation. State that deleted direct KV is not a guarantee of erasing all influence of earlier text, since surviving model state can already depend on it. This exercise studies inference approximation, not machine unlearning.

Part 7 - Engineering Interpretation and Philosophy

Explain the resource saved and the computation or future work changed by each action. A useful retention policy has an honest approximation contract, a checked lifecycle, and quality evidence rather than a single memory-saving percentage.

19.39.2 Exercise 01

Exercise Title: Establish a Full-KV Baseline and Measure VRAM Growth, Decode Latency, Perplexity, and Retrieval Accuracy as Context Length Increases

Part 1 - Exercise Contract and Why It Matters

Establish full-context KV behavior over increasing bounded context lengths. Measure useful cache growth, complete VRAM peaks, decode latency, token-weighted perplexity, and controlled retrieval accuracy. Preserve the model's supported context range and separate implementation validation from meaningful language quality measurement.

Part 2 - System and Memory Mental Model

Full KV retains every processed position required by the declared attention architecture. Cached token count differs from output tokens sampled but not forwarded. Static reservation and dynamic-growth copies produce different memory curves. Perplexity depends on tokenization, evaluation targets, and available preceding context. Retrieval accuracy depends on whether the model can perform the baseline task at all; a random-weight toy decoder cannot establish useful long-range language quality.

Part 3 - Quantitative Prediction Before Execution

Predict unquantized useful bytes from layer specifications, KV heads, dimensions, dtype, and ragged processed lengths. Define

$$\mathrm{PPL} = \exp\left(\frac{\sum_i \ell_i}{N_{\mathrm{scored}}}\right),$$

where each loss term scores a declared target once under its allowed context. Specify retrieval answer normalization and success criteria. Predict capacity and latency separately and identify limits where a full-KV reference is not feasible rather than inventing results beyond them.

Part 4 - Experimental Design and Instrumentation

Use fixed model/tokenizer revisions, zero dropout, no gradients, stable precision, and explicit causal masks. Score the same target positions for all future policies; document window/stride and padding exclusions. Build retrieval cases with known answers at controlled distances and distractor counts. Separate prefill from decode and teacher-forced evaluation from free generation. Warm deliberately, synchronize at completed region boundaries, and repeat timing. Store selected CPU reference outputs outside the measured GPU lifetime.

Freeze tokenizer and scoring conventions before comparing context lengths. Use an identical set of target tokens where policies can be fairly compared, and state how context available to each target differs. For fixed-length model evaluation, record stride and overlap, mask unscored targets, and avoid scoring one target repeatedly merely because it appears in several windows. Report any prefix whose first token has no valid preceding prediction context under the chosen evaluation protocol.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class FullKVQualityCase:
    trace_id: str
    context_tokens: int
    scored_target_positions: tuple
    retrieval_answer: object
    evaluation_protocol: str

def evaluate_full_kv(model, cases, measurement_contract):
    # Preserve full valid history and count each scored target exactly once.
    ...

def measure_retrieval(prediction, expected_answer, normalization_policy):
    # Apply the predefined task criterion without post-hoc reinterpretation.
    ...

def E01(config):
    # Establish capacity, timing, perplexity, and retrieval reference evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful and capacity bytes, backend allocated/reserved peaks, processed lengths, scored-token counts, NLL, perplexity, retrieval outcomes, and latency spread. Do not average perplexities from unequal token counts as though that were corpus perplexity. Separate a baseline task failure from an eviction-induced failure. Mark unsupported lengths, model availability, and device measurements explicitly.

Keep local-language and known-answer retrieval datasets separately identified. A model unable to retrieve the full-cache answer provides a baseline failure, not proof of eviction damage. Preserve those cases in aggregate reporting and provide a competent-baseline diagnostic stratum without hiding the original population. Record maximum supported positions and refuse unvalidated extrapolation. A short toy model can validate the measurement pipeline while meaningful quality claims require an actually executed trained model and suitable data.

Part 7 - Engineering Interpretation and Philosophy

Explain which quality and resource baselines later policies must be compared against. Preserve a smaller feasible reference for correctness when a longer full-cache workload does not fit, without claiming measured parity at the unexecuted larger size.

19.39.3 Exercise 02

Exercise Title: Implement a Fixed Sliding-Window KV Cache That Evicts the Oldest Tokens Once a Maximum Token Budget Is Reached

Part 1 - Exercise Contract and Why It Matters

Implement a fixed-budget sliding cache that retains the newest processed positions and removes older entries. Preserve ordered token identities, correct per-layer K/V association, and the declared positional convention. Measure actual backing rather than assuming logical slicing releases memory.

Part 2 - System and Memory Mental Model

Cache slot indices and model positions are distinct. In the primary policy, retained keys preserve original absolute positions and query position advances with total processed tokens, not retained length. A ring buffer can bound capacity but needs logical ordering and masks. A slice view can retain the whole original storage. Evicting old KV does not recompute surviving values under a truncated text context and does not automatically match a model trained with native sliding-window attention.

Part 3 - Quantitative Prediction Before Execution

For token budget W, hand-simulate append and retention at lengths $W-1$, W, and $W+1$. Define whether the budget includes the current query's new K/V and reserve before append accordingly. Predict valid entries, backing capacity, compaction copies, and any provisional slot. List expected absolute key/query positions and visibility after the first wraparound.

Part 4 - Experimental Design and Instrumentation

Start with coordinate-coded KV and a CPU retained-position oracle. Implement a bounded ring or explicit compaction policy and document its temporary peak. Use one retention set across layers. Test zero/invalid budgets, multi-token appends larger than available capacity, ragged requests, and repeated wraparound. Then compare model outputs against the same explicitly pruned reference, not an assumed full-context equivalence. Keep positional limits valid and measure prefill pruning separately from decode admission.

Use a tiny retained-position oracle with absolute positions deliberately far from ring indices. Fill every layer's K and V with coordinate-coded values before wraparound tests. Compare current-token admission before and after the capacity boundary, including a multi-token suffix. If compaction is used, protect source values from overlapping writes and count its temporary destination. If a ring is used, validate consumer order independently from physical layout.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class SlidingKVState:
    total_processed_tokens: int
    retained_absolute_positions: object
    valid_slot_count: int
    ring_generation: int
```

```
def append_sliding_kv(state, layer_values, positions, budget):
    # Admit current values and evict oldest positions under the exact contract.
    ...

def ordered_sliding_view(state, consumer_contract):
    # Preserve key order and absolute positions without retaining hidden backing.
    ...

def E02(config):
    # Validate wraparound, masks, capacity, and the changed attention computation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact retained IDs and K/V values for synthetic cases, then report model-quality differences from full KV. Audit allocated slot capacity, metadata, compaction temporaries, and backend peaks. A view with fewer elements is not evidence of reclaimed backing. Changing only position metadata cannot correct already positionally transformed keys if another reindexing policy is attempted.

Test that a sparse retained set preserves correct causal visibility rather than letting every retained key participate in every query. An earlier query in a multi-query suffix must not see later keys. If experimenting with compact positions, treat it as a separate positional model and transform keys/queries correctly; changing integer labels on already rotated keys is insufficient. Measure backing capacity directly so a short slice of a large tensor cannot masquerade as bounded physical storage.

Part 7 - Engineering Interpretation and Philosophy

Explain the bounded-memory guarantee and the contextual information no longer directly available. State which positional model was actually implemented and avoid describing a generic newest-token policy as a reproduction of every streaming-attention method.

19.39.4 Exercise 03

Exercise Title: Compare Full Cache and Sliding-Window Cache on Local Continuation and Long-Range Retrieval Tasks

Part 1 - Exercise Contract and Why It Matters

Compare full and sliding KV on local continuation and long-range retrieval using matched inputs and evaluation rules. Identify quality effects by distance, retained evidence, and task type rather than expecting one global quality number to explain every retention trade-off.

Part 2 - System and Memory Mental Model

A recent window may preserve local transitions while removing the only explicit retrieval evidence. Remaining hidden states can still carry indirect information, so loss of direct KV does not guarantee failure. Full KV can also fail difficult tasks. Retention changes model state over time; feeding identical teacher-forced tokens controls input history but does not make the internal histories identical. Free generation introduces further divergence.

Part 3 - Quantitative Prediction Before Execution

Construct evidence positions inside and outside several tested windows. Predict which source positions survive at answer time and what each policy can directly attend to. Define local quality through token-weighted NLL and a separate generation rubric if used. Define retrieval success and stratify by distance, distractors, and context length. Estimate memory and latency without assuming fewer keys always yield faster complete decoding.

Part 4 - Experimental Design and Instrumentation

Fix model/tokenizer, prompts, target tokens, precision, positions, masks, and attention backend. Use held-out local text and controlled fact-retrieval cases with known answers. Compare teacher-forced losses at identical targets, then separately evaluate generated answers. Randomize irrelevant fact placement and wording with fixed seeds. Retain baseline-failure cases in the report and distinguish them from eviction damage. Keep compaction and gather costs inside complete performance regions while reporting diagnostic stages separately.

Construct matched prompt families with a fact just inside and just outside the tested recent windows. Vary distractors independently from answer distance. For local continuation, score identical targets instead of comparing different freely generated text as if it were the same workload. For generation, freeze sampling parameters and report the resulting history divergence. Define answer normalization before evaluation so a desired policy does not receive more lenient retrieval grading.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RetentionTaskCase:
    case_id: str
    task_kind: str
    evidence_positions: tuple
    answer_positions: tuple
    expected_answer: object

def compare_context_policies(model, cases, policies, evaluation_contract):
    # Match targets and report evidence retention with actual task outcomes.
    ...

def summarize_distance_effects(result_rows):
    # Preserve baseline failures, uncertainty, and task-specific denominators.
    ...

def E03(config):
    # Evaluate local and long-range behavior without conflating their metrics.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report retained evidence IDs, local NLL/PPL, retrieval accuracy, generated answer outcomes, bytes, and complete latency. Include uncertainty across the tested cases and seeds. A coherent-looking continuation is not a retrieval success, and one lost fact is not proof every long-range task fails. Preserve counterexamples to simple recency claims rather than selecting only expected wins or losses.

Report byte and timing observations for the same execution region and separate quality-only diagnostic overhead. A smaller attention set can still lose end-to-end because of score collection or compaction. Preserve full-cache failures, eviction failures, and occasional wins distinctly. Include an uncertainty estimate appropriate to the finite task set rather than treating one example as a corpus-wide conclusion. State which dependency distances the tested model actually handles without eviction.

Part 7 - Engineering Interpretation and Philosophy

Choose a window only in relation to a task's tested dependency pattern. Explain which quality loss the capacity saving purchases and where the evidence does not justify deployment to another corpus, model, or context distribution.

19.39.5 Exercise 04

Exercise Title: Implement FIFO Token Eviction and Measure How Aggressive Memory Reduction Changes Generation Quality

Part 1 - Exercise Contract and Why It Matters

Implement FIFO token eviction and compare its quality-capacity behavior with the fixed sliding reference. Define insertion order, admission quantum, and protected exceptions explicitly. Use this exercise to expose policy identity and implementation costs rather than manufacture a distinct algorithm where the semantics coincide.

Part 2 - System and Memory Mental Model

For one append-only request with no reinsertion or protected tokens, FIFO removing the oldest inserted token is equivalent to retaining the most recent fixed-size window. Differences can arise from batched admission, global versus per-request queues, or protection rules, all of which must be named. A global FIFO can sacrifice one request's history to another's arrivals. Neither policy is lossless active-context cache management.

Part 3 - Quantitative Prediction Before Execution

Hand-simulate a token trace under FIFO and sliding retention and identify conditions producing identical retained sets. Add a multi-request global FIFO case with different arrivals and predict which request loses evidence. Calculate budget usage before and after an eviction quantum and include queue metadata and physical compaction. Define quality thresholds before sweeping aggressive budgets.

Part 4 - Experimental Design and Instrumentation

Build a checked insertion queue using stable request and absolute token identities. Compare per-request FIFO with the existing sliding implementation through a retained-set oracle. Introduce global FIFO only as a separate fairness experiment. Use the same local and retrieval tasks, targets, model, precision, positional policy, and masks. Test stale entries after request

completion, duplicate notifications, large appends, and shared backing restrictions. Measure complete useful work and real reclaimed bytes.

Make the insertion clock independent of token numeric ID, since repeated token IDs at different positions are different cache entries. Test one-request FIFO equivalence first, then a global queue where arrivals interleave. Include stale entries from a completed request generation and require rejection before victim selection. Define batch-append eviction quantum explicitly; removing several entries at once can create different transient costs even when final retained sets coincide.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass(frozen=True)
class FIFOEntry:
    request_id: int
    request_generation: int
    absolute_position: int
    insertion_sequence: int

def choose_fifo_victims(queue, admission, protection, scope):
    # Preserve declared global/per-request semantics and hard eligibility.
    ...

def apply_fifo_eviction(cache, victims, completion_evidence):
    # Update logical visibility and safely reclaim only owned storage.
    ...

def E04(config):
    # Prove the simple equivalence and evaluate any explicit policy differences.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require identical retained sets for equivalent FIFO/sliding cases. Report any difference as an implementation error until a semantic distinction explains it. Keep per-request quality, starvation, bytes, and latency visible under global capacity. Do not report two versions of the same retention rule as independent evidence for algorithmic superiority.

Compare queue metadata and physical movement for implementations with equal retention semantics. An apparent quality difference between equivalent FIFO and sliding sets may indicate a position, validity, or masking bug. For global FIFO, report per-request retained evidence and completion metrics so one request's capacity gain cannot hide another's starvation. Keep protected-owner rules as hard constraints rather than permitting an old shared block to be freed solely because its insertion time is small.

Part 7 - Engineering Interpretation and Philosophy

Explain why precise policy definitions prevent misleading comparisons. Use FIFO as an auditable baseline and state exactly which extra constraint, protection, or scheduling rule changes the result.

19.39.6 Exercise 05

Exercise Title: Protect the Most Recent Tokens from Eviction and Determine the Minimum Recent Window Required to Preserve Local Coherence

Part 1 - Exercise Contract and Why It Matters

Protect a recent-token quota while allowing other eligible entries to be pruned. Determine the smallest tested recent window meeting a predefined local quality criterion within a named workload. Do not present this empirical result as a universal minimum context needed for coherence.

Part 2 - System and Memory Mental Model

Recency uses absolute processed positions within each request, not current physical slot order. The protected quota consumes the same total token budget as every other retained entry. Short histories can overlap other protection sets and must be counted once. Local coherence is not a single intrinsic cache property: token-weighted likelihood, grammatical continuity, and task consistency are different measurements. Long-range facts can fail even when local continuation remains fluent.

Part 3 - Quantitative Prediction Before Execution

For total budget B and protected recent quota R, derive remaining eligible capacity and reject $R > B$. Predict retained sets for short histories, window crossing, and multiple-token appends. Define a tested window grid and quality threshold before evaluation. Do not assume quality is monotonic in window size or use an unjustified binary search to claim the global minimum. Estimate both stable storage and boundary-copy peaks.

Part 4 - Experimental Design and Instrumentation

Use a fixed policy for the unprotected portion so only recent quota changes. Compare against pure recency and full KV on held-out local continuation and separate retrieval tasks. Record model/tokenizer, positions, masks, precision, seeds, and score protocol. If using human coherence ratings, define the rubric and blind policy labels; do not replace objective measurements with a few selected anecdotes. Measure all tested windows with repetitions and retain failures. Charge protection metadata and physical layout costs.

Specify the exact recent-position set from total processed length, including the current query's committed or prepared status. Validate empty histories, short histories, and protected-union overlap. Use a small explicit grid rather than assuming a monotone quality curve. If an initial quota is also protected, subtract only distinct positions from the total budget. Reject an infeasible protection contract before launching a model step or silently increasing physical capacity.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RecentProtectionPolicy:
    total_token_budget: int
    protected_recent_tokens: int
    remainder_policy: str
    quality_threshold_identity: str

def protected_recent_positions(processed_length, policy):
    # Define the absolute-position set and deduplicate overlapping protection.
    ...

def evaluate_recent_windows(cases, policies, quality_contract):
    # Report the smallest tested passing setting with its uncertainty.
    ...

def E05(config):
    # Sweep recent quotas without changing total capacity or task semantics.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report every tested quota, actual protected set, total retained tokens, quality metrics, byte peaks, and latency. Mark no passing configuration when appropriate. A passing mean can hide severe cases, so preserve distribution and retrieval outcomes. State calibration versus held-out use and avoid choosing thresholds after seeing the preferred policy's result.

Keep calibration and held-out window selection separate. Report the smallest tested setting that passes, its neighboring failures, and whether the metric is mean, worst-case, or percentile quality. Subjective coherence ratings need a stated rubric and sample set; they cannot establish retained factual accuracy. Track boundary-copy or ring-update costs and protection metadata. A tested window suitable for local continuation may still fail an older explicit fact, which must remain visible in the recommendation.

Part 7 - Engineering Interpretation and Philosophy

Recommend a recent quota conditional on model, corpus, task, and total budget. Explain the uncertainty in the smallest tested passing value and the dependency types that remain unsupported despite acceptable local continuation.

19.39.7 Exercise 06

Exercise Title: Protect Initial Attention-Sink Tokens While Evicting Middle-Context KV Entries and Measure the Effect on Long-Sequence Stability

Part 1 - Exercise Contract and Why It Matters

Protect a bounded set of initial attention-sink candidates alongside recent positions while pruning middle KV. Measure stability, quality, and storage under the same total budget. Treat the sink mechanism as an empirical hypothesis, not proof that initial tokens preserve all removed information.

Part 2 - System and Memory Mental Model

Some models assign substantial attention mass to initial positions even when those tokens carry little task content. Retaining such entries can alter normalization and stability, but does not restore middle-context facts. Initial tokens may also contain meaningful instructions or data. Keep semantic content and structural behavior separate. The primary implementation retains original absolute positions; a compact or shifted positional scheme is a separate model-specific experiment requiring correctly transformed keys and queries.

Part 3 - Quantitative Prediction Before Execution

For initial quota S, recent quota R, and total budget B, calculate their union and remaining capacity without double-counting short histories. Predict source positions surviving a middle deletion. Construct a retrieval fact in the discarded middle and a local continuation case. Estimate protected block rounding if token-level choices are later mapped to physical pages. State stability metrics and expected failure evidence before execution.

Part 4 - Experimental Design and Instrumentation

Compare full KV, recent-only, initial-plus-recent, and a matched-size control protecting different positions. Keep total budget, precision, model, masks, positions, and task traces fixed. Measure selected attention distributions, losses, retrieval, and generation under a declared rubric. Stay within supported positional limits. If exploring a published streaming position scheme, implement and validate its model-specific transformation separately; do not relabel this simple ablation as a complete reproduction. Count diagnostic attention workspace outside the primary throughput path or explicitly within its budget.

Create an initial-protection control with the same number of noninitial positions so capacity alone cannot explain a benefit. Record whether initial tokens contain model delimiters, meaningful task content, or ordinary filler. Count overlap with recent protection once. Use finite streams inside the primary model's positional support, and keep any long-stream positional extension separately identified. Sink-related literature motivates the test, not a borrowed result for the chosen model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class SinkRetentionPolicy:
    initial_tokens: int
    recent_tokens: int
    total_tokens: int
    positional_convention: str
```

```
def select_sink_recent_union(history, policy):
    # Preserve absolute IDs and resolve overlap within the fixed quota.
    ...

def evaluate_sink_ablation(model, cases, policies):
    # Separate normalization/stability evidence from retained factual content.
    ...

def E06(config):
    # Test initial protection and middle-loss counterexamples honestly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report protected identities, union size, quality, retrieval, stability, attention diagnostics, and complete cost. Include a case where the proposed sink benefit is not observed or record that no such counterexample appeared in the tested range. Do not equate stable fluent generation with successful retention of distant facts. A position-label change alone cannot rephase already encoded rotary keys.

Measure local loss and retrieval separately from apparent generation stability. A stable attention denominator or fluent output does not restore a removed middle fact. When comparing alternate positional conventions, account for any key transformation, extra storage, and recomputation. Do not call the simple initial-plus-recent reference an exact implementation of a published streaming system. Preserve negative controls where initial protection provides no benefit or displaces genuinely useful evidence under the fixed total budget.

Part 7 - Engineering Interpretation and Philosophy

Explain which evidence supports a sink-related effect and which uncertainty remains. Choose initial protection only when its measured benefit justifies capacity displaced from other context under the tested model and task.

19.39.8 Exercise 07

Exercise Title: Record Token-Level Attention Scores Across Decode Steps and Rank Cached Tokens by Accumulated Attention Importance

Part 1 - Exercise Contract and Why It Matters

Record bounded token-level attention evidence and rank retained positions by accumulated attention mass. Define score units, scope, aggregation, and update timing before using them for decisions. Measure instrumentation cost and preserve the distinction between an observed attention weight and causal task importance.

Part 2 - System and Memory Mental Model

Post-softmax attention weights describe one query over the currently visible keys. Raw logits have different scale and cannot be substituted silently. Aggregate across layers and query heads under a declared rule, including GQA head mapping. Eviction changes the denominator and future attention distribution. Older tokens may accumulate more observations simply because

they existed longer. An optimized attention API may not expose weights, so a transparent diagnostic consumer or separate measured instrumentation is required.

Part 3 - Quantitative Prediction Before Execution

Derive score shape for the retained absolute-position set and predict its metadata bytes. Compare cumulative sum, age-normalized average, and bounded history windows on a short synthetic attention trace. Specify newborn-token initialization, tie handling, and removal of retired score entries. Estimate diagnostic attention-matrix memory and show why retaining all steps' matrices can exceed the cache savings being studied.

Part 4 - Experimental Design and Instrumentation

Validate score arithmetic on hand-defined weights before model execution. Use zero dropout and explicit valid-key masks. Map every score back to request, absolute token, layer/head scope, and observation count. Compare instrumented attention outputs with the ordinary reference and report backend differences. Keep only bounded online aggregates in production measurements. A full-history oracle can diagnose missed evidence offline, but cannot supply scores for already removed tokens to an online policy without disclosing extra storage and computation.

Write the aggregation rule in explicit layer/head/query terms. Use query-head weights consistently under GQA and do not accidentally count duplicated storage as extra semantic evidence. State how invalid padding and fully masked queries are handled or excluded. Maintain observation counts separately from accumulated mass. A newborn-token rule and a bounded-history rule need independent tests because they change ranking even with identical raw attention weights.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TokenAttentionEvidence:
    request_generation: int
    absolute_position: int
    accumulated_mass: float
    observation_count: int
    aggregation_identity: str

def update_attention_evidence(state, weights, token_ids, scope):
    # Validate normalization, head mapping, age handling, and bounded storage.
    ...

def rank_attention_tokens(evidence, ranking_contract):
    # Preserve stable identities, ties, and explicit unsupported observations.
    ...
```

```
def E07(config):
    # Validate scores independently from eviction and quantify monitoring cost.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report score definitions, counts, ranks, missing observations, temporary matrix peaks, and instrumentation overhead. A large accumulated weight does not prove semantic relevance or future use. Include an old low-use token and a newborn important token to expose age bias. Reject score updates attached to stale request generations or physical slot indices instead of token identity.

Compare an ordinary consumer with the diagnostic weight-producing reference for numerical parity and backend cost. Keep only bounded score vectors for currently tracked identities rather than every attention matrix from every step. Full-history offline scores may explain a lost fact, but supplying them to the online selector would add inaccessible information or uncounted work. Report unavailable weights explicitly. Attention evidence should remain associated with absolute token and request generation through every physical relocation.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest auditable attention signal suitable for later experiments. Explain its observational limitations and why a policy using it needs direct quality tests rather than an assumption that high mass always means valuable context.

19.39.9 Exercise 08

Exercise Title: Implement Heavy-Hitter KV Eviction That Retains High-Attention Tokens While Removing Low-Importance Cache Entries

Part 1 - Exercise Contract and Why It Matters

Retain high-ranked attention tokens and remove lower-ranked eligible entries under a fixed budget. Build an attention-based baseline inspired by heavy-hitter methods, with exact selection and update rules. Measure quality and real storage reclamation without claiming a reproduction of a published algorithm unless its complete protocol is implemented.

Part 2 - System and Memory Mental Model

Selection can use only evidence available before the decision. If new attention weights are needed to choose victims, the current step must already have admissible storage; it cannot exceed a strict budget invisibly. Retained positions can be sparse while preserving absolute model positions and causal visibility. Stable sorting, score initialization, protection, and prefill pruning affect behavior. Surviving KV still reflects its original computation history, not recomputation on the selected text.

Part 3 - Quantitative Prediction Before Execution

Hand-simulate a fixed budget with previous-step scores, a new token, ties, and a late important token. Predict victims and attention visibility before and after pruning. Count selection metadata and gather/compaction temporaries. Specify prefill treatment separately:

full-prompt prefill followed by pruning has a different peak from budget-aware incremental ingestion. Define quality metrics against full KV and simple recency before running the model.

Part 4 - Experimental Design and Instrumentation

Validate selector output using a CPU oracle and coordinate-coded KV. Use one retained-position set across layers initially. Reserve append capacity before dispatch, update online scores only at declared observation points, and publish coherent mapping changes. Compare on local and retrieval tasks with fixed weights, precision, positions, masks, and targets. Measure scoring, selection, relocation, attention, and complete decode. Test stale scores, unknown observations, repeated token IDs at different positions, and no eligible victim under protection.

Specify decision order for append, attention, score update, victim selection, and publication. A strict budget may require selecting from prior observations before a new token enters; a post-attention selector needs an explicitly reserved temporary slot. Prefill followed by pruning must report its larger initial peak. Use deterministic tie handling and newborn initialization so replays can identify whether a quality change comes from selection or incidental implementation order.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class HeavyHitterPolicy:
    token_budget: int
    score_contract: str
    append_admission_policy: str
    tie_policy: str
    prefill_policy: str

def choose_heavy_hitter_victims(history, evidence, policy):
    # Use available observations and preserve hard ownership/protection rules.
    ...

def apply_token_retention(cache, keep_positions, readiness):
    # Preserve K/V identity, positions, and all required lifetime boundaries.
    ...

def E08(config):
    # Validate selection then compare complete quality-capacity behavior.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report retained IDs, score ages, actual bytes, scoring overhead, full peaks, quality, and failures. Use a distractor case to test attention importance rather than assume it. Logical selection that only masks entries in a fully retained allocation must not be presented as reclaimed VRAM. Keep simulated selector success separate from actual model and CUDA validation.

Test a case with high-scoring distractors and a late low-observation fact. Preserve all candidate scores available at decision time, then compare actual retention with the CPU oracle. If physical compaction is absent, label a mask-only result as logical sparsity rather than reclaimed storage. Include selection and weight-observation cost in complete performance. A sound imitation of the broad heavy-hitter idea is not automatically a reproduction of every published method's per-head budgets and update schedule.

Part 7 - Engineering Interpretation and Philosophy

Explain where the measured attention signal helps and where recency or simple protection performs as well. State the exact policy scope and avoid transferring published quality or speedups to this transparent reference.

19.39.10 Exercise 09

Exercise Title: Combine Heavy-Hitter Retention with a Protected Recent Window and Compare It Against Pure Recency and Pure Attention Policies

Part 1 - Exercise Contract and Why It Matters

Combine a protected recent quota with attention-based retention under one fixed token budget. Compare pure recency, pure attention, and the hybrid with matched scoring and measurement rules. Test whether the hybrid addresses real failure modes rather than receiving extra hidden capacity.

Part 2 - System and Memory Mental Model

Recent protection and heavy-hitter sets can overlap. Count their union once, fill remaining capacity deterministically, and specify what happens when the history is shorter than the budget. The current token's admission belongs to the same capacity contract. Adding an initial sink quota is a separately labeled extension whose slots must come from the existing budget. No quota guarantees recovery of already deleted history.

Part 3 - Quantitative Prediction Before Execution

For budget B and recent quota R, predict the eligible historical quota and select from synthetic scores with overlaps and ties. Calculate actual union size, metadata, and append peak. Construct a local-dependency case, a long-range fact case, and an abrupt topic change. Predict how pure attention's age bias and pure recency's missing distant evidence could produce different outcomes, then leave model results to measurement.

Part 4 - Experimental Design and Instrumentation

Use identical prompts, targets, token budget, positions, precision, model, and attention consumer. Fix score aggregation and update timing. Sweep a small set of quota splits on calibration traces and validate held-out cases. Include no-protection and all-recent endpoints. Report monitoring overhead fairly; if pure recency does not require weights, its production path should not be charged unnecessary attention instrumentation except in a separately labeled matched-observation diagnostic. Test growth, short histories, and infeasible protected sets.

Use synthetic histories where every recent token is also a heavy hitter, where the two sets are disjoint, and where history is shorter than the quota. Define deterministic fill order so the retained set reaches capacity only when enough candidates exist. Keep any sink quota as an explicit ablation. The same bytes and semantic support must be available to every comparator; additional protected entries cannot be hidden outside the reported total.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class HybridRetentionPolicy:
    total_tokens: int
    recent_tokens: int
    attention_ranking: str
    overlap_fill_policy: str

def select_hybrid_positions(history, evidence, policy):
    # Form a deduplicated protected union and fill only remaining capacity.
    ...

def compare_retention_quotas(cases, policies, evaluation_contract):
    # Preserve equal budget and separate required instrumentation costs.
    ...

def E09(config):
    # Validate quota arithmetic and held-out hybrid quality trade-offs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual quota use, retained positions, quality distributions, storage, selection cost, and complete latency. A hybrid that wins only by retaining more entries has not met the comparison contract. Preserve cases where the hybrid loses or the ranking is uncertain. A passing calibration result is not evidence that the chosen split is universally robust.

Compare both fixed equal-token budgets and actual block-rounded capacity when the implementation becomes paged. A recent quota can protect an entire partial physical block, changing usable remaining bytes. Report required instrumentation separately for policies that do not need attention weights. Use held-out abrupt topic changes to expose stale accumulation. Preserve per-request quality distributions and rejected protected-set configurations rather than presenting a favorable average as universal robustness.

Part 7 - Engineering Interpretation and Philosophy

Choose a quota split conditional on tested tasks and available signals. Explain which failure it mitigates and which context dependencies remain vulnerable under a finite approximation budget.

19.39.11 Exercise 10

Exercise Title: Build a Block-Level Eviction Policy for Paged KV Cache and Evict Physical Blocks Instead of Individual Token Entries

Part 1 - Exercise Contract and Why It Matters

Implement eviction at the physical KV block level and compare it with logical token pruning. Measure real reclaimable capacity, retained token overshoot, and quality under an equal byte budget. Keep block ownership and pending device readers as hard reclamation constraints.

Part 2 - System and Memory Mental Model

Selecting fewer tokens does not free a block that still contains live selected entries. Masking positions in a retained slab can save no backing. Block eviction removes every active mapping in its logical scope only under a declared approximation policy; otherwise it can reclaim only unused payload. Aggregate token scores to blocks using a named rule. Block size, partial tails, shared owners, and protected sink/recent entries change eligibility and reclaimed bytes.

Part 3 - Quantitative Prediction Before Execution

Construct a four-block example where one retained token remains in every block. Predict token sparsity and zero whole-block reclamation without compaction. Compare sum, mean, and maximum token-score aggregation on unequal valid lengths. Calculate block-rounded protected capacity and temporary copies for optional compaction. Predict which block can actually return to a reusable pool after mapping removal and reader completion.

Part 4 - Experimental Design and Instrumentation

Use checked block tables with request, layer, token-position, and generation identity. Start with one owner and synchronous retirement, then add controlled pending leases. Compare equal-budget token selection, whole-block selection, and a separately charged compaction variant. Preserve positions and causal masks after sparse retention. Evaluate quality on matched tasks and report score/selection/gather overhead. Recompute actual unique backing from the pool rather than inferring VRAM relief from a count of deleted table entries.

Give each physical block at least one selected token in a diagnostic trace and verify that whole-block reclamation remains zero without relocation. Then run a separately charged compaction control that preserves every selected ID and position. Protect retained source values from overlapping movement. Report score aggregation over valid tokens only; padding must not lower a block's average importance or create an apparently empty victim while valid entries remain.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
```

```
class KVEvictionBlock:
    handle: object
    absolute_positions: tuple
    valid_tokens: int
    capacity_bytes: int
    protected_positions: tuple
    ownership_state: object

def aggregate_block_scores(blocks, token_evidence, rule):
    # Define valid-length handling and keep hard eligibility separate.
    ...

def evict_physical_blocks(engine, victims, completion_evidence):
    # Apply supported logical changes and reclaim only safe whole backing.
    ...

def E10(config):
    # Audit the gap between sparse token retention and physical memory relief.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report selected tokens, retained blocks, protected overshoot, reclaimed capacity, free retained pool slots, compaction copies, quality, and latency. A reusable free slot still occupies backed pool capacity until destroyed or reused. Distinguish application admission relief from backend memory release. Do not claim successful block eviction when a shared owner or pending kernel still requires the payload.

Audit unique backing, mapped capacity, pending readers, and reusable slots after every deletion and completion. A returned free-list slot may improve application admission while keeping backend allocated memory constant. A slab cannot release an individual slot's backing independently. Compare quality at actual physical-byte budgets as well as logical token budgets. Include whole-block collateral loss when only one low-ranked token motivated a victim, so reclaimed bytes are assessed alongside the information removed.

Part 7 - Engineering Interpretation and Philosophy

Explain the quality and placement granularity purchased by whole-block policy. Choose a block strategy only after accounting for protection rounding, reclamation feasibility, and the consumer's actual working set.

19.39.12 Exercise 11

Exercise Title: Use KV Block Reference Counts to Prevent Eviction of Prefix Blocks Still Shared by Active Sequences

Part 1 - Exercise Contract and Why It Matters

Use checked reference ownership to prevent global reclamation of prefix blocks still needed by active requests. Separate one request detaching its logical mapping from deleting shared backing. Validate prefix lifetime under completion, cancellation, pruning, and delayed attention reads.

Part 2 - System and Memory Mental Model

Count active mapping entries, retained reusable-prefix ownership, and in-flight leases separately. A request may prune its own mapping under its approximation contract while another request keeps the shared prefix intact. That detach does not free physical storage. A zero active-request count may still leave a reusable cached prefix, and zero logical ownership may still leave pending readers. Protection by ownership is a hard gate, not a score that an aggressive policy can override.

Part 3 - Quantitative Prediction Before Execution

For three requests sharing two prefix blocks and owning private tails, predict counts and reusable capacity through multiple completion orders. Add one logical prune and one delayed read lease. Calculate unique backing versus total mapped capacity. Predict an attempted global eviction while one active owner remains and the correct rejection. Define whether duplicate mappings within one request are supported and how they contribute.

Part 4 - Experimental Design and Instrumentation

Route all attach/detach operations through one authority and independently recompute counts from live tables and cache records. Test duplicate detach, stale block generation, request-ID reuse, cancellation, and old completion after retirement. Validate each surviving request's KV and outputs against its declared retention reference. Keep host updates serialized initially. If mutating a shared tail, require copy-on-write before publication rather than assuming reference counts alone make writes safe.

Create three active mappings to one prefix block and detach them in different orders. Track inactive cache-retention ownership separately from request ownership, and retain one delayed attention lease after all mappings disappear. The block becomes globally reclaimable only when the supported cache owner is removed and all device obligations end. A request-local prune can be legal without producing any physical relief while another request still maps the same backing.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVBlockOwners:
    active_mappings: int
    reusable_prefix_owners: int
    inflight_leases: int
    block_generation: int

def can_reclaim_prefix(handle, owners, completion_evidence):
```

```
    # Enforce hard lifetime gates independently of any eviction score.
    ...

def detach_request_prefix(request, mapping, ownership_authority):
    # Remove only that request's ownership without invalidating other readers.
    ...

def E11(config):
    # Validate shared lifetime and delayed-reader reclamation cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative independently audited counts and no reusable block reachable by an authorized mapping or lease. Report logical removals separately from physical relief. A prevented eviction is a correct outcome under active sharing. Verify that a delayed event references the exact generation it protected and cannot free newly assigned storage with the same numeric slot.

Recompute ownership from a mapping multiset rather than trusting the counters under test. Reject duplicate detach and stale generations before decrementing. A delayed callback for retired storage must not act on a new generation with the same slot ID. Test that pruning one owner never changes another's retained values or positions. Prefix mutation requires a separate copy-on-write protocol; reference counts alone authorize neither writes nor unsafe global eviction.

Part 7 - Engineering Interpretation and Philosophy

Explain why sharing changes which memory can be reclaimed without changing another request's computation. Preserve the distinction between a quality choice for one logical context and a global ownership obligation for backing used by several contexts.

19.39.13 Exercise 12

Exercise Title: Implement LRU Eviction for Unreferenced Prefix KV Blocks and Compare Cache Hit Rate Against FIFO Block Eviction

Part 1 - Exercise Contract and Why It Matters

Implement LRU and FIFO replacement for inactive reusable prefix blocks. Compare verified hit rate, avoided prefill work, time-to-first-token, and capacity under equal ownership constraints. This exercise evicts reusable cached results, not required active history.

Part 2 - System and Memory Mental Model

Eligible blocks have no active mapping or unfinished reader and can release their cache-retention ownership safely. LRU needs a declared last-use event; FIFO needs insertion order. Reusing a cached prefix must verify complete causal prefix identity, model context, format, positions, and generations. A miss recomputes from original input under the reference protocol, so correct replacement affects cost rather than authorizing context omission. Cache retention itself consumes host metadata and backed GPU capacity.

Part 3 - Quantitative Prediction Before Execution

Hand-simulate a finite prompt-arrival trace under equal byte or block capacity. Predict eligible victims, verified prefix hits, and skipped prefill positions. Include a scan pattern and a repeated-prefix pattern where policy rankings can differ. Distinguish block hit rate, token-weighted hit rate, and useful compute avoided. A full-prompt KV hit still requires a defined boundary-output policy for next-token logits.

Part 4 - Experimental Design and Instrumentation

Use canonical token prefixes and fixed model/format context. Record active reference transitions independently from replacement metadata. Test duplicate insertion, hit/touch updates, stale lookup after recycling, missing ancestor blocks, and forced identity mismatch. Compare LRU/FIFO on a fixed calibration trace and held-out arrivals. Preserve identical full inference outputs by recomputing misses. Measure index lookup, recomputation, retained capacity, and complete request latency. Invalidate lookup reachability before freeing backing.

Define LRU touch as a verified supported reuse event, not an unsuccessful lookup or a speculative probe, unless the policy explicitly chooses otherwise. FIFO insertion order needs a rule for duplicate content and reinsertion. Keep the same active-reference gates and byte capacity for both policies. A parent-prefix miss may prevent using a later cached block even when that block's token IDs match, so count verified usable prefixes rather than raw dictionary hits.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class InactivePrefixRecord:
    verified_identity: tuple
    handle: object
    insertion_order: int
    last_verified_use: int
    eligible: bool

def choose_prefix_replacement(records, required_capacity, policy):
    # Select only inactive safe candidates under the same byte budget.
    ...

def reuse_or_recompute_prefix(request, index, decoder_contract):
    # Verify hits and preserve complete inference semantics on misses.
    ...

def E12(config):
    # Compare cache replacement without conflating it with active pruning.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report eligible capacity, hit definitions, reused tokens, computed prefill, latency, metadata, and output parity. A higher block hit rate can save less work if hits cover smaller or cheap prefixes. No policy may reclaim an active block to improve its score. Retain miss costs and failed admissions in the result table rather than reporting only successful hits.

Verify complete outputs on misses by recomputing required history, including the final prompt boundary needed for logits. KV alone is not necessarily ready next-token output state. Report lookup, prefill skipped, prefill recomputed, retained capacity, and end-to-end request latency. Include a streaming scan that defeats recency and a reuse pattern favorable to it. Replacement quality here concerns saved work and latency, not permission to omit active semantic context.

Part 7 - Engineering Interpretation and Philosophy

Recommend replacement from observed request reuse and complete cost. Explain why this lossless reuse-cache experiment has a different correctness contract from approximate attention-history pruning, even though both use the word eviction.

19.39.14 Exercise 13

Exercise Title: Build a Composite Eviction Score from Recency, Attention Mass, Block Size, Prefix Sharing, and Estimated Future Reuse

Part 1 - Exercise Contract and Why It Matters

Build a composite candidate score using recency, attention evidence, size, sharing, and predicted reuse. Keep incompatible semantics in separate candidate classes and enforce ownership/resource feasibility before ranking. Compare against simple baselines with held-out quality and complete cost.

Part 2 - System and Memory Mental Model

Active-context pruning trades quality for capacity; inactive-prefix eviction trades possible future recomputation for capacity. Their raw scores are not interchangeable. Normalize feature units and state the objective within each class. Active owners and pending readers are hard eligibility gates, not soft penalties. A shared block's physical relief can be zero when only one mapping is detached. Future-reuse estimates cannot use unseen answers or future traces in an online policy.

Part 3 - Quantitative Prediction Before Execution

Construct candidates with equal attention mass but different byte sizes, and candidates with equal recency but different sharing. Predict actual reclaimable bytes and compare a weighted score with a cost-per-byte formulation. Include uncertainty in estimated reuse and quality damage. Calculate metadata and selection overhead. Define what the controller does when every high-scoring candidate is ineligible or no action meets quality/resource gates.

Part 4 - Experimental Design and Instrumentation

Start with a small feature set and documented normalization. Calibrate weights on separate traces, then freeze them for evaluation. Compare recency, attention-only, activity-aware, and composite policies using matched budgets and tasks. Add feature ablations to identify mechanisms. Preserve per-request quality and fairness, not only aggregate token throughput. Record

every candidate's semantic class, evidence age, eligibility reason, predicted relief, chosen action, and later outcome in bounded scalar logs.

Attach units and support status to every feature. Recency in steps, bytes, attention mass, owner count, and expected reload time cannot be summed as uninterpreted raw numbers. Enforce zero-ownership and completion rules before ranking candidates. A large sharing feature must never make active backing eligible. Use actual reclaimable bytes as the resource effect, not the size of a tensor whose storage another mapping continues to retain.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVEvictionCandidate:
    action_semantics: str
    reclaimable_bytes: int
    recency_feature: object
    attention_feature: object
    sharing_state: object
    predicted_reuse: object
    eligible: bool
    uncertainty: object

def score_eviction_candidates(candidates, objective_contract):
    # Normalize valid features after hard lifetime and semantic gates.
    ...

def evaluate_composite_policy(cases, baselines, held_out_contract):
    # Separate prediction quality from actual quality/capacity/latency outcomes.
    ...

def E13(config):
    # Validate scoring with counterexamples and complete held-out comparisons.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw features, normalization, selected actions, real reclaimed bytes, quality, hit/recompute cost, monitoring overhead, and failures. Preserve unknown features as unknown instead of substituting zeros. A fitted score is not a proof of causal importance. Include a case where the composite loses to a simple baseline and state whether that outcome changes the recommendation.

Keep separate objective and outcome tables for approximate active pruning and inactive-prefix replacement. A coefficient fitted to retrieval quality cannot be assumed meaningful

for future prefill reuse. Evaluate feature ablations and uncertainty on held-out traces. If all features are stale or unsupported, use a declared simple fallback or reject the action. A score that predicts its own labels well may still fail to improve complete quality, capacity, or latency.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest policy supported by measured benefit and uncertainty. Explain which features predict a useful decision in the tested semantic class and which add complexity without improving complete work.

19.39.15 Exercise 14

Exercise Title: Construct an Adversarial Structured Prompt Where Attention-Based Eviction Retains Irrelevant Structural Tokens and Diagnose the Failure

Part 1 - Exercise Contract and Why It Matters

Construct a controlled structured-prompt test for the hypothesis that attention-based retention can overprotect structural tokens while losing answer-bearing evidence. Diagnose an observed failure or report that the hypothesis was not reproduced. Do not invent a model outcome to satisfy the exercise title.

Part 2 - System and Memory Mental Model

Delimiter, role, punctuation, and repeated-template tokens can affect attention and may also carry genuine task structure. High attention mass is not sufficient evidence that they are irrelevant, nor is a human structural label sufficient evidence that they are safe to remove. The experiment must link retained identities, lost evidence, and an actual task outcome. Sink behavior and semantic content are competing explanations to test.

Part 3 - Quantitative Prediction Before Execution

Design prompts containing a known answer-bearing fact, repeated structural scaffolding, distractors, and a controlled query. Predict which positions are likely candidates under the declared score, but leave observed ranks unknown. Specify equal-budget controls with structure reduced, evidence relocated, and a retention oracle used only offline. Define retrieval scoring and model baseline competence before inspecting eviction results.

Part 4 - Experimental Design and Instrumentation

Use fixed model/tokenizer and seeded variations of layout, delimiter frequency, fact distance, wording, and query location. Compare full KV, pure attention, recency, and the hybrid. Record token-level labels, attention ranks, retained positions, and generated/teacher-forced outcomes. Hold task content constant where a control changes only formatting and record token-count differences. Reduce any failure to a smaller prompt preserving the mechanism. Report instrumentation workspace and selection overhead separately from production performance.

Use multiple structured templates with the same answer-bearing content, and controls where delimiters or role labels actually carry the answer. Preserve tokenizer revision and annotate exact token positions rather than human-visible character spans alone. Record baseline model competence, evidence distance, structural token count, and retained ranks. If formatting changes token count, match or report that difference instead of assuming only one variable changed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class StructuredRetentionCase:
    case_id: str
    token_ids: tuple
    structural_positions: tuple
    evidence_positions: tuple
    expected_answer: str
    control_family: str

def build_structured_cases(spec, tokenizer, seed):
    # Create matched, auditable cases without assuming the hypothesized failure.
    ...

def diagnose_structural_bias(result_rows, retained_position_logs):
    # Test rank, evidence loss, and outcome links with controlled alternatives.
    ...

def E14(config):
    # Reproduce and minimize a failure, or explicitly record no reproduction.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report full-cache competence, ranks, structural/evidence retention, quality, bytes, and every tested control. A correlation between structural mass and failure is not enough to establish the mechanism; controlled replays should change the suspected choice while preserving other conditions. Do not discard unfavorable or non-reproducing cases. Human labels are diagnostic annotations, not ground-truth attention importance.

Require the diagnosis to connect a specific victim choice with lost evidence and a changed outcome through controlled replay. An offline oracle can force retention to test the mechanism, but must not be presented as an online policy. Reduce an observed failure without removing the critical structure or fact. If the trained model, attention signal, or hardware is unavailable, provide only the designed protocol and mark results unmeasured. No hypothesized failure may become a fabricated observation.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest supported failure mechanism and its limits. Use the counterexample to motivate a testable filter, while preserving the possibility that structural tokens are useful and aggressive removal can worsen quality.

19.39.16 Exercise 15

Exercise Title: Build a Role-Aware or Content-Aware Eviction Filter That Reduces Structural-Token Bias Without Increasing the KV Memory Budget

Part 1 - Exercise Contract and Why It Matters

Add a role- or content-aware retention filter to test the diagnosed structural bias without increasing the KV budget. Preserve protected lifetime rules and compare against an unchanged attention selector. Treat labels as imperfect features whose usefulness must be measured on held-out prompts.

Part 2 - System and Memory Mental Model

Role boundaries, delimiters, punctuation, and template tokens may carry important instructions, syntax, or evidence. A blanket structural-token ban can damage the task. Labels must map tokenizer spans to exact absolute token positions and model/chat-template revision. The filter changes ranking or eligibility under a declared approximation contract, not the text presented to the original model. Sink protection and semantic role rules can overlap and must share the same total capacity.

Part 3 - Quantitative Prediction Before Execution

Define a small label schema and a deterministic filter or score adjustment. Predict retained sets on the minimized failure and controls where structure is answer-bearing. Calculate quota overlap, byte rounding, label metadata, and selection cost. Compare equal token and equal physical-byte budgets explicitly. State what happens when protected labels exceed capacity rather than silently expanding the cache.

Part 4 - Experimental Design and Instrumentation

Calibrate on separate structured cases and freeze labels/weights before held-out evaluation. Use exact tokenizer offsets or a validated alignment protocol. Compare no filter, role-only, content-only, and a minimal combined variant. Include nested structure, code, repeated delimiters, meaningful role headers, and facts split across subword tokens. Preserve model, positions, masks, precision, target protocol, and total budget. Test ordinary text and retrieval to detect regressions beyond the motivating failure.

Validate alignment from role/content spans to subword token IDs, including facts split across multiple tokens and nested structured fields. Record labels as features with uncertainty rather than immutable truth. Keep a control where punctuation, code syntax, or a role boundary is necessary. If sink/recent protection overlaps a content label, deduplicate it. All additional labels and scores consume metadata capacity even when the number of retained KV entries stays fixed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class TokenRetentionLabel:
    absolute_position: int
```

```
    role: str
    content_class: str
    alignment_identity: str
    uncertainty: object

def label_retention_tokens(prompt, tokenizer, template_contract):
    # Align imperfect labels to exact model token positions.
    ...

def filter_eviction_candidates(candidates, labels, policy, budget):
    # Adjust only supported choices without adding hidden capacity.
    ...

def E15(config):
    # Test the targeted fix and held-out structural/content counterexamples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report alignment errors, label uncertainty, retained evidence, quality, physical capacity, metadata, overhead, and regressions. A fix that wins only on the constructed prompt is not general validation. Include a case where structural tokens are necessary and the filter should retain them or fail honestly. If no robust gain appears, recommend the simpler baseline.

Test whether the filter fixes the minimized failure while preserving ordinary retrieval and local-continuation quality. Compare the same byte budget after block rounding; token counts alone can hide extra backing. Use held-out templates and task domains to reveal overfitting. Report no improvement when warranted. A role-aware filter is a heuristic retention rule, not a general proof that one category of prompt tokens is dispensable or that attention magnitude has been causally corrected.

Part 7 - Engineering Interpretation and Philosophy

Explain what the filter actually learned from available annotations and where those annotations are unreliable. Prefer a small tested correction to a universal claim that attention or a structural label reveals semantic value.

19.39.17 Exercise 16

Exercise Title: Dynamically Increase the KV Budget When Model Confidence Falls and Prune More Aggressively When Next-Token Confidence Is High

Part 1 - Exercise Contract and Why It Matters

Adapt the retained-token budget using an explicit next-token confidence signal, bounded capacity, and calibrated uncertainty. Increase available retention when the signal warrants it and prune more only under the tested policy. Evaluate high-confidence errors and the irreversibility of previous context deletion.

Part 2 - System and Memory Mental Model

Maximum next-token probability, entropy, and logit margin are different signals and depend on temperature and evaluation conventions. None is a direct proof that older context is unnecessary. A confident wrong answer can follow missing evidence. Increasing the budget prevents some future deletions but does not restore already discarded KV. Restoration requires explicit CPU backing or recomputation from retained input under a supported protocol, including its capacity, time, and state-transition cost.

Part 3 - Quantitative Prediction Before Execution

Define one confidence statistic from unsampled logits under a fixed convention. Hand-simulate low/high thresholds, hysteresis, minimum and maximum budgets, and shared global headroom. Include confident-wrong and uncertain-correct controls. Predict what a budget increase can recover with backing, without backing, and with a charged recomputation path. Estimate transition demand rather than treating a larger integer limit as available memory.

Part 4 - Experimental Design and Instrumentation

Calibrate confidence against task outcomes on separate traces, then freeze the policy for held-out tests. Keep full-reference outputs unavailable to the online decision unless their cost is explicitly included. Bound budget changes and preserve request fairness. Test topic changes, delayed evidence needs, and exhausted physical headroom. Compare fixed-budget, recency-adaptive, and confidence-adaptive controls under matching resource envelopes. Record the action, available evidence, recovery support, and later quality without claiming a universal online accuracy guarantee.

Choose one statistic and freeze its temperature, vocabulary, masking, and sampling convention. Compute confidence from the appropriate current logits, not from future reference answers. Entropy and maximum probability may rank cases differently, so evaluate them separately before selecting one. Include high-confidence wrong retrieval and low-confidence correct continuation cases. Budget adaptation must respect per-request minima, a global maximum, and fairness for other active requests.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ConfidenceRetentionEvidence:
    statistic_name: str
    value: float
    temperature_convention: str
    calibrated_domain: str
    current_budget: int
    recoverable_history: bool
    available_capacity_bytes: int

def choose_confidence_budget(evidence, policy, ownership_state):
```

```
    # Respect hard headroom, calibration limits, and restoration availability.
    ...

def apply_budget_change(plan, engine):
    # Distinguish future protection from explicit history reconstruction.
    ...

def E16(config):
    # Evaluate confidence failures and bounded adaptive retention honestly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report confidence/quality calibration, chosen budgets, actual bytes, reconstruction work, latency, and rejected actions. A high confidence score must not override ownership or capacity limits. Do not label a larger budget as restored context when missing entries remain absent. Preserve cases where the adaptive policy loses despite a plausible confidence signal.

Test a budget increase after irreversible deletion and require an honest record of which positions remain missing. If recovery is implemented, charge original-token storage, CPU backing, transfers, and model recomputation. Rebuilt history cannot repair outputs already emitted. Report calibration quality on held-out tasks and domain changes; a good calibration curve does not guarantee every individual retention action. Use hysteresis and a measured fallback rather than treating confidence as an unconditional accuracy certificate.

Part 7 - Engineering Interpretation and Philosophy

Explain whether confidence predicts a useful retention choice in the tested domain. Choose conservative limits or a fixed policy when uncertainty, irreversible loss, or overhead makes adaptation unjustified.

19.39.18 Exercise 17

Exercise Title: Combine Eviction, Quantization, and CPU Offloading into a Three-Level KV Policy That Chooses Delete, Compress, Offload, or Keep

Part 1 - Exercise Contract and Why It Matters

Combine keep, compress, offload, and permanent logical deletion in one explicit KV decision policy. Use three named retained-representation levels and a separate deleted state. Compare capacity, quality, transfer, reconstruction, and complete inference cost without treating these actions as interchangeable.

Part 2 - System and Memory Mental Model

Keeping full-width GPU KV preserves current representation; quantizing it adds approximation; CPU offloading preserves the chosen representation but requires restoration; deleting active history changes future attention. Deleting an inactive reusable prefix has different semantics. Track authority, format, shared ownership, and completion. Promoting compressed data does not recover lost precision, and increasing residency cannot resurrect deleted values without

backing or recomputation. Subsequent retained KV may already reflect earlier approximation history.

Part 3 - Quantitative Prediction Before Execution

For each candidate block, predict final and transitional GPU bytes, host backing, code metadata, decoded workspace, transfer cost, and quality evidence. Compare a GPU-float, GPU-compressed, CPU-backed hierarchy with a deleted state, recording CPU format explicitly. Construct actions whose final state fits but whose conversion peak fails. Define hard eligibility and calibrated quality gates before using a composite cost objective.

Part 4 - Experimental Design and Instrumentation

Integrate the validated codecs, transfer tickets, tables, reference counts, and retention rules through one authority. Start with deterministic transitions before adding concurrency. Test shared blocks with conflicting desired actions, dirty versions, partial tails, compression before offload, and active-reader retirement. Compare fixed keep-only, lossless offload, uniform compression, pruning-only, and combined policies on matched traces. Preserve explicit masks, positions, model context, and calibration identities. Count original-token logs, host originals, and recomputation if they provide recovery.

For each action, record visibility change, representation change, authority, recoverability, and actual capacity relief. CPU-backed quantized data should retain its format/version metadata just as GPU data does. Shared owners may disagree about approximation, requiring a compatible common policy or private replacement. Count old readers, new encoded payload, decoded workspace, and pinned staging during transitions. A final low-byte state is insufficient if the path to it exceeds the admitted budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class KVHierarchyAction:
    block_identity: tuple
    semantic_scope: str
    action: str
    target_format: tuple
    final_gpu_bytes: int
    transition_gpu_bytes: int
    host_bytes: int
    quality_evidence: object

def plan_kv_hierarchy_actions(candidates, budgets, quality_contract):
    # Gate lifetime, recovery, and semantic consequences before ranking.
    ...

def commit_kv_hierarchy_action(plan, readiness, ownership_authority):
```

```
    # Publish exact-version representation or visibility changes safely.
    ...

def E17(config):
    # Validate each action and compare the complete integrated trade-off.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report each action class, actual relief, host growth, copies/transfers, retained positions, quality, and complete latency. Do not claim a lossless combined policy when it deletes active context or quantizes values. Prevent cached lookup entries from exposing recycled or incompatible approximate prefixes. A rejected transition is correct when no action satisfies resource and declared quality prerequisites.

Compare one-shot and repeated approximation histories explicitly. Wider codes cannot recover values lost earlier, and restoring a page to GPU does not restore deleted positions. Prefix reuse identity must account for compatible retention/precision trajectories or a canonical reconstruction protocol, not only matching text tokens. Track host originals and token logs if they enable recovery. Keep inactive-prefix eviction separate so a lossless miss/recompute path is not confused with permanent active-context pruning.

Part 7 - Engineering Interpretation and Philosophy

Explain which hierarchy level solves which bottleneck and what information can actually be recovered. Recommend the smallest action set supported by measurements, keeping empirical accuracy limits distinct from hard owned-byte and lifetime guarantees.

19.39.19 Exercise 18

Exercise Title: Stress-Test Adaptive KV Eviction with Long Retrieval Tasks, Shared Prefixes, Multiple Concurrent Requests, Abrupt Topic Changes, and Severe VRAM Pressure

Part 1 - Exercise Contract and Why It Matters

Stress-test retention and hierarchy policies with long retrieval tasks, shared prefixes, concurrent requests, topic changes, and small bounded KV budgets. Search for minimal quality and lifecycle counterexamples. Separate expected approximation failures from corrupted positions, stale metadata, and unsafe storage reuse.

Part 2 - System and Memory Mental Model

Abrupt topic changes can make accumulated attention stale, while shared prefixes constrain physical reclamation. Concurrent admission introduces fairness and transition peaks. A low-memory run can be operationally correct but fail its retrieval threshold. A high-quality sample can conceal leaked or still-live blocks. Maintain independent semantic-position, ownership, resource, and task-quality checks, with explicit recovery assumptions for deleted or compressed history.

Part 3 - Quantitative Prediction Before Execution

Predict a short trace involving shared protection, middle pruning, a late retrieval query, and request cancellation. Calculate maximum live backing, provisional copies, score metadata, and

offload staging. Define quality failures and expected admission rejections in advance. Include impossible working-set and protection-union cases whose correct result is refusal rather than unlimited progress. State the model's positional and context-range support.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, finite arrival traces, known-answer tasks, bounded output lengths, host/GPU budgets, and pending-operation limits. Begin with CPU selector and deterministic completion simulation before actual supported CUDA runs. Keep policy calibration separate from held-out stress. Check retained IDs and code/format integrity after each event and model outcomes at selected checkpoints. Inject preparation failures before publication, not illegal device races. Save failing traces and minimize them without removing required prefix population, calibration, or sharing setup.

Separate deliberate rejection controls from failures in valid histories. Save task, model, and calibration identifiers, retained sets, and completion order along with seeds. Actual asynchronous timing may not reproduce from a seed alone. Start with deterministic examples of protected-union overflow, old-score domination after a topic shift, and a shared block with no physical relief. Bound score histories and diagnostic payload so stress monitoring cannot become an unreported leak.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class AdaptiveRetentionStressBounds:
    maximum_requests: int
    maximum_context_tokens: int
    gpu_bytes: int
    host_bytes: int
    maximum_pending_actions: int
    steps: int

def generate_retention_trace(seed, bounds, task_contract):
    # Mix supported histories, topic shifts, and labeled invalid controls.
    ...

def audit_adaptive_retention(engine, position_oracle, ownership_oracle):
    # Separate exact invariants from empirical quality and resource evidence.
    ...

def minimize_retention_failure(trace, replay):
    # Preserve model/task/calibration and asynchronous setup dependencies.
    ...
```

```
def E18(config):
    # Test adversarial small traces before bounded integrated stress.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, exact histories, failure phases, smallest counterexamples, reproducibility, quality thresholds, and actual execution support. Include stale scores, protected-set overflow, shared-block reclamation rejection, confidence miscalibration, lost retrieval facts, and shutdown with pending readers. An unobserved or unreproduced failure remains a stated limitation, not permission to invent hardware or quality evidence.

Audit after final drain and controlled cancellation, including old table versions, shared owners, transfer endpoints, and pending score updates. Minimize a failure only while preserving the setup that causes it; a missing prefix initialization is a different error. Report quality failures, operational corruption, infeasible admission, and unsupported execution separately. A finite clean trace supports a tested-envelope claim, not proof that every future context, concurrency pattern, or confidence transition is safe.

Part 7 - Engineering Interpretation and Philosophy

Identify the highest-impact remaining uncertainty and its next bounded experiment. State the tested envelope without claiming universal quality, progress, or concurrency correctness from a finite stress run.

19.39.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Adaptive KV Cache Manager That Dynamically Chooses Which Context to Keep, Compress, Offload, or Permanently Evict Under Accuracy and VRAM Constraints

Part 1 - Exercise Contract and Why It Matters

Integrate an adaptive manager choosing keep, compress, offload, or delete under explicit quality and resource contracts. Benchmark completed inference, context retention, prefix reuse, and recovery cost. Deliver an auditable support matrix and held-out evidence; the scaffold leaves substantive implementation to the learner.

Part 2 - System and Memory Mental Model

The manager coordinates active visibility, absolute positions, per-layer validity, scores, representation, residency, shared owners, and pending users. Separate active pruning from inactive-prefix replacement throughout the API. Quality is an empirical approximation envelope unless a specified online oracle is genuinely available and charged. The attention consumer defines working-set needs and monitoring overhead. One authority must prevent a score decision from bypassing ownership, generation, or complete transition admission.

Part 3 - Quantitative Prediction Before Execution

Predict useful context, physical capacity, score/label/index metadata, compressed parameters, residuals, host backing, reconstruction workspace, and pending old/new copies. Compare full KV, recency, attention-only, hybrid, role-aware, and integrated hierarchy policies on equal supported traces. Define quality-qualified capacity and include latency/fairness constraints.

Estimate both steady savings and transient peaks. Distinguish analytical capacity from tested completed requests.

Part 4 - Experimental Design and Instrumentation

Freeze support for positional handling, model context, grouping, sharing, append, pruning, compression, migration, restoration, cancellation, and shutdown. Validate synthetic selectors, codecs, ownership, and masks before model quality. Use separate calibration, selection, and held-out evaluation. Record software, hardware, model/tokenizer revisions, precision, attention backend, seeds, budgets, task identities, and initial state. Include prefill, instrumentation, selection, compaction, transfers, reconstruction, attention, and drain in complete cost. Run ablations without loosening correctness or resource gates.

Publish a support matrix before performance: active pruning, inactive-prefix replacement, sink/recent protection, scoring, label alignment, quantization, offload, restoration, cancellation, and shutdown each need precise semantics. Keep attention instrumentation and consumer changes visible. Use a trained model for meaningful quality results and a tiny reference for exact state invariants. Separate analytical context capacity from actual quality-qualified completed inference and retain the fixed model's positional limits.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AdaptiveKVManagerContract:
    model_context: tuple
    position_policy: str
    gpu_bytes: int
    host_bytes: int
    attention_consumer: str
    quality_policy_identity: str
    recoverable_history_policy: str
    supported_actions: tuple

class AdaptiveKVCacheManager:
    def __init__(self, contract):
        # Establish tables, authority, scores, formats, residency, and budgets.
        ...

    def observe(self, request, model_evidence):
        # Retain only supported bounded signals with age and uncertainty.
        ...

    def plan(self, demands):
        # Gate semantics, lifetime, quality evidence, fairness, and full peaks.
        ...
```

```
    def step(self):
        # Order admitted work and commit coherent context/representation state.
        ...

    def audit(self):
        # Recompute token visibility, ownership, formats, and unique backing.
        ...

    def shutdown(self):
        # Drain or safely cancel owned work and report unresolved obligations.
        ...

def E19(config):
    # Validate integrated contracts before held-out quality/capacity benchmarks.
    ...
    # Export evidence, counterexamples, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct retained IDs, positions, masks, format decoding, shared lifetime, bounded resources, and declared tested quality. Report perplexity with scored counts, retrieval outcomes, retained evidence, prefix hits/recompute work, confidence behavior, action counts, byte peaks, latency, and rejected/unfinished requests. Keep predictions, observations, and interpretations separate. An unfinished scaffold supplies no measured hardware or model-quality result.

Report an unfavorable policy case, a confident wrong prediction, a structural counterexample or honest non-reproduction, a shared-block rejection, and a transition with insufficient headroom. Include rejected and unfinished requests alongside successful survivors. Hard byte/lifetime invariants and empirical accuracy evidence have different strengths. Recommend the simplest supported policy with its measured trade-off and next required experiment, without inventing speedups, retrieval scores, or universal accuracy guarantees.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest policy supported by complete evidence, including full retention when approximation is unjustified. Explain what was kept, changed, moved, or permanently lost and the capacity-quality-latency exchange. Separate proposed optimized kernels or broader model support from tested capabilities and remaining uncertainty.

19.40 DMM38

Chapter Title: Fully Sharded Data Parallel (FSDP) Memory Management
Specialization: Dynamic Memory Management and CUDA Systems

19.40.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Parameter, Gradient, and Optimizer-State Sharding Across Multiple GPUs

Part 1 - Exercise Contract and Why It Matters

Model parameter, gradient, and optimizer ownership across ranks and time. Deliver a diagram separating persistent shards, temporary gathered units, activations, collective buffers, and optimizer updates. Use one CUDA device per process on one multi-GPU host; two physical computers are not required. Capacity claims must include initialization and complete training, not only idle post-wrap state.

Part 2 - System and Memory Mental Model

The primary API track is FSDP1, the FullyShardedDataParallel wrapper, because these exercises study its sharding strategies, auto-wrap policies, and rate limiter. Pin the installed version and do not mix its constructor controls with FSDP2 fully_shard, DTensor state, or FSDP2 precision/offload policies. FSDP2 is a separate supported-design comparison. Under full sharding, local persistent state shrinks while full parameters for a computation unit are materialized when needed. Activations and ignored or replicated objects do not automatically divide by world size.

Part 3 - Quantitative Prediction Before Execution

For a named all-trainable model, derive an ideal persistent-state estimate from parameter, gradient, and optimizer bytes divided by sharding-group size. Add replicated state, padding, gathered units, prefetch overlap, and workspace separately. Explain why

$$M_{\text{peak}} \neq M_{\text{single}}/W$$

in general. Distinguish global world size from the size of a particular sharding group and calculate a one-unit versus nested-unit example before execution.

Part 4 - Experimental Design and Instrumentation

Use a small deterministic model first, fixed precision and optimizer, identical initial weights, and one forward/backward/update per step. Bind LOCAL_RANK to its CUDA device, initialize the declared process group, and verify rank-consistent topology and configuration. Construct the optimizer after FSDP wrapping. Record model/wrap manifest, software and NCCL versions, device/link topology, seeds, batches, allocator backend, and initial-state ID. Start without accumulation, CPU offload, or mixed precision so later changes are controlled.

Write the rank map and collective groups before launching. Distinguish local CUDA index, global rank, and group-local rank even when a single-host example makes their numbers coincide. Freeze the process count and model/wrap manifest for a trial. Include a rank-consistency check before the first model collective and a finite failure protocol. Configuration disagreement should stop the trial rather than enter incompatible collective order and wait indefinitely.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist
from torch.distributed.fsdp import FullyShardedDataParallel as FSDP

@dataclass
```

```
class FSDPExperimentContract:
    api_track: str
    world_size: int
    sharding_group_size: int
    per_rank_batch: int
    optimizer_identity: str
    wrap_manifest_identity: str

def predict_rank_memory(contract, model_inventory, execution_plan):
    # Separate persistent ownership and temporary computation/collective state.
    ...

def E00(config):
    # Validate rank/device setup and the version-pinned FSDP1 experiment model.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require per-rank phase records and a declared aggregation: maximum rank peak, rank distribution, and useful global throughput. Keep predictions, observations, and interpretation separate. Do not fabricate multi-GPU results when only a CPU model or fewer devices are available. All ranks must execute compatible collectives; a local failure cannot safely be hidden while peers continue the same training loop.

Define the training boundary as forward, loss, backward, optimizer update, and the declared gradient-clearing point. State whether data transfer, collation, checkpointing, and recovery are timed. Require fixed-seed numerical checks and additional seeds for repeatability, without claiming all kernels are bitwise deterministic. The evidence ledger should distinguish initialization, first update, and warmed execution on every rank, then report the maximum operational peak rather than only rank zero's convenient observation.

Part 7 - Engineering Interpretation and Philosophy

Explain the memory-communication exchange and the minimum unit that still must fit on one GPU. A sharded runtime increases feasible capacity only when its transient computation, initialization, and communication also fit the available hardware.

19.40.2 Exercise 01

Exercise Title: Measure Per-GPU Parameter, Gradient, and Optimizer-State Memory in Standard DistributedDataParallel as a Baseline

Part 1 - Exercise Contract and Why It Matters

Measure standard DistributedDataParallel model, gradient, optimizer-state, and communication residency per GPU. Establish a complete-step baseline with identical initial values and useful global data accounting. Separate startup, first optimizer update, and warmed training.

Part 2 - System and Memory Mental Model

Ordinary DDP replicates model parameters on every rank and synchronizes gradients. An ordinary per-rank optimizer also maintains replicated state; this baseline does not use a sharded optimizer. Optimizer tensors may appear lazily after the first update. Gradient buckets can alias gradient storage under certain settings, so logical gradient bytes and unique backing are different. Buffers, activations, input batches, allocator reservation, and communication-library allocations need separate accounting.

Part 3 - Quantitative Prediction Before Execution

For an all-trainable float32 parameter count P, calculate parameter and gradient payload, then derive state for the actual optimizer and observed state dtypes. An Adam-like two-moment estimate is not a universal optimizer formula. Predict the first-step increase from lazy state and possible foreach workspace. Define global batch from world size, local batch, and accumulation count, with accumulation fixed to one in the initial baseline.

Part 4 - Experimental Design and Instrumentation

Initialize identical model values, shard the dataset explicitly, and keep rank-local work shapes matched. Fix DDP bucket and gradient-view settings and record them. Measure before forward, after forward, after backward, after update, and after gradient clearing at deliberate diagnostic boundaries. Use a separate minimally instrumented run for complete step time. Capture CPU-only scalar inventories without retaining graphs or duplicate GPU tensors. Compare losses and a small reference update under matching loss normalization.

Enumerate actual optimizer tensor fields after the first update instead of assuming an empty state dictionary means the optimizer has no memory cost. Record step counters and non-tensor state separately from large tensor moments. Choose a fixed gradient-bucket view policy and inspect unique backing after warm-up. Test gradient clearing with the declared set-to-none behavior, because it changes whether gradient payload remains live at the next observation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.nn.parallel import DistributedDataParallel as DDP

@dataclass
class RankStateInventory:
    rank: int
    phase: str
    parameter_bytes: int
    gradient_bytes: int
    optimizer_bytes: int
    communication_scope: str

def inventory_ddp_state(model, optimizer, phase, measurement_contract):
    # Deduplicate backing and record lazy state, views, and unsupported bytes.
    ...
```

```
def run_ddp_reference_step(model, optimizer, local_batch):
    # Preserve distributed data/loss semantics through a complete update.
    ...

def E01(config):
    # Establish per-rank memory and useful global-step reference evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual state tensors, dtypes, phases, unique backing, allocated and reserved peaks, step duration, and global sample count. Do not attribute every residual byte to DDP or sum aliased buckets twice. Rank timing must include completed CUDA work. A first-step measurement cannot stand in for warmed steady state when optimizer initialization or bucket rebuilding changes memory.

Use deterministic distinct sample IDs on each rank and compare their global multiset with the intended batch. DDP does not by itself prove the dataset was sharded correctly. Equal local mean losses need compatible normalization for a matching global update. Avoid collecting every rank's activations on rank zero for validation. Export reduced scalar checks or a small deliberate parameter-inspection replay outside the primary memory and timing region.

Part 7 - Engineering Interpretation and Philosophy

Explain which replicated components FSDP can target and which remain driven by workload or kernel execution. Preserve the DDP baseline as both a numerical reference and a clearly scoped resource measurement.

19.40.3 Exercise 02

Exercise Title: Wrap a PyTorch Model with FSDP and Verify That Model State Is Sharded Across the Distributed World Size

Part 1 - Exercise Contract and Why It Matters

Wrap a small model with version-pinned FSDP1 full sharding and verify persistent ownership of parameters, gradients, and optimizer state. Use the same data-parallel training semantics as DDP. Demonstrate sharding with an inventory rather than inferring it from a wrapper name.

Part 2 - System and Memory Mental Model

Managed parameters can be flattened and replaced by views during execution. Use a declared use_orig_params setting consistently; the primary simple track uses the flattened-parameter mode. Outside computation, persistent managed storage is sharded; forward and backward may temporarily expose gathered values. Buffers and ignored modules may remain replicated. The optimizer must reference wrapped parameters, and its state must be measured after a real update rather than assumed present at construction.

Part 3 - Quantitative Prediction Before Execution

Predict local managed payload from each unit's global elements and sharding group size, then include padding and unsharded objects separately. Calculate expected gradient and optimizer ownership after synchronization/update under fixed precision. Predict the larger forward materialization. Explain why inspecting parameters inside a full-parameter gathering context would change the state being measured.

Part 4 - Experimental Design and Instrumentation

Bind rank/device, initialize the group, create the same model and wrap manifest on every rank, then build the optimizer. Use supported device and initial-state synchronization rules. Run one deterministic training step and compare outputs or reconstructed small-model values with the DDP reference at a deliberate validation boundary. Inventory persistent state after each phase and note parameter-view identity changes. Avoid calling an unwrapped internal submodule directly when its FSDP hooks would be bypassed.

Record which parameter objects the optimizer receives after wrapping and reject obsolete references from the unwrapped model. Do not keep saved parameter views across forward calls when FSDP changes their backing interpretation. Start with all parameters trainable and a simple supported ownership layout; frozen/tied mixtures are separate support tests. Verify the chosen device and initial-state synchronization path on every rank before training.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist
from torch.distributed.fsdp import FullyShardedDataParallel as FSDP
from torch.distributed.fsdp import ShardingStrategy

def construct_fsdp1_model(model_spec, distributed_context, wrap_contract):
    # Build matching units and validate the chosen full-shard API settings.
    ...

def construct_wrapped_optimizer(sharded_model, optimizer_spec):
    # Bind optimizer ownership after wrapping, not to obsolete parameters.
    ...

def verify_persistent_shards(model, optimizer, inventory_contract):
    # Measure supported post-phase local backing without forcing full gathers.
    ...

def E02(config):
    # Validate small-model sharding and one complete distributed update.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report rank, group, wrap units, logical global sizes, local bytes, padding status, buffers, and optimizer state. Require numerical agreement within a predeclared tolerance after the matching update. Do not claim every state object is sharded or every rank has identical byte counts. Unsupported private layout details must remain unknown instead of being inferred from names.

Observe a quiescent sharded phase and a deliberate small-model gathered validation phase separately. The latter changes memory and cannot supply the former's measurement. Inspect optimizer state after a completed update and gradients before their declared clearing point. Validate globally reconstructed small-model values only through a supported collective path with all required participants. If public metadata cannot explain a layout detail, record the unknown rather than accessing unstable internals as a general solution.

Part 7 - Engineering Interpretation and Philosophy

Explain the ownership evidence that establishes actual full sharding and its phase dependence. State the initialization and wrapping assumptions needed before scaling the model or adding more complex training options.

19.40.4 Exercise 03

Exercise Title: Compare Per-GPU Peak VRAM Between DDP and FSDP Under the Same Model, Batch Size, Precision, and Optimizer

Part 1 - Exercise Contract and Why It Matters

Compare complete per-GPU peaks for DDP and FSDP with the same model, world size, local/global batch, precision, optimizer, and useful updates. Separate feasibility, memory savings, and throughput. Keep wrapping policy and activation workload visible in the comparison.

Part 2 - System and Memory Mental Model

FSDP reduces persistent replicated state but adds gather and reduce-scatter work and temporary full parameters. DDP has its own gradient communication and bucket behavior. Neither method guarantees lower total peak for every small model or workload. Data distribution and loss normalization determine whether the updates are genuinely comparable. The maximum rank peak and slowest completed rank matter for operational capacity and step time.

Part 3 - Quantitative Prediction Before Execution

Predict parameter, gradient, optimizer, activation, and temporary components for both cases. Define expected persistent savings and a separate range for materialization peaks. Calculate global sample count per update and an explicit throughput denominator. Include first-step initialization and warmed-step measurements separately. Identify a case dominated by activations where state sharding alone is unlikely to yield proportional peak reduction.

Part 4 - Experimental Design and Instrumentation

Use independent clean trials with identical initial checkpoint, sampler trace, model dimensions, precision, optimizer flags, and zeroing policy. Reset allocator peaks around a complete forward/backward/update region after declared warm-up. Synchronize deliberately and aggregate completed durations without adding hidden per-layer barriers. Validate a short loss/update trajectory before performance. Keep profiling and full-state numerical inspection outside the primary timed region. Record initialization peaks as a separate admission constraint rather than omitting them.

Use matching logical batches, loss scaling, optimizer flags, zeroing policy, and successful update counts. A lower memory result obtained by skipping an update is invalid. Use clean independent trials so allocator history or retained profiling tensors from the first method do not contaminate the second. Declare whether model construction is outside step timing while still measuring its admission peak. Repeat close timing comparisons before ranking configurations.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ParallelTrainingCase:
    method: str
    world_size: int
    local_batch: int
    precision_identity: str
    optimizer_identity: str
    initial_state_identity: str

def compare_ddp_fsdp(cases, model_spec, data_trace, measurement_contract):
    # Enforce matching updates and include complete per-rank training peaks.
    ...

def aggregate_rank_results(rank_rows):
    # Preserve maximum peaks, timing spread, and useful global samples.
    ...

def E03(config):
    # Validate semantics before interpreting memory or throughput differences.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-rank allocated/reserved peaks, host scope, step latency spread, throughput, loss parity, and failure phase. A DDP-infeasible large case is a capacity result, not a measured finite DDP step time. Use a smaller matched case for numerical comparison. Avoid changing batch or precision only for one method and calling the result a controlled sharding experiment.

For timed distributed regions, ensure required CUDA work completes and then aggregate rank durations under the declared start/end protocol. Summing rank times is not step latency. Report global useful samples divided by the complete operational duration and retain straggler spread. A comparison at another world size must state how local and global batch changed; otherwise communication and activation differences can be mistaken for a pure sharding effect.

Part 7 - Engineering Interpretation and Philosophy

Explain which memory components changed and what communication cost was purchased. Recommend a method for the tested capacity/performance objective, preserving cases where DDP remains preferable.

19.40.5 Exercise 04

Exercise Title: Calculate Expected Per-Rank Parameter Shard Size and Compare It Against Real CUDA Memory Measurements

Part 1 - Exercise Contract and Why It Matters

Calculate expected local parameter shards unit by unit and compare them with supported CUDA storage measurements. Separate ideal partitioning, implementation padding, replicated objects, and temporary gathers. Produce an auditable reconciliation rather than expecting exact total VRAM from parameter count alone.

Part 2 - System and Memory Mental Model

A FSDP1 managed unit can flatten multiple logical parameters into local storage. Shared/tied parameters must be counted once in the logical inventory. Padding, alignment, representation settings, and group size affect actual shards. A local parameter view may not expose the same shape as the original logical parameter. FULL_SHARD post-phase state differs from a gathered computation state or another sharding strategy.

Part 3 - Quantitative Prediction Before Execution

For a unit with n_i managed elements and group size W_i, use $\lceil n_i/W_i \rceil$ as a clearly labeled padded-partition model when its assumptions match the representation. Sum units using their actual element widths and add ignored/replicated payload separately. Predict a nondivisible unit and a tiny unit. Keep unknown extra alignment distinct from arithmetic padding rather than silently forcing the prediction to match measurements.

Part 4 - Experimental Design and Instrumentation

Capture a logical CPU metadata inventory before wrapping without retaining full GPU copies. Freeze wrap manifest, use_orig_params, strategy, precision, and process groups. Measure at a quiescent full-shard boundary after a complete step. Deduplicate unique backing and exclude validation gathers from the measurement region. Test uneven unit sizes and tied weights supported by the chosen layout. Compare multiple available world sizes only with explicitly updated batch/scaling rules.

Capture logical parameter identity, shape, dtype, ties, ignored ownership, and target unit before flattening. Count a tied storage once even when it has multiple names. Test a small unit with fewer elements than ranks and a unit whose size is not divisible by its group. Record the declared original-parameter representation so local view sizes are not confused with the logical inventory.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
```

```
class ParameterShardPrediction:
    unit_identity: str
    logical_elements: int
    sharding_group_size: int
    element_bytes: int
    predicted_padding_elements: object
    replicated_bytes: int

def predict_unit_shards(logical_inventory, wrap_manifest, representation):
    # State padding assumptions and preserve unsupported alignment as unknown.
    ...

def reconcile_shard_storage(predictions, measured_local_backing):
    # Separate persistent shards from gathers, aliases, and allocator overhead.
    ...

def E04(config):
    # Audit divisible, nondivisible, tied, and ignored-state examples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw logical counts, unique ties, unit membership, group sizes, dtypes, predicted padding, measured backing, and unexplained residuals. Do not use the global world size when the actual sharding group is smaller. A zero-sized original-parameter view is not proof the model lost that parameter. Do not label total allocator reservation minus shard bytes as fragmentation.

Compare modeled shard padding with observed local storage only at matching phases. Additional implementation alignment must be identified or left unknown, not silently inserted into the formula after measurement. Add buffers and ignored parameters separately. Check that no source reference in the accounting code keeps a full pre-wrap GPU model alive. The total allocator reservation includes retained capacity and other allocations, so reconciliation should explain scope rather than force an exact equality to model payload.

Part 7 - Engineering Interpretation and Philosophy

Explain how far the prediction accounts for the observed persistent state and what remains implementation- or allocator-specific. Use the reconciled model for planning without promoting it to a guarantee about full training peak memory.

19.40.6 Exercise 05

Exercise Title: Trace Parameter All-Gather Before Forward Computation and Reduce-Scatter During Backward with PyTorch Profiler

Part 1 - Exercise Contract and Why It Matters

Trace parameter gathering before computation and gradient reduction/sharding during backward. Associate collective events with FSDP units and memory phases. Distinguish application payload estimates, profiler event durations, and actual link traffic; none is automatically a substitute for the others.

Part 2 - System and Memory Mental Model

Full sharding restores unit parameters for computation and returns gradients to shard ownership through the supported reduction protocol. Backward can require parameter gathers again after forward resharding. Prefetch overlaps communication with another unit's work, and repeated/shared execution can change collective counts. Profiler names and attribution vary by build. Collective ordering must be compatible across ranks; a local trace cannot establish complete distributed correctness by itself.

Part 3 - Quantitative Prediction Before Execution

Predict a simple unit execution sequence and expected gather/reduce-scatter payloads using actual padded sizes and communication dtypes. State any collective algorithm assumption when estimating per-rank traffic. Do not equate full-tensor payload with each rank's wire bytes. Draw expected overlapping and serialized intervals and identify where parameter and gradient buffers can coexist. Leave unsupported traffic measurements unknown.

Part 4 - Experimental Design and Instrumentation

Warm the process group and model before a short bounded profiler run with CPU/CUDA activities and declared memory recording. Add public user scopes around model phases and unit calls where supported. Export a trace per rank with rank/device/group identity and compare collective sequence metadata. Avoid full state-dict collection or global synchronization inside each unit. Run a separate unprofiled timing control. Validate a complete optimizer update before interpreting communication overlap or reducing scheduling constraints.

Label events by rank, group, unit, step, and phase, then align collectives using their supported sequence information. Do not compare raw CUDA event origins across devices as a universal common clock. A collective can have CPU launch, enqueue, and device execution intervals; preserve which one the profiler exposed. Include warm-up that initializes communication so startup is not attributed to every training step.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.profiler import profile, ProfilerActivity, record_function

@dataclass
class CollectiveEvidence:
    rank: int
    group_identity: str
    unit_identity: str
    collective_kind: str
    payload_bytes: object
    attribution_support: str
```

```
def profile_fsdp_step(runtime, profiler_contract):
    # Record bounded traces without changing collective order across ranks.
    ...

def map_collectives_to_units(trace_rows, wrap_manifest):
    # Preserve uncertain attribution and distinguish payload from wire traffic.
    ...

def E05(config):
    # Compare predicted ordering, measured traces, and unprofiled complete time.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report observed event families, unit mapping support, payload model, durations, memory intervals, and profiler overhead. Do not sum overlapping communication durations as total step cost. Cross-device clocks do not provide a shared timestamp origin automatically. A missing event label can be a tracing limitation rather than proof that sharding communicated nothing.

Derive traffic estimates from actual padded unit payloads and dtypes under a stated algorithm model. A gather's logical full payload is not each rank's measured bus traffic, and a sum of overlapping event durations is not wall time. Report profiler overhead with an unprofiled control. Missing allocation attribution or kernel labels must remain unsupported, while numerical update validation confirms the trace came from a correct training execution.

Part 7 - Engineering Interpretation and Philosophy

Explain which collectives are exposed on the critical path and which overlap useful work. Use evidence to choose the next memory/scheduling experiment, without treating communication presence alone as a performance diagnosis.

19.40.7 Exercise 06

Exercise Title: Measure Temporary Full-Parameter Materialization Peaks During FSDP Forward Execution

Part 1 - Exercise Contract and Why It Matters

Measure temporary full-parameter residency during forward and relate peaks to wrapping granularity and prefetch. Separate transient gathered capacity from persistent shards and activations. Demonstrate why an apparently small idle model can still have a large computation peak.

Part 2 - System and Memory Mental Model

A full computation unit must become available on each participating rank under this data-parallel FSDP design. Its full payload can coexist with local shards, activations, prefetched

units, and collective workspace, depending on implementation lifetimes. Root-managed parameters and ignored objects matter. Memory counters alone do not label the owner of a peak. A diagnostic that forces a full-model gather changes the phenomenon being measured.

Part 3 - Quantitative Prediction Before Execution

Calculate the largest managed unit, its gather dtype, and a bounded set of simultaneously live units under the configured schedule. Add persistent state and forward activations without double-counting alias backing. Compare a single root unit with nested blocks under the same useful forward. Predict when the largest unit or its temporary overlap exceeds the local budget even though ideal persistent shards fit.

Part 4 - Experimental Design and Instrumentation

Use bounded models and the already validated wrap manifest. Capture phase counters, a short profiler trace, and supported memory history/snapshots in separate diagnostic runs. Compare root-only wrapping, smaller units, and prefetch settings without changing model arithmetic or inputs. Reset peaks for the declared forward region but also report complete-step and initialization peaks. Avoid retaining parameter views in hooks or evidence records. Measure unprofiled throughput separately from heavily synchronized attribution.

Use a model with a known large root-managed object and smaller repeated blocks so the dominant gather can be predicted independently of module count. Record possible current/next overlap under each scheduling option. Add a control with the same parameters but a different input shape to isolate activation contribution. If hooks record tensors rather than scalar metadata, they can extend full-parameter lifetime and create the very peak being investigated.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MaterializationPrediction:
    unit_identity: str
    full_payload_bytes: int
    persistent_shard_bytes: int
    possible_overlap_units: tuple
    attribution_limitations: tuple

def predict_forward_materialization(manifest, precision, schedule):
    # Model live backing and leave unknown alias/workspace relationships explicit.
    ...

def measure_forward_peaks(runtime, observation_contract):
    # Observe without forcing a full state dict or retaining parameter views.
    ...
```

```
def E06(config):
    # Link temporary peaks to auditable units and controlled schedule changes.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw peak/current allocated and reserved values, unit sizes, activation context, schedule, and attribution evidence. An external device monitor includes memory not captured by PyTorch tensor accounting. Do not call every unexplained byte a gathered parameter. Include a counterexample to peak equals persistent shard bytes and preserve cases where smaller units increase other overhead.

Keep three resource results distinct: persistent post-step state, forward region peak, and complete training peak. Resetting a counter around forward does not prove backward or optimizer fit. Compare allocator counters with a short supported history trace and external device scope only where available. Do not treat a numerical residual between these layers as a named tensor owner. A bounded model can demonstrate the materialization mechanism without requiring a real out-of-memory event.

Part 7 - Engineering Interpretation and Philosophy

Explain the minimum materialization constraint and the capacity/performance trade-off of splitting units. Recommend a next wrap or schedule change only when the observed peak mechanism supports it.

19.40.8 Exercise 07

Exercise Title: Compare Different FSDP Sharding Strategies and Quantify Their Memory-Communication Trade-Offs

Part 1 - Exercise Contract and Why It Matters

Compare FSDP1 sharding strategies with explicit ownership and reshard timing. Measure per-rank memory, collective payload, and complete step time under matched useful training. Keep topology-dependent hybrid strategies optional when the available process-group layout supports a meaningful comparison.

Part 2 - System and Memory Mental Model

FULL_SHARD, SHARD_GRAD_OP, and NO_SHARD differ in which state is sharded and when full parameters remain available. NO_SHARD is not a promise of FSDP memory savings; ordinary DDP is the practical replication baseline. Hybrid sharding uses a shard group plus replication, so dividing by global world size can be wrong. FSDP2 expresses comparable behavior through a different API and must not receive FSDP1 strategy enums as if they were interchangeable.

Part 3 - Quantitative Prediction Before Execution

Predict persistent parameters, post-forward full residency, synchronized gradients, optimizer state, and backward gathers for each configured strategy. Use the actual shard and replication group sizes. Estimate collective payload with stated dtype and padding assumptions. Include

the gradient-accumulation configuration in the prediction even though the primary comparison uses one forward/backward/update. Define a topology where hybrid dimensions are both nontrivial and mark unavailable layouts untested.

Part 4 - Experimental Design and Instrumentation

Rebuild independent trials from identical initial weights, batches, optimizer, precision, and wrap units. Verify group construction and configuration on all ranks before collective work. Measure cold and warmed complete steps, post-forward/post-backward diagnostics, and per-rank peak distributions. Compare a short numerical update trajectory. Record unsupported version/strategy combinations rather than silently falling back. A single-host multi-GPU machine is sufficient for the primary comparisons; multi-node setup is not required.

Build process-group membership deterministically and verify every rank's view before strategy comparison. For hybrid experiments, record shard and replica dimensions explicitly. A single-host group can support the conceptual test if enough devices exist, but two GPUs do not create every nondegenerate hybrid layout. Keep unsupported cases unexecuted instead of choosing an undocumented fallback that changes the policy being compared.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
from torch.distributed.fsdp import ShardingStrategy

@dataclass
class ShardingStrategyCase:
    strategy_identity: str
    sharding_group_ranks: tuple
    replication_group_ranks: tuple
    wrap_manifest_identity: str
    precision_identity: str

def validate_strategy_topology(case, distributed_context):
    # Check supported groups and rank-consistent collective membership.
    ...

def compare_sharding_strategies(cases, training_trace):
    # Preserve matching updates and record phase-specific state ownership.
    ...

def E07(config):
    # Evaluate feasible strategy/topology combinations without invented scaling.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report group sizes, state phases, actual bytes, collective counts/payload scope, step times, and numerical checks. Do not compare a hybrid configuration with different total useful work without labeling the changed experiment. A degenerate replication dimension is not evidence of a full hybrid topology. Retain failures and untested configurations explicitly.

Compare state at the phase named by the strategy contract. Post-forward parameter residency can differ even when post-update ownership looks similar. Record gradient synchronization and accumulation settings; a no_sync extension can retain larger gradients and is a separate workload. Keep optimizer state and data normalization fixed. Explain each observed change through group sizes, reshard timing, or communication evidence rather than a universal stage label that hides implementation-specific lifetime behavior.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest strategy satisfying the tested capacity objective with acceptable communication cost. Explain when retaining parameters trades memory for fewer gathers and why the result depends on topology and unit lifetimes.

19.40.9 Exercise 08

Exercise Title: Build an Auto-Wrap Policy That Shards Transformer Blocks at a Chosen Module Granularity

Part 1 - Exercise Contract and Why It Matters

Build a FSDP1 auto-wrap policy selecting Transformer block boundaries at a declared granularity. Produce a deterministic ownership manifest covering all managed parameters, including root leftovers and ties. Validate construction and one training update before tuning performance.

Part 2 - System and Memory Mental Model

Wrapping defines gather units, not merely visual module labels. A root wrapper still owns parameters not assigned to child units. Embeddings, heads, and normalization can dominate that root payload. Shared/tied parameters require supported consistent ownership rather than arbitrary independent wrapping of both aliases. All ranks must create the same model and wrap plan. Optimizer references are established after wrapping.

Part 3 - Quantitative Prediction Before Execution

Inventory each candidate block's unique parameter elements and estimate its full gather bytes and local shards. Predict unit count and root-managed residual. Compare grouping several consecutive blocks with one wrapper per block. Calculate the largest materialized unit and possible prefetch overlap. Identify ties crossing proposed boundaries and reject unsupported ownership before timing.

Part 4 - Experimental Design and Instrumentation

Use explicit block classes or a validated size/type policy with the public FSDP1 wrapping interface. Test a small model containing embedding, repeated blocks, final normalization, and an output head. Include a supported tied-weight case as a separate validation. Export only CPU metadata for unit ownership, not full GPU weights. Check no unmanaged gap or duplicate ownership. Keep use_orig_params, strategy, initial values, and optimizer configuration fixed. Record the installed API signature and reject FSDP2-only controls.

Audit the root remainder after selecting Transformer blocks. Embedding and output-head aliases can cross apparent module boundaries, so choose a supported common ownership plan or reject the proposed partition. A type predicate and a size predicate may produce different units on the same model; record the actual manifest, not merely the policy name. All ranks must agree on that manifest before optimizer construction and collective execution.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
from torch.distributed.fsdp.wrap import transformer_auto_wrap_policy

@dataclass
class FSDPWrapPlan:
    block_class_names: tuple
    blocks_per_unit: int
    root_parameter_names: tuple
    shared_parameter_groups: tuple
    expected_unit_manifest: tuple

def build_fsdp1_wrap_policy(model, plan):
    # Choose supported boundaries and preserve shared ownership constraints.
    ...

def audit_wrap_ownership(model, logical_inventory, plan):
    # Reconcile every unique parameter and root-managed remainder.
    ...

def E08(config):
    # Validate deterministic wrapping before memory/communication experiments.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report unit boundaries, unique sizes, root leftovers, ties, ignored state, construction peak, and update parity. Module count is not parameter ownership. A policy that wraps every block but leaves one huge root embedding still has a huge materialization constraint. Do not correct rank-dependent plans by allowing mismatched collective sequences to run.

Test the policy on a tiny model where expected unique parameters and units are hand-auditable, including a large embedding and a supported tie. Verify numerical output and one optimizer update. Do not introduce rank-dependent wrapping to balance uneven shapes. If extending to frozen parameters or original-parameter mode, document those constraints as a new case. Keep actual initialization peak in the result so an apparently ideal execution plan is not accepted when construction already exceeds capacity.

Part 7 - Engineering Interpretation and Philosophy

Explain how wrapping granularity creates the memory schedule later experiments will tune. Prefer an auditable type-based plan over a complicated heuristic until root ownership and shared-parameter behavior are verified.

19.40.10 Exercise 09

Exercise Title: Sweep FSDP Wrapping Granularity and Measure Peak VRAM, Communication Volume, Kernel Utilization, and Step Time

Part 1 - Exercise Contract and Why It Matters

Sweep wrapping granularity and measure complete peaks, communication, compute gaps, and step time. Hold model and useful training fixed while varying only documented unit grouping. Select a tested compromise under explicit per-rank capacity and throughput constraints.

Part 2 - System and Memory Mental Model

Fine units can reduce full-parameter peaks but increase collective count, launch overhead, and scheduling work. Coarse units can expose larger gathers with fewer calls. Root state, mixed precision, activations, and prefetch can change the result. Profiler utilization is a scoped observation, not a universal measure of device efficiency. Communication payload estimates and measured bus traffic must remain distinct.

Part 3 - Quantitative Prediction Before Execution

For each grouping, predict unit sizes, root residual, padded shard capacity, collective count, and overlap envelope. State assumptions for byte-volume estimates and identify a candidate whose largest unit is infeasible. Define complete global samples per second and rank-tail step time. Construct a case where the smallest parameter unit is not the fastest configuration.

Part 4 - Experimental Design and Instrumentation

Use a bounded set of groupings, independent initial-state replays, and the same per-rank samples, precision, optimizer, strategy, and scheduling flags. Separate initialization, first update, warmed timing, and a short profiler run. Reset declared peaks and aggregate maximum rank usage. Validate numerical updates before admitting a candidate as feasible. Test the chosen grouping on a held-out shape/length trace without changing collective execution order. Report failures rather than silently reducing the batch only for difficult candidates.

Use a fixed global model and a small explicit grouping grid, including a root-only control and several nested choices. Keep the same successful update count and data trace. Predict the root-managed residual and largest gather for every candidate before launching. If a case is analytically unsafe, record that admission result rather than deliberately allocating to failure. Retain initialization and first-optimizer-state peaks as separate feasibility gates.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
```

```
class FSDPGranularityTrial:
    blocks_per_unit: int
    wrap_manifest_identity: str
    per_rank_budget_bytes: int
    training_trace_identity: str

def predict_granularity_trial(trial, model_inventory, schedule):
    # Count root, units, padding, and complete materialization requirements.
    ...

def benchmark_granularity_trial(trial, runtime_contract):
    # Validate equal work and keep profiler overhead out of primary timing.
    ...

def E09(config):
    # Select a robust feasible grouping with explicit uncertainty.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw manifests, rank peaks, step distributions, payload scope, collective counts, separate compute and communication intervals, and validation outcomes. A small average rank memory cannot hide one infeasible rank. A profile with more busy time does not prove higher useful throughput. Preserve uncertainty when close timing differences are smaller than run-to-run variation.

Report rank-tail latency and maximum per-rank peak, not only mean values. Profile a short diagnostic trace separately from the primary timing loops. A higher utilization percentage can reflect more overhead work rather than more useful training. Preserve uncertainty in communication-volume estimates and close performance rankings. Validate the selected point on held-out shapes with compatible module order and keep all rejected, unsupported, or failed candidates in the comparison ledger.

Part 7 - Engineering Interpretation and Philosophy

Explain which mechanism determines the selected grouping and its tested shape/topology dependence. Keep a simple stable configuration when tuning complexity offers no demonstrated benefit.

19.40.11 Exercise 10

Exercise Title: Combine FSDP with Mixed Precision and Measure Parameter, Gradient, and Communication Memory Changes

Part 1 - Exercise Contract and Why It Matters

Combine the validated FSDP1 runtime with an explicit mixed-precision policy. Measure persistent parameters, gathered computation values, gradients, reduction communication, buffers,

optimizer state, and complete peaks separately. Keep a full-precision reference for numerical and update validation.

Part 2 - System and Memory Mental Model

FSDP1 MixedPrecision distinguishes parameter computation, reduction, and buffer dtypes. Persistent parameter shards and optimizer state need not use the gathered parameter dtype. Gradient storage after reduction depends on settings such as keeping low-precision gradients and optimizer compatibility. Autocast is another arithmetic control, not the entire sharding policy. Hardware support, overflow handling, and norm clipping must be validated rather than inferred from a dtype label.

Part 3 - Quantitative Prediction Before Execution

Predict bytes for each state/communication component using its actual dtype. Compare reduced gather precision with unchanged full-width persistent shards. Estimate temporary cast buffers and reduction payload. State whether loss scaling is needed for the chosen path; a supported bfloat16 case and an fp16 case require different numerical considerations. Predict memory savings without assuming every optimizer tensor or gradient automatically halves.

Part 4 - Experimental Design and Instrumentation

Start with a supported low-precision policy on the small deterministic model and unchanged batch, optimizer, wrapping, and data trace. Record every FSDP1 precision field and autocast scope. Verify optimizer state dtypes after a real step. If using fp16, use a version-supported distributed/FSDP-aware scaling and overflow protocol so ranks do not silently disagree about skipped updates. Use the supported FSDP norm-clipping path when clipping is enabled. Compare loss, gradients through a supported inspection boundary, and a short parameter trajectory within predeclared tolerances.

Inventory parameter computation, persistent shards, buffers, reduction communication, stored gradients, optimizer moments, and cast workspace using their actual dtypes. Keep input casting and autocast scopes explicit, especially when nested units use different policies. A low-precision communication flag does not establish the dtype of persistent optimizer state. Test supported hardware before selecting a format and record unsupported combinations rather than substituting another dtype without labeling the changed case.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.distributed.fsdp import MixedPrecision

@dataclass
class FSDPPrecisionContract:
    parameter_compute_dtype: str
    reduction_dtype: str
    buffer_dtype: str
    keep_low_precision_gradients: bool
    autocast_policy: str
    distributed_overflow_policy: str
```

```
def build_fsdp1_precision_policy(contract, hardware_support):
    # Validate dtype/scaler/optimizer compatibility for the pinned API.
    ...

def inventory_precision_states(model, optimizer, phase):
    # Observe actual persistent, gathered, gradient, and optimizer dtypes.
    ...

def E10(config):
    # Validate coherent updates before complete memory/communication comparison.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual dtypes, payloads, cast temporaries, overflows/skipped updates, communication scope, peaks, and complete time. Equal sample counts with different numbers of successful optimizer updates are not identical training work. Do not loosen numerical tolerances after seeing a preferred result without justifying the changed contract. Mark unsupported hardware/precision cases explicitly.

Verify successful update counts and any overflow decisions agree across ranks. Compare a short loss and parameter trajectory with the full-precision reference under predeclared tolerances. If clipping is used, use a supported global/sharded norm protocol rather than clipping each shard independently and assuming equivalence. Record state after backward and after update separately. A lower peak obtained through skipped work or incompatible optimizer gradients is not a valid mixed-precision training improvement.

Part 7 - Engineering Interpretation and Philosophy

Explain which representation changed and what numerical/communication trade-off was measured. Recommend only a supported policy whose complete-step benefit and numerical behavior meet the stated experiment contract.

19.40.12 Exercise 11

Exercise Title: Combine FSDP with Activation Checkpointing and Determine Whether Their VRAM Savings Target Independent Memory Components

Part 1 - Exercise Contract and Why It Matters

Combine FSDP state sharding with activation checkpointing and evaluate a factorial comparison: neither, checkpointing alone, FSDP alone, and both. Determine which memory components each technique targets and whether their combined execution introduces extra communication or recomputation.

Part 2 - System and Memory Mental Model

FSDP primarily changes model-state ownership and materialization; checkpointing changes saved activation lifetimes by recomputing operations during backward. These targets differ

but their execution costs interact. Checkpoint boundaries can trigger FSDP hooks or repeated gathers depending on wrapping and reshard policy. Savings are not automatically additive. RNG behavior, dropout, mutation, and checkpoint implementation affect numerical correctness.

Part 3 - Quantitative Prediction Before Execution

Predict persistent state, saved activations, gathered units, recomputation, and collective sequence for each case. Use a bounded non-reentrant checkpoint reference with explicit boundaries. Estimate the complete peak rather than subtracting two independently measured savings from one baseline. Construct a model where activations dominate and another where model state dominates, keeping every comparison's useful update semantics documented.

Part 4 - Experimental Design and Instrumentation

Use public checkpointing with an explicit use_reentrant choice, initially non-reentrant, and a deterministic block model. Freeze sharding, precision, optimizer, batch, and data trace. Validate loss and parameter updates before resource timing. Add RNG-preservation tests separately when dropout is introduced. Record checkpoint and FSDP unit manifests and observe the actual collective sequence during recomputation. Separate diagnostic profiling from complete training timing. Include backward and optimizer update; a forward-only measurement cannot establish checkpointing's training peak.

Draw checkpoint recomputation boundaries alongside FSDP gather units and predict where hooks will execute again. Keep use_reentrant explicit and start with a deterministic no-dropout reference. If adding stochastic operations, validate RNG preservation and resumed update semantics independently. A checkpoint function must not change its computation between original forward and recomputation. Do not retain activation tensors in diagnostics while measuring the memory savings intended from dropping them.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.utils.checkpoint import checkpoint

@dataclass
class FSDPCheckpointingCase:
    fsdp_enabled: bool
    activation_checkpointing_enabled: bool
    checkpoint_boundaries: tuple
    use_reentrant: bool
    rng_policy: str

def apply_activation_checkpoint_plan(model, case, wrap_contract):
    # Preserve supported hook order and deterministic recomputation behavior.
    ...

def compare_memory_components(cases, training_trace):
```

```
    # Validate updates and measure recomputation/collectives with full peaks.
    ...

def E11(config):
    # Test independent targets and interacting execution costs explicitly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report saved-activation scope, state shards, materialization peaks, recomputed work, collective counts, complete latency, and numerical outcomes. A lower activation estimate does not prove a lower total peak if extra gathers overlap differently. Do not claim additive savings or identical communication without trace evidence. Preserve unsupported checkpoint/wrapping combinations as explicit limitations.

Measure the four factorial cases under the same model, batch, optimizer, precision, and successful updates. Report full-step peaks and recomputation communication instead of combining separately observed savings arithmetically. A forward-only trace misses the primary recomputation phase. Include a case where extra work is too costly for the achieved capacity and preserve it in the final recommendation. Verify that the selected wrapper/checkpoint order uses only the supported version-specific integration.

Part 7 - Engineering Interpretation and Philosophy

Explain when the two techniques complement each other and when their extra work is not justified. Choose boundaries from measured component lifetimes rather than a blanket rule to checkpoint every wrapped module.

19.40.13 Exercise 12

Exercise Title: Enable FSDP CPU Offloading and Quantify the Trade-Off Between GPU Memory Savings and Host-Device Transfer Cost

Part 1 - Exercise Contract and Why It Matters

Enable supported FSDP1 parameter/gradient CPU offload and measure GPU relief, host capacity, transfers, optimizer placement, and complete step time. Preserve the validated training semantics and make restrictions part of the experiment support matrix.

Part 2 - System and Memory Mental Model

FSDP1 CPUOffload moves supported parameter and gradient state according to its protocol; optimizer placement and state must be observed after update. CPU memory is finite and shared by all rank processes on the host. Pinned staging, local shards, temporary gathers, and initialization can coexist. The documented FSDP1 accumulation restrictions matter: the primary test uses one forward/backward/update and does not assume arbitrary accumulation outside no_sync is supported with CPU offload.

Part 3 - Quantitative Prediction Before Execution

Predict GPU persistent payload removed, host shards/state added, H2D/D2H traffic, and computation-unit materialization that remains necessary. Estimate transfer time from measured effective bandwidth and actual dtype/bytes. Include CPU optimizer time and pinned-memory scope. Compare GPU-only and offloaded configurations under equal useful updates, and identify a case where host capacity or transfer becomes the limiting resource.

Part 4 - Experimental Design and Instrumentation

Use the pinned FSDP1 CPUOffload interface on the small model first. Build the optimizer after wrapping and inspect actual state devices after a real step. Keep world size, batches, precision, wrap units, and data fixed. Validate numerical updates, then measure complete steps including CPU work and final transfer completion. Record host memory per rank and a host-wide scope without blindly summing overlapping RSS. Bound allocations and test only supported accumulation/offload combinations as separately labeled extensions.

Keep the initial offload experiment to one synchronized backward and optimizer update per step. Do not enable a generic accumulation loop by copying a DDP pattern; validate the documented FSDP1/no_sync restrictions first. Record where optimizer moments and scalar counters actually reside. Measure host capacity across all workers sharing the machine, including construction replicas and pinned staging, while keeping per-process RSS distinct from unique physical memory when sharing cannot be resolved.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.distributed.fsdp import CPUOffload

@dataclass
class FSDPCPUOffloadContract:
    enabled: bool
    optimizer_device_policy: str
    host_budget_bytes: int
    pinned_scope: str
    accumulation_steps: int
    supported_accumulation_protocol: str

def configure_fsdp1_cpu_offload(contract, version_support):
    # Reject unsupported accumulation/optimizer combinations before launch.
    ...

def measure_cpu_offload_step(runtime, measurement_contract):
    # Include CPU optimizer, migration, materialization, and complete updates.
    ...

def E12(config):
```

```
    # Compare honest host/GPU/transfer trade-offs with the resident reference.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report state devices/dtypes, host backing, known pinned payload, device peaks, transfer evidence, CPU update time, complete throughput, and parity. Do not infer host-optimizer state solely from an offload flag. A GPU memory saving that exceeds the host budget is infeasible. Preserve unsupported total pinned-memory counters as unknown instead of equating them with one tensor's payload.

Compare complete work rather than only device attention or backward kernels. CPU optimizer and transfers can dominate an apparently small GPU trace. Record actual copied dtype and payload, and use completed transfer intervals for bandwidth. If total pinned-memory usage is unavailable, report supported known-live payload only. A host-memory infeasible configuration cannot qualify as a solution merely because its GPU allocation decreases. Keep an explicit support matrix for optimizer, precision, and accumulation extensions.

Part 7 - Engineering Interpretation and Philosophy

Explain which capacity moved to the CPU and which GPU minimum remains. Recommend offload only when complete measured work and host limits justify its transfer and CPU-computation cost.

19.40.14 Exercise 13

Exercise Title: Reproduce an FSDP Memory Spike Caused by Excessive Concurrent All-Gathers and Diagnose It with CUDA Memory Statistics

Part 1 - Exercise Contract and Why It Matters

Construct a bounded experiment testing whether aggressive gather issuance or prefetch produces a larger live materialization peak. Compare the FSDP1 rate limiter enabled and disabled under a compatible static execution trace. Reproduce an observed spike or record that it was not reproduced; actual OOM is not required.

Part 2 - System and Memory Mental Model

Outstanding collective calls and simultaneously live full-parameter buffers are different counts. CPU issuance can run ahead of GPU execution, while allocator reuse and dependencies affect residency. FSDP1 limit_all_gathers constrains its supported gather schedule; FSDP2 has a different memory-management model and no interchangeable flag. CUDA counters alone cannot attribute a peak to concurrent gathers without a trace or controlled comparison.

Part 3 - Quantitative Prediction Before Execution

Predict unit sizes and a conservative overlap envelope for rate-limited and aggressive schedules. Add activations, gradients, root state, and workspace. Select dimensions whose tested bound stays below a declared safe budget. Identify evidence that would support the spike hypothesis: more live gathered capacity at a matched phase and a reproducible peak change under the control. Do not predict a guaranteed hardware failure.

Part 4 - Experimental Design and Instrumentation

Use identical weights, units, batches, optimizer, precision, and static module execution. Change only supported limiter/prefetch settings in clean trials. Record per-rank counters, peaks, and a short memory/collective trace. Warm the process group and separate profiling from timing. Stop bounded trials when admission estimates become unsafe. If a rank fails, terminate/restart the distributed trial through a coordinated protocol; do not catch an exception on one rank and let peers continue mismatched collectives.

Predict a safe upper envelope before disabling the limiter in any trial. Use small units and finite steps so the test explores relative peaks without requiring actual OOM. Match execution order and all useful computation between controls. Distinguish a count of queued collective launches from allocations that remain concurrently live. A trace without a spike is an honest non-reproduction, not a reason to change unrelated workload dimensions until a desired claim appears true.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class AllGatherPressureCase:
    limit_all_gathers: bool
    forward_prefetch: bool
    backward_prefetch_identity: str
    wrap_manifest_identity: str
    per_rank_safe_budget_bytes: int

def predict_gather_pressure(case, unit_inventory, phase_model):
    # Separate issued operations, live buffers, and unsupported attribution.
    ...

def run_bounded_gather_pressure(case, distributed_trial):
    # Preserve matched work and coordinated lifecycle with diagnostic evidence.
    ...

def E13(config):
    # Reproduce the peak mechanism or report an honest non-reproduction.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report rank peaks, live-buffer attribution support, collective sequence, settings, time, and reproducibility. A CPU launch gap can be intentional rate limiting and is not proof of GPU idle time. A peak difference caused by changed activations or workload does not establish excessive all-gather concurrency. Preserve unavailable fields and failed/non-reproducing cases.

Collect rank-local phase records and supported allocation history in a separate diagnostic replay. Do not infer owner identity from the difference between reserved and allocated counters alone. Repeat an observed peak change and test whether restoring the limiter reverses the mechanism. If a worker fails, record the phase and stop/restart the trial coherently; independent local retries can create mismatched collectives. Preserve failed and unavailable hardware cases explicitly in the evidence ledger.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest supported mechanism and the next controlled scheduling change. Use a reproducible capacity signal rather than deliberately exhausting the machine or inventing an OOM result.

19.40.15 Exercise 14

Exercise Title: Limit or Schedule Parameter All-Gathers to Reduce Peak VRAM Without Introducing Excessive GPU Idle Time

Part 1 - Exercise Contract and Why It Matters

Limit or schedule FSDP1 gather work to reduce complete per-rank peaks with acceptable exposed communication and idle intervals. Evaluate documented limiter and prefetch controls under a validated execution pattern rather than patching private allocator or stream internals.

Part 2 - System and Memory Mental Model

Less lookahead can reduce simultaneous full parameters while exposing communication before computation. More prefetch can hide latency at the cost of extra live state. FSDP1 backward-prefetch modes and forward prefetch have specific version/execution assumptions; forward prefetch must not be blindly applied to an incompatible dynamic order. A CPU rate-limiter wait and a GPU critical-path wait are different observations.

Part 3 - Quantitative Prediction Before Execution

Draw candidate dependency schedules and predict materialized capacity, gradient overlap, and exposed gather waits. Compare limiter enabled with bounded prefetch choices and a conservative serialized diagnostic control. Define a maximum acceptable peak and complete-step regression before evaluation. Identify when memory saved is too small to justify lost throughput, and when a slower feasible schedule is the only admissible choice.

Part 4 - Experimental Design and Instrumentation

Rebuild clean matched trials with rank-consistent settings and a static small model first. Validate losses and updates, then use short profiles for attribution and unprofiled repeats for complete time. Keep all unit sizes, precision, batch, optimizer, and data fixed. Measure maximum rank peak and slowest completed duration, not just rank zero. Test selected settings on held-out shapes with compatible collective execution. Record unsupported scheduling combinations and coordinated failure/restart behavior.

Use a small schedule grid with documented FSDP1 controls and no private stream surgery. Validate static-order assumptions before enabling forward prefetch. Keep current/next unit sizes, gradient state, and activation demand in the peak model. A limiter can intentionally pause CPU issuance while GPU work continues; only a device timeline and complete timing establish exposed idle cost. Do not interpret host gaps as automatic throughput loss.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
from torch.distributed.fsdp import BackwardPrefetch

@dataclass
class GatherScheduleContract:
    limit_all_gathers: bool
    backward_prefetch_identity: str
    forward_prefetch: bool
    static_order_required: bool
    maximum_rank_peak_bytes: int
    maximum_step_regression: float

def validate_gather_schedule(contract, execution_manifest):
    # Check public API support and identical collective order on every rank.
    ...

def compare_gather_schedules(cases, training_trace):
    # Measure full peaks, exposed waits, and complete useful work.
    ...

def E14(config):
    # Select a feasible evidence-based memory/communication compromise.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report configuration, capacity, observed CPU/GPU waits, collective overlap, complete throughput, numerical checks, and uncertainty. No scheduling option guarantees the GPU never waits. Do not remove essential dependencies to improve a utilization metric. A documented limiter's effect is scoped to its buffers, not a universal bound on activations or all process memory.

Select a schedule on calibration traces, then verify held-out compatible workloads. Report feasibility and timing uncertainty independently. A slightly slower point can be necessary to meet capacity, while a lower peak that saves no useful admission may not justify extra stalls. Keep every rank's setting identical and rebuild at a validated boundary rather than mutating the active collective schedule mid-step. Essential dependencies must remain even when a utilization metric would look better without them.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest tested scheduling change that achieves the required capacity while preserving useful work. Explain when a deliberate wait is a correct resource-control cost rather than an implementation failure.

19.40.16 Exercise 15

Exercise Title: Build Full and Sharded Model Checkpoints and Compare Save-Time RAM, Storage Size, and Reload Behavior

Part 1 - Exercise Contract and Why It Matters

Save full and sharded model/optimizer checkpoints and compare per-rank GPU peaks, host RAM, file payload, save time, and reload correctness. Use a committed training boundary and distinguish logical state size from distribution of that state across files or ranks.

Part 2 - System and Memory Mental Model

A full checkpoint may gather model and optimizer state and concentrate host capacity on a designated rank. Sharded checkpoints distribute state and need metadata plus compatible loading logic. Aggregate useful state does not become world-size times smaller merely because each rank writes a shard. Full-state collection can require participation from every rank even when only rank zero writes the final file. Checkpoint extraction is itself a memory workload.

Part 3 - Quantitative Prediction Before Execution

Predict parameter, optimizer, scalar, and metadata bytes in both formats. Estimate rank-zero full-state RAM and simultaneous model/optimizer extraction capacity. Predict sharded per-rank payload and aggregate file size with padding and metadata separated. Define save completion and consistent restart state: optimizer update, scheduler, per-rank RNG, sampler progress, and logical step. Do not confuse dispatched prefetched batches with committed training progress.

Part 4 - Experimental Design and Instrumentation

Use a small trained model first and freeze the FSDP1 checkpoint adapter. For full state, use supported full-state configuration with CPU offload and rank-zero-only result materialization while all required ranks participate. For sharded state, use version-supported distributed state-dict and DCP save APIs with all ranks. Include optimizer conversion/layout handling through supported APIs. Save at a completed update boundary with declared gradient clearing. Compare synchronous save first; asynchronous staging is a separately budgeted extension. Validate reload and the next matching update.

Capture model, optimizer, scheduler, sampler position, per-rank random state, and successful update count at a coherent boundary. Define gradients as cleared or explicitly included. A checkpoint from different logical steps on different ranks is not a valid restart. For full extraction, distinguish participation from result ownership: all required ranks execute collection even if only rank zero stores the full CPU result. Charge simultaneous extracted model and optimizer state to save-time RAM.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed.checkpoint as dcp
from torch.distributed.checkpoint.state_dict import get_state_dict
```

```
@dataclass
class FSDPCheckpointContract:
    format_identity: str
    api_track: str
    optimizer_included: bool
    cpu_offload_result: bool
    full_result_rank_zero_only: bool
    committed_step: int

def save_full_fsdp1_checkpoint(runtime, destination, contract):
    # Participate collectively and materialize/write only supported full state.
    ...

def save_sharded_checkpoint(runtime, destination, contract):
    # Preserve distributed model/optimizer layout and completion metadata.
    ...

def E15(config):
    # Compare save-time resources, aggregate bytes, and resumed-update parity.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-rank host/device peaks, aggregate logical/file bytes, metadata, completed save duration, and next-update parity. Mark partial checkpoints uncommitted until the declared completion protocol succeeds. Do not call rank-zero-only ordinary saving a valid sharded checkpoint. Record software, format, architecture, wrap, and optimizer compatibility rather than promising arbitrary cross-version reload.

Count filesystem bytes once on a shared destination and separately report logical tensor payload, padding, and metadata. Sharding changes distribution, not necessarily aggregate storage. Use a declared completion marker/protocol and filesystem assumptions before labeling a checkpoint committed. Inject an incomplete-save control only in an isolated test destination and require reload to reject it. Compare the next resumed update, not merely successful key parsing. Asynchronous save is a separate experiment with staging and completion costs explicitly charged.

Part 7 - Engineering Interpretation and Philosophy

Explain which format meets training-restart and deployment needs with available host capacity. Preserve the difference between storage distribution, full-state interchange, and a complete reproducible training checkpoint.

19.40.17 Exercise 16

Exercise Title: Load a Sharded Checkpoint Directly into an FSDP Model Without Creating an Unnecessary Full-Model Copy on Every Rank

Part 1 - Exercise Contract and Why It Matters

Load distributed checkpoint state into a pre-established FSDP layout without creating a full-model copy on every rank. Measure construction, target allocation, read/staging, application, and first resumed-update peaks. Avoid moving an unnecessary full model through CPU or GPU before sharding.

Part 2 - System and Memory Mental Model

The target model and optimizer need supported sharding/layout metadata before DCP can place local state. A checkpoint directory is not simply an ordinary file loaded independently in full by every worker. Meta/deferred construction can avoid eager data allocation, but FSDP1 parameter initialization and unit materialization still have real peaks. A param_init_fn must follow the documented own-module initialization contract instead of recursively reinitializing children or silently breaking tied ownership.

Part 3 - Quantitative Prediction Before Execution

Predict target persistent shards, largest initialization unit, loader staging, optimizer state, and temporary duplicates. Compare an unnecessary full-per-rank load with the supported sharded path on a small feasible control. Calculate host-wide and worst-rank peaks. State whether world-size resharding is supported by the saved metadata and loader; test it only on sizes that fit the destination configuration.

Part 4 - Experimental Design and Instrumentation

Build matching model structure through a validated bounded/meta initialization path, establish FSDP1 ownership, and create the optimizer afterward. Use public distributed state-dict targets and DCP loading, then apply model/optimizer state through the supported adapter. Do not run an uninitialized forward or make an untracked optimizer update just to prepare loading. Restore committed step, RNG, scheduler, and sampler state. Validate missing/incompatible keys explicitly. Compare small-model tensors and the next update with an uninterrupted reference, then measure a larger bounded case.

Audit construction before loading. A full CPU model on every rank can defeat the host-memory objective even when GPU loading is sharded. Use a supported meta/bounded materialization adapter and initialize only the documented own-module state, preserving ties and child ownership. FSDP1 initialization happens before its flatten/shard operation for the relevant unit, so largest-unit peaks still need admission. Do not call a global model-to-CUDA move and later claim that only local shards were ever created.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed.checkpoint as dcp
from torch.distributed.checkpoint.state_dict import get_state_dict, set_state_dict

@dataclass
class ShardedLoadPlan:
    checkpoint_identity: str
```

```
    target_world_size: int
    target_wrap_manifest: tuple
    initialization_policy: str
    optimizer_layout_policy: str
    version_support_identity: str

def build_sharded_load_target(plan, model_spec, optimizer_spec):
    # Establish valid local storage/layout without eager full-model replicas.
    ...

def load_and_apply_sharded_state(runtime, plan):
    # Load compatible distributed targets and restore committed training state.
    ...

def E16(config):
    # Validate restart parity and audit every initialization/loading peak.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report bytes read/staged, target state, host/device peaks, construction phases, supported resharding, and resumed-update errors. A successful local load on one rank is not proof of a consistent distributed restart. Do not promise zero allocation or zero full-unit materialization. If the chosen initialization path still constructs full data on every rank, disclose and correct that path before claiming the exercise objective.

Prepare model and optimizer layout targets through compatible public state-dict APIs and apply state at a supported update boundary. Check canonical parameter identity and optimizer mapping, not only tensor counts. Do not perform an unrecorded training step to initialize lazy state. Test world-size changes on a smaller feasible model and keep global data/update semantics documented. A larger destination-infeasible reload must be rejected or marked untested, not presented as automatic unlimited resharding.

Part 7 - Engineering Interpretation and Philosophy

Explain which unnecessary copies were removed and which layout/initialization costs remain unavoidable. Recommend the smallest compatible restart protocol whose correctness and resource behavior were actually validated.

19.40.18 Exercise 17

Exercise Title: Diagnose Rank-Imbalanced Memory Usage Caused by Uneven Module Wrapping, Shared Parameters, or Rank-Specific Workloads

Part 1 - Exercise Contract and Why It Matters

Diagnose unequal per-rank memory using synchronized phase evidence, wrap ownership, shared parameters, and workload shape. Distinguish legitimate layout/padding differences, rank-specific work, measurement skew, and invalid rank-dependent collective structure.

Part 2 - System and Memory Mental Model

All ranks normally require a compatible model and wrap plan. Uneven unit sizes common to every rank do not by themselves prove large rank imbalance. Rank-dependent wrapping can be an invalid distributed program, not a useful balancing option. Shared parameters need consistent supported ownership. Different sequence lengths, extra validation, rank-zero checkpoint materialization, retained graphs, or different phase timing can explain asymmetric peaks without unequal global model ownership.

Part 3 - Quantitative Prediction Before Execution

Predict shard padding and replicated state per rank, then add rank-local input/activation demand and any rank-zero-only work. Define imbalance from named per-rank scopes and leave empty denominators undefined. Construct a legitimate variable-shape case with identical collective order and a static manifest mismatch that must be rejected before training. Predict which phase each proposed mechanism should affect.

Part 4 - Experimental Design and Instrumentation

Collect rank/device IDs, wrap-manifest hashes, unit sizes, tied groups, input shapes, optimizer state, and observation phase. Compare matched shape controls before variable shapes. Keep conditional execution compatible with collectives; do not make one rank skip a wrapped module for an imbalance test. Record rank-zero diagnostic/checkpoint work separately. Use controlled interventions that remove one suspected cause while preserving updates. Gather scalar evidence at explicit boundaries without retaining all ranks' tensors on rank zero.

Hash and compare rank manifests before profiling a valid workload. Unequal module sizes shared by every rank are not equivalent to rank-dependent wrapping. Use variable input lengths only when every rank still follows compatible module/collective order and step count. Normalize losses to the intended global sample or valid-token objective. Record padding and sampler behavior so a short final batch cannot quietly change both memory and optimization semantics.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RankImbalanceEvidence:
    rank: int
    phase: str
    wrap_manifest_identity: str
    input_shape: tuple
    local_state_bytes: int
    allocated_peak_bytes: int
    extra_work_identity: str

def validate_rank_manifests(rank_manifests):
    # Reject incompatible ownership/collective structure before execution.
```

```
    ...

def diagnose_rank_memory(rows, controlled_replays):
    # Separate layout, workload, instrumentation, and unsupported attribution.
    ...

def E17(config):
    # Reproduce a valid imbalance and test its cause with matched controls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report rank distributions and worst rank, not only averages. A higher reserved value may reflect allocator history rather than more live shards. Shared parameter names are not independent bytes. Preserve uncertainty when observations were taken at different execution phases. A manifest mismatch requires repair before meaningful performance conclusions, not an attempt to tolerate mismatched collectives.

Control rank-zero validation, checkpoint extraction, tensor logging, and extra buffers separately. A retained autograd graph can create rank-specific growth even with identical shards. Compare matched phases and allocator history before attributing differences to persistent ownership. Shared/tied names must be deduplicated and their supported wrapper ownership verified. An invalid manifest should fail preflight; it must not be used as a live imbalance experiment that risks stranding other ranks in collectives.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest supported cause and a coordinated corrective action. Use attribution evidence rather than assuming all per-rank memory must match exactly or all differences come from wrapping.

19.40.19 Exercise 18

Exercise Title: Stress-Test FSDP with a Model That Cannot Fit Fully on Any Single GPU and Measure Scaling Across Increasing GPU Counts

Part 1 - Exercise Contract and Why It Matters

Test a bounded model whose declared fully resident training configuration cannot fit on one available GPU, then evaluate feasible FSDP configurations across available GPU counts. Separate actual distributed execution, analytical infeasibility, and unsupported hardware. One multi-GPU host is sufficient.

Part 2 - System and Memory Mental Model

Specify what cannot fit: parameters alone, complete persistent training state, or complete unsharded training peak. These are different claims. FSDP still needs each computation unit and workspace locally. A model with parameters too large for one GPU may also exceed sharded optimizer budgets at small world size; sharding alone is not guaranteed to make it feasible. A huge meta-only structure demonstrates construction, not an executed large-model training result.

Part 3 - Quantitative Prediction Before Execution

Calculate persistent shards, largest gather unit, activations, optimizer state, initialization, and checkpoint peaks for each candidate rank count. Use actual shard-group size and precision. Define strong scaling with fixed global work separately from weak scaling with fixed local work. Predict infeasible candidates before launch. Include a model whose largest indivisible unit cannot fit even when average shards would, and explain why more ranks alone do not solve that constraint.

Part 4 - Experimental Design and Instrumentation

Validate small-model numerical behavior first. Select dimensions and local batches from a safe capacity model, then run complete updates with warm-up and repeated bounded trials. Use only available device counts; mark others as estimated or untested. Avoid a full-model GPU construction before nested sharding. Measure host initialization and optional checkpoint/reload capacity. If offload or precision changes are needed for feasibility, label them as separate configurations rather than attributing all gains to world size. Coordinate failure/restart of the worker group.

State precisely whether the nonfitting claim concerns parameters alone, all persistent training state, or the complete unsharded execution. Build a phase-specific feasibility table before launch. More ranks do not reduce the full computation unit that one GPU must gather under this design. Use only available device counts and mark other points analytical. A one-rank FSDP configuration may not represent the intended multi-rank sharding behavior, so label its actual supported strategy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class FSDPCapacityTrial:
    model_identity: str
    nonfitting_claim_scope: str
    world_size: int
    scaling_mode: str
    global_batch: int
    precision_identity: str
    offload_identity: str

def admit_capacity_trial(trial, predicted_phases, device_budgets):
    # Reject known-infeasible construction, units, or complete training state.
    ...

def run_capacity_scaling(trials, available_devices, training_contract):
    # Record actual complete work separately from estimates and unsupported N.
    ...
```

```
def E18(config):
    # Test feasible larger models without uncontrolled single-GPU OOM probing.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report claim scope, dimensions, rank counts, per-rank/host peaks, useful samples or tokens, complete time, update validity, and failure phase. A two-GPU run does not establish four- or eight-GPU scaling. A skipped infeasible single-GPU run has no measured throughput. Record the largest tested feasible case as a bound within the explored configuration set, not a proof of globally maximum model capacity.

For strong scaling, hold global useful work fixed and document local-batch changes; for weak scaling, hold local work fixed and acknowledge global batch growth. Preserve optimizer semantics and successful updates within each comparison. A logically huge meta model is a construction result until real training executes. Include initialization, first optimizer state, and checkpoint feasibility. Report the largest tested admissible model/configuration as a measured lower bound on explored capacity, not an exhaustive maximum over every possible precision, offload, or wrap policy.

Part 7 - Engineering Interpretation and Philosophy

Explain which constraints sharding relieved and which remain at unit, activation, host, or link level. Recommend the next bounded capacity experiment supported by the available hardware instead of extrapolating unmeasured scaling.

19.40.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch FSDP Training Runtime That Maximizes Model Capacity While Balancing Per-GPU VRAM, Communication, CPU Memory, and Throughput

Part 1 - Exercise Contract and Why It Matters

Integrate a version-pinned FSDP1 training runtime with deterministic wrapping, precision/offload support, gather scheduling, per-rank monitoring, and distributed checkpoint/restart. Benchmark quality-preserving useful updates while maximizing tested feasible model capacity under GPU, host, and throughput constraints. Substantive implementation remains learner work.

Part 2 - System and Memory Mental Model

One rank-consistent configuration governs model ownership, collectives, optimizer references, precision, checkpoint layout, and data/loss semantics. Persistent sharding does not remove full-unit materialization or activation peaks. Public FSDP1 controls must not be mixed with FSDP2 semantics. Changing wrap/strategy or optimizer layout during live training requires a separately validated coordinated rebuild/restart protocol, not arbitrary local attribute mutation. Distributed errors can strand peers if lifecycle handling is not coordinated.

Part 3 - Quantitative Prediction Before Execution

Predict construction, persistent state, gathered units, gradients, activations, optimizer workspace, CPU offload, communication, and checkpoint peaks for candidate configurations. Define quality/update parity, per-rank budgets, host budget, complete throughput, and failure criteria before selection. Compare DDP, conservative FSDP, and a few tested improvements under equal supported work. Keep strong/weak scaling and changed precision/offload configurations separately identified.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and validate small deterministic updates before capacity tuning. Use separate calibration and held-out shape traces. Record hardware topology, PyTorch/CUDA/NCCL versions, API track, groups, wrap manifest, use_orig_params, precision fields, optimizer flags, data/sampler state, seeds, and committed-step IDs. Measure full training and checkpoint lifecycle, including first-update and initialization costs. Run ablations for wrapping, precision, checkpointing, offload, and scheduling without weakening correctness. Select configuration before launch or through a validated coordinated restart.

Publish supported API/version, optimizer, precision, accumulation, checkpoint, wrap, and topology combinations before benchmarking. Start from small correct updates and admission estimates. Use rank-consistent configuration selection before launch, with any change requiring a validated coordinated restart. Keep complete-phase budgets and worst-rank peaks as hard feasibility gates. A throughput objective must not hide dropped samples, skipped updates, incomplete checkpoints, or rank failures.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class FSDPTrainingRuntimeContract:
    api_track: str
    model_identity: str
    wrap_manifest_identity: str
    per_rank_budget_bytes: int
    host_budget_bytes: int
    precision_identity: str
    optimizer_identity: str
    checkpoint_protocol: str
    supported_features: tuple

class FSDPTrainingRuntime:
    def __init__(self, contract):
        # Establish rank-consistent topology, model, optimizer, and monitoring.
        ...

    def train_step(self, local_batch):
        # Preserve matching collectives and complete useful update semantics.
```

```
        ...

    def checkpoint(self, destination, committed_state):
        # Save a compatible complete distributed restart boundary.
        ...

    def restore(self, checkpoint_identity):
        # Rebuild valid target layout and verify coherent resumed progress.
        ...

    def audit(self):
        # Reconcile phase-specific state, peak scopes, and rank invariants.
        ...

    def shutdown(self, outcome):
        # Coordinate owned work/process-group lifecycle and report failures.
        ...

def E19(config):
    # Validate runtime contracts before held-out capacity/throughput evaluation.
    ...
    # Export evidence, limitations, counterexamples, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct updates, compatible collective order, supported state/precision handling, bounded resource phases, and validated checkpoint restart. Report all rank peaks, host scope, communication evidence, useful samples/tokens, completed/failed updates, timing distributions, checkpoint cost, and tested capacity. Keep prediction, observation, and interpretation distinct. An incomplete scaffold supplies no measured multi-GPU result.

Evaluate an unfavorable FSDP case, a gather-limited case, host-limited offload, a checkpoint/reload boundary, and an unavailable GPU-count point. Report useful samples/tokens, complete wall time, rank spread, communication evidence, actual resource scopes, and numerical outcomes. An operational failure needs a whole-group lifecycle response, not a local catch-and-continue loop. Recommend the smallest validated configuration and name the next bounded experiment needed before adding FSDP2 migration, runtime rewrapping, or untested scaling claims.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest validated configuration meeting the real constraint, including DDP when it wins. Explain the capacity gained and communication, recomputation, host memory, or latency paid. Separate measured features from proposed FSDP2 migration, additional GPU counts, or unsupported runtime adaptation.

19.41 DMM39

Chapter Title: ZeRO-Style Memory Partitioning

Specialization: Dynamic Memory Management and CUDA Systems

19.41.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Redundant Model States in Data Parallel Training and How ZeRO Eliminates Replication

Part 1 - Exercise Contract and Why It Matters

Model redundant training state and the successive ownership changes called ZeRO stages. Deliver a phase diagram for parameters, reduced gradients, Adam state, communication, and temporary computation buffers. Build an explicit educational PyTorch engine rather than claim a complete DeepSpeed reimplementation or silently delegate the exercise to a high-level trainer.

Part 2 - System and Memory Mental Model

Stage 0 replicates model state. Stage 1 partitions optimizer ownership; Stage 2 also partitions reduced gradients; Stage 3 partitions persistent parameters and materializes computation units when needed. These labels do not specify every peak, bucket, or synchronization detail. The primary track uses float32, a static functional dense model, all trainable parameters used each step, one process per CUDA device, and one multi-GPU host. Arbitrary modules, mutation, higher-order gradients, ties, and conditional execution need separately validated support.

Part 3 - Quantitative Prediction Before Execution

Let P, G, and O denote full parameter, reduced-gradient, and optimizer payload bytes under declared dtypes, and let N be partition-group size. Predict ideal persistent payloads:

$$M_0 = P + G + O, \quad M_1 = P + G + O/N, \quad M_2 = P + (G + O)/N, \quad M_3 = (P + G + O)/N.$$

Add padding, replicas, activations, buckets, gathered units, and workspaces. These are ownership estimates, not exact peak-VRAM formulas.

Part 4 - Experimental Design and Instrumentation

Define one canonical logical parameter/offset map on every rank. Preserve parameter IDs, valid spans, padding, dtype, and optimizer step semantics. Validate small single-rank Adam behavior, then a distributed replicated reference before partitioning. Record local/global rank, device binding, group membership, model/layout identity, versions, topology, seeds, data/loss normalization, and initial state. Use one update per step initially. Keep custom collectives separate from DDP synchronization so gradients are never reduced twice.

Create a state-ownership table with rows for logical parameters, reduced gradients, first moments, second moments, step counters, gathered copies, and communication workspaces. Give each row an owner, replication factor, creation phase, last reader, and release condition. In a two-rank paper trace, follow one scalar through local gradient production, averaging, owner update, and publication to both ranks. Show the corresponding change for each stage. Use this trace to distinguish eliminating redundant storage from discarding necessary information. Include non-model allocations in a separate context row so the model-state diagram does not masquerade as a complete device inventory. Identify one invariant that remains identical at every stage: the intended global optimizer update.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class ZeROStyleContract:
    stage: int
    partition_group_size: int
    model_layout_identity: str
    parameter_dtype: str
    gradient_dtype: str
    optimizer_identity: str
    supported_graph_identity: str

def predict_zero_ownership(contract, state_inventory, phase_plan):
    # Separate ideal persistent state and complete live execution capacity.
    ...

def E00(config):
    # Freeze the restricted engine semantics and validate canonical rank layout.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation distinct. Require correct useful updates, compatible collective order, complete phase accounting, and honest execution support. A smaller post-step state is not proof of a smaller backward peak. Export bounded CPU scalar evidence without retaining full GPU state. Unrun multi-GPU results remain unmeasured rather than being filled with published benchmark numbers.

Part 7 - Engineering Interpretation and Philosophy

Explain how partitioning removes redundancy without eliminating each rank's need for correct computation inputs and synchronized updates. The strongest outcome is an auditable restricted engine whose limits are clear before adding persistence, prefetch, or offload.

19.41.2 Exercise 01

Exercise Title: Calculate Per-GPU Memory for Parameters, Gradients, and Adam Optimizer States Before Applying Any ZeRO Partitioning

Part 1 - Exercise Contract and Why It Matters

Calculate replicated per-rank parameter, gradient, and Adam-state memory before partitioning. Separate actual float32 storage from a conventional mixed-precision model with master parameters. Validate the calculation after optimizer state exists and record excluded workspace and metadata.

Part 2 - System and Memory Mental Model

Adam tracks first and second moments plus step-related state. Its dtypes, lazy allocation, epsilon, bias correction, weight decay, and implementation flags matter. The primary all-float32 model does not need a second float32 master copy. A mixed-precision implementation may retain one, which belongs in the optimizer/authority ledger exactly once. Gradient buckets, parameter views, tied storage, and foreach/fused temporaries must not be double-counted.

Part 3 - Quantitative Prediction Before Execution

For n all-trainable elements, derive payload from each component's element width. Compare float32 parameters/gradients/two float32 moments with a separately declared low-precision parameter/gradient plus float32 master/moment model. Explain why two configurations can have the same nominal bytes for different reasons. Add step counters and padding separately. Calculate memory before and after the first optimizer update.

Part 4 - Experimental Design and Instrumentation

Use small tensors with a standard PyTorch Adam reference and fixed supported flags; begin without weight decay or AMSGrad. Inspect actual moment and counter state after a complete step. Deduplicate storage and count trainable, frozen, or unused entries only under declared semantics. Include zero versus absent gradient behavior as a separate support test. Record parameter shapes, dtypes, loss reduction, optimizer settings, gradient-clearing policy, and measurement boundaries. Compare payload accounting with allocated/reserved CUDA observations under their separate scopes.

Use two explicit optimizer inventories rather than one customary bytes-per- parameter constant. The primary inventory has FP32 parameters and gradients with FP32 first and second moments. The optional mixed-precision inventory must declare whether it actually stores an FP32 master copy, its gradient dtype, and which process owns each representation. List integer or floating step counters according to observed implementation, including per-parameter rather than assumed per-element costs. Compare numerical element counts with unique backing storage to avoid double-counting views. If an optimizer implementation retains additional tensor lists or update workspaces, report them as measured implementation overhead. Never subtract an imaginary master copy from a run that never allocated one.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AdamStateSpec:
    parameter_element_bytes: int
    gradient_element_bytes: int
    moment_element_bytes: int
    master_element_bytes: int
    master_copy_present: bool
    optimizer_flags: tuple

def predict_replicated_adam_bytes(parameter_inventory, spec):
```

```
    # Count each representation once and leave workspace outside payload.
    ...

def inspect_initialized_adam(model, optimizer, phase):
    # Observe lazy state, actual dtypes, counters, and unique backing.
    ...

def E01(config):
    # Reconcile declared formulas with initialized optimizer storage.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report element counts, actual tensor fields, dtype widths, master-copy policy, scalar state, useful payload, workspace, and backend peaks. An empty optimizer state before its first update is not evidence of zero steady-state Adam cost. Do not apply a familiar bytes-per-parameter rule without its dtype and master-copy assumptions. Preserve unknown overhead rather than labeling it fragmentation.

Part 7 - Engineering Interpretation and Philosophy

Explain which bytes partitioning can distribute and which belong to data, activations, communication, or implementation overhead. Use the inventory as the shared basis for later stage comparisons.

19.41.3 Exercise 02

Exercise Title: Build a Standard PyTorch Data-Parallel Baseline and Measure Replicated Model-State Memory Across All GPU Ranks

Part 1 - Exercise Contract and Why It Matters

Build a standard PyTorch distributed data-parallel training baseline and measure replicated state across all ranks. Establish numerical update, global data, and complete-step timing references before introducing custom ownership or synchronization.

Part 2 - System and Memory Mental Model

DDP replicates parameters and synchronizes gradients; an ordinary local Adam keeps its state on every rank. DDP does not distribute input samples automatically. Local loss normalization and rank reduction together define the global update. Optimizer state can appear lazily, gradient buckets can alias gradients, and first-step initialization can change memory. The custom engine later replaces the gradient communication path rather than stacking another reduction on top of DDP.

Part 3 - Quantitative Prediction Before Execution

Predict replicated parameter, gradient, moment, buffer, and bucket payload for each rank. Define global batch from local batch, world size, and accumulation, with accumulation initially one. Predict initialization and first-update peaks separately from warmed execution. Define

global samples or valid tokens per completed elapsed second and use a named worst-rank timing/peak aggregation.

Part 4 - Experimental Design and Instrumentation

Bind devices using local rank, initialize the supported process group, construct identical model values, and use explicit distributed sampling. Run fixed seeded batches with matching loss reduction and optimizer flags. Compare a small update with a single-process global-batch reference. Capture state before/after forward, backward, update, and clearing in a diagnostic replay. Use separate minimally instrumented timing and scalar logs, avoiding rank-zero collection of live tensors from every worker.

Keep the primary dataset small enough to make global sample identities auditable. Record the rank-local sample IDs and verify that their concatenation matches the reference global batch at each update. Avoid batch-normalization state and stochastic layers in this first oracle. A reported mean of local loss scalars is comparable only when the weighting and sample counts agree. Document whether a final partial batch is dropped or weighted. Measure DDP communication buffers separately when observable and include their capacity in device peaks. Confirm that all parameters have received gradients before sampling initialized Adam state. Use an additional seed to check repeatability without changing the primary comparison's initial-state identifier.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist
from torch.nn.parallel import DistributedDataParallel as DDP

@dataclass
class ReplicatedRankEvidence:
    rank: int
    phase: str
    state_bytes: object
    allocated_peak_bytes: int
    reserved_peak_bytes: int
    completed_samples: int

def build_replicated_reference(model_spec, distributed_context):
    # Establish correct data, optimizer, and DDP ownership/synchronization.
    ...

def measure_replicated_steps(runtime, trace, measurement_contract):
    # Validate complete updates and preserve rank-specific resource scopes.
    ...
```

```
def E02(config):
    # Establish the replicated numerical and resource baseline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report rank distributions, initialized state, unique backing, complete peaks, successful update count, sample coverage, and latency variability. Do not sum aliased gradient buckets twice or infer total device usage solely from tensor inventories. An unsynchronized host interval is not completed training time. Missing devices or unsupported collectives must remain explicit execution limits.

Part 7 - Engineering Interpretation and Philosophy

Identify the replicated state targeted by Stage 1 and the baseline costs that will remain. Preserve this reference for small-model equivalence even when later larger models become infeasible without partitioning.

19.41.4 Exercise 03

Exercise Title: Implement a Simplified ZeRO Stage 1 Optimizer-State Partitioning Scheme Across Multiple PyTorch Processes

Part 1 - Exercise Contract and Why It Matters

Implement a restricted Stage 1 scheme that partitions Adam state while keeping model parameters and reduced gradients replicated. Use a canonical flattened layout and explicit owner-span updates, then synchronize updated parameters so every rank starts the next step identically.

Part 2 - System and Memory Mental Model

Each valid element has one optimizer owner with local moments and correct logical-parameter step state. Owner updates operate on its span of the replicated parameter backing; they need not create an uncounted master replica in the all-float32 primary model. The gradient is averaged exactly once before owner updates. Updated spans must reach every rank afterward. A simple owner-broadcast protocol can use more communication than optimized production ZeRO and must be measured as implemented.

Part 3 - Quantitative Prediction Before Execution

Predict valid/padded elements and moment bytes per owner, replicated P/G, step metadata, and synchronization payload. Hand-simulate two ranks updating different spans over several Adam steps with identical hyperparameters. Include a logical parameter crossing a partition boundary and define its step-counter consistency. Estimate full-gradient reduction plus owner-parameter broadcast cost without borrowing an optimized algorithm's traffic formula.

Part 4 - Experimental Design and Instrumentation

First validate partitioned scalar Adam arithmetic against torch.optim.Adam on a small deterministic model. Freeze rounding/epsilon/decay conventions and start with all logical parameters used each update. Implement custom communication without DDP's reducer: aggregate gradients under the declared averaging rule, update only valid owned spans, then broadcast

canonical updated spans in the same order on all ranks. Exclude padding from optimization. Use one host process per available CUDA device and verify layout hashes before collective work.

For a logical parameter cut by an ownership boundary, attach both owned spans to the same logical optimizer-step record. Their elementwise moment updates must use the same hyperparameters and bias-correction step. A rank with no valid elements still participates in required communication but need not create an invalid empty optimizer instance. Pad only the communication representation; exclude padding from state initialization, norms, and updates. Build a tiny reference with two differently sized parameters so a counter accidentally advanced per span becomes visible after several steps. Run parameter publication in a fixed owner order on every rank, including owners whose valid ranges are empty, according to the chosen common protocol.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class OptimizerOwnerSpan:
    owner_rank: int
    flat_start: int
    valid_elements: int
    padded_elements: int
    logical_parameter_intersections: tuple

class PartitionedAdam:
    def initialize_owned_state(self, layout, optimizer_contract):
        # Allocate only owned moments and required step/master state.
        ...

    def update_owned_spans(self, replicated_parameters, averaged_gradients):
        # Match Adam semantics and leave nonowned/padded elements untouched.
        ...

def synchronize_updated_parameters(layout, parameters, group):
    # Publish every owner update through a canonical matching collective order.
    ...

def E03(config):
    # Validate several updates against the replicated Adam reference.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require matching global updated parameters, moments on their owners, and loss trajectory within a predeclared tolerance. Record communication, source lifetimes, padding, local state bytes, and complete peaks. A rank updating only its own span without synchronizing replicas has not implemented correct Stage 1 training. Reject unsupported absent-gradient or shared-parameter semantics rather than silently approximating them.

Part 7 - Engineering Interpretation and Philosophy

Explain what was partitioned and the extra synchronization chosen for this transparent implementation. Keep production ZeRO efficiency claims separate from the educational engine's actual protocol and supported graph.

19.41.5 Exercise 04

Exercise Title: Verify That Every Rank Stores Only Its Assigned Adam State Partition While Model Parameters and Gradients Remain Replicated

Part 1 - Exercise Contract and Why It Matters

Verify optimizer-state ownership independently of the Stage 1 counters. Confirm that parameters and reduced gradients remain replicated at their declared phase, while moment/master state exists only for each rank's assigned valid span. Validate ownership and numerical correctness together.

Part 2 - System and Memory Mental Model

Logical parameter names and physical span ownership are different views. A parameter can intersect multiple owner spans; its step semantics must still match the reference. Padding may occupy storage but is not a trainable element. Debug references, conversion copies, or full optimizer reconstruction can accidentally retain replicated state. A memory drop alone cannot prove unique ownership, and matching loss alone cannot prove memory was partitioned.

Part 3 - Quantitative Prediction Before Execution

From the canonical map, calculate each rank's valid intersections, moment tensors, optional masters, and counters. Predict which components must be equal across replicas after synchronization. Construct a deliberately duplicated moment allocation and a missing owner interval as negative controls in a bounded metadata/state test. Define a unique-coverage invariant over all valid logical elements.

Part 4 - Experimental Design and Instrumentation

Enumerate actual state tensors after multiple updates and compare them with a recomputed interval-cover oracle. Inspect full parameter/gradient parity only at a small deliberate validation boundary, then release copies before memory timing. Test empty owner spans, nondivisible sizes, boundary-crossing parameters, stale layout IDs, and padding. Verify all ranks use the same map and successful update count. Keep the primary all-used-gradient contract explicit so zero and absent gradients are not accidentally conflated.

Audit absence of hidden replicas by traversing actual state tensor storages, not by counting dictionary keys. For each owned interval, verify coverage, nonoverlap, dtype, device, and logical parameter identity. Keep a compact CPU manifest for cross-rank comparison rather than collecting all moments on every GPU. As a controlled failure, intentionally retain a full moment copy in a separate diagnostic replay and show that the audit catches its bytes even

if the optimizer never uses it. Check parameter replicas after publication, because owner-only moments with unsynchronized parameter updates would pass a narrow state audit while implementing incorrect data parallel training. Preserve both checks as independent acceptance conditions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class Stage1OwnershipEvidence:
    rank: int
    layout_identity: str
    valid_owned_intervals: tuple
    moment_storage_bytes: int
    master_storage_bytes: int
    logical_step_state: tuple

def audit_stage1_ownership(layout, actual_state_rows):
    # Recompute exact coverage and reject gaps, duplicates, and invalid padding.
    ...

def verify_replicated_values(parameters, gradients, validation_contract):
    # Check supported post-sync parity without retaining diagnostic full copies.
    ...

def E04(config):
    # Validate ownership, replica agreement, and negative controls independently.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual state allocations, interval coverage, dtype, padding, replica differences, and retained debug storage. A checksum can be a useful screen but needs an exact small-tensor comparison to establish the oracle. Do not infer private ownership solely from an optimizer class name or rank-local state dictionary size. Preserve unsupported introspection fields as unknown.

Part 7 - Engineering Interpretation and Philosophy

Explain the evidence proving that redundancy was removed without losing required updates. Use the same ownership oracle when gradients and parameters become partitioned in later stages.

19.41.6 Exercise 05

Exercise Title: Measure ZeRO Stage 1 Per-Rank VRAM Savings and Compare Them Against the Theoretical Optimizer-State Partitioning Formula

Part 1 - Exercise Contract and Why It Matters

Measure the memory saved by optimizer-state partitioning and reconcile it with the ownership audit. Deliver both a steady-state comparison and the maximum allocated memory of a complete training step. A smaller optimizer state dictionary alone is insufficient evidence of a lower training peak.

Part 2 - System and Memory Mental Model

Use the same parameter and gradient dtypes in both runs. Stage 1 retains replicated parameters and gradients while splitting the selected optimizer state. Temporary update buffers, packed communication payloads, allocator rounding, and the distribution of valid elements can change the observed saving. The simple formula predicts a persistent component, not the entire process. Adam initializes state lazily, so compare after every supported parameter has received an update. Retaining a full reference optimizer in the measured process would erase the intended saving; use a separate correctness replay instead.

Part 3 - Quantitative Prediction Before Execution

With byte quantities from E01, predict

$$M_0 = P + G + O, \qquad M_1 = P + G + O/N, \qquad \Delta M = O(1 - 1/N).$$

Evaluate this for one million FP32 elements and two ranks, counting the two FP32 moments and listing counters separately. Then replace equal division by each rank's actual assigned valid state. Predict why the most heavily loaded rank can determine feasibility even when the mean agrees with the ideal.

Part 4 - Experimental Design and Instrumentation

Warm both implementations from identical initial values and identical data. Record allocation after initialization, after backward, after update, and after parameter synchronization. Reset peaks only at the declared full-step boundary. Use repeated warmed steps and independent process launches. Synchronize at measurement boundaries, not after every layer. Record model dimensions, seed, Adam options, device identity, backend, versions, topology, world size, and whether timing includes input transfer. Gather CPU scalar summaries after the region. Preserve every rank's peak rather than averaging away the worst rank.

Add a phase in which gradients are cleared using the same policy in both runs, and state whether clearing releases storage or merely zeroes retained buffers. Otherwise the sampled boundary can manufacture a difference unrelated to optimizer partitioning. Use a CPU-side category ledger and deduplicate shared storage before summing. Compare the sum with allocator observations without assuming equality: the allocator also serves temporary and rounded requests. Record the discrepancy's sign and phase before proposing a cause. Include world size one as a sanity check where ownership partitioning alone predicts no redundancy saving. For larger world sizes, use the actual rank assignment rather than scaling one observed rank mechanically.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def predict_stage1_bytes(inventory, owner_map, world_size):
    ...

def sample_training_phases(engine, batch, measurement):
    ...

def E05(config):
    # Separate correctness replay from the warmed memory comparison.
    ...
    # Reconcile per-rank persistent state and complete-step peaks.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted persistent bytes, observed live storage by category, peak allocated bytes, reserved bytes, and discrepancy for each rank. Distinguish rounding and temporary allocations from unexplained residuals. A reserved-memory plateau can persist after tensors are released; do not call it a replicated optimizer without inspecting storage ownership. Include an uninitialized-Adam negative control to expose a misleading comparison. If Stage 1 has a larger peak because of the educational synchronization protocol, report that outcome and its phase. Do not manufacture an expected improvement.

Part 7 - Engineering Interpretation and Philosophy

Explain which portion of the measured saving follows from ownership and which portion depends on implementation details. Choose a diagnostic that could invalidate the formula's assumptions before using it for capacity planning.

19.41.7 Exercise 06

Exercise Title: Extend the Runtime to ZeRO Stage 2 by Partitioning Reduced Gradients Alongside Optimizer States

Part 1 - Exercise Contract and Why It Matters

Extend the educational runtime so each rank retains only its owned reduced gradient shard along with its optimizer state. Keep parameters replicated. Deliver a correct Stage 2 update and a precise statement of whether the implementation reduces only persistent gradients or also their production peak.

Part 2 - System and Memory Mental Model

A gradient is first produced by local differentiation and then combined across ranks. Its final owner does not imply that only that owner produced it. An initial reference implementation may form a full gradient vector on every rank before reduce-scatter. This can demonstrate sharded retention, but its backward peak still includes the full vector. A bounded production path needs an explicit bucket lifecycle or validated custom differentiation boundary. Returning

None from an ordinary tensor gradient hook does not suppress normal gradient accumulation. Do not label an unverified hook as a memory-saving reducer.

Part 3 - Quantitative Prediction Before Execution

For equal ownership, predict persistent model state

$$M_2 = P + (G + O)/N, \qquad M_1 - M_2 = G(1 - 1/N).$$

Draw separate timelines for full-gradient production followed by partitioning and for bounded bucket production. Add the largest live production bucket, its communication input, its output shard, and overlapping buffers to the appropriate phase. Explain why a persistent saving need not reduce the maximum allocated bytes of the first timeline.

Part 4 - Experimental Design and Instrumentation

Start with one tiny functional network, FP32, fixed execution order, and all parameters used. Obtain local gradients, pack them in the canonical order, combine them exactly once, update owner spans, and synchronize changed parameter spans before the next forward. Compare against the same global-batch Adam reference for several updates. Only after correctness passes, implement a bounded producer with a documented ownership transfer at each boundary. Prevent rank-local readiness from changing collective order. Record whether full leaf gradients, packing copies, or stale aliases survive in each implementation.

Treat the gradient producer as a separately named component with its own correctness and memory contract. The simple full-gradient producer is allowed as a reference but must retain that label in tables and plots. A bounded producer must demonstrate that no full gradient replica survives outside its declared window, including leaf gradients, packing aliases, and temporary outputs. Validate the producer on a two-unit graph before applying it to the whole network. If the implementation cannot meet this condition, preserve the correct Stage 2 retention result and state the missing peak-memory property. Do not blur a future optimization plan with a capability already demonstrated by the completed learner implementation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

def produce_gradient_buckets(graph, batch, layout, schedule):
    # Declare full-gradient reference or validated bounded producer.
    ...

def stage2_step(engine, batch, evidence):
    # Reduce each canonical bucket once and retain only owned results.
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare reconstructed gradients and parameters with the reference outside the production timing region. Audit both post-reduction bytes and backward peak bytes. Reject double averaging, omitted parameter spans, and simultaneous DDP reduction plus custom reduction. Use explicit unsupported status for a producer that cannot safely bound its full gradients. Inspect gradients after a second step to catch accidental accumulation from retained full replicas. An unchanged peak is a useful result when activations or full-gradient production dominate.

Part 7 - Engineering Interpretation and Philosophy

Explain the difference between choosing the destination of a result and controlling the memory needed to produce it. State the additional engineering work required before the runtime may claim bounded gradient memory.

19.41.8 Exercise 07

Exercise Title: Implement Reduce-Scatter for Gradient Partitioning and Verify That Each Rank Retains Only the Gradient Shard It Owns

Part 1 - Exercise Contract and Why It Matters

Implement and validate reduce-scatter for the canonical gradient layout. Each rank must receive the correct reduced slice, with padding excluded from logical updates. Deliver an independently checked collective protocol before using the operation as an optimization.

Part 2 - System and Memory Mental Model

For the equal-size tensor interface, pack rank-ordered output chunks into one contiguous input. Every participating rank supplies a matching layout and compatible dtype, count, device, group, and collective sequence. The output contains one reduced chunk, not a full reduced vector. Uneven logical ownership can be represented with explicit padding and a valid-element mask. Do not assume that changing a rank's local length changes the collective contract. Keep input and output storage alive until the selected completion protocol permits reuse; launch completion and downstream CUDA consumption require correct stream dependencies.

Part 3 - Quantitative Prediction Before Execution

Let a padded gradient vector contain NQ elements. Predict an output of Q elements per rank and account separately for the full input buffer. For rank r, the average-gradient oracle is

$$y_r = \frac{1}{N} \sum_{j=0}^{N-1} x_j[rQ : (r+1)Q].$$

Use rank-distinct integer-like FP32 inputs to calculate every output by hand. Then identify how unequal local sample counts would change the loss weighting; world-size division alone is insufficient for arbitrary uneven batches.

Part 4 - Experimental Design and Instrumentation

Use equal local batch sizes in the primary experiment. Compare the result with an all-reduce-and-slice oracle in a separate replay. Cover one rank, two available ranks, a nondivisible logical length, a zero-valid owner, and a logical parameter crossing a chunk boundary. Preserve identical collective order on all ranks. Test synchronous execution first, then an asynchronous

variant with explicit completion and consumer dependencies. Capture launch, completion, and first use as distinct trace events. Never intentionally hang a real run to test inconsistent counts; validate contracts before launch.

Include a hand-computed case with different contributions from every rank so a scatter without reduction cannot accidentally pass. Use another case with identical contributions to expose double division by world size. Check a logical parameter that spans two output chunks and verify each slice against its expected global index range. Padding values should begin from a known neutral contribution for SUM, but no padded output may reach Adam. Inspect storage extents for asynchronous input and output reuse. The collective validator should compare metadata before launch using a compatible control path and terminate the group coherently on rejection. Do not place an extra debug collective into only one rank's execution path.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

def pack_padded_gradient(local_gradient, layout):
    ...

def reduce_scatter_owned(packed, layout, group, completion):
    # SUM, normalization, output ownership, and waits remain learner work.
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report maximum and relative error on valid elements, padding behavior, normalization convention, and the exact output interval for every rank. Check that input aliases are not overwritten before completion. Distinguish algorithmic tensor payload from measured link traffic: backend algorithms can move data differently. Preserve the oracle's extra storage outside the memory comparison. Include a deliberate omitted-normalization case and show the resulting update discrepancy without presenting it as a valid implementation.

Part 7 - Engineering Interpretation and Philosophy

Explain why a collective is also an agreement about shape, ordering, ownership, and time. Identify the smallest metadata mismatch your validator catches before it could become a distributed failure.

19.41.9 Exercise 08

Exercise Title: Compare ZeRO Stage 1 and Stage 2 by Peak VRAM, Communication Volume, Gradient Memory, and Training Throughput

Part 1 - Exercise Contract and Why It Matters

Compare validated Stage 1 and Stage 2 implementations with identical training semantics. Measure persistent gradients, complete-step memory, communication, and throughput. Keep the full-gradient Stage 2 reference and any validated bounded producer as separate named implementations.

Part 2 - System and Memory Mental Model

Stage 1 can use full-gradient all-reduce followed by owner updates and parameter broadcasts. The educational Stage 2 substitutes gradient reduce-scatter while retaining the same explicit parameter synchronization. Its communication need not match the optimized algorithms reported for a production ZeRO implementation. Packing, launch count, overlap, update scheduling, and activation memory can dominate the practical comparison. The two stages must still implement the same averaged global objective and the same Adam recurrence; a faster incorrect update is not a valid point.

Part 3 - Quantitative Prediction Before Execution

Predict retained gradient bytes for each rank from the actual ownership map. Build a communication ledger listing operation, payload dtype, tensor count, valid elements, padding, and calls per update. Keep logical payload separate from a backend-dependent estimate of transmitted bytes. Predict a case where Stage 2 saves persistent storage but does not improve throughput, and another where a larger usable model offsets additional communication.

Part 4 - Experimental Design and Instrumentation

Use fresh jobs and the same seed, logical parameter initialization, global batch, local batch, accumulation schedule, Adam configuration, and number of updates. Validate several parameter updates before the timed region. Warm kernels and optimizer states, then measure a complete forward, backward, update, and replica synchronization. Collect rank-local times and report the slowest synchronized step as the distributed critical path. Run profiling separately from low-overhead timing. Include both a communication-light network and a larger network within the tested device budget; do not change model size inside the primary equal-model comparison.

State how throughput is computed from completed global examples rather than multiplying an arbitrary rank's local counter. If accumulation is fixed, include all microbatches belonging to an optimizer update in the timing region. Keep CPU evidence gathering after the region and bound its frequency so logging does not dominate the experiment. For communication, show the educational parameter broadcasts even if the gradient collective becomes smaller. A table that includes only gradient traffic would hide an unchanged or dominant cost. Use repeated runs to report variability and preserve a slow-rank trace when the average appears attractive. Compare the same successful logical updates, not merely the same number of kernel launches.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_communication_ledger(engine, measured_steps):
```

```
    ...

def compare_stage1_stage2(replay_specs, evidence):
    ...

def E08(config):
    # Correctness, isolated replays, and comparison remain incomplete.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export per-rank persistent gradient bytes, peak allocated and reserved bytes, phase durations, examples per second, collective counts, and numerical errors. Label link-level traffic unsupported if only tensor payload is known. Explain any rank imbalance before summarizing across ranks. Include a case where full-gradient production hides the retained-gradient saving at the peak. Do not interpret a lower peak after a changed batch size as a stage-only effect. If no bounded producer was validated, limit the conclusion accordingly.

Part 7 - Engineering Interpretation and Philosophy

Choose the stage on evidence about the limiting resource. Explain why model-state theory, communication scheduling, and observed throughput answer different questions, and identify the next experiment that would resolve an ambiguous result.

19.41.10 Exercise 09

Exercise Title: Add Contiguous Gradient Buffers and Measure Their Effect on Allocation Count, Fragmentation, and Communication Efficiency

Part 1 - Exercise Contract and Why It Matters

Add contiguous gradient buffers with a declared capacity and reuse policy. Compare allocation behavior and communication packing overhead while preserving the verified reduction and optimizer semantics. Deliver a storage alias map and a lifetime trace, not merely a flat tensor allocation.

Part 2 - System and Memory Mental Model

A contiguous buffer may replace many gradient storages, or it may become an additional copy beside them. Those cases have different memory costs. Preallocation can reduce repeated allocation requests while retaining capacity between steps. Neither fewer allocations nor one flat address proves lower allocator fragmentation. Distinguish tensor creation, allocator block requests, reserved capacity, and driver allocation activity. Contiguous gradients do not make the full model state contiguous or remove activation workspaces.

Part 3 - Quantitative Prediction Before Execution

For bucket capacity C elements, predict bytes for producer storage, communication input, owned output, padding, and any overlap between successive buckets. Count distinct storage once when views share a backing allocation. Estimate collective calls from the canonical bucket

boundaries, including a partial final bucket. Compare a reuse implementation with a copy-then-reduce implementation and predict which can have the larger live peak despite identical payload sizes.

Part 4 - Experimental Design and Instrumentation

Freeze parameter ordering and bucket boundaries across ranks. Build a storage inventory before and after backward. Determine whether the producer writes directly into communication storage or copies into it. If using custom autograd or hooks, document when ordinary gradient storage is created and released; do not assume a hook eliminates it. Sweep a small set of bucket capacities using independent replays. Gate launch order by canonical sequence rather than local readiness. Test a second update, a partial bucket, and an accumulation boundary. Keep addresses only as diagnostic metadata and record storage identity plus offset and extent for aliases.

Test buffer capacity at one element below, exactly at, and just above a logical bucket boundary. Verify that reshaping a view does not create an unrecorded independent storage and that a stale view cannot mutate a bucket already assigned to the next step. If gradients accumulate in place, define when zeroing occurs relative to communication completion. Compare stable shape reuse with a separately controlled capacity-growth event. Include the allocation and initialization cost of growth in cold behavior instead of removing it from all reports. A permanent oversized gradient arena is a legitimate design choice only when its retained capacity is visible in the memory budget and comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class GradientBufferPlan:
    def allocate(self, layout, capacity, device):
        ...

    def accept_produced_gradient(self, parameter_id, gradient):
        ...

    def release_after_completion(self, bucket_id, completion):
        ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report payload, allocated capacity, internal padding, copied bytes, allocation events supported by the selected instrument, and complete-step peaks. Use native allocator statistics only with their backend-specific scope; unknown counters remain unsupported. Include a synthetic fragmented free-set example to show why allocation count cannot diagnose fit for a later

request. Check buffer versions across steps and fail on premature overwrite. A lower packing time with a higher reserved plateau is a legitimate trade-off.

Part 7 - Engineering Interpretation and Philosophy

Decide whether the buffer improves this workload through reuse, reduced copying, fewer launches, or another measured mechanism. Avoid turning a useful layout technique into a universal claim about fragmentation.

19.41.11 Exercise 10

Exercise Title: Extend the Runtime to ZeRO Stage 3 by Partitioning Model Parameters in Addition to Gradients and Optimizer States

Part 1 - Exercise Contract and Why It Matters

Partition persistent parameters in addition to gradients and optimizer state. Build a restricted Stage 3 runtime whose gathered computation units are temporary and whose local shards are the authoritative trainable state. Deliver correct multi-step training before claiming the ideal memory reduction.

Part 2 - System and Memory Mental Model

Ordinary autograd may retain a full weight for an input-gradient calculation. Replacing its data with an empty tensor after forward does not establish a valid release protocol. Use a restricted custom autograd unit: gather parameters for forward, save inputs and shard/version metadata rather than full weights, regather the same version in backward, and recompute the functional unit under gradient recording. Reduce-scatter its parameter gradients exactly once and return local shard gradients to the sharded leaf parameters. Do not additionally wrap this path in a DDP reducer.

Start with deterministic dense units, no dropout, no mutable running buffers, no shared parameters, and first-order gradients only. These restrictions are part of the contract, not general properties of Stage 3. Save tensors through the appropriate autograd mechanism and reject unsupported higher-order use.

Part 3 - Quantitative Prediction Before Execution

Predict ideal persistent bytes as

$$M_3 = (P + G + O)/N.$$

Add the largest gathered unit, recomputation intermediates, live activations, full unit-gradient production, reduction buffers, and allocator capacity on a phase timeline. Explain why one giant computation unit can destroy much of the apparent saving. Count local shards and gathered copies separately.

Part 4 - Experimental Design and Instrumentation

Initialize local shards directly from a canonical small-model state and verify reconstruction outside the timed region. Implement one custom linear unit, check its input and parameter gradients, then compose several units. Compare several Adam updates with the Stage 0 oracle. Keep optimizer updates after all backward readers of the old version have completed. Rebuild each stage from the same logical initialization; changing a stage flag cannot convert optimizer

ownership and storage layout safely. Record the gather, recompute, reduce-scatter, and release boundaries explicitly.

For the custom differentiation boundary, list every tensor input and the matching backward return entry. Non-tensor runtime arguments require the appropriate no-gradient result. The sharded leaf must receive the owned parameter derivative once; the unit input must receive its ordinary local input derivative so earlier units can differentiate correctly. Test the first unit with ordinary inputs that do not require gradients as well as an interior unit whose inputs do. Recompute from the exact recorded parameter version. For the first implementation, reject stochastic recomputation and mutation of saved inputs. These restrictions keep a memory demonstration from silently changing the function whose gradients the optimizer receives.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

class ShardedFunctionalUnit(torch.autograd.Function):
    @staticmethod
    def forward(ctx, inputs, local_shard, runtime, unit_id):
        # Gather, execute, save required inputs/version, and release.
        ...

    @staticmethod
    def backward(ctx, output_gradient):
        # Regather old version, recompute, reduce once, return shard grad.
        ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit saved tensors to detect unintended full-parameter retention. Compare outputs, input gradients, owned gradient shards, moments, and updated parameters. Reconstruct state only in a separate correctness replay. Reject an implementation that matches forward outputs but corrupts backward. Distinguish the persistent formula from measured peaks, including recomputation cost. Mark arbitrary modules, tied weights, and higher-order differentiation unsupported until separately implemented and validated.

Part 7 - Engineering Interpretation and Philosophy

Explain which invariants permit full weights to disappear between uses. State why the educational recomputation design is one valid restricted approach rather than a description of every production ZeRO implementation.

19.41.12 Exercise 11

Exercise Title: Gather Parameter Shards Immediately Before Layer Execution and Repartition Them After Their Required Computation Completes

Part 1 - Exercise Contract and Why It Matters

Build the gather and release lifecycle for a computation unit. Materialize only the required parameter version, wait before consumption, and release only after every relevant reader completes. Demonstrate both forward and backward lifetimes with the validated custom unit from E10.

Part 2 - System and Memory Mental Model

A Python reference, an autograd dependency, and an outstanding CUDA read are separate reasons storage may remain live. The custom unit avoids saving full parameters across forward and backward, but it still needs a full unit during execution and recomputation. A host-side return from a launch does not prove that GPU readers finished. Gather completion must precede computation; release or reuse must follow the last reader. The authoritative local shard must retain the required version until backward no longer needs it.

Part 3 - Quantitative Prediction Before Execution

For each unit, draw a state sequence from sharded to gathering, ready, in use, and releasable. Assign a byte count and completion condition to every transition. Predict the maximum number of simultaneously live gathered units for a serialized schedule. Then add one prefetched unit and explain which storage intervals overlap. Specify whether a release returns capacity to an application pool or actually drops a PyTorch allocation.

Part 4 - Experimental Design and Instrumentation

Implement the serialized path first. Gather one unit in a rank-consistent order, execute it, and use explicit completion records before reusing its buffer. In backward, regather the recorded old version, recompute, reduce parameter gradients, and complete input-gradient production before release. Validate each boundary with a small known network. Add delayed CUDA work as a lifetime test without depending on a particular race reproducing. Keep all ranks on the same collective sequence. Avoid device-wide synchronization inside the final overlap path, while retaining deliberate boundary synchronization for isolated measurement.

Keep the lease ledger separate from the allocator cache: logical release can make an application buffer reusable while its storage remains allocated. Record both events if the application pool retains capacity. For backward, identify the last input-gradient computation that reads the gathered weight; reducing weight gradients alone does not establish that lifetime has ended. Use generation numbers to distinguish a new lease from a recycled address. Validate no consumer holds an old-generation view when the buffer is reused. On failure, retain a short CPU event trace with unit, rank, generation, and version so the explanation survives without keeping the problematic GPU tensors alive through the evidence system.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class GatherLease:
    unit_id: int
    parameter_version: int
    storage: object
    completion: object
    readers: int

def acquire_unit(runtime, unit_id, version):
    ...

def release_unit(runtime, lease, final_reader_event):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export lease generation, unit version, gather completion, first read, last read, release request, and reuse eligibility. Ensure logs contain CPU metadata rather than tensors that retain full storage. Compare against a safe serialized oracle. Treat an early reuse detected by the state machine as a failure even if outputs happen to match in one run. A peak that remains large after release may reflect pool retention or another live alias; inspect both before assigning a cause.

Part 7 - Engineering Interpretation and Philosophy

Describe the release proof in terms of ownership and completed readers. Explain why an address that gets reused is insufficient evidence that its previous contents were no longer needed.

19.41.13 Exercise 12

Exercise Title: Build a Parameter Persistence Policy That Keeps Small or Frequently Reused Parameters Resident Instead of Repeatedly Gathering Them

Part 1 - Exercise Contract and Why It Matters

Add a bounded persistence policy for gathered parameters that are small or repeatedly used. Compare communication avoided with additional residency. Keep local shards authoritative and require every persistent full copy to carry an explicit parameter version.

Part 2 - System and Memory Mental Model

Persistence is a cache of a gathered representation, not a second independent optimizer owner. After an owner update, cached replicas become stale and must be invalidated or refreshed before use. Parameter selection must agree across ranks because bypassing a gather

changes collective order. A per-parameter size threshold alone does not bound cumulative residency. Production DeepSpeed configuration is a reference for policy concepts; its parameter-count thresholds are measured in elements, whereas this exercise's application budget is explicitly in bytes.

Part 3 - Quantitative Prediction Before Execution

Predict saved gather calls and bytes for a static repeated-unit trace. Calculate the sum of retained full copies plus local shards, gradients, optimizer state, and required execution workspace. Construct many individually small parameters whose cumulative persistence exceeds the budget. Give a second case where a frequently used parameter changes version every update, limiting cross-step reuse despite high apparent access frequency.

Part 4 - Experimental Design and Instrumentation

Use a rank-consistent manifest of candidates and a deterministic budgeted selection rule. Start with persistence within one update, where versions are fixed until the optimizer boundary. Then add invalidation across updates and verify that no stale full copy reaches forward or backward. Compare no persistence, a size threshold, and a bounded reuse-aware selection. Replay the same training inputs and collective schedule. Record admitted bytes, rejected candidates, cache hits by version, refresh work, and peak gathered capacity. Keep diagnostic reference copies outside the measured process.

Separate a reused unit's logical access count from the number of distinct parameter versions it accesses. A repeated unit within one update can have valuable same-version reuse, whereas the same unit across many optimizer steps needs refresh. In the restricted primary graph, use a static repeated functional unit only after its accumulated parameter gradient is validated; otherwise use an offline access trace for policy prediction and label it as such. Make admission decisions from a common manifest rather than each rank's local memory query. Local free-memory readings can differ and cannot safely determine whether one rank alone skips a collective. Record the manifest fingerprint with every persistence comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PersistentEntry:
    unit_id: int
    version: int
    bytes: int
    lease: object

def choose_persistent_units(manifest, byte_budget, schedule):
    ...
```

```
def invalidate_after_update(cache, changed_versions):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check equality with the no-persistence oracle across several optimizer updates, not just within one forward. Include a negative control that reuses an old version and detect its numerical error. Report cumulative retained bytes and observed complete-step peaks. Separate savings in calls from savings in actual transmitted traffic. An unfavorable memory-throughput trade-off is an admissible outcome; do not assume persistence helps every small unit.

Part 7 - Engineering Interpretation and Philosophy

Choose a persistence rule whose budget and invalidation conditions can be audited. Explain how a local cache optimization becomes a distributed protocol decision when it changes which collectives execute.

19.41.14 Exercise 13

Exercise Title: Prefetch Future Parameter Shards and Tune Prefetch Distance to Hide Collective Communication Without Causing VRAM Spikes

Part 1 - Exercise Contract and Why It Matters

Prefetch future gathered units while current computation proceeds. Tune lookahead under a byte budget and prove that readiness, versioning, and collective order remain correct. Compare the pipelined schedule with the serialized E11 oracle.

Part 2 - System and Memory Mental Model

Prefetch overlaps communication with available computation but creates additional live full-parameter storage. A collective's asynchronous work handle, CUDA stream ordering, and the lifetime of its buffers all need explicit handling. Use documented backend completion semantics; a host launch time is not a device-ready timestamp. Keep the rank-consistent schedule static at first. Forward and backward have different use orders, so a forward-only lookahead predictor is insufficient for the whole step.

Part 3 - Quantitative Prediction Before Execution

Estimate a next-unit gather duration and the current-unit compute interval, then predict a lower-bound uncovered wait as the positive part of their difference. State the assumptions: independent resources, no contention, and available buffer capacity. Calculate the maximum live gathered bytes for lookahead zero, one, and two using actual unit sizes. Explain why longer lookahead can increase latency through contention even when it hides an individual gather wait.

Part 4 - Experimental Design and Instrumentation

Start with one outstanding prefetch and a dedicated communication stream where supported. Establish producer-to-consumer and final-reader dependencies, retain input/output

buffers until completion, and reject mismatched versions. Advance collectives in the same order on every rank. Admit a prefetch only when its full capacity fits the measured application budget and required workspace reserve. Sweep a short list of lookahead settings using fresh identical replays. Capture profiling traces separately from timing and include both forward and backward. Record stalled admission, ready-before-use time, exposed waits, and actual peak residency.

Maintain a monotonically increasing collective sequence number and attach unit and version metadata to each issued request. Allow local completion times to differ without allowing issue order to diverge. Compare the planned lookahead with actually admitted lookahead because the byte budget may reject larger units. Plotting only the requested distance would conceal that behavior. A prefetched unit that becomes unusable must still finish its outstanding work before its buffers are reclaimed. In the static primary schedule, unneeded prefetch should be rare; test cancellation bookkeeping with a controlled offline schedule first. Keep communication stream dependencies explicit when handing a gathered tensor to the default compute stream.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

class ParameterPrefetcher:
    def admit(self, unit_id, version, required_bytes):
        ...

    def launch_next(self, canonical_schedule):
        ...

    def acquire_ready(self, unit_id, consumer_stream):
        ...

    def retire(self, lease, final_reader_event):
        ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require numerical agreement with the serialized runtime and no version or lease violations. Report gather wait, total step time, outstanding work, live gathered bytes, and rejected admissions per rank. Identify overlap from an execution timeline rather than from non_blocking or async_op flags alone. If hardware cannot overlap the selected collectives and kernels effectively, report the measured limitation. Do not reuse a buffer merely because the Python work object was dropped.

Part 7 - Engineering Interpretation and Philosophy

Choose lookahead by the joint latency and residency evidence. Explain which part of the prediction fails when communication contention or a slow rank changes the available overlap window.

19.41.15 Exercise 14

Exercise Title: Reproduce a Stage 3 Memory Spike Caused by Excessive Live Gathered Parameters and Control It with a Maximum-Live-Parameter Budget

Part 1 - Exercise Contract and Why It Matters

Create a controlled Stage 3 trace in which excessive gathered residency raises the peak. Add an admission policy for maximum live parameter capacity and show whether it controls that peak while preserving training correctness. A reproduced spike is sufficient; a physical CUDA OOM is not required.

Part 2 - System and Memory Mental Model

Multiple gathered units can remain live because of prefetch, persistence, active readers, or accidental aliases. A live-capacity policy must include all of those categories, pending gathers, and allocation rounding within its scope. It does not reserve the entire GPU against activations, backend workspaces, other processes, or allocator growth. DeepSpeed's max_live_parameters concept uses parameter elements; the educational controller must label its byte units and convert from dtype explicitly instead of copying a number blindly.

Part 3 - Quantitative Prediction Before Execution

Construct a static sequence of unequal units. Compute the live gathered set at every event for an aggressive schedule and for a bounded schedule. Predict the earliest rejected admission and the additional wait it introduces. Include the unavoidable largest-unit requirement: a budget below the required unit plus working reserve needs a clear unsupported or infeasible result, not a retry loop that can never make progress.

Part 4 - Experimental Design and Instrumentation

Use a bounded workload that fits the declared test environment. Increase lookahead or persistence gradually and record the observed peak without assuming an OOM. Repeat with the byte controller enabled and the same logical training work. Count unique gathered storage once while separately counting local shards and other categories. Release completed readers before admitting queued gathers. Make the rank-consistent decision before collective launch. If an allocation failure occurs, stop and recreate the whole worker group from a committed checkpoint; do not let one rank continue alone.

Use a ledger invariant that reserved pending capacity plus admitted ready capacity never exceeds the application gather budget. Do not charge the same lease twice when it changes from pending to ready. Conversely, do not stop charging it at a Python release request before readers complete. A bounded schedule can deadlock if it waits for space held by an object whose consumer cannot execute; validate progress on the static event graph. Provide a clear infeasible result for the oversized-unit case. Compare observed budget compliance with total CUDA allocation separately so a correct ledger is not misrepresented as control over activations, external allocations, or another process using the device.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class LiveParameterBudget:
    def request(self, unit_id, version, capacity_bytes):
        ...

    def record_pending(self, lease):
        ...

    def complete_release(self, lease, completion):
        ...

def E14(config):
    # Compare predicted live sets with bounded and aggressive replays.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted and observed live capacity, total allocated and reserved peaks, admission stalls, and correctness status. Use phase evidence to attribute a spike to gathered parameters; an allocated-minus-reserved subtraction cannot prove that cause. Include accidental retention as a separate diagnostic case. If the spike does not reproduce, retain that outcome and state the tested range. Verify progress for a unit exactly at the admissible capacity boundary.

Part 7 - Engineering Interpretation and Philosophy

Explain the scope of the controller's guarantee and the remaining GPU headroom uncertainty. Choose a conservative reserve based on measured working requirements rather than claiming a byte budget makes real allocation infallible.

19.41.16 Exercise 15

Exercise Title: Compare ZeRO Stages 0, 1, 2, and 3 Under the Same Model and Report Per-GPU Memory, Communication, Throughput, and Maximum Trainable Model Size

Part 1 - Exercise Contract and Why It Matters

Compare stages zero through three using one common model and training contract. Report memory, communication, throughput, and an independently measured capacity sweep. Keep the equal-model experiment separate from the largest-model experiment so their conclusions remain interpretable.

Part 2 - System and Memory Mental Model

Stage labels identify progressively partitioned state, but the educational implementations also differ in collective protocol and Stage 3 recomputation. Those costs must remain visible. The largest trainable model depends on activations, unit granularity, batch size, optimizer

temporaries, and available headroom, not only persistent state. One machine with multiple CUDA devices is sufficient for the distributed comparison; do not require two computers. Only claim world sizes actually tested. Single-rank runs are useful controls but cannot demonstrate removal of inter-rank replication.

Part 3 - Quantitative Prediction Before Execution

Use the four ideal persistent-state expressions from E00 and the actual padding map to predict per-rank bytes. Add measured or separately estimated peak working components without treating all category maxima as simultaneous. Specify a model-width or depth sweep and a fixed global batch. Predict the largest feasible candidate as a hypothesis, then define how successful full updates will confirm only a tested lower bound on capacity.

Part 4 - Experimental Design and Instrumentation

Launch each stage in a fresh worker group with the same logical initial parameters, data order, precision, loss normalization, and Adam settings. Validate several updates against the reference at a small shared size. Measure the fixed model first. For capacity, increase one documented dimension with a bounded search, requiring complete forward, backward, optimizer update, and parameter synchronization or publication. Record initialization failure separately from training failure. Keep activation checkpointing and offload disabled unless they are a separately named experimental factor. Include warm state allocation and several steady updates before declaring a candidate usable.

For the capacity sweep, preserve identical optimizer and precision choices across stages even when one stage could support a more favorable setting. Any later mixed-precision optimization belongs to a separately labeled sweep. Require the same input shape family and training objective at each model-size candidate. A candidate that initializes successfully but cannot complete the first initialized-Adam update is not trainable under the declared contract. Record whether validation and checkpoint export are included in capacity acceptance or measured separately. Avoid gathering a full model onto every rank just to print a checksum during a capacity run. Use the small-model correctness suite and compact integrity metadata instead.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_stage_replay(stage, logical_initial_state, config):
    ...

def compare_fixed_model(replays, evidence):
    ...

def search_tested_capacity(stage, bounded_candidates, config):
    ...
```

```
def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export one row per rank and stage with persistent categories, complete-step peak, reserved peak, communication ledger, step latency, throughput, and correctness status. Report the maximum rank as well as the distribution. For capacity, preserve successful and failed candidate IDs and failure phases. Do not import theoretical production communication constants into the naive broadcast implementation. Attribute Stage 3 recomputation time explicitly. If a test ends at the largest permitted candidate without failure, report a lower bound rather than an exact maximum.

Part 7 - Engineering Interpretation and Philosophy

Choose a stage for a stated resource budget and training objective. Explain why the most partitioned stage can be essential for capacity yet unnecessary for a smaller model whose communication dominates.

19.41.17 Exercise 16

Exercise Title: Add CPU Optimizer-State Offloading to the ZeRO Runtime and Measure the Trade-Off Between VRAM Savings, RAM Usage, and PCIe Traffic

Part 1 - Exercise Contract and Why It Matters

Move owner-local optimizer state to CPU while preserving the distributed update contract. Measure GPU savings, host memory, staging capacity, PCIe traffic, and CPU update time. Implement the educational offload path explicitly rather than assume the performance of a specialized production CPU optimizer.

Part 2 - System and Memory Mental Model

The owning rank remains responsible for its update even when moments live in host memory. Transfer its reduced gradient shard to a valid CPU staging area, perform the same Adam recurrence, and publish the resulting parameter version back to CUDA. Stage 1 and Stage 2 then synchronize replicated parameter spans; Stage 3 publishes updated owner shards before later gathers. An FP32 CPU parameter authority, if retained for update, is additional state that must be counted. It is not free simply because the moments were already offloaded. Pinned staging enables particular transfer paths but consumes a separate bounded host resource.

Part 3 - Quantitative Prediction Before Execution

Predict device bytes removed for owner moments and device bytes added for staging. List host moments, optional parameter authority, gradient staging, update staging, and pending copies separately. For one optimizer update, estimate transfer payload from the actual chosen protocol, not the whole model by default. Establish an optimistic bandwidth lower bound and identify CPU compute, launch overhead, and dependency waits it omits.

Part 4 - Experimental Design and Instrumentation

Start with serialized D2H, CPU update, H2D, and parameter synchronization. Compare moments and updated parameters with the GPU-only reference over several steps. Then add bounded pinned buffers and asynchronous transfers with explicit completion before CPU reads

and before GPU consumes updates. Do not overwrite CPU or CUDA staging while a copy still uses it. Keep accumulation semantics unchanged and update once at the declared optimizer boundary. Measure process host memory, pinned capacity when observable, CPU update time, exposed transfer waits, and distributed step time in separate instrumented replays.

Account for CPU update arithmetic and host thread configuration in the reproducibility record. A changed thread count can alter offload latency without changing transfer volume. State whether host RSS includes pinned staging and whether system metrics count shared pages more than once. If pinned-memory usage cannot be measured directly, report allocated pinned capacity under application control and preserve the broader quantity as unknown. Compare a serialized correct path with the overlapped path before claiming overlap benefits. Include an update whose shard size exceeds one staging chunk to prove chunk boundaries preserve logical Adam counters and publication waits. Never publish a mixture of old and new owner chunks.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class OwnerOptimizerOffload:
    def allocate_host_state(self, ownership, config):
        ...

    def receive_gradient(self, owned_gradient, completion):
        ...

    def update_on_cpu(self, logical_step):
        ...

    def publish_cuda_version(self, runtime, completion):
        ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit the latest authoritative version across CPU and CUDA at each transition. Require matching moments, counters, parameters, and losses within declared numerical tolerances. Report actual bytes copied and distinguish those from measured bus traffic if unavailable. A low GPU peak with excessive RAM or a much slower update is a trade-off, not a failed measurement. Do not reuse CPU buffers after a nonblocking D2H launch until completion is established. Include first-update host-state allocation outside warmed timing but report its cold-start cost separately.

Part 7 - Engineering Interpretation and Philosophy

Explain whether the workload is limited by GPU capacity, host update compute, or transfer dependencies after offload. State which resource the technique releases and which resources it consumes.

19.41.18 Exercise 17

Exercise Title: Extend Stage 3 with Parameter Offloading to CPU or NVMe and Build a Three-Tier Residency Plan for Partitioned Model State

Part 1 - Exercise Contract and Why It Matters

Extend owner-shard residency across CUDA, CPU, and optional NVMe files. Build a bounded three-tier plan with explicit authoritative versions and materialization prerequisites. Treat disk-backed residency as an educational extension, not a claim to reproduce ZeRO-Infinity's optimized implementation.

Part 2 - System and Memory Mental Model

A parameter shard must be available on CUDA before its collective gather can consume it. NVMe file reading, CPU materialization, H2D completion, collective completion, and computation readiness are distinct events. Ordinary file access is not direct GPU storage access. CPU page cache, mapped pages, pinned staging, and application buffers contribute different host-memory views. After an optimizer update, a stale on-disk shard cannot replace the new version. Dirty writeback must complete before discarding the only current copy. State checkpoints must include optimizer state and logical progress, not just a collection of parameter files.

Part 3 - Quantitative Prediction Before Execution

For each owner shard, record its valid bytes, tier, version, file extent, and required future use. Predict CUDA and host staging peaks for one incoming and one outgoing shard. Add storage service time and transfer time to a serialized critical-path estimate. Then specify which intervals could overlap under a bounded pipeline and which dependencies remain unavoidable.

Part 4 - Experimental Design and Instrumentation

Implement CPU residency first, then add optional rank-local file extents with dtype, shape, logical offsets, ownership, version, and integrity metadata. Write to a temporary generation and publish a committed manifest only after all required rank state is durable under the declared filesystem assumptions. Validate file bounds and metadata before allocating or reading. Stage owner shards through bounded host buffers and issue gathers in the canonical order. Limit outstanding disk and CUDA work. Test a small round trip, a modified shard, interrupted publication in an isolated directory, and restart from the last committed update. Never overwrite an unrelated user file.

Use separate file namespaces for rank, checkpoint generation, and logical shard identity. Validate that two ranks cannot unintentionally write the same extent. Record whether file storage is local NVMe, another block device, or an unavailable optional tier; device names alone do not establish measured bandwidth. A successful operating-system write call is not automatically the durability guarantee required by a crash-recovery claim. Define the chosen commit assumptions and test only those assumptions. During restoration, verify parameter and moment generations together before any forward executes. Keep duplicate generations visible in disk-space accounting even when they are no longer resident in the explicit application buffers.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ShardLocation:
    parameter_id: int
    owner_rank: int
    version: int
    tier: str
    byte_extent: tuple
    integrity: object

def materialize_owner_shard(record, staging, runtime):
    ...

def commit_partitioned_state(engine, checkpoint_directory):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-tier resident capacity, queued bytes, file bytes read and written, exposed disk waits, transfer waits, and end-to-end update time. Distinguish cold and warm filesystem-cache behavior without claiming a particular cache state that was not controlled. Verify resumed updates against an uninterrupted run and reject mixed checkpoint generations. Mark NVMe unsupported if unavailable rather than substituting fabricated disk results. Do not claim total process RAM is bounded solely because explicit staging is.

Part 7 - Engineering Interpretation and Philosophy

Explain how tiering changes the capacity bottleneck into a scheduling problem. Identify the minimum metadata and commit protocol required to avoid restoring numerically valid but outdated parameter shards.

19.41.19 Exercise 18

Exercise Title: Stress-Test ZeRO-Style Partitioning with Uneven Parameter Sizes, Gradient Accumulation, Communication Contention, CPU Offload, and Severe Per-GPU VRAM Limits

Part 1 - Exercise Contract and Why It Matters

Stress the partitioned runtime with uneven layouts, accumulation, communication contention, offload, and constrained per-rank capacity. Require correct updates and bounded, explicit failure behavior. Produce small counterexamples that isolate violated assumptions before attempting large runs.

Part 2 - System and Memory Mental Model

Partition boundaries may split a logical parameter or leave an owner with no valid elements. Padding must never enter the optimizer recurrence. Gradient accumulation changes when reduction and update occur and can retain additional buffers. A zero gradient differs from an absent gradient for Adam state and step semantics. Dynamic or unused parameters are unsupported in the primary fixed graph; a stress extension must implement a rank-consistent presence protocol or reject them clearly. Rank-local branches must not silently change collective order.

Part 3 - Quantitative Prediction Before Execution

Construct cases with prime-sized tensors, a parameter larger than one shard, and more ranks than valid elements where hardware permits. Predict valid and padded ownership and logical step counters. For equal microbatches, derive the loss weighting that produces the same global mean as the reference. Compare reducing each microbatch with deferring reduction, including their different live gradient requirements. Predict a contention case that increases wait time without changing logical communication payload.

Part 4 - Experimental Design and Instrumentation

Run a deterministic small-model matrix before capacity stress. Cover one and multiple accumulation steps, uneven parameter sizes, a final partial bucket, no-valid owner behavior, CPU staging pressure, and delayed communication. Use a bounded application memory limit first; severe physical allocation pressure is optional. Keep all test seeds and schedule traces. Inject logical errors into an offline validator instead of launching mismatched collectives. If a worker fails, terminate and recreate the entire group from a committed checkpoint. Record expected rejection separately from incorrect training or an unexpected backend failure.

Construct a zero-versus-absent-gradient diagnostic in a separate extension with a tiny conditional graph. If the engine has no validated presence protocol, require rejection before launching a divergent sequence. If it does, compare Adam counters and moments against the reference rather than accepting only matching parameter values after one step. For accumulation, use an uneven final microbatch only with correctly derived sample weighting. Otherwise reject that configuration or restrict the test to equal sizes. Keep resource-pressure changes independent from semantic changes so a failed update has a useful explanation. Minimize failures first by removing offload, then prefetch, then partition complexity while preserving the mismatch.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_partition_stress_cases(config):
    ...
```

```
def validate_accumulated_update(engine, reference, case):
    ...

def recover_worker_group(committed_checkpoint, launcher):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

For each case, export layout, seed, global and local batch sizes, accumulation count, reduction timing, resource budgets, peak memory, latency, outcome, and failure phase. Compare parameters, moments, and counters after several updates. Include the smallest mismatch reproducer and distinguish normal tolerance drift from a missing or double update. If an optional shared parameter or conditional path is unsupported, preserve a clear rejection instead of treating it as a passing stress test. Absence of an OOM or race in the tested range is not proof of universal safety.

Part 7 - Engineering Interpretation and Philosophy

Choose the most informative counterexample and explain the invariant it breaks. Describe how deterministic rejection and checkpointed group recovery make a restricted runtime more trustworthy than silent partial progress.

19.41.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch ZeRO-Style Distributed Training Engine That Progressively Partitions Optimizer States, Gradients, and Parameters While Coordinating Gather, Reduce-Scatter, Prefetch, and Offload

Part 1 - Exercise Contract and Why It Matters

Integrate the validated components into a PyTorch educational distributed engine exposing stages zero through three, optional owner-state offload, bounded gathers, and explicit prefetch. Deliver an auditable benchmark and a capability matrix. Keep the implementation visible and intentionally complete it as learner work rather than hiding it in a high-level trainer.

Part 2 - System and Memory Mental Model

The engine combines a logical parameter registry, owner map, gradient protocol, optimizer recurrence, versioned gather leases, and tiered residency. All components must agree on the same update boundary. Stage selection is a construction-time choice in the primary implementation. Converting an active engine to a different stage requires an explicit state migration protocol; a flag assignment is insufficient. The restricted functional graph and first-order differentiation contract remain in force. Production DeepSpeed supports substantially more cases and optimizations than this exercise.

Part 3 - Quantitative Prediction Before Execution

Before coding the integration, predict persistent bytes for every stage, actual owner imbalance, live gather capacity, reduction-buffer capacity, offload staging, and complete-step critical path. State assumptions beside each prediction. Define acceptance criteria for update correctness, memory budget compliance within the application's scope, progress, and checkpoint restart. Choose a primary two-rank run only if two CUDA devices are available; otherwise label the distributed benchmark not measured.

Part 4 - Experimental Design and Instrumentation

Build the engine from one canonical initialization and deterministic schedule. Validate the smallest supported model against ordinary Adam and Stage 0 before benchmarking. Run equal-model stage comparisons, then bounded capacity sweeps and the stress suite. Keep correctness reconstruction, profiling, and ordinary timing in separate replays. Preserve a committed partitioned checkpoint and compare resumed training with uninterrupted training. Record hardware, topology, versions, allocator backend, precision, optimizer options, model dimensions, seed, batch semantics, stage, bucket capacity, prefetch distance, persistence budget, and tier budgets. Include forward, backward, update, and required synchronization in training timing.

Publish a capability matrix in the exercise evidence with separate entries for replicated baseline, owner-only moments, sharded reduced gradients, bounded gradient production, autograd-safe gathered units, persistence, prefetch, CPU optimizer offload, parameter tiering, and restart. Each entry needs supported, rejected, or not-tested status and a validating run ID. Do not treat a scaffold signature as implemented support. Include the smallest counterexample that invalidates any proposed universal speed or memory claim, or state that none was observed in the tested range. Keep external API versions in the record because backend behavior and production configuration interfaces can change independently of the educational engine's explicitly stated mathematical contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

class EducationalZeROEngine:
    def construct(self, logical_model, stage, config):
        ...

    def forward_backward(self, batch, accumulation_boundary):
        ...

    def update_and_publish(self):
        ...

    def checkpoint_committed_state(self, destination):
        ...

    def export_cpu_evidence(self):
        ...
```

```
def E19(config):
    # Assemble validated components and run independent benchmark replays.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export prediction, observation, and interpretation in separate columns. Every run needs an ID, configuration, input shape, world size, resource budgets, per-rank memory peaks, elapsed time, throughput, numerical errors, outcome, and failure phase. Use explicit unsupported and not-measured values. Do not retain live autograd graphs in evidence logs. Reject conclusions based only on forward equality, uninitialized optimizer state, or a theoretical memory formula. Report any capacity or throughput regression with its trace evidence. A failure to reproduce a predicted spike remains an experimental outcome.

Part 7 - Engineering Interpretation and Philosophy

Select an operating point for a concrete budget and explain the remaining uncertainty. The strongest result is a runtime whose update semantics, ownership, temporary residency, and unsupported cases can all be checked, with measured trade-offs rather than promised universal speedups.

19.42 DMM40

Chapter Title: Tensor Parallel Memory Placement
Specialization: Dynamic Memory Management and CUDA Systems

19.42.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Tensor Parallelism, Sharded Matrix Operations, Local Tensor Storage, and Cross-GPU Communication

Part 1 - Exercise Contract and Why It Matters

Define tensor parallelism as partitioned computation within a logical layer. Deliver a layout ledger relating global tensors, local storage, mathematical operations, and collective dependencies. Distinguish this design from data parallel replicas and from temporary full-parameter materialization in FSDP or ZeRO Stage 3.

Part 2 - System and Memory Mental Model

Use the convention $X \in \mathbb{R}^{M \times K}$ and PyTorch Linear weight $W \in \mathbb{R}^{N \times K}$, so $Y = XW^T + b$. Column-parallel means partitioning output features: stored weight dimension zero. Row-parallel means partitioning input features: stored weight dimension one. These names refer to the conventional untransposed matrix formulation; never infer the stored axis from the word column alone.

All ranks in one TP group cooperate on the same logical batch. They are not independent data replicas. Start with FP32, deterministic dense operations, equal feature partitions, and no dropout. Training requires correct distributed derivatives and one logical loss, not merely matching forward outputs.

Part 3 - Quantitative Prediction Before Execution

Let TP degree be T and element width be s bytes. Derive local weight bytes for each partition and list which inputs or outputs remain replicated. Draw a two-layer path from replicated input through sharded hidden features to a reduced output. Predict where communication is required in forward and backward. Add gradients, optimizer states, temporary buffers, and activations before proposing a complete training-memory estimate.

Part 4 - Experimental Design and Instrumentation

Freeze a global parameter registry, axis convention, group membership, input layout, output layout, and loss semantics. Establish small serial forward, gradient, and update oracles. Bind one process to each CUDA device and validate rank-consistent configuration before collective work. Record PyTorch and CUDA versions, backend, topology, seed, dtype, model dimensions, batch and sequence shapes, allocator backend, and initial-state identity. Treat API availability as a checked capability: reference documentation does not establish what the installed environment supports.

Build a paper trace for two ranks with a four-feature input and six-feature output. Label every local tensor as complete replica, disjoint shard, or unfinished contribution. Carry those labels through matrix multiplication, bias addition, activation, and the next layer. Add backward arrows with the required derivative ownership. This trace must explain why TP participants consume the same logical samples, whereas data replicas consume different samples. Define a single logical loss at the outer boundary and document how its replicated representation is differentiated. Avoid adding a data-parallel average to tensor-parallel sums. Extend the trace to one optimizer update so parameter shards, replicated small parameters, and Adam moments all have explicit owners. Use that completed trace as the contract for later APIs, rather than inferring semantics from their class names.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class TensorParallelContract:
    global_weight_shape: tuple
    stored_shard_axis: int
    input_layout: str
    output_layout: str
    tensor_parallel_degree: int
    logical_loss_identity: str

def predict_layout_storage(contract, phase_plan):
    ...
```

```
def E00(config):
    # Validate layout, derivative, and measurement contracts first.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Require exact coverage of logical features and numerical agreement within declared floating-point tolerances. Missing devices, unsupported operators, and unrun training remain explicit statuses. Do not infer physical memory from a global DTensor shape or claim reduced communication from an attractive diagram alone.

Part 7 - Engineering Interpretation and Philosophy

Explain how a tensor layout constrains both local work and required communication. The objective is a checkable distributed computation whose memory benefits and synchronization costs follow from explicit ownership.

19.42.2 Exercise 01

Exercise Title: Split a Large PyTorch Weight Matrix Across Two GPUs and Verify That Each Rank Stores Only Its Local Tensor Shard

Part 1 - Exercise Contract and Why It Matters

Place disjoint shards of one logical weight on two CUDA ranks and verify actual local storage ownership. Deliver reconstruction evidence on a small case and a capacity audit on a larger bounded case without retaining an unnecessary full CUDA weight on every rank.

Part 2 - System and Memory Mental Model

A slice can be a view retaining its entire parent storage. Copying a slice to an independent local allocation and dropping the parent has different storage behavior. The full logical matrix may exist on CPU for a small oracle, but startup CUDA peaks still count if a construction path first creates the whole weight on each GPU. Parameter initialization must produce the same logical values as the reference; using independent random draws with the same seed does not automatically reproduce global slices.

Part 3 - Quantitative Prediction Before Execution

For divisible output width, predict NKs/T useful local weight bytes and an N/T by K local shape. Compare this with the backing size of a view into a full allocation. Calculate offsets and valid extents for a small matrix whose entries encode row and column indices. Separate useful bytes, padding, retained parent capacity, and construction-time temporary bytes.

Part 4 - Experimental Design and Instrumentation

Use a tiny CPU reference to validate shard boundaries and reconstruction. Then construct local CUDA storage from bounded CPU slices or a validated coordinate-based initializer. Preserve the global initialization contract, including fan-in, rather than applying a locally changed initialization rule silently. Check device binding, dtype, contiguity, storage extent, and absence of parent references. Collect only CPU metadata for the large case. Reconstruct full weights in a separate small replay so the audit does not create the replication it is supposed to measure.

Test both stored axes even though the primary construction uses output features. A row slice and a column slice can have different stride and contiguity behavior, and a contiguous conversion can allocate another buffer. Record the conversion before dropping its source. For initialization, compare against a tiny global reference by coordinate, including bias and global fan-in. A local row-parallel layer initialized with its smaller local fan-in can use a different distribution from the original layer, invalidating a controlled comparison before any communication occurs. Keep global reference construction on CPU bounded and use shard-wise loading for larger cases. Count file-loading or host staging separately if introduced. The large-case claim must concern actual independent local storage, not only an attractive printed shape or the expected arithmetic byte count.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class WeightShardRecord:
    rank: int
    global_shape: tuple
    local_shape: tuple
    global_interval: tuple
    useful_bytes: int
    backing_bytes: int

def construct_independent_local_weight(spec, rank, device):
    ...

def audit_local_weight_storage(weight, spec):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful and backing bytes, global coverage, local shape, initialization peak, and reconstruction error. Include a negative control retaining a full parent allocation behind a small view. Pointer values from different processes cannot establish shared storage or disjoint ownership by themselves; combine logical intervals with rank-local backing inventories. Require no gaps or overlap in valid logical weight coverage.

Part 7 - Engineering Interpretation and Philosophy

Explain why a small local tensor shape is insufficient proof of a small allocation. Choose a construction route whose startup memory is consistent with the intended steady-state placement.

19.42.3 Exercise 02

Exercise Title: Implement Column-Wise Parallel Linear Algebra from Scratch and Reconstruct the Full Output Across Multiple GPU Ranks

Part 1 - Exercise Contract and Why It Matters

Implement output-feature partitioned linear algebra explicitly and reconstruct the full output for validation. Preserve the same logical input on all TP ranks. Deliver forward equivalence plus a separate derivative check before using the scratch implementation in training.

Part 2 - System and Memory Mental Model

Partition stored weight rows and the matching bias entries. Each rank computes distinct output features from the full input. Concatenating outputs in feature order reconstructs the result; summing them is incorrect. An all-gather used only for diagnostics must be kept outside production timing. Raw communication calls are not automatically a complete autograd-aware TP operator. Define the derivative contract explicitly or use validated DTensor training later in the chapter.

Part 3 - Quantitative Prediction Before Execution

For partition r, derive

$$Y_r = XW_r^T + b_r, \qquad Y = \operatorname{concat}_r Y_r.$$

Given a global upstream derivative D, derive local weight and bias gradients from its matching feature slice. Input-gradient contributions must sum across feature owners. This is a sum over one logical layer, not an average over independent data replicas. Predict local output bytes and the extra replicated capacity required by a diagnostic gather.

Part 4 - Experimental Design and Instrumentation

Start with rank-distinct known weights, common input values, and divisible widths. Compare reconstructed outputs with ordinary Linear. Supply one known global upstream derivative and validate local weight gradients and the summed input gradient analytically. If building a custom autograd boundary, check its return arity and replicated-input gradient semantics. Do not attach a naive gather to a local loss and assume training equivalence. Run the forward benchmark only after the small correctness replay, then release reconstructed outputs before memory sampling.

Use an upstream derivative with different values in every output feature so incorrect concatenation and feature-to-gradient matching cannot cancel. Compute each rank's input-gradient contribution and show that omitting one changes at least one input element. Check a noncontiguous input separately if the scratch implementation accepts it; otherwise reject it clearly. The diagnostic gather may need packed contiguous payloads and temporary receive storage, which belong to its own accounting region. If later adding a differentiable gather, define whether outputs represent one replicated logical value or independently consumed rank-local values before choosing its adjoint. Validate the exact intended contract with the serial oracle. Do not turn a

working inference gather into a training primitive solely by leaving requires_grad enabled on its input.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

def column_parallel_forward(inputs, local_weight, local_bias):
    ...

def reconstruct_output_for_validation(local_output, feature_map, group):
    ...

def verify_column_derivatives(reference, shards, upstream_gradient):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report local and global output shapes, reconstruction order, maximum error, local parameter bytes, and diagnostic gather capacity. Detect reversed rank concatenation and an omitted input-gradient sum with small counterexamples. Use nonzero bias to ensure its partition is tested. A forward-only result must remain labeled forward-only until derivatives and several updates pass. Do not divide TP feature contributions by world size.

Part 7 - Engineering Interpretation and Philosophy

Explain why output sharding permits independent local matrix products but leaves a backward dependency for shared inputs. State when reconstructing the full output is needed for a consumer and when it is merely a debugging cost.

19.42.4 Exercise 03

Exercise Title: Implement Row-Wise Parallel Linear Algebra from Scratch and Use Collective Reduction to Produce the Correct Final Output

Part 1 - Exercise Contract and Why It Matters

Implement input-feature partitioned linear algebra and combine partial outputs with a collective sum. Verify the final result, bias placement, and derivative semantics. Deliver a valid row-parallel counterpart to E02.

Part 2 - System and Memory Mental Model

Partition stored weight columns and matching input features. Every rank produces a contribution to every output feature, so equal local output shapes do not imply replicated complete values. Bias belongs after the contribution sum, or requires an explicitly equivalent distributed treatment. Adding the full bias on every rank before SUM multiplies it by TP degree. A Partial layout denotes these unfinished contributions rather than ordinary replicas.

Part 3 - Quantitative Prediction Before Execution

Derive

$$Z_r = X_r W_r^T, \qquad Y = \sum_r Z_r + b.$$

Compute a small example by hand, including nonzero bias. Predict local input and weight bytes alongside the full-sized partial output. Derive weight and input-slice gradients for one global upstream derivative. Explain why repeated evaluation of the same replicated loss must not introduce another factor of T through an inappropriate backward reduction.

Part 4 - Experimental Design and Instrumentation

Use matching feature intervals for the input and weight. Implement a forward SUM, then add bias once in logical semantics. Validate the scratch backward analytically with the same upstream derivative on the complete output. A custom replicated-output boundary must preserve the single-logical-output interpretation; the generic adjoint of independent rank-local losses is a different problem. Compare several updates only after that contract is tested. Use the DTensor path for integrated training if a scratch differentiable collective has not been validated. Record all temporary reduction buffers.

Choose a hand example in which both ranks make nonzero contributions to every output and the bias is also nonzero. Verify the wrong result produced by adding bias before reduction and derive its dependence on TP degree. For derivative validation, use the same complete upstream derivative on the logical output and inspect each weight/input interval independently. A replicated bias needs the reference update once logically; it must not accumulate duplicate loss copies through an unexamined generic collective backward. Keep the scratch analytical check separate from the high-level DTensor training path. Report whether input partitioning begins with local slices of an already replicated input or with genuinely sharded upstream storage, because those construction choices have different memory lifetimes despite identical local matrix products.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
import torch.distributed as dist

def row_parallel_partial(local_input, local_weight):
    ...

def combine_row_partials(partial_output, bias, group):
```

```
    # SUM contributions and implement bias exactly once logically.
    ...

def verify_row_derivatives(reference, shards, upstream_gradient):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require complete-output agreement, correct bias gradients, local weight gradients, and reconstructed input gradients. Include the deliberately incorrect pre-reduction full-bias case and expose its error. A local partial output that coincidentally equals the answer for zero-valued other shards is not a sufficient test. Preserve forward-only status when training derivatives are unfinished. Report logical payload separately from backend link traffic.

Part 7 - Engineering Interpretation and Philosophy

Explain why row sharding trades smaller local inputs for full-sized partial outputs and reduction work. Relate the bias rule to the difference between ownership of a contribution and ownership of a complete value.

19.42.5 Exercise 04

Exercise Title: Compare Column-Wise and Row-Wise Tensor Parallelism by Per-GPU Parameter Memory, Activation Memory, Communication Volume, and Latency

Part 1 - Exercise Contract and Why It Matters

Compare column and row layouts for the same logical Linear operation. Measure parameter storage, activation boundaries, communication, and completed latency. Include the cost of satisfying a common external input/output contract so the comparison does not favor a layout by omitting conversion.

Part 2 - System and Memory Mental Model

Column partitioning naturally consumes replicated inputs and returns feature shards. Row partitioning naturally consumes feature shards and reduces to complete outputs. Their useful local weight counts can be equal while activation residency and collective work differ. A caller that already owns sharded inputs has a different starting point from one with full replicas. Backward and optimizer costs must be measured separately from a forward-only algebra comparison.

Part 3 - Quantitative Prediction Before Execution

For fixed M, K, N, T, s, calculate weight payload, natural input capacity, natural output capacity, and conversion buffers for each layout. Use one comparison with natural boundaries and another with replicated input and replicated output on both paths. Predict which gather, slice, or reduction is needed. Estimate collective payload and state an explicit algorithmic assumption before translating it into estimated transmitted bytes.

Part 4 - Experimental Design and Instrumentation

Run isolated replays from the same logical values and input data. Validate outputs first. Then benchmark natural boundaries and common boundaries as separate experiments. Measure warmed execution with boundary synchronization, CUDA timing where appropriate, and end-to-end host timing for completed work. Reset peaks for the named region and report cold allocation separately. If testing training, include forward, backward, optimizer update, and necessary layout communication. Profile in a separate replay so trace overhead does not become the reported baseline latency.

Include a workload with narrow output and wide input, then reverse the aspect ratio while keeping the accounting rules fixed. This exposes which activation boundary dominates rather than assuming square matrices represent all layers. Count local slices that retain full input backing by their backing capacity in the common-boundary comparison. Record whether reduction is in-place, whether the unreduced partial is retained, and whether a full output gather overlaps the source shard. Those details can change the peak without changing the final answer. Use repeated process launches to estimate variability and preserve the slowest rank's evidence. Compare reported logical payload with supported trace events, but leave physical traffic unknown when the instrument only knows tensor sizes. Explain any performance claim within its measured shape and topology range.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LinearBoundaryContract:
    input_layout: str
    output_layout: str
    includes_backward: bool
    includes_optimizer: bool

def compare_linear_layouts(spec, boundary_contract, measurements):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export each boundary contract, per-rank useful/backing bytes, allocated and reserved peaks, communication calls and payload, elapsed time, and numerical error. Do not count a diagnostic output gather only on one side. Report cases where the lower-memory layout is slower. Identify whether a result comes from matrix shape, conversion, reduction, or another traced dependency before attributing it to a universal advantage of column or row sharding.

Part 7 - Engineering Interpretation and Philosophy

Choose a layout based on its neighbors and the limiting resource. A layer's isolated local parameter size cannot determine the best distributed layout for an entire model.

19.42.6 Exercise 05

Exercise Title: Build a DeviceMesh with PyTorch and Map Logical Tensor-Parallel Dimensions onto Physical CUDA Devices

Part 1 - Exercise Contract and Why It Matters

Create a DeviceMesh that maps a logical TP dimension to actual CUDA ranks. Verify membership, coordinate order, process groups, and device binding before running tensor operations. Deliver an explicit mapping rather than assuming rank adjacency implies a particular physical interconnect.

Part 2 - System and Memory Mental Model

A mesh describes logical rank organization and communication groups. It does not manufacture faster links or move an already allocated tensor merely by assigning a dimension name. Global rank, local rank, CUDA ordinal, and mesh coordinate are related but distinct identifiers. Every participating process must construct a consistent mesh definition. Conflicting definitions can lead to incorrect groups or hangs, so validate a shared configuration before issuing data collectives.

Part 3 - Quantitative Prediction Before Execution

For two ranks, list the ordered membership of the one-dimensional TP mesh and the feature interval assigned to each coordinate. For a hypothetical four-rank grid with named data and tensor dimensions, enumerate the two kinds of subgroup. Explain why reshaping the same rank list can change which devices communicate. Predict mapping metadata only for unavailable topologies; do not report hypothetical link performance as a measurement.

Part 4 - Experimental Design and Instrumentation

Bind CUDA devices from launcher-provided local rank, establish the process group, and create a named mesh from the validated configuration. Export a CPU record of rank, coordinate, device, and subgroup membership. Run a small rank-distinct collective to check ordering. Compare the mapping with available physical topology evidence and record unknown links. Keep one-process-per-GPU execution as the primary track. Validate world-size products, unique rank membership, and device availability before starting the distributed program. Use offline negative tests for inconsistent meshes instead of creating hangs.

Name the mesh dimension and persist the rank order with the experiment. A rank permutation changes the association between a feature interval and its producer even if all local tensor shapes remain equal. Test that the output reconstruction uses mesh coordinates rather than an unrelated CUDA ordinal. In a multi-dimensional plan, pass the one-dimensional TP submesh to parallelize_module instead of the whole grid. Validate that subgroup dimensions have the intended sizes and that no rank appears twice in the mesh. Separate launcher environment validation from collective execution so a missing device is diagnosed before the computation begins. If topology evidence is unavailable, record only the logical mapping and leave link assumptions unverified. A successful numerical test does not measure bandwidth or prove a placement is optimal for the physical machine.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist
from torch.distributed.device_mesh import init_device_mesh

@dataclass
class MeshCoordinateRecord:
    global_rank: int
    local_rank: int
    cuda_device: int
    mesh_coordinate: tuple
    tensor_group_ranks: tuple

def build_and_validate_tp_mesh(launch_context, mesh_spec):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require complete and consistent mapping records across ranks. A successful mesh constructor alone does not validate data ordering or topology assumptions. Report group creation cost separately from warmed execution. Record backend and software versions because mesh and TP interfaces evolve. Mark unavailable multi-dimensional experiments not measured while retaining their offline membership checks.

Part 7 - Engineering Interpretation and Philosophy

Explain how logical organization affects placement and synchronization without promising a physical bandwidth guarantee. Choose a mapping that can be justified by the devices and links actually available.

19.42.7 Exercise 06

Exercise Title: Create a DTensor and Experiment with Shard, Replicate, and Placement Changes Across a Multi-GPU Device Mesh

Part 1 - Exercise Contract and Why It Matters

Construct DTensors with Shard and Replicate placements and inspect their logical shapes alongside local storage. Introduce Partial as pending contributions requiring reduction. Deliver a placement ledger and numerical checks for each representation.

Part 2 - System and Memory Mental Model

DTensor metadata describes one logical tensor distributed over a mesh. Its global numel is not the number of elements allocated on each rank. Creating a DTensor from local tensors asserts that those pieces already obey the supplied placement; it is not a request to magically distribute unrelated local values. Replicate requires consistent complete values. Partial requires contributions to a declared reduction. Keep global shape and stride metadata correct, especially when local shard shapes are uneven.

Part 3 - Quantitative Prediction Before Execution

Choose a small two-dimensional logical tensor. Predict its local shapes and useful bytes for sharding each axis and for replication. Give a valid sum-partial example whose local contributions differ but whose sum equals the reference. Explain why the same local buffers cannot simply be relabeled from Partial to Replicate without changing values. Distinguish metadata construction from an actual redistribution operation.

Part 4 - Experimental Design and Instrumentation

Use public DTensor creation APIs under the installed version's contract. Validate local contents before construction; enable supported checks in a diagnostic replay and account for their communication separately. Compare local shape, placement, mesh, global shape, dtype, stride, and backing bytes. Reconstruct small cases outside timing. For uneven local shards, supply required global metadata explicitly and test reconstruction rather than relying on equal-shard inference. Start with inference-only creation, then validate the documented autograd path using a small differentiable computation.

Use coordinate-coded tensor entries to distinguish sharding axis zero from sharding axis one even when a square tensor makes local shapes ambiguous. Build a replica test with intentionally different original values, verify the precondition failure, and distinguish that from an optional check mode that broadcasts one source's values. Record the values before such a check if the audit needs to establish original consistency. For Partial, construct actual summands of a known logical result and verify the declared reduction. Do not create arbitrary placements by calling an internal tensor subclass constructor. When crossing to_local, preserve an explicit description of the local value and future gradient layout. The returned Python tensor does not carry the whole placement contract for an unaware downstream consumer. Validate gradients on this boundary before including it in training.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor import (
    DTensor, Shard, Replicate, Partial, distribute_tensor,
)

def create_checked_dtensor(local_tensor, mesh, layout_spec):
    # Establish valid local values and global metadata before construction.
    ...
```

```
def inspect_global_and_local_storage(distributed_tensor):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report global and local shapes, actual local bytes, placement, creation communication, and reconstruction error. Reject rank-distinct values falsely claimed to be replicas. Treat checks that broadcast replica data as observable behavior, not proof that arbitrary original values were already consistent. Do not use private DTensor construction as a substitute for a validated public autograd route. Preserve unsupported creation modes explicitly.

Part 7 - Engineering Interpretation and Philosophy

Explain how a distributed layout is a semantic claim about values as well as a storage description. Identify which information is lost when a DTensor is converted to a plain local tensor without a boundary contract.

19.42.8 Exercise 07

Exercise Title: Redistribute a DTensor Between Sharded and Replicated Layouts and Measure the Collective Communication Triggered by Each Layout Change

Part 1 - Exercise Contract and Why It Matters

Redistribute a valid DTensor among supported placements on the same mesh and measure the resulting work. Build a transition ledger containing expected collectives, observed events, temporary storage, and correct values.

Part 2 - System and Memory Mental Model

A shard-to-replica transition needs missing pieces, whereas replica-to- shard can select local pieces. Sum-partial to replica completes a reduction; sum-partial to shard combines reduction with partitioned output. Changing the sharded tensor axis can require data exchange. The public implementation and backend may introduce padding, packing, or alternative event names. Limit the primary experiment to supported same-mesh transitions instead of assuming arbitrary cross-mesh redistribution.

Part 3 - Quantitative Prediction Before Execution

Predict all-gather for Shard to Replicate, local selection for Replicate to Shard, all-reduce for sum-Partial to Replicate, and reduce-scatter for sum-Partial to Shard. Include a supported shard-axis change as an additional exchange experiment. For each, calculate logical input/output bytes and a live-buffer timeline. State that local selection can retain a larger parent backing even when its useful output size decreases.

Part 4 - Experimental Design and Instrumentation

Construct valid source values for each transition, warm the path, and measure forward redistribution independently from any backward communication. Use a second replay to profile

actual operations and a third small replay to check values and derivatives where supported. Keep creation checks outside the transition region. For asynchronous execution, wait through the documented completion path before reading values or stopping a completed-work timer. Retain buffers until communication and consumers finish. Record dtype casts only if explicitly requested as part of a separate experiment.

Use a fresh valid source for every transition so a previous redistribution cannot alter the intended baseline. For a no-op same-placement request, record whether the implementation returns an alias and whether any local allocation occurs. For shard-axis exchange, count possible packing or padding rather than asserting that an all-to-all event must be the only visible work. Test asynchronous completion with a dependent consumer and verify its output, not merely a successful launch. Keep source and destination references only as long as the declared region requires; retaining every sweep result would inflate later peaks. Do not use undocumented conversion to Partial as a portable shortcut. The primary four transitions can be constructed from valid replicated, sharded, and sum-partial sources without assuming arbitrary placement relabeling is permitted by the installed version.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor import Shard, Replicate, Partial

def predict_redistribution(source_spec, target_placements):
    ...

def measure_redistribution(source, target_placements, measurement):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Match predicted transitions with observed traces and explain differences without inventing backend traffic. Count forwards and backwards separately. Report useful local output bytes and retained backing capacity. A transition with no network collective can still allocate or copy locally; do not label it cost-free from its name. Preserve unknown link traffic and unsupported transitions. Validate that asynchronous timing did not measure launch only.

Part 7 - Engineering Interpretation and Philosophy

Explain when a layout change pays for missing information and when it only discards redundant local information. Choose one transition whose temporary memory matters more than its final output size.

19.42.9 Exercise 08

Exercise Title: Apply PyTorch ColwiseParallel to a Linear Layer and Verify Local Parameter Shapes and Distributed Output Layouts

Part 1 - Exercise Contract and Why It Matters

Apply ColwiseParallel to a supported Linear layer and verify parameter shards and output layouts. Compare its behavior with E02 while preserving DTensor metadata long enough to audit the boundary and gradients.

Part 2 - System and Memory Mental Model

The API's style name does not change PyTorch's stored weight orientation. Inspect the local parameter rows and the output feature partition explicitly. A plain local output can represent only one feature shard even though its Python type looks ordinary. Use explicit input/output placements and the local-output setting rather than relying on defaults. The input annotation must describe what the caller really supplies; falsely annotating different inputs as replicas changes the logical computation.

Part 3 - Quantitative Prediction Before Execution

Predict local weight and bias shapes, global output shape, and local output extent for a divisible test layer. Predict the difference between retaining a feature-sharded output and requesting a replicated output. Calculate the additional reconstruction capacity and expected communication. For backward, identify the reduction needed for the replicated input derivative and the ownership of weight-gradient elements.

Part 4 - Experimental Design and Instrumentation

Check installed API signatures, build the mesh, and parallelize a small layer using a declared plan. Initialize from the same logical reference and inspect parameters before the optimizer is created. Keep distributed outputs for layout inspection, then cross a plain-tensor boundary only with known local semantics. Compare outputs, input derivatives, weight-gradient shards, and several Adam updates with the serial reference. Measure larger bounded layers in isolated runs without retaining the full reference model on CUDA. Record conversion and initialization peaks separately.

Inspect the logical parameter registry after parallelization and before optimizer construction. Verify that weight, bias, and their gradients use the expected ownership and that old full parameters are not retained by a reference optimizer or debugging closure. Compare the local bias slice as well as the matrix because zero-bias tests can conceal a wrong partition. Record the installed default settings, but make the experiment's choices explicit so a later default change does not silently modify its contract. If output is a plain local tensor, check the next consumer's expected feature extent before execution. If output remains a DTensor, verify global reshaping and placement propagation using supported operators. Both paths require numerical checks; the abstraction alone does not establish that an arbitrary module between the Linear layers respects its distributed layout.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor import Shard, Replicate
from torch.distributed.tensor.parallel import (
    parallelize_module, ColwiseParallel,
)

def build_colwise_plan(boundary_contract):
    ...

def audit_colwise_layer(module, inputs, reference, mesh):
    ...

def E08(config):
    # Apply the plan, validate updates, and measure local storage.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require matching logical values, valid local storage, correct parameter coverage, and update equivalence. Record whether output is DTensor or plain local Tensor and whether it is sharded or replicated. A global shape printed from a DTensor must not be reported as local allocation. Detect a consumer that accidentally treats local output width as full width. Mark API or dtype combinations unsupported when they fail the capability check.

Part 7 - Engineering Interpretation and Philosophy

Explain which correctness obligations the distributed abstraction handles and which remain at plain-tensor boundaries. Decide whether retaining output metadata makes the next layer's contract easier to audit.

19.42.10 Exercise 09

Exercise Title: Apply RowwiseParallel to the Following Linear Layer and Build a Communication-Efficient Two-Layer Tensor-Parallel MLP

Part 1 - Exercise Contract and Why It Matters

Pair the column-parallel first Linear with a row-parallel second Linear to form a two-layer MLP. Preserve sharded hidden features through the activation and avoid an unnecessary full hidden reconstruction. Validate complete training updates as well as the expected communication path.

Part 2 - System and Memory Mental Model

An elementwise activation can act independently on feature shards. The following row-parallel layer consumes those same feature intervals and combines its partial outputs. Gathering hidden features and then splitting them again introduces work without changing the logical MLP. More complex operations between the layers can change this reasoning: normalization

over hidden features or a global feature permutation needs additional treatment. Bias and replicated-output loss semantics remain part of the contract.

Part 3 - Quantitative Prediction Before Execution

For hidden width F, derive the local shapes of stored weights $W_1 \in \mathbb{R}^{F\times H}$ and $W_2 \in \mathbb{R}^{H\times F}$. Predict hidden activation bytes $BSFs/T$ for a feature-sharded buffer. Compare this with a gathered hidden buffer and include simultaneous source/destination capacity. Predict forward output reduction and backward input-contribution combination for the basic replicated-boundary MLP.

Part 4 - Experimental Design and Instrumentation

Use deterministic GELU or another fixed elementwise activation, identical logical parameters, and common input values across TP ranks. Set the two styles' boundary placements explicitly. Validate output, input gradients, local parameter gradients, and Adam updates for several steps. Compare the compatible pair with a deliberately redundant gather-then-split plan in fresh replays. Include forward, backward, and update in training timing. Keep final output reconstruction consistent across variants and record its cost if required by the common loss boundary.

Use a hidden activation whose feature values differ across every interval. Compare the compatible pair with a diagnostic gather that reconstructs all features in the correct order, so the inefficient reference remains numerically valid. At the second layer, verify that its weight columns correspond exactly to the first layer's output rows. Changing rank order between those assignments can preserve all local dimensions while computing a permuted MLP. Validate the intermediate activation separately in a tiny replay, then remove its reconstruction from production timing. Inspect backward communication too: eliminating a forward gather does not imply all backward exchanges disappear. Keep replicated input and output boundaries consistent when comparing complete training steps. Report whether the optimizer stores local moments for shards and full moments for any replicated bias parameters.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor import Shard, Replicate
from torch.distributed.tensor.parallel import (
    parallelize_module, ColwiseParallel, RowwiseParallel,
)

def make_paired_mlp_plan(boundary_contract):
    ...

def validate_mlp_updates(model, reference, batches, mesh):
    ...

def E09(config):
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Report hidden useful and backing bytes, collective events by phase, complete-step peaks, latency, and update errors. Confirm that no hidden gather survives in the intended compatible pair. A missing collective is not a success if a local shard was misinterpreted as a full tensor. Include nonzero bias and a second optimizer update to reveal stale replicas or incorrect reduction semantics.

Part 7 - Engineering Interpretation and Philosophy

Explain why choosing adjacent layouts together can outperform optimizing each layer in isolation. State the algebraic property that permits the activation to remain local and a counterexample where that property fails.

19.42.11 Exercise 10

Exercise Title: Tensor-Parallelize Transformer Attention Projection Matrices and Verify Correct Head and Hidden-Dimension Partitioning Across GPUs

Part 1 - Exercise Contract and Why It Matters

Partition Transformer query, key, value, and output projections with correct head ownership. Start with ordinary multi-head attention whose query and KV head counts are equal and divisible by TP degree. Deliver attention output and gradient equivalence before optional grouped-query extensions.

Part 2 - System and Memory Mental Model

Column-parallel Q, K, and V projections produce local complete heads. Each local head still attends over all required sequence positions. The output projection is row-parallel over concatenated head features. Local tensors must reshape with local head counts; DTensor-aware reshaping must preserve the intended global layout. Splitting a head's feature dimension accidentally is not equivalent to splitting whole independent heads. Grouped-query or multi-query attention needs a declared query-to-KV mapping and may require KV replication when KV heads cannot be evenly partitioned.

Part 3 - Quantitative Prediction Before Execution

With hidden width $H = hd$, batch B, and length S, predict local Q/K/V shapes and projection storage for h/T heads. Derive local attention-score capacity only for an implementation that actually materializes the score matrix. Contrast that with a memory-efficient attention backend without assuming identical workspace. Predict which operation combines the output projection's partial results. Check the causal mask's logical positions.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic attention block with dropout disabled, fixed position handling, and one named attention implementation. Validate projection slices and head identities with coordinate-coded values. Compare final outputs, input gradients, projection gradients, and several optimizer updates with a serial oracle. Inspect transpose, reshape, and concatenation boundaries. Maintain identical masks and positions across TP ranks. Test a nontrivial causal sequence rather than a single token only. Reject unsupported head counts before collective

launch. Keep GQA as a separately validated extension, not an automatic consequence of splitting the hidden dimension.

Test each projection separately before the attention composition. For fused QKV storage, define whether the global ordering groups all queries then keys then values or interleaves them by head; a naive contiguous slice can split the wrong logical groups. The primary exercise may use separate Q, K, and V layers to keep this mapping auditable. Preserve positional transforms on the correct head coordinates and absolute token positions. If testing GQA, require that every local query head can access its corresponding KV head and count any replicated KV storage explicitly. A query-head count divisible by degree does not establish KV compatibility. Keep attention scaling, causal masking, precision settings, and backend fixed across the reference and TP runs, allowing declared floating-point tolerance rather than promising bitwise identity after a changed reduction order.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor.parallel import (
    parallelize_module, ColwiseParallel, RowwiseParallel,
)

def plan_attention_heads(attention_spec, tp_degree):
    ...

def verify_local_head_mapping(module, layout, reference):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export global and local head counts, head dimension, weight placements, local activation bytes, selected attention backend, mask identity, errors, and collective events. Check parameter and input gradients, not only logits. Label KV replication explicitly when tested. Avoid a universal quadratic memory formula for a backend that does not retain full scores. An unavailable operator sharding rule is unsupported rather than permission to silently gather every projection and call the result fully tensor parallel.

Part 7 - Engineering Interpretation and Philosophy

Explain why head independence permits local attention while sequence coverage must remain complete. Identify how a plausible reshape can preserve shape compatibility yet change which logical heads the model computes.

19.42.12 Exercise 11

Exercise Title: Tensor-Parallelize Transformer Feed-Forward Layers and Compare Their Memory and Communication Behavior with Attention Layers

Part 1 - Exercise Contract and Why It Matters

Tensor-parallelize Transformer feed-forward layers and compare their memory and communication with the validated attention block. Include an ordinary two-matrix MLP and, optionally, a separately validated gated MLP.

Part 2 - System and Memory Mental Model

The feed-forward expansion and contraction naturally form a column/row pair. In a gated MLP, both expansion branches must assign the same hidden feature intervals before the elementwise product. A matching shape alone cannot prove that gate and value features align. Attention additionally reshapes heads and may have sequence-dependent workspace, whereas the MLP's large expansion activation scales with its intermediate width. Compare complete blocks under the same boundary layout and training semantics.

Part 3 - Quantitative Prediction Before Execution

For expansion width F, predict the two-matrix weight elements $2HF$ and feature-sharded hidden activation elements BSF/T. For a three-matrix gated design, derive the changed weight count and the lifetimes of both branches and their product. Do not sum all buffer maxima as if they necessarily coexist. Compare those timelines with the selected attention implementation at the same B, S, H, T and precision.

Part 4 - Experimental Design and Instrumentation

Build the ordinary paired MLP first, then align gate/value shard manifests if implementing the gated variant. Validate output and gradient equivalence with a deterministic serial block. Measure attention and feed-forward regions in diagnostic replays, then measure the whole Transformer block to capture cross-region lifetimes. Keep norm and residual boundary layouts explicit. Sweep sequence length and expansion width independently. Record saved activations, temporary elementwise outputs, communication buffers, and the initial-state identifier. Fix optimizer and attention backend across the primary comparison.

Measure saved activations and transient forward outputs separately. A gated product can retain both branches for backward, so its cost cannot be inferred from the product's local size alone. Do not use logging hooks that keep GPU tensors alive beyond their actual computation lifetimes. Export metadata or detached CPU scalars at deliberate boundaries. In the attention comparison, state whether the backend materializes probabilities and whether its backward recomputes intermediates; the MLP comparison must use the same training-region definition. Add a controlled expansion-width sweep at fixed sequence length and a sequence-length sweep at fixed expansion width. These experiments distinguish linear activation growth from the selected attention implementation's behavior. Report the observations even if parameter sharding saves less peak memory than the expanded intermediate or another replicated boundary consumes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor.parallel import (
    parallelize_module, ColwiseParallel, RowwiseParallel,
)

def plan_feed_forward(spec, feature_partition):
    ...

def verify_gate_feature_alignment(branch_layouts):
    ...

def compare_attention_and_mlp(replay_specs, evidence):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful local parameters, retained activations, peak allocated and reserved bytes, collective payload, completed latency, and numerical errors for each region and the full block. Identify the lifetime that controls the whole-block peak. Include a permuted gate-shard negative control. Do not infer that equal parameter counts imply equal activation memory or that isolated region peaks can simply be added to predict the training peak.

Part 7 - Engineering Interpretation and Philosophy

Choose an optimization target from measured memory components. Explain why the MLP may dominate one configuration while attention dominates another, and how a compatible boundary layout affects both.

19.42.13 Exercise 12

Exercise Title: Introduce Sequence Parallelism for LayerNorm or RMSNorm Activations and Measure the Reduction in Replicated Activation Memory

Part 1 - Exercise Contract and Why It Matters

Shard sequence-position activations around a supported LayerNorm or RMSNorm and integrate that boundary with TP attention and MLP. Measure which replicated activations disappear and which all-gather or reduce-scatter operations replace the previous boundary communication.

Part 2 - System and Memory Mental Model

For batch-sequence-hidden layout, sequence sharding assigns complete hidden vectors for different positions to different ranks. Normalization over hidden features can remain local for each token; hidden-feature sharding would need different normalization logic. Norm parameters

remain replicated and their gradient contributions from different token subsets must be combined correctly. Sequence parallelism around norms is not context-parallel attention: ordinary head-parallel attention still needs its full relevant token sequence.

Part 3 - Quantitative Prediction Before Execution

Predict selected boundary activation bytes changing from $BSHs$ to $BSHs/T$ per rank for divisible length. Add full-sequence inputs materialized for attention or MLP, retained saved activations, and redistribution buffers. Draw the path from sequence shards through gathered inputs to row-parallel outputs reduced into sequence shards. Explain why the whole-model peak need not fall by a factor of T.

Part 4 - Experimental Design and Instrumentation

Use an explicitly supported normalization module and check installed SequenceParallel behavior. Initialize replicated norm weights consistently, including custom initialization. Set sequence dimension from the actual tensor layout. Preserve DTensor metadata through residual additions and prepare the attention and MLP input layouts explicitly. Validate outputs, norm parameter gradients, other parameter gradients, and updates against the no-SP reference. Start without dropout. Compare isolated norm storage and complete-step peaks in separate replays. Test multiple blocks so an unintended gather at every boundary becomes visible.

Validate normalization with nontrivial scale and bias where supported, not only default unit weights. Their replicas must agree before computation and after every optimizer update. Token-sharded norm gradients contain contributions from different positions; verify that the distributed path combines them according to the full logical objective. Otherwise matching forward values can conceal divergent replicated weights after the first step. Check residual additions with both operands on the same sequence intervals. Test two consecutive blocks and the final loss boundary so a local sequence shard is never silently treated as a complete sequence. Use a supported LayerNorm as the primary norm if RMSNorm implementation support is uncertain. A full-context attention gather can remain necessary even when norm and residual activations are successfully sharded; include that temporary capacity in the end-to-end measurement.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor import Shard, Replicate
from torch.distributed.tensor.parallel import (
    SequenceParallel, PrepareModuleInput, parallelize_module,
)

def plan_sequence_boundaries(model_spec, tensor_order):
    ...

def verify_replicated_norm_updates(model, reference, batches):
    ...
```

```
def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report boundary placements, local token intervals, norm parameter parity, collectives by phase, useful activation bytes, and complete-step peaks. Detect an incorrect norm that operates on only a hidden-feature slice. If a particular RMSNorm implementation lacks support, use a verified supported implementation or mark it unsupported. Do not infer reduced attention context or altered causal semantics from the phrase sequence parallelism.

Part 7 - Engineering Interpretation and Philosophy

Explain which independent token computations permit sequence sharding and which consumers require more information. Distinguish a scoped activation saving from a guarantee about the model's total peak memory.

19.42.14 Exercise 13

Exercise Title: Trace All-Gather, All-Reduce, Reduce-Scatter, and Redistribution Operations Produced by Tensor-Parallel Execution

Part 1 - Exercise Contract and Why It Matters

Trace communication generated by the validated TP model and connect each operation to a layout requirement. Cover all-gather, all-reduce, reduce-scatter, and redistribution work without assuming a fixed event name across versions and backends.

Part 2 - System and Memory Mental Model

One high-level redistribution may create packing, padding, communication, and local-copy events. Forward and backward can need different collectives. Initialization, diagnostic reconstruction, data-parallel synchronization, and TP execution must remain distinguishable. Trace event counts are not a direct measurement of physical link bytes. A communication launch nested inside a Python scope may complete after that scope exits, so dependency-aware timelines are needed to interpret overlap.

Part 3 - Quantitative Prediction Before Execution

Construct an expected ledger for the paired MLP and the SP-enabled block. For every operation, specify source layout, target layout, logical tensor shape, dtype, group, phase, and payload bytes. Mark input-gradient combination separately from forward output reduction. Predict which collectives should vanish in a no-op same-layout transition and which remain required by the logical computation.

Part 4 - Experimental Design and Instrumentation

Annotate model regions and collective boundaries in an instrumented replay. Collect traces on all participating ranks with common step IDs. Warm the model before the traced steady region and record initialization separately. Inspect both forward and backward, then run ordinary timing without profiler overhead. Map supported backend events to the layout ledger and preserve ambiguous matches as unknown. Use completion dependencies to distinguish useful

overlap from queued launches. Keep full_tensor debug reconstruction outside the production region. Export compact CPU summaries and trace artifact references.

Maintain a common logical step and region identifier in every rank's trace. Where clock alignment is unavailable, compare rank-local durations and causal dependencies rather than treating unaligned absolute timestamps as simultaneous. Attribute collective groups explicitly so an FSDP gather is not counted as a TP activation gather in the optional composition. Include a same-layout transition control and a deliberately redundant gather-then-split boundary as known trace cases. Record profiler configuration and whether memory tracing was enabled. Bound instrumentation overhead through a separate ordinary run. A communication kernel with a long duration can include waiting for a slow rank; inspect launch and dependency evidence before interpreting it as poor link bandwidth. Preserve unmatched or fused events as uncertain instead of forcing a one-to-one mapping that the trace does not support.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.profiler import profile, record_function

def expected_tp_collective_ledger(layout_plan, training_contract):
    ...

def correlate_trace_events(trace, expected_ledger, rank_metadata):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted and observed calls, unmatched events, group membership, payload estimates, exposed wait, overlap, and trace overhead. Do not sum concurrent event durations and call the result step latency. A collective absent from one rank's trace can reflect incomplete capture; check other ranks and the recording window. State when physical traffic cannot be measured. Retain at least one explained mismatch between a naive expectation and the actual trace if one is observed.

Part 7 - Engineering Interpretation and Philosophy

Explain communication as an information dependency rather than an unqualified overhead category. Choose one operation that can be removed by layout compatibility and another required by the current mathematical contract.

19.42.15 Exercise 14

Exercise Title: Detect an Incorrect Tensor Placement That Causes an Unnecessary Collective Operation and Rewrite the Layout to Eliminate It

Part 1 - Exercise Contract and Why It Matters

Introduce an inefficient layout boundary that causes unnecessary communication, detect it with E13, and rewrite the plan. Keep inefficient but correct layouts separate from false annotations that compute wrong values.

Part 2 - System and Memory Mental Model

A gathered MLP intermediate immediately split for the next row-parallel layer is a candidate redundancy. Removing the gather is valid only if the consumer receives the correct feature interval and every intervening operation supports the sharded layout. Relabeling a partial result as complete can remove a collective while corrupting the function. A successful optimization must preserve outputs, gradients, optimizer updates, and any external boundary contract that the original program promised.

Part 3 - Quantitative Prediction Before Execution

Predict the gather payload and live hidden capacity in a deliberately replicated intermediate plan. Derive the feature-compatible alternative and identify which events should disappear. Include any changed packing or local copy cost. Construct a counterexample with normalization over the full hidden axis to show why an arbitrary gather cannot be removed without redesigning the intervening operation.

Part 4 - Experimental Design and Instrumentation

Use the paired MLP as the primary reproducer, with exactly one changed boundary. Verify both versions against the same reference before profiling. Inspect the collective ledger and retained storage, then implement the compatible sharded edge. Repeat correctness over several updates and an additional seed. Measure completed forward and training latency in separate regions, with equivalent output reconstruction and logging. Audit a plain local output boundary so it does not silently discard placement knowledge. Do not introduce fusion, dtype changes, or a different activation into the same controlled comparison.

Represent the rewrite as a change to one producer-consumer edge with its before/after placements, local feature map, and required operator rules. Verify those preconditions independently of the profiler. The original and rewritten versions must start from identical parameter values and receive the same upstream loss meaning. Compare local weight-gradient slices and replicated parameters after several updates, because a shape-compatible wrong annotation can escape a single forward check. Include an intervening feature permutation as another boundary test: it may be local only if its mapping respects the shard intervals or is redesigned explicitly. A lower collective count is evidence about work, not sufficient evidence about correctness or speed. Keep the smallest correct redundant example and the smallest invalid rewrite as distinct artifacts in the learner's evidence record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def find_redundant_layout_edges(graph, layout_plan, trace_ledger):
    ...
```

```
def propose_compatible_edge(edge, operator_capabilities):
    ...

def verify_layout_rewrite(original, rewritten, reference, batches):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a trace showing the expected removed work and numerical evidence for the rewritten model. Report old/new local capacity, allocated and reserved peaks, payload, latency, and any new work. If latency does not improve, examine remaining bottlenecks and variability rather than inventing a speedup. Include a false-placement negative control detected before benchmarking. Keep a minimal reproducer of the redundant boundary in the evidence.

Part 7 - Engineering Interpretation and Philosophy

Explain the proof that the removed communication was redundant. State the operator or layout assumption whose violation would invalidate that proof.

19.42.16 Exercise 15

Exercise Title: Build a Memory Cost Model That Predicts Parameter, Activation, and Communication Buffer Memory for Different Tensor-Parallel Degrees

Part 1 - Exercise Contract and Why It Matters

Build a placement-aware memory cost model for candidate TP degrees. Predict persistent parameters, gradients, optimizer state, activations, and communication buffers per rank and phase. Validate the model against measured storage rather than equating global numel divided by TP degree with peak VRAM.

Part 2 - System and Memory Mental Model

Large projection weights can be sharded while normalization parameters, selected biases, boundary activations, and workspaces remain replicated. Optimizer state follows actual parameter ownership and optimizer dtype policy. Gathered and partial buffers have lifetimes that may overlap with saved activations. Backend allocations and allocator retention extend beyond the logical tensor inventory. A useful model preserves those scopes and exposes unknowns instead of forcing every residual into fragmentation.

Part 3 - Quantitative Prediction Before Execution

Let P_s and P_r be sharded and replicated parameter bytes. Start with

$$P_{\text{local}} = P_s/T + P_r.$$

Replace equal division with actual local extents where necessary. Add gradient and initialized optimizer bytes under declared dtypes. Define peak prediction as a maximum over phase-specific live unique storage, including padding, communication, and workspace allowances. Do not add unrelated category maxima without a common timeline. Produce optimistic and conservative estimates when workspace information is incomplete.

Part 4 - Experimental Design and Instrumentation

Inventory each supported tensor by global identity, local shape, placement, dtype, backing storage, creation, and last use. Calibrate a small number of known workspace or rounding terms on one configuration and validate on held-out shapes and degrees. Keep uninitialized-optimizer and warmed measurements separate. Use actual collective traces to refine buffer lifetimes. Report prediction residuals by phase and rank. Preserve the cost model's calibration inputs and assumptions so later selection does not silently learn from the same test results it claims to predict.

Include construction as a separate phase in the cost model. A plan with small warmed shards can still fail if initialization creates a full model on every CUDA device. Count model loading, parallelization conversion, and optimizer creation under their own lifetimes. For optimizer estimates, inspect actual initialized moments and any master copy instead of applying a familiar bytes-per-parameter constant without assumptions. Represent aliases with a common backing identity so views do not multiply payload counts. Workspace bounds should name the attention and matrix-multiplication configurations to which they apply. Validate on a held-out sequence length where activation memory matters, not only another weight size. Report a predicted feasible plan that failed if encountered, and use its phase evidence to revise the model without rewriting the original prediction.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TensorLifetimeCost:
    logical_identity: str
    placement: tuple
    local_capacity_bytes: int
    first_phase: str
    last_phase: str
    storage_identity: str

def predict_rank_peak(layout_plan, lifetimes, workspace_bounds):
    ...

def validate_cost_model(predictions, held_out_measurements):
    ...
```

```
def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw component bytes, assumptions, predicted phase peaks, measured peaks, residuals, and uncertainty status. Check storage aliases before summing. An underestimated attention workspace or optimizer temporary needs its own explanation. Include a case with substantial replicated activation memory to invalidate an all-memory-divides-by-T rule. Do not use reserved memory as if it were simultaneously live tensor payload. A prediction interval is not an allocator reservation or a guarantee of successful allocation.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest model that preserves the distinctions needed for placement decisions. Explain which uncertainty can be reduced by profiling and which depends on backend behavior or concurrent device use.

19.42.17 Exercise 16

Exercise Title: Sweep Tensor-Parallel Degree Across Available GPUs and Identify When Lower Per-GPU VRAM Is Offset by Higher Communication Cost

Part 1 - Exercise Contract and Why It Matters

Sweep TP degree across available devices and identify the trade-off between lower per-rank memory and communication cost. Separate equal-model latency from the ability to run a larger model, and keep global useful work constant within each comparison.

Part 2 - System and Memory Mental Model

TP ranks cooperate on one batch, so adding TP ranks does not multiply the number of independent examples processed. A smaller local matrix can be less efficient, and launch and communication overhead can dominate at small sizes. Physical topology and contention affect performance. Degree one is a useful baseline, while degrees requiring unavailable GPUs remain predictions or not measured. One multi-GPU machine is sufficient for the available-degree experiments.

Part 3 - Quantitative Prediction Before Execution

Use E15 to predict peak bytes at each permitted degree and calculate local matrix dimensions, heads, and divisibility constraints. Build an optimistic latency model from local compute plus exposed communication, stating the assumed overlap and bandwidth. Predict a small-workload case where increasing degree is slower and a capacity-limited case where sharding permits useful work otherwise infeasible. Do not claim linear speedup.

Part 4 - Experimental Design and Instrumentation

Launch fresh jobs for each supported degree with the same logical initialization, batch, sequence, precision, optimizer, attention backend, checkpointing policy, and number of updates. Validate small-model updates before timing. Warm kernels and Adam state, reset peaks for full training steps, and synchronize only at declared boundaries. Record rank-local timings and the

distributed critical path. Profile representative cases separately. Run the equal-model sweep first, then a bounded capacity sweep whose changed model sizes are clearly labeled. Include cold startup and parallelization cost outside warmed timing but preserve them in the report.

Use global useful-token counts that exclude padding where the objective excludes it. TP participants processing the same tokens contribute only one logical count, while independent data groups contribute distinct counts. Keep degree sweeps on a fixed device subset specification and record rank mapping, because a different link arrangement can change results independently of degree. If only two CUDA devices are available, the empirical sweep is limited to degrees one and two; larger degrees can remain cost-model scenarios. Do not replace unavailable points with benchmark numbers from another machine. For capacity search, preserve candidate dimensions, successful complete update count, first failing phase, and whether validation or checkpointing belongs to the acceptance region. A model that passes forward but fails initialized Adam update does not satisfy the training capacity contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def enumerate_available_tp_degrees(device_inventory, model_spec):
    ...

def run_isolated_degree_replay(degree, logical_state, config):
    ...

def compare_degree_tradeoffs(rows, resource_budget):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-rank peak allocated and reserved bytes, persistent components, step latency distribution, global examples or valid tokens per second, communication payload, correctness, and failure phase. Count each logical example once across a TP group. Preserve failed candidate configurations and not-measured degrees. A maximum trainable size is only a tested lower bound when the search ends without a failure boundary. Do not compare a smaller batch on one degree as if the difference came from degree alone.

Part 7 - Engineering Interpretation and Philosophy

Select a degree for a stated memory and throughput goal. Explain why the optimum can change with hidden width, sequence length, batch size, or interconnect even when the local parameter formula is unchanged.

19.42.18 Exercise 17

Exercise Title: Combine Tensor Parallelism with FSDP on Separate DeviceMesh Dimensions and Verify That Tensor and Data Sharding Do Not Conflict

Part 1 - Exercise Contract and Why It Matters

Compose tensor parallelism and FSDP on separate named mesh dimensions. Verify that TP partitions computation while FSDP partitions state among data replicas of each TP coordinate. Require correct data ownership, gradients, and optimizer updates before reporting combined memory savings.

Part 2 - System and Memory Mental Model

Use a mesh shaped data-degree by TP-degree. TP groups hold cooperating ranks at a fixed data coordinate; FSDP groups connect corresponding TP coordinates across data replicas. Inputs match within a TP group and differ appropriately across data groups. Apply a supported DTensor-based TP plan and the compatible fully_shard route in a version-checked order. Avoid mixing configuration and parameter semantics from incompatible FSDP generations. A full parameter inside an FSDP group is still that group's TP-local slice, not necessarily the full global matrix.

Part 3 - Quantitative Prediction Before Execution

For data degree D and TP degree T, require DT ranks. Enumerate a 2 by 2 mesh and its four two-rank groups. Predict large parameter shard bytes near $P_s/(DT)$ only at the persistent boundary, then add transient FSDP gathers of TP-local parameters and replicated components. Explain why two devices cannot demonstrate both dimensions larger than one. A degenerate mesh is a control, not proof of nontrivial two-dimensional composition.

Part 4 - Experimental Design and Instrumentation

Validate mesh membership offline, then use at least four available CUDA ranks for the primary nontrivial run. If unavailable, complete metadata checks and label the distributed experiment not measured. Compare a small combined update against the same global-batch serial reference and against TP-only training where feasible. Construct the optimizer after the supported parallelization transformations. Check parameter placements at rest and during execution, gradient ownership, optimizer state, and sample IDs. Keep FSDP communication distinguishable from TP events in traces. All devices may be on one host; multiple computers are not required.

Check data sampling by TP and data coordinates. All ranks in a TP group must operate on matching sample identities, masks, and target values, while data groups cover the intended distinct portions of the global batch. Compute the global loss normalization accordingly; do not average again over the TP dimension. Inspect optimizer state after actual updates and compare reconstructed logical parameters only in a separate small-model replay. Keep the one-dimensional TP submesh and the data-sharding submesh explicit when applying the compatible APIs. Test a degenerate grid as a software control without labeling it a full composition benchmark. A nontrivial two-by- two grid can run on four GPUs in one host; the mathematical group requirement is about ranks and devices, not about requiring multiple networked computers.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.device_mesh import init_device_mesh
from torch.distributed.tensor.parallel import parallelize_module
from torch.distributed.fsdp import fully_shard

def validate_two_dimensional_groups(mesh_spec, available_devices):
    ...

def build_tp_fsdp_model(model, named_mesh, plans):
    ...

def verify_global_batch_update(engine, reference, batch_manifest):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report group maps, at-rest and transient local shapes, initialized state, collective classification, complete peaks, errors, and supported status. Do not reuse the same ranks as both data and tensor groups without a valid orthogonal mesh. Detect identical data across all data replicas and divergent inputs within a TP group. Preserve unavailable hardware and version support as explicit limits rather than simulating GPU benchmark results.

Part 7 - Engineering Interpretation and Philosophy

Explain which redundancy each dimension removes and which transient representations remain necessary. Describe why group orthogonality and data semantics are as important as local tensor sizes.

19.42.19 Exercise 18

Exercise Title: Stress-Test Tensor Parallelism with Large Hidden Dimensions, Long Sequences, Uneven Tensor Shapes, and Tight Per-GPU VRAM Budgets

Part 1 - Exercise Contract and Why It Matters

Stress the TP runtime with large widths, long sequences, uneven shapes, and constrained application budgets. Require numerical correctness, rank- consistent rejection, and bounded recovery behavior. Distinguish an unsupported layout from an incorrect execution or genuine resource exhaustion.

Part 2 - System and Memory Mental Model

DTensor support for uneven shards does not imply every high-level TP style, attention reshape, collective path, or kernel supports them. Primary high-level plans may require evenly partitioned feature dimensions. Padding can enable a separate implementation only when

padded features are masked out of all relevant algebra, losses, and updates. Large sequence lengths can shift the bottleneck from weights to activations or attention workspace. Rank-local resource decisions must not change collective order independently.

Part 3 - Quantitative Prediction Before Execution

Construct bounded cases with widths just below and above divisibility boundaries, head counts incompatible with degree, and sequence lengths not divisible by the SP degree. Predict accept, explicit reject, or a separately validated uneven/padded path. Calculate valid versus padded storage and choose a capacity limit that can be tested without depending on a physical OOM. Predict the rank with the largest local extent.

Part 4 - Experimental Design and Instrumentation

Run small deterministic correctness cases first, then increase one shape or resource-pressure variable at a time. Include zero-length or empty local shards only where the installed operator path supports them. Compare actual outputs and updates against a serial reference before scaling. Validate configuration on every rank before launching data collectives. Save committed training state at safe boundaries. If a worker fails, recreate the entire group from a committed state rather than allowing one rank to continue. Use additional seeds and keep the smallest mismatch reproducer.

Build an offline support matrix before launching the stress jobs. Include feature divisibility, head mapping, sequence partition, dtype, norm module, attention backend, and optimizer path. Uneven DTensor construction can pass while the following high-level layer rejects its shape, so validate the whole path. If padding is implemented, test that padded channels cannot influence unpadded outputs through bias, normalization, gating, or loss. Keep padded moment state and capacity visible even when logical gradients are masked. Exercise shapes just around bucket or allocation boundaries without asserting a particular allocator failure will occur. On unsupported input, prefer coherent validation failure before a collective rather than rank-specific exceptions after divergent launches. Preserve the minimized shape and seed for every numerical mismatch that survives the support checks.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_tp_stress_cases(model_spec, available_degrees):
    ...

def classify_layout_support(case, installed_capabilities):
    ...

def run_bounded_stress_replay(case, reference, evidence):
    ...
```

```
def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export shape, valid and padded extents, degree, sequence layout, backend, resource budget, per-rank peaks, elapsed time, numerical errors, outcome, and failure phase. A correct rejection counts as rejection, not as successful training. Record OOM or performance instability that does not reproduce as such. Check padding gradients and optimizer state if padding is implemented. Do not attribute every failure to communication without a phase trace and support check.

Part 7 - Engineering Interpretation and Philosophy

Choose a counterexample that breaks a naive placement rule and explain the missing assumption. A restricted runtime with explicit rejection is more useful than a broad claim that silently changes the model or loses gradients.

19.42.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Tensor-Parallel Transformer Runtime That Chooses Sharding Layouts to Minimize Per-GPU Memory While Controlling Collective Communication

Part 1 - Exercise Contract and Why It Matters

Integrate the verified layouts into an explicit tensor-parallel Transformer runtime and benchmark a bounded placement selector. Minimize per-rank memory among tested correct candidates while controlling collective cost. Keep model computation, plan construction, validation, and evidence visible rather than hiding the exercise in a high-level trainer.

Part 2 - System and Memory Mental Model

The runtime combines a logical parameter registry, mesh, operator capability map, boundary placements, autograd semantics, and memory/communication costs. A legal plan must preserve attention heads, residual layouts, normalization, loss meaning, and optimizer ownership. Choosing a plan is a constrained search, not proof of a global optimum. Start with a fixed deterministic Transformer, ordinary multi-head attention, FP32, and no dropout; enable other features only with named validation. FSDP composition remains optional and hardware-gated.

Part 3 - Quantitative Prediction Before Execution

Enumerate candidate degree and layout combinations, including paired projection layouts and optional sequence boundaries. Predict persistent bytes, phase peaks, collective payload, and exposed waits before benchmarking. Define accuracy tolerances, application memory limits, required training progress, and a latency objective. Reject unsupported candidates before costly runs. Record why each remaining candidate is expected to meet the budget, including workspace uncertainty and construction-time requirements.

Part 4 - Experimental Design and Instrumentation

Build one canonical logical initialization and apply each candidate in a fresh replay. Validate small-model outputs, gradients, and several optimizer updates against the serial reference. Run separate profiling, ordinary timing, and capacity experiments. Include forward, backward, optimizer update, and required collectives in training timing. Export only CPU scalar evidence

and bounded metadata. Preserve device identity, topology, versions, allocator, seed, model dimensions, precision, optimizer settings, batch/sequence shape, mesh, layouts, attention backend, and initial-state identifier. Validate a sharded save/reload round trip before treating the runtime as restartable; avoid a full CUDA reconstruction merely for checkpoint export.

Define a finite candidate set and deterministic selection rule before benchmarking. Use the cost model to prune obvious infeasible plans, then validate and measure the survivors. Report any feasible plan rejected by an overly conservative model if later tested, rather than claiming the selector found a universal optimum. Keep the capability matrix separate from the scaffold's method names: a checkpoint signature does not prove restart correctness. Require a save/reload comparison of subsequent updates for supported restart. Export versioned local shard metadata with parameter IDs, mesh coordinates, global extents, dtype, and logical optimizer progress. Make final recommendations conditional on the measured shapes, devices, and backend. Preserve unsupported features such as arbitrary GQA layouts, dropout RNG handling, or unavailable FSDP composition instead of treating them as implicitly supported by the integrated runtime.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class TensorParallelTransformerRuntime:
    def validate_candidate(self, logical_model, mesh_spec, layout_plan):
        ...

    def construct_local_state(self, logical_initialization):
        ...

    def forward_backward_update(self, batch):
        ...

    def export_cpu_evidence(self):
        ...

    def checkpoint_local_state(self, destination):
        ...

def E19(config):
    # Assemble validated components and benchmark isolated candidates.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation in separate columns. Every run needs an ID, configuration, input shape, budgets in bytes, per-rank peak allocated and reserved bytes, elapsed seconds, useful throughput, numerical errors, outcome, and failure phase. Use explicit

unsupported and not-measured values. Include the smallest counterexample to a proposed universal rule or state that none was observed in the tested range. Do not invent multi-GPU results or substitute published performance for the local experiment. Report the best tested feasible plan with its limitations.

Part 7 - Engineering Interpretation and Philosophy

Justify the selected plan using verified values, gradients, ownership, and resource measurements. Identify untested configurations that could change the decision.

19.43 DMM41

Chapter Title: Pipeline Parallelism and Pipeline Memory Scheduling
Specialization: Dynamic Memory Management and CUDA Systems

19.43.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Pipeline Stages, Micro-Batches, Activation Transfers, Pipeline Bubbles, and Per-Stage Memory Residency

Part 1 - Exercise Contract and Why It Matters

Define the pipeline as a dependency graph of stage executions and boundary messages. Deliver a model of parameter ownership, microbatch state, activation lifetime, and idle capacity. Use synchronous flushed training as the primary contract: every microbatch in one optimizer update uses the same parameter version.

Part 2 - System and Memory Mental Model

Pipeline ranks own different model stages, not independent replicas of the full model. Microbatches partition one logical minibatch. Forward activations travel downstream; their derivatives travel upstream. In a manual multi-process implementation, raw send/receive does not preserve an autograd graph across processes. Each receiver needs an explicit local differentiation boundary and the runtime must route its input derivative back to the sender. GPipe-style fill/drain and synchronous 1F1B reorder work without authorizing an optimizer update after each microbatch.

Part 3 - Quantitative Prediction Before Execution

For p balanced stages and m microbatches, derive the ideal fill/drain step time $(m + p - 1)(t_f + t_b)$ under uniform per-stage forward/backward costs, negligible communication, and no recomputation. Derive the corresponding idle fraction $(p - 1)/(m + p - 1)$. State why this idealization cannot predict arbitrary imbalance, overlap, or GPU utilization. Sketch live activation sets separately from the execution timeline.

Part 4 - Experimental Design and Instrumentation

Start with a deterministic sequential dense model, FP32, no dropout, no batch-dependent normalization, no cross-stage tied weights, and one process per CUDA device on one host. Define stage IDs, rank placement, boundary shapes, message identity, global batch, loss denominator, and update boundary. Validate small serial outputs, gradients, and Adam updates. Record hardware, versions, backend, topology, seeds, precision, model dimensions, and initial-state ID. Check installed pipeline API capabilities before adopting a documented feature.

Make a paper trace with two stages, four microbatches, and one shared optimizer-update generation. Label each event by stage, microbatch, direction, and parameter version. Show where the final-stage loss seeds backward and where the earliest stage receives its boundary derivative. Mark all graph and transport readers before assigning a release event. State whether the reported bubble is idle time per stage, aggregate idle device-time, or a fraction of makespan; these denominators are not interchangeable. The primary model deliberately excludes batch-coupled operations so a serial full-batch oracle is meaningful. Document this exclusion before evaluating schedules, not after a mismatch appears. Treat stochastic-layer equivalence, tied weights, and arbitrary branching as separate capabilities rather than consequences of implementing a sequential stage chain correctly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class PipelineContract:
    stage_to_rank: tuple
    microbatch_count: int
    logical_batch_size: int
    boundary_specs: tuple
    loss_denominator: object
    optimizer_boundary: str

def validate_pipeline_contract(contract, model_spec):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct logical sample coverage, message matching, derivatives, and parameter versions. Export CPU metadata without retaining live graphs. A smaller bubble prediction is not measured throughput, and a count of live microbatches is not a byte measurement. Unsupported configurations and unrun multi-GPU results remain explicit rather than borrowing published outcomes.

Part 7 - Engineering Interpretation and Philosophy

Explain how scheduling changes memory lifetimes while preserving the intended update. Identify the assumptions that must remain visible when comparing two schedules.

19.43.2 Exercise 01

Exercise Title: Split a Deep PyTorch Model Manually Across Two GPUs and Verify Correct Forward Execution Through Explicit Stage Boundaries

Part 1 - Exercise Contract and Why It Matters

Split a small deep model across two CUDA devices and verify manual forward execution through a named stage boundary. Deliver a layer ownership manifest, boundary specification, and reference comparison before introducing concurrent microbatches or distributed backward.

Part 2 - System and Memory Mental Model

A stage boundary cuts computation and may require carrying multiple values, masks, or metadata. The primary model uses a single sequential tensor edge so the ownership is explicit. A single-process cross-device tensor copy can participate in ordinary autograd, whereas a multi-process send/receive needs the explicit derivative protocol developed later. Keep these execution modes distinct. Construct only the assigned stage on each device instead of retaining a full CUDA model behind references to selected layers.

Part 3 - Quantitative Prediction Before Execution

Choose a cut after a named layer and derive each stage's parameter bytes and boundary tensor shape. Calculate forward transfer payload from actual shape and dtype. Predict the serialized critical path as stage computation plus exposed transfer and receiving work. Include initialization copies and input/output staging as separate memory phases. Explain which part of the model stays on each GPU.

Part 4 - Experimental Design and Instrumentation

Build a tiny serial CPU reference from the same logical initialization. Assign consecutive layers to the two stages, establish device/rank identity, and implement a serialized forward path. Validate boundary values and final outputs using coordinate-coded and seeded random inputs. Run multiple batches to expose stale receive buffers. Keep the inference-only baseline explicitly without backward; a training extension must validate parameter and input gradients separately. Preserve sample IDs and target ordering. Use a bounded larger case only after the small reference passes.

Verify the complete forward expression, including reshapes, activations, and positional or mask arguments that are not standalone parameterized layers. A partition made by slicing a module list can lose work performed between list entries. Compare the boundary tensor against the serial intermediate before checking the final answer. Use a tiny input whose values differ by sample and feature so a stale buffer or sample permutation cannot pass by symmetry. If using the single-process cross-device baseline, record it as such and do not mix its automatic copy-gradient behavior with the multi-process P2P runtime. Include both devices' initialization peaks and confirm that a reference to the original full CUDA model is not retained by an optimizer, closure, or debug object. Keep a full logical reference only in the separate small correctness replay.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class StageBoundarySpec:
    source_stage: int
    target_stage: int
    shape: tuple
    dtype: str
    tensor_order: tuple

def construct_manual_stage(model_spec, stage_id, device):
    ...

def run_serialized_forward(stages, inputs, boundary_transport):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report stage ownership, local parameter backing bytes, boundary values, output errors, and transfer payload. Detect a missing non-module operation such as an activation between two layer lists. A correct layer manifest alone does not prove the split forward matches the original graph. Record full-model reference storage outside the measured CUDA process, and flag ties or skip edges unsupported until their boundary protocol is implemented.

Part 7 - Engineering Interpretation and Philosophy

Explain which computation edge was cut and why all information required by the next stage still reaches it. Use this explicit partition as the fixed reference for later scheduling experiments.

19.43.3 Exercise 02

Exercise Title: Measure Parameter, Activation, and Temporary Buffer Memory Separately on Every Pipeline Stage

Part 1 - Exercise Contract and Why It Matters

Measure parameter, activation, and temporary-buffer storage separately on every stage. Include gradient and initialized optimizer state in the training inventory. Deliver a phase-aware byte ledger that can be reconciled with per-device allocator peaks.

Part 2 - System and Memory Mental Model

Parameters persist across microbatches; saved tensors persist until their backward readers finish; transport and kernel temporaries have different lifetimes. Views may share backing storage, and a small retained view can keep a larger allocation alive. Category maxima may occur

at different times. Allocator reserved capacity is not the sum of live tensor payloads. Stage-local Adam state can be absent until the first update, making cold measurements misleading for steady training.

Part 3 - Quantitative Prediction Before Execution

For stage i, derive persistent parameter, gradient, and optimizer bytes under the declared FP32 policy. Define activation bytes as a function of microbatch shape and execution phase, including internal saved tensors rather than boundary outputs alone. Add communication buffers and workspace bounds on a timeline. Predict a stage whose parameters are smaller but whose saved activations make its training peak larger.

Part 4 - Experimental Design and Instrumentation

Inventory unique local backing storage at initialization, forward, backward, update, and clearing boundaries. Use supported saved-tensor metadata instrumentation in a diagnostic replay without storing extra GPU references. Reset allocator peaks for a complete declared region and synchronize only at deliberate boundaries. Warm all used optimizer state before steady comparisons. Record allocated and reserved peaks on every device separately. Profile in a different replay from ordinary timing. Preserve unknown kernel workspace or non-PyTorch allocation scope rather than calling the residual activation memory automatically.

Keep parameter bytes, gradient clearing policy, and optimizer initialization state explicit at every sampled boundary. Setting a gradient to None and zeroing an existing gradient have different storage retention behavior; use the same policy in comparisons. Saved-tensor instrumentation should record shape, dtype, capacity, storage identity, and lifetime metadata without copying or retaining the graph. If a saved view shares parameter backing, identify its category overlap instead of adding its full size to an invented independent activation allocation. Compare a warmed full-update peak with the corresponding phase ledger, not an unrelated forward-only measurement. Include receive buffers allocated before the first forward and output buffers retained for merging. These capacities can remain present even when no microbatch graph is logically live.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class StageMemoryRow:
    stage_id: int
    phase: str
    parameter_bytes: object
    gradient_bytes: object
    optimizer_bytes: object
    saved_activation_bytes: object
    communication_bytes: object
    allocated_peak_bytes: int
```

```
def inventory_stage_storage(stage, phase, lifetime_ledger):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw storage counts, dtypes, aliases, category lifetimes, and allocator observations. Include an intentionally retained activation in a separate diagnostic replay and show the ledger catches it. Do not obtain activation memory by subtracting independently measured peaks. A gap between inventory and allocator totals needs a scoped explanation or an unknown label. Report first-update allocation separately from warmed execution.

Part 7 - Engineering Interpretation and Philosophy

Choose the memory component that actually limits each stage. Explain why balancing only parameter bytes can leave the pipeline infeasible.

19.43.4 Exercise 03

Exercise Title: Build Point-to-Point Activation Transfer Between Pipeline Stages and Measure Communication Latency and Transfer Volume

Part 1 - Exercise Contract and Why It Matters

Implement explicit point-to-point activation transport and measure its payload and completed latency. Extend the protocol to return boundary derivatives for training. Deliver matching-message and buffer-lifetime checks before attempting overlapping sends and computation.

Part 2 - System and Memory Mental Model

A message needs update generation, microbatch ID, stage edge, direction, shape, dtype, and ordering. On receipt for training, create a local leaf requiring gradients; retain its upstream correspondence and the sender's local output graph. After local backward, send the received leaf's input derivative upstream and apply it to the matching saved output there. Raw P2P does not supply that routing automatically. Keep send and receive buffers alive until the documented completion and CUDA dependency conditions permit reuse.

Part 3 - Quantitative Prediction Before Execution

Calculate forward bytes from boundary activations and backward bytes from their actual derivative dtype. Separate useful payload from metadata, packing, and backend traffic. Predict round-trip dependency time for a small boundary. Define one-way timing only with a valid clock/acknowledgment method; a host launch interval cannot establish completed transfer latency.

Part 4 - Experimental Design and Instrumentation

Begin with a serialized matched send/receive sequence on two ranks. Validate rank-distinct known payloads, then a two-stage differentiable network. Check received inputs, returned

derivatives, and several optimizer updates against a serial reference. Define a rank-consistent communication order and prevalidate counts so negative tests do not intentionally hang the backend. Then introduce nonblocking work with explicit waits and downstream stream dependencies. Measure multiple sizes after warmup and capture packing costs in a named boundary contract. Record intra-host topology without assuming peer-to-peer bandwidth from device numbering.

Separate the application message key from any backend tag support. Do not assume a backend can distinguish arbitrarily reordered messages by tag; use a validated matching order where necessary. A source activation can be noncontiguous, in which case packing may allocate a new buffer with its own completion and release events. Validate the reverse derivative shape and microbatch identity before applying local backward. If an input derivative is not needed at the first stage, define the protocol's termination rather than sending an unmatched message. Use a ping-pong or acknowledged sequence for transfer timing when cross-device clocks are not aligned, and state whether the reported value is round-trip or an inferred one-way estimate. Do not divide by two without naming the symmetry assumptions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
import torch.distributed as dist

@dataclass
class PipelineMessageKey:
    update_id: int
    microbatch_id: int
    stage_edge: tuple
    direction: str
    buffer_generation: int

def transfer_boundary(payload, message_key, transport, completion):
    ...

def route_boundary_backward(stage_state, received_gradient, key):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report payload, completed latency, packing, waits, buffer generations, and numerical errors. Check gradients at the earliest stage; correct final outputs can hide a detached training graph.

Detect stale-generation delivery and premature reuse through protocol validation even if a race does not reproduce. If physical link traffic cannot be measured, preserve it as unknown instead of equating it with logical tensor bytes.

Part 7 - Engineering Interpretation and Philosophy

Explain how transport correctness includes differentiation and lifetime, not just delivery of values. Identify the smallest protocol violation that would corrupt a later microbatch without changing tensor shapes.

19.43.5 Exercise 04

Exercise Title: Split a Mini-Batch into Micro-Batches and Execute Them Sequentially Across Pipeline Stages as a Baseline

Part 1 - Exercise Contract and Why It Matters

Split one logical minibatch into microbatches and run them sequentially through the complete pipeline. Complete backward for each microbatch before starting the next, accumulate gradients, and update once after the full batch. Use this low-concurrency path as the numerical and lifetime baseline.

Part 2 - System and Memory Mental Model

Microbatching changes execution grouping, not the intended objective. For separable losses, contributions must be weighted by their valid sample or token counts. Averaging microbatch means equally is correct only when those denominators match. Primary experiments use deterministic layers without batch-dependent state. Clear parameter gradients once per optimizer update, not once per microbatch. Do not average across pipeline stages: they own different parts of the same computation.

Part 3 - Quantitative Prediction Before Execution

For microbatch loss sums S_j and a global valid count D, define

$$L = \frac{\sum_j S_j}{D}.$$

Derive accumulated gradients by backpropagating each S_j/D. Calculate a case with unequal microbatch sizes and show why an unweighted mean of means fails. Predict the sequential schedule's maximum activation residency and its lack of stage concurrency.

Part 4 - Experimental Design and Instrumentation

Start with divisible batch sizes, then add a separately supported unequal final chunk. Preserve sample and target identities. On the final stage compute the globally normalized loss contribution, route boundary derivatives upstream, and finish each microbatch before reuse. Accumulate all stage-local parameter gradients, validate against a serial full-batch reference, and perform one Adam update per stage only after the pipeline is drained. Repeat multiple updates to check moment state and clearing. Keep the same reference values and objective for later GPipe and 1F1B comparisons.

Build a concrete three-sample example split into chunks of two and one. Choose losses with different means and derive the global objective and each chunk's coefficient. For token losses, replace sample counts with the valid unmasked-token denominator; equal sample counts

can still have unequal valid tokens. Handle a zero-valid-token chunk through a declared safe convention or reject it in the primary path. Ensure targets are chunked along the same logical sample axis as inputs and metadata. Validate gradients before Adam because an adaptive optimizer can conceal a uniform gradient-scale mistake in a short parameter-only comparison. Compare moments and counters after several updates as well as parameters. Keep the logical batch unchanged when later scheduling moves these chunks into overlapping execution.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def split_logical_batch(batch, microbatch_spec):
    ...

def run_sequential_microbatches(runtime, microbatches, loss_contract):
    # Normalize once, route backward, accumulate, and update after drain.
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report sample coverage, valid counts, scalar loss, all stage gradients, Adam moments, updated parameters, elapsed time, and memory peaks. Include an incorrect equal-weight mean-of-means control for unequal chunks. A matched loss scalar alone is insufficient; inspect gradients before update. Reject unsupported batch-coupled layers rather than claiming microbatch equivalence for arbitrary models. Keep unequal-shape support separate from the primary static communication-buffer path.

Part 7 - Engineering Interpretation and Philosophy

Explain why this deliberately serialized schedule is a strong oracle. Identify the semantics that concurrent schedules must preserve even when execution and release order change.

19.43.6 Exercise 05

Exercise Title: Build a GPipe-Style Schedule and Measure Pipeline Fill, Drain, Bubble Time, Activation Memory, and GPU Utilization

Part 1 - Exercise Contract and Why It Matters

Build a GPipe-style synchronous fill/drain schedule with all forward microbatches before the backward wave. Measure fill, drain, dependency idle time, activation residency, and completed training throughput against E04. Keep activation checkpointing disabled in the primary schedule-only comparison.

Part 2 - System and Memory Mental Model

Fill/drain permits different stages to execute different microbatches concurrently. Forward graphs accumulate until their backwards release them. The last stage starts backward only after the forward phase required by the chosen schedule. Parameters remain at one version throughout the logical update. This exercise studies the fill/drain ordering; it does not assume all recomputation choices or optimizations of the original GPipe system. GPU activity, communication wait, and dependency bubbles need separate definitions.

Part 3 - Quantitative Prediction Before Execution

Derive the balanced no-communication estimate from E00 and draw a complete two-stage, four-microbatch event graph. Mark fill and drain explicitly and count saved microbatches per stage. Estimate saved bytes from the actual microbatch activation function. Predict how a slow stage or a large boundary transfer invalidates the uniform-slot model. State which idle intervals are schedule dependencies rather than measured kernel inefficiency.

Part 4 - Experimental Design and Instrumentation

Generate one global event plan and validate every receive dependency, forward-before-backward condition, and message order offline. Execute the small deterministic model using retained per-microbatch stage graphs. Route derivatives with E03 and accumulate gradients with E04's loss normalization. Update only after all backwards and outstanding readers complete. Compare several updates with the sequential oracle before measuring larger cases. Capture stage compute and communication timelines separately from ordinary timing. Record warmup, fill, forward steady region where present, backward region, and final drain under clearly named intervals.

Distinguish all-forward-then-backward ordering from an implementation that launches every forward without waiting for required upstream data. Every event still needs its predecessors complete. Keep the exact backward microbatch order in the plan because different valid drain orders can produce different transient lifetimes. Use the same parameter version for every local graph and verify it before applying its backward derivative. A global drained boundary must also account for outstanding sends, not merely completion of Python backward calls. Report fill and drain as portions of a complete update, including cases with too few microbatches to have a substantial steady region. Do not compare only a favorable central interval against E04's full elapsed step. Record diagnostic GPU utilization separately from a theoretically computed dependency-idle fraction.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_fill_drain_plan(stage_count, microbatch_count):
    ...

def validate_pipeline_event_dependencies(plan, boundary_specs):
    ...
```

```
def execute_gpipe_style(runtime, plan, microbatches, evidence):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted and observed makespan, per-stage busy/idle intervals, peak live microbatches, saved bytes, allocated/reserved peaks, and update errors. Do not call the fraction of time without a compute kernel a pure pipeline bubble without checking transfer and host work. A fill/drain schedule can improve concurrency while increasing retained activations relative to E04. Report that trade-off without promising a speedup on every interconnect.

Part 7 - Engineering Interpretation and Philosophy

Explain why concurrency requires retained state and why bubbles are properties of the schedule and stage costs together. Preserve this measured fill/drain path as the GPipe-style reference for 1F1B.

19.43.7 Exercise 06

Exercise Title: Increase Micro-Batch Count and Quantify the Trade-Off Between Smaller Pipeline Bubbles and Larger Activation Residency

Part 1 - Exercise Contract and Why It Matters

Sweep microbatch count and distinguish two different experiments: fixed global batch with smaller chunks, and fixed chunk size with a larger global batch. Quantify bubbles, activation bytes, buffer capacity, and step time without assuming their trends must be monotonic.

Part 2 - System and Memory Mental Model

More chunks can reduce an ideal bubble fraction but increase launches, messages, metadata, and allocator overhead. At fixed global batch, per-chunk activation size often falls as chunk count rises; fill/drain retained bytes may stay roughly constant in a simple linear model. At fixed chunk size, retaining more forward graphs can increase bytes. Kernel efficiency, padding, workspace selection, and nonlinear activation costs can change both cases. A microbatch-count headline must always name which batch quantity stayed fixed.

Part 3 - Quantitative Prediction Before Execution

Let logical batch $B = mb$ in the divisible case and let $a_i(b, S)$ denote saved bytes per microbatch on stage i. Compare $ma_i(B/m, S)$ with $ma_i(b, S)$ under their different controls. Add per-microbatch fixed overhead. Predict the ideal bubble trend and a counterexample where many tiny chunks increase total latency. Do not extend a linear memory approximation to every kernel or variable-length workload.

Part 4 - Experimental Design and Instrumentation

Use a short valid count sweep with equal chunks for the primary run. Rebuild shape-specific buffers and stage wrappers outside warmed timing where required, recording reconstruction cost separately. Preserve initial parameters, logical examples, loss objective, schedule, optimizer, dtype, and sequence length in the fixed-global-batch comparison. Run the fixed-chunk-size experiment as a separate series with changed logical batches explicitly labeled. Validate gradients and several updates for every configuration. Collect per-stage residency traces and completed-step timing after warmup, with profiling in separate replays.

Add a synthetic activation-cost function with a per-chunk fixed term and a batch-proportional term. At fixed logical batch, show that the proportional part can stay constant while the fixed part grows with chunk count. Then add padding to a shape bucket and derive the resulting discontinuity. Use this calculation to formulate predictions before measuring a real model. Keep parameter gradients and optimizer state unchanged in the fixed-batch sweep so the activation effect remains interpretable. If small chunks use views into a full input batch, include the full backing retained by those views. If output merging retains every microbatch result, account for that capacity or use the same supported no-merge policy across runs. A change in message count can alter latency even when total useful payload remains equal.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_microbatch_sweep(logical_batch, count_candidates, policy):
    ...

def predict_microbatch_residency(stage_costs, sweep_case, schedule):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export global batch, chunk sizes, valid counts, live microbatch counts, actual retained bytes, padding, message counts, bubble definitions, latency, and update errors. Reject a claim that more microbatches always consumes more activation bytes. Show both useful bytes and retained backing capacity when small views keep a larger parent alive. Explain any throughput deterioration through trace evidence rather than treating the ideal bubble formula as a measurement.

Part 7 - Engineering Interpretation and Philosophy

Choose a microbatch count for the declared batch policy and resource limit. Explain why the same count can be favorable for one batch policy and unfavorable for the other.

19.43.8 Exercise 07

Exercise Title: Build a 1F1B Forward-Backward Schedule and Compare Peak Activation Memory Against GPipe Under the Same Global Batch

Part 1 - Exercise Contract and Why It Matters

Build a synchronous flushed 1F1B schedule with warmup, alternating steady work, and cooldown. Compare activation memory with the GPipe-style schedule under the same logical batch, chunk sizes, partition, and optimizer semantics.

Part 2 - System and Memory Mental Model

1F1B can retire old microbatch graphs earlier by interleaving forward and backward. The resident set depends on stage position, pipeline depth, microbatch count, and exact event order. It is not one microbatch on every stage. This primary schedule performs no asynchronous per-microbatch updates and needs no claim about PipeDream weight stashing. Reducing activation residency does not automatically reduce the ideal synchronous pipeline bubble or improve measured utilization.

Part 3 - Quantitative Prediction Before Execution

Construct two-stage and three-stage event graphs offline. Count warmup forwards and the largest outstanding forward set on each stage, including transient forward-before-backward ordering within a slot. Compare those sets with fill/drain for identical microbatch activation costs. Predict the same parameter and optimizer residency but different activation lifetimes. Derive makespan from the event graph rather than asserting a universal 1F1B speedup.

Part 4 - Experimental Design and Instrumentation

Validate the global plan before running communication. Use a consistent message order or supported batched P2P pattern that avoids both peers blocking on unmatched sends. Route matching derivatives, retain each local graph until its backward completes, and accumulate globally weighted losses exactly as in E04. Drain the whole update before stepping any optimizer. Compare outputs, gradients, moments, and several updates with GPipe and the serial oracle. Measure peak live graphs and actual storage independently. Add stage imbalance only after the balanced correctness case passes.

Enumerate forward and backward dependencies before deciding which local event alternates next. Warmup differs by stage position, and a short update with few microbatches may never enter the steady alternating region assumed by a textbook diagram. Validate those small counts instead of applying a large-count approximation blindly. Keep the final-stage loss and earliest-stage input derivative cases explicit. If transport uses batched send/receive calls, verify operation ordering and buffer lifetimes against the installed backend. A rank cannot reclaim a saved output merely because another stage began backward for that microbatch. Compare gradients accumulated at the drained boundary and inspect Adam moments to detect missed or duplicated microbatch contributions. Present the memory advantage, if measured, independently from any claim about a smaller bubble or faster step.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_flushed_1f1b_plan(stage_count, microbatch_count):
    ...

def prove_message_progress(plan, transport_contract):
    ...

def execute_flushed_1f1b(runtime, plan, microbatches):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report each stage's maximum live microbatch count and activation bytes. Include complete-step peaks, communication, makespan, and numerical errors. Include the warmup and cooldown in timing. An implementation that updates weights while old microbatches still require them violates this exercise's contract even if it is called 1F1B. If memory improves but throughput does not, preserve that result and identify the remaining critical path.

Part 7 - Engineering Interpretation and Philosophy

Explain which release opportunities 1F1B creates and which schedule dependencies remain. State why a name shared by synchronous and asynchronous pipeline systems cannot establish identical training semantics.

19.43.9 Exercise 08

Exercise Title: Trace the Exact Lifetime of Every Micro-Batch Activation from Forward Production Until Its Backward Consumer Completes

Part 1 - Exercise Contract and Why It Matters

Trace each microbatch activation from production through its final backward and transport readers. Deliver an exact logical event ledger for the controlled runtime and distinguish logical release, completed device use, and retained allocator capacity.

Part 2 - System and Memory Mental Model

A boundary output can be sent downstream while its local graph remains necessary for backward. A received input leaf can retain backing needed by local differentiation. Send completion alone does not prove the activation is no longer needed. Conversely, backward completion can leave an outstanding gradient send using related storage. Python references, autograd saved tensors, and CUDA operations impose separate lifetimes. A recorded host launch is not a completed GPU reader event.

Part 3 - Quantitative Prediction Before Execution

Define allocation, first write, send completion, backward start/end, last-reader completion, release eligibility, and reuse events for one stage and microbatch. Predict different lifetimes under sequential, fill/drain, and 1F1B plans. Track unique storage plus view intervals so two names for one allocation do not create two physical byte contributions. Explain where the logical schedule gives exact order but instrumentation only bounds completion.

Part 4 - Experimental Design and Instrumentation

Assign update, microbatch, stage, storage, and buffer-generation IDs. Instrument a tiny run with explicit dependency events, keeping CPU metadata rather than live GPU tensors. Use supported saved-tensor inspection without changing saved values or extending their lifetime. Trace forward/backward buffers and both transport directions. Validate against a hand event graph, then compare with a low-overhead run for instrumentation effects. Test a controlled early-release request in an offline state validator; do not require a nondeterministic CUDA race to prove the invariant is necessary.

Use one cache key containing update generation, virtual stage, microbatch, and tensor role. A key containing only microbatch ID becomes ambiguous across updates and when multiple local stages exist. Record storage generations as well as addresses because a new allocation may reuse an old pointer. Keep all last-reader events, including delayed sends and local backward kernels, attached to the activation record until release is justified. Avoid calling item or global synchronization for every event in the final timing path; use a separate diagnostic replay with explicit overhead reporting. If the instrument cannot observe an internal saved tensor's last consumer precisely, report a conservative interval rather than an invented exact timestamp. Validate that this conservative record never underestimates the hand-checked small runtime's logical residency.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ActivationLifetimeEvent:
    update_id: int
    microbatch_id: int
    stage_id: int
    storage_identity: str
    generation: int
    event_kind: str
    completion_reference: object

def record_lifetime_event(ledger, event):
    ...
```

```
def validate_release_eligibility(ledger, activation_key):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export expected and observed event order, timing scope, outstanding readers, and actual reuse eligibility. A repeated data_ptr does not prove that a previous graph was safely finished. Preserve missing completion evidence as unknown instead of calling a host timestamp exact. Verify that logging itself does not retain activation storage. Check that backward for one microbatch cannot consume another microbatch's cached output.

Part 7 - Engineering Interpretation and Philosophy

Explain release as a proof about completed consumers rather than an instruction to delete a variable. Use the ledger to distinguish application reuse from physical memory returned by the allocator.

19.43.10 Exercise 09

Exercise Title: Build an Activation Residency Timeline and Calculate the Maximum Number of Simultaneously Live Micro-Batches per Stage

Part 1 - Exercise Contract and Why It Matters

Convert validated lifetime events into per-stage and per-device residency timelines. Calculate maximum simultaneous live microbatches and peak unique activation bytes. Compare schedule predictions with observed storage without conflating the two quantities.

Part 2 - System and Memory Mental Model

A microbatch can retain several buffers of different sizes. Counts are useful for equal-cost synthetic cases, but heterogeneous sequence lengths or checkpoint policies require weighted byte intervals. Distinct virtual stages on one device contribute to the same physical memory budget. Release and allocation events at the same timestamp need a defined ordering; otherwise a sweep can undercount a transient overlap. Retained pools remain separate from logically live activation bytes.

Part 3 - Quantitative Prediction Before Execution

For intervals $[a_k, r_k)$ with unique storage capacities c_k, define

$$A_i(t) = \sum_{k \in \mathcal{L}_i(t)} c_k, \qquad A_i^{\max} = \max_t A_i(t).$$

Deduplicate backing identities and apply byte changes only when their storage becomes live or fully releasable. Construct equal-count states with unequal bytes and a transient overlap example. Calculate counts and bytes by hand before processing real traces.

Part 4 - Experimental Design and Instrumentation

Validate the sweep on synthetic no-overlap, nested, aliasing, pending-send, and simultaneous-event cases. Build schedule-predicted intervals separately from instrumented intervals and compare by update and microbatch ID. Aggregate all local virtual stages on each device before taking a device maximum. Include confidence or unknown status for incomplete completion events. Compare with allocated and reserved peaks under their different scopes. Export CPU rows suitable for an auditable timeline; do not retain activations to draw it.

Define how the sweep orders allocation and release events with equal host timestamps. Prefer causal completion references or a conservative overlap when ordering is unknown. Count a backing allocation once while any of its retained views or pending consumers keeps it live. Track useful subranges separately if the application reuses an arena, but do not report those subrange bytes as released physical capacity while the arena remains allocated. Build a two-microbatch example where one large activation dominates bytes and another example where several small activations dominate count. Export the peak-contributing set so a learner can audit the maximum without replaying the whole trace. When aggregating virtual stages, take a common device timeline rather than adding maxima sampled at unrelated points in time.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ResidencyInterval:
    stage_id: int
    device_id: int
    microbatch_id: int
    storage_identity: str
    capacity_bytes: int
    start_event: object
    release_event: object

def sweep_unique_storage_residency(intervals, event_order):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report maximum live microbatch count, live bytes, peak time/event, and the storage IDs contributing to it. Explain differences between stage and device maxima. Flag incomplete intervals instead of assuming release at the end of the log. Provide a minimal counterexample showing why multiplying one average activation size by a peak count can fail. Reconcile the timeline with E08's release proof and allocator observations.

Part 7 - Engineering Interpretation and Philosophy

Choose whether counts, byte intervals, or conservative bounds are needed for the next scheduling decision. Explain why a precise count can still be a poor memory predictor.

19.43.11 Exercise 10

Exercise Title: Partition Transformer Layers Across Pipeline Stages by Parameter Count and Demonstrate Why Equal Layer Count Can Still Produce Memory Imbalance

Part 1 - Exercise Contract and Why It Matters

Partition Transformer blocks across pipeline stages and compare equal layer count with parameter-aware cuts. Demonstrate why neither layer count nor parameter count alone guarantees balanced training peaks or stage time.

Part 2 - System and Memory Mental Model

Embedding and output projections can concentrate parameters near the ends, while attention, feed-forward width, sequence length, and selected kernels shape activation and workspace costs. Early pipeline stages can retain more microbatches under a given 1F1B schedule. Residual connections inside complete blocks simplify boundaries; splitting inside a block may require multiple messages. Primary experiments use untied embeddings and output weights. Cross-stage tied parameters need a separate ownership and gradient protocol.

Part 3 - Quantitative Prediction Before Execution

Inventory parameter bytes per ordered block plus embeddings and output head. Predict equal-count and equal-parameter stage totals. Add stage-specific activation residency from the chosen schedule and fixed input shape. Construct a small heterogeneous example where the equal-parameter cut produces a larger activation peak on one stage. Predict the bottleneck using both memory and forward/backward service time.

Part 4 - Experimental Design and Instrumentation

Use a small deterministic Transformer with masks and positional inputs explicitly routed to the correct stages. Preserve complete blocks in the primary partition. Build equal-count and parameter-aware contiguous cuts from the same logical model. Validate serial outputs, gradients, and updates before measuring. Profile each stage with the actual microbatch shape and schedule rather than one isolated block only. Record embedding/head ownership and input/target placement. Keep attention backend, checkpointing, precision, and optimizer fixed while comparing cuts. Test a deliberately heterogeneous block width or head placement as a controlled imbalance case.

Start with untied embedding and output weights so the primary partition has unambiguous owners. If a tied-weight extension crosses stages, it must specify synchronization and gradient combination before it can be accepted. Keep attention masks and positional metadata with the samples they describe, including any non-tensor arguments that must be replicated or reconstructed at a later stage. Profile the actual stage module with its microbatch shape, not only a standalone layer whose surrounding saved activations are absent. Use a named attention backend because long-sequence workspace can differ substantially across implementations. Preserve the same complete Transformer when comparing cuts. Moving a memory-heavy head while silently changing its vocabulary width would not demonstrate a partitioning benefit. Report which stage controls memory feasibility and which controls compute throughput.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def inventory_transformer_units(model_spec, dtype_policy):
    ...

def make_parameter_aware_contiguous_cuts(units, stage_count):
    ...

def compare_stage_balance(partitions, schedule, measurements):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report parameter and initialized-state bytes, live activation peaks, workspace observations, boundary payload, service time, and complete device peaks for every stage. Demonstrate imbalance with measured evidence if it occurs; otherwise preserve the tested outcome. Equal layer counts should not be called equal work without cost evidence. Verify targets and masks after repartitioning and keep cross-stage ties unsupported unless validated.

Part 7 - Engineering Interpretation and Philosophy

Explain whether the observed imbalance comes from persistent state, activation lifetimes, compute, or transport. Identify a partition change that targets the actual bottleneck rather than a convenient layer-count statistic.

19.43.12 Exercise 11

Exercise Title: Build a Memory-Aware Stage Partitioning Algorithm from Parameter Bytes, Activation Bytes, and Estimated Compute Cost

Part 1 - Exercise Contract and Why It Matters

Build a constrained partitioner for contiguous model units using parameter bytes, activation residency, boundary payload, and estimated compute costs. Choose the best feasible plan within a finite candidate set and expose its assumptions rather than claiming a globally optimal arbitrary graph partition.

Part 2 - System and Memory Mental Model

Stage cost depends on the cut and the schedule. Per-layer isolated activation peaks do not add directly to a stage peak, and moving a cut changes both boundary traffic and the number

of retained stage inputs. A memory budget must include gradients, initialized optimizer state, transport buffers, and workspace reserve. A plan that minimizes maximum compute time can violate memory constraints, while a plan with fewer boundary bytes can worsen compute balance.

Part 3 - Quantitative Prediction Before Execution

Define candidate contiguous cuts and a per-stage predicted memory bound under a specified schedule and microbatch shape. Minimize a stated objective such as predicted makespan subject to each device's byte limit. Include infeasible-unit detection and uncertainty margins. Construct a small ordered cost list and enumerate all legal cuts by hand to validate the algorithm's choice and tie-breaking.

Part 4 - Experimental Design and Instrumentation

Calibrate unit and boundary costs on small representative shapes in separate replays. Use exhaustive search or dynamic programming only when its cost assumptions match the modeled structure; otherwise label a greedy or bounded search honestly. Evaluate candidates with the event simulator to capture schedule residency and communication dependencies. Keep calibration and held-out validation configurations separate. Validate numerical equivalence of the chosen partition and measure all stage peaks and complete-step time. Preserve rejected candidates, rejection reasons, and predicted versus observed costs. Do not migrate live optimizer state implicitly when changing cuts.

Validate search behavior on an ordered list small enough for exhaustive manual enumeration. Include a single unit that exceeds every available stage budget so infeasibility is detected without futile search. Include another case with two equally scored plans and define deterministic tie-breaking. If the objective uses maximum service time as a proxy for makespan, label that approximation and validate it against the event simulator. Add boundary transfer estimates and schedule-specific saved-input lifetimes before declaring a plan feasible. Keep the parameter-only baseline even when it performs poorly; its failure explains which added cost information matters. Stage migration at runtime is outside the primary search: construct a fresh model from the same logical state for each measured partition. An offline chosen cut does not itself implement optimizer-state movement.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PartitionCandidate:
    contiguous_cuts: tuple
    predicted_stage_peaks: tuple
    predicted_stage_times: tuple
    boundary_payload_bytes: tuple
    feasibility: str

def search_memory_feasible_partition(units, schedule, budgets, costs):
```

```
    ...

def validate_selected_partition(candidate, held_out_measurements):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report candidate count, objective, constraints, uncertainty, selected cuts, measured peaks, makespan, and numerical errors. Preserve a prediction that underestimated memory rather than overwriting it after the run. Compare against equal-count and parameter-only baselines. A plan rejected because its uncertainty bound is too large is different from a measured infeasible plan. Use actual local optimizer and activation costs rather than global model bytes divided by stage count.

Part 7 - Engineering Interpretation and Philosophy

Explain why the selected plan is the best tested feasible candidate under the declared objective. State which model or cost changes require repartitioning and which can be handled by schedule tuning alone.

19.43.13 Exercise 12

Exercise Title: Use torch.distributed.pipelining.PipelineStage to Implement the Same Model Partition and Compare It Against the Manual Runtime

Part 1 - Exercise Contract and Why It Matters

Implement the same fixed partition with PipelineStage and a supported schedule. Compare the framework path with the validated manual runtime under identical model values, logical batch, loss normalization, and update boundary.

Part 2 - System and Memory Mental Model

PipelineStage manages stage communication and backward support, but its shape, dtype, chunking, and module contracts still need validation. Use an explicit static microbatch specification for the primary experiment. Some versions expose first-microbatch metadata inference; that does not establish unrestricted variable shapes within a schedule. Check the installed version rather than relying on contradictory general descriptions or main-branch features. Framework communication-buffer allocation can differ from the manual runtime even with the same logical partition.

Part 3 - Quantitative Prediction Before Execution

Predict stage input/output shapes from microbatch dimensions, not the full logical batch. Count the framework's expected buffers separately from local model state. Derive the gradient scaling for the chosen loss. For a loss that already returns each microbatch sum divided by the global denominator, ensure the schedule does not divide again. For equal-size microbatch means, verify the supported schedule scaling instead of applying both conventions.

Part 4 - Experimental Design and Instrumentation

Check public imports and signatures, construct only the assigned submodule, and provide representative boundary metadata under the supported API. Configure loss reduction and schedule gradient scaling explicitly. Compare outputs, all stage gradients, Adam moments, and several updates against E04 and the serial reference. Test one schedule first. Keep module modes, optimizer flags, precision, sample order, and output collection equal across implementations. Measure buffer construction outside warmed timing but record its cost and peak. Use diagnostic framework logs in separate correctness replays.

Verify the installed schedule's loss-gradient scaling with a tiny known gradient before using the full model. One supported convention is a globally normalized sum loss with schedule division disabled; another uses equal-sized microbatch means with exactly one count-based division. Do not combine the two. Scalar loss lists may contain unscaled microbatch values, so compute the reported global objective according to the declared convention rather than assuming the list's mean is always correct. Use representative microbatch examples for shapes and dtypes, including tuple outputs if supported. Treat newer first-microbatch inference as a version-specific feature with tested limits, not as permission for arbitrary shape changes. Keep manual and framework output-merging behavior equal because retaining merged outputs can change the peak even when both schedules compute identical gradients.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.pipelining import PipelineStage, ScheduleGPipe

def build_checked_pipeline_stage(local_module, stage_spec, group):
    ...

def configure_schedule_loss_scaling(stage, batch_contract, api_caps):
    ...

def compare_framework_manual_updates(replay_specs, reference):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report installed version, supported metadata mode, chunking contract, loss/scaling settings, buffer capacity, peaks, latency, and update errors. Detect double division by microbatch count with a known-gradient test. Do not interpret an API constructor accepting examples as proof that every later shape is supported. A framework failure on an unsupported contract must be recorded clearly rather than bypassed through undocumented internal state mutation.

Part 7 - Engineering Interpretation and Philosophy

Explain which bookkeeping the framework replaces and which mathematical contracts remain the learner's responsibility. Choose the runtime for later experiments using measured support and correctness evidence.

19.43.14 Exercise 13

Exercise Title: Compare ScheduleGPipe, Schedule1F1B, and Interleaved Scheduling by Peak VRAM, Bubble Fraction, Communication, and Step Time

Part 1 - Exercise Contract and Why It Matters

Compare ScheduleGPipe, Schedule1F1B, and a supported interleaved schedule using complete training updates. Separate schedule-order effects from changes to the logical model's virtual-stage partition and physical placement.

Part 2 - System and Memory Mental Model

Single-stage-per-rank schedules and multi-stage schedules have different interfaces and constraints. Interleaving can create extra communication edges and several live local stage states. It is not a promise of lower memory or fewer bubbles for every model. Use one flushed optimizer update per logical batch throughout. Check installed admissibility rules for microbatch counts and rank/stage mapping; do not assume a divisibility restriction from another release is universal.

Part 3 - Quantitative Prediction Before Execution

Generate explicit event plans for the tested schedules. Predict live storage, critical path, message counts, and the definition of dependency idle fraction. For GPipe versus 1F1B, keep the same cuts. For interleaving, report the additional virtual cuts and compare against a suitable control with those cuts where supported. Explain why a single ideal bubble formula cannot decide the interleaved result.

Part 4 - Experimental Design and Instrumentation

Validate every plan with the same logical initialization, samples, objective, precision, and optimizer. Run small serial update oracles before larger benchmarking. Measure fill, warmup, steady intervals, cooldown, output collection, and required completion under the same timing boundary. Capture all ranks' traces separately from ordinary timing. Keep activation checkpointing disabled in the primary schedule comparison. Report the virtual-to-physical stage map and supported constraints alongside each run. Treat unsupported schedule/count combinations as rejected candidates before launching.

Use a candidate table that records physical rank count, virtual stage count, cut locations, microbatch count, and installed admissibility status. This makes a changed interleaved partition visible instead of hiding it behind a schedule name. For the direct GPipe-versus-1F1B comparison, use exactly the same stage modules and loss convention. For the interleaved case, compare against a reference with the same complete logical model and explain any additional virtual boundaries. Measure per-device union busy time rather than summing overlapping compute and transfer durations. If profiling clocks cannot be aligned across ranks, use rank-local durations and dependency relations rather than a fabricated shared timestamp axis. Preserve a case where reduced activation bytes fails to improve throughput, or state that none occurred in the tested range.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.pipelining import (
    ScheduleGPipe, Schedule1F1B, ScheduleInterleaved1F1B,
)

def validate_schedule_candidate(candidate, installed_caps):
    ...

def compare_pipeline_schedules(replay_specs, reference, evidence):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export per-device peak VRAM, virtual-stage live sets, bubble definition, collective/P2P payload, complete-step time, useful throughput, and numerical errors. Attribute additional messages to virtual partitioning when appropriate. Do not sum overlapping event durations as makespan or report launch time as completed training time. A schedule with lower activation bytes can still be slower; preserve the actual trade-off and rank imbalance.

Part 7 - Engineering Interpretation and Philosophy

Select a schedule within the tested topology and workload. Explain which part of the comparison isolates scheduling and which part includes the cost of a different virtual-stage layout.

19.43.15 Exercise 14

Exercise Title: Place Multiple Pipeline Stages on Each Rank and Measure How Interleaving Changes Stage Memory and Pipeline Utilization

Part 1 - Exercise Contract and Why It Matters

Place multiple ordered virtual stages on each physical rank and execute a validated interleaved schedule. Measure device-wide memory and utilization while preserving logical layer order and the single-update training contract.

Part 2 - System and Memory Mental Model

A device can own nonadjacent logical stages, so stage ID is not rank ID. The communication graph may revisit a rank and contain both local edges and cross-rank edges. Local edges still have autograd and buffer-lifetime rules. All local stage parameters, gradients, optimizer states, and simultaneous activation sets share one device budget. Adding each stage's independent

peak can overestimate or underestimate the real joint timeline depending on what was included; aggregate actual live storage first.

Part 3 - Quantitative Prediction Before Execution

Map four virtual stages onto two ranks in a declared looped order and list every logical edge and physical transfer. Predict local persistent bytes, message count, and live activation intervals under the chosen schedule. Contrast with two contiguous physical stages implementing the same logical model. Identify whether smaller chunks reduce exposed bubbles enough to offset extra transfers and local scheduling overhead.

Part 4 - Experimental Design and Instrumentation

Validate the global virtual-stage order and physical placement offline. Construct only assigned submodules, with a common logical parameter registry. Use a supported multi-stage scheduler and version-checked microbatch constraints. Compare outputs, gradients, and several updates with the noninterleaved reference. Capture per-virtual-stage service times and per-device union busy time. Audit local edge semantics and outstanding transport work before reuse. Measure ordinary completed steps in separate replays. Keep the same complete model and global batch; report changed cut locations as part of the configuration.

Test two local virtual stages receiving the same microbatch ID during one update. Their caches, gradients, and message identities must remain distinct. A local edge may use a normal differentiable tensor connection or an explicit local boundary protocol; select one validated approach and avoid accidentally applying its derivative twice. Count parameters and moments for every assigned local module in the device inventory. Include concurrent saved graphs from nonadjacent virtual stages in the residency sweep. Compare a looped mapping with a contiguous mapping only under a supported scheduler and document the changed physical edge traffic. More virtual stages can increase messages and bookkeeping even while shortening compute chunks. Do not infer that independent logical stages can execute compute simultaneously on a physical GPU without measured stream and resource evidence.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class VirtualStagePlacement:
    virtual_stage_id: int
    owner_rank: int
    logical_layer_interval: tuple
    predecessor: object
    successor: object

def validate_virtual_stage_mapping(mapping, model_registry):
    ...
```

```
def measure_joint_device_residency(local_stages, lifetime_events):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report virtual and physical maps, unique device-wide capacity, peak contributing stages, message payload, busy-time union, step time, and numerical errors. Detect a rank-based cache key that confuses two local stages for the same microbatch. Do not claim physical concurrency between two compute regions merely because they belong to different virtual stages on one GPU. Preserve cases where interleaving adds traffic without improving makespan.

Part 7 - Engineering Interpretation and Philosophy

Explain how finer logical partitioning changes scheduling opportunities while leaving physical capacity finite. Identify when the added placement complexity is justified by the measured workload.

19.43.16 Exercise 15

Exercise Title: Reproduce a Pipeline OOM Caused by Excessive In-Flight Micro-Batches and Build a Memory Admission Limit for the Schedule

Part 1 - Exercise Contract and Why It Matters

Reproduce an excessive-activation admission failure in a bounded pipeline experiment and build a byte-aware schedule limit. Use a deterministic application quota as the primary reproducer; label a real CUDA OOM separately and run it only as an optional isolated test.

Part 2 - System and Memory Mental Model

Live activations, pending sends, receive capacity, and saved graphs all consume resources. Limiting forward launches changes the event graph and can prevent progress. A fill/drain schedule that requires all forwards before backward cannot simply pause below that requirement while waiting for backward to free space. Either reject the configuration or select an explicitly changed valid schedule. A controller must leave capacity for backward and communication, not fill the device with forward state and hope release becomes possible.

Part 3 - Quantitative Prediction Before Execution

Construct a synthetic stage with known activation costs and a quota that rejects a specified admission. Predict the failure event and peak live set. Determine the minimum warmup/progress requirements of the chosen 1F1B plan. Add a backward workspace reserve and pending-transfer capacity. Explain why a count-only cap can admit a large variable-shape microbatch that violates the byte limit.

Part 4 - Experimental Design and Instrumentation

Validate admission and progress on the offline event graph first. Execute a small fitting run, then a quota-rejected excessive-residency run, followed by a feasible revised plan with identical

logical training semantics. Make schedule decisions rank-consistent before issuing messages. Do not insert rank-local waits that strand peers on unmatched communication. Preserve the initial prediction and compare observed live sets. If a real worker allocation failure is tested, terminate and recreate the whole group from a committed state. Never label a simulated quota failure as a measured CUDA OOM.

Build a minimal quota example where the next forward would exceed the budget but a ready backward can release an older activation. Verify that the selected schedule can choose that backward without violating message order. Contrast it with strict fill/drain, where the same cap can make the plan impossible unless it is rejected or explicitly changed. A windowed fill/drain extension changes the schedule and must retain one optimizer update for the full logical batch; it cannot silently step after every window. Reserve output-gradient and backward workspace capacity before admitting the last allowable forward. Validate progress in the offline dependency graph, then measure the small quota reproducer. If real CUDA exhaustion is not run, state that no hardware OOM evidence was collected even when the simulated failure matches the predicted event.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class PipelineAdmissionPolicy:
    def validate_progress(self, event_plan, resource_bounds):
        ...

    def reserve_for_forward(self, microbatch, stage_id, cost_bound):
        ...

    def release_after_last_reader(self, activation_key, completion):
        ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report quota versus physical failure type, rejected event, reserved pending bytes, live capacity, workspace allowance, revised plan, and update correctness. A lower peak is invalid if some microbatches were silently skipped. Verify all logical samples still contribute once and the pipeline drains. An application ledger cannot guarantee arbitrary real allocations against external device use or unknown workspaces; state its precise scope.

Part 7 - Engineering Interpretation and Philosophy

Explain how memory admission and dependency progress constrain each other. Choose a limit that is both byte-feasible and executable under the validated schedule.

19.43.17 Exercise 16

Exercise Title: Combine Pipeline Parallelism with Activation Checkpointing and Determine Which Stages Benefit Most from Recomputation

Part 1 - Exercise Contract and Why It Matters

Add activation checkpointing to selected pipeline stages and determine which choices improve feasible memory or throughput. Compare identical schedules and logical batches before re-tuning the schedule with recomputation enabled.

Part 2 - System and Memory Mental Model

Checkpointing retains a smaller set of inputs and recomputes selected intermediates during backward. Boundary inputs, communication buffers, and parameter/optimizer state still consume memory. Recomputation lengthens stage service time and can change the bottleneck and bubble pattern. Keep distributed send/receive operations outside checkpointed local functions in the primary design so backward recomputation does not issue duplicate protocol messages. Preserve parameter versions and deterministic local computation across original forward and recomputation.

Part 3 - Quantitative Prediction Before Execution

For each candidate stage, estimate bytes removed from saved intermediates, bytes retained for checkpoint inputs, and added backward compute. Apply those lifetimes to the current schedule and predict the new device peak and critical path. Construct a case where checkpointing a noncritical memory-heavy stage helps and another where checkpointing the slowest stage worsens makespan. Mark estimates that depend on unsupported saved-tensor instrumentation.

Part 4 - Experimental Design and Instrumentation

Use a supported checkpoint route with use_reentrant explicitly selected; start with the documented non-reentrant path where compatible. Keep dropout disabled initially. Validate outputs, stage gradients, moments, and several updates against the uncheckpointed oracle. Test no stages, one selected stage, and all eligible stages in separate replays. Measure recomputation and communication separately. Keep schedule and microbatch count fixed in the first comparison, then run a separately labeled re-tuning experiment. Count all retained boundary inputs and framework buffers rather than equating checkpointing with zero activation residency.

Place checkpoint boundaries entirely inside local stage computation in the first implementation. Keep P2P sends, receives, evidence logging, and mutable schedule state outside the recomputed function. Validate that the recomputed values use the original parameter version and unchanged inputs. A checkpointed stage still needs its received boundary input and any state required by the selected checkpoint API. If stochastic operations are later introduced, test RNG restoration under the documented device assumptions; moving tensors to an unexpected device inside recomputation can change those assumptions. Compare several optimizer updates because stateful side effects can escape a one-step output check. Record whether saved-tensor memory and recompute time are measured directly or estimated, and keep checkpoint-induced changes in the slowest stage's service time visible in the makespan model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.checkpoint import checkpoint

def select_local_checkpoint_regions(stage_spec, cost_model):
    ...

def execute_checkpointed_local_region(module, inputs, policy):
    # Keep distributed communication outside the recomputed function.
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export checkpoint regions, retained input bytes, saved-byte changes, recompute time, stage service times, complete peaks, makespan, and numerical errors. If stochastic layers are added, validate RNG and device assumptions explicitly. Detect state mutation or parameter updates between forward and recomputation. Do not claim the original schedule's critical path remains unchanged after adding compute. Preserve unfavorable stage selections as counterexamples to blanket checkpointing rules.

Part 7 - Engineering Interpretation and Philosophy

Choose checkpointing by the joint memory and scheduling evidence. Explain why the most activation-heavy stage is not automatically the best place to spend additional compute.

19.43.18 Exercise 17

Exercise Title: Build an Adaptive Pipeline Scheduler That Changes Micro-Batch Count from Per-Stage VRAM Headroom, Bubble Time, and Communication Cost

Part 1 - Exercise Contract and Why It Matters

Build an adaptive microbatch selector using per-stage memory, dependency idle time, and communication costs. Change configuration only between fully drained optimizer updates in the primary runtime. Preserve one fixed logical batch and loss objective while choosing a new valid chunking plan.

Part 2 - System and Memory Mental Model

Changing microbatch count changes tensor shapes, kernel efficiency, message sequences, and possibly framework communication buffers. Updating a schedule field in place cannot establish compatibility. All ranks must agree on the new generation and supported shape contract before execution. Free VRAM is contextual evidence rather than a reservation. Use measured bounds, reserves, and hysteresis to avoid oscillation. Stage repartitioning remains a separate operation requiring explicit state migration or a fresh replay.

Part 3 - Quantitative Prediction Before Execution

Define a finite count set dividing the primary logical batch, plus supported schedule constraints. Predict candidate peaks and critical paths from E09 and E11. State an objective and admission margin. Construct a trace where a small noisy headroom change should not trigger reconfiguration and a sustained pressure change should. Include buffer reconstruction and lost warmup time in the amortized cost.

Part 4 - Experimental Design and Instrumentation

Calibrate on named training shapes, then test on held-out updates and controlled pressure changes. Drain the old plan, finish pending work, agree on a rank-consistent choice, rebuild required shape-specific wrappers/buffers, and preserve optimizer state and logical progress. Verify that no microbatch is duplicated or omitted across the transition. Start with conservative reject-and-keep behavior when evidence is insufficient. Compare against fixed counts and an offline best-tested configuration. Include monitoring and reconfiguration overhead in end-to-end timing. Use fresh jobs for stage-cut changes instead of silently moving live parameters.

Keep a monotonic configuration generation in every message and activation cache. Reconfiguration is allowed only after the old generation is fully drained and its communication buffers are no longer in use. All ranks must agree before any new message sequence begins. At fixed logical batch, prefer count candidates that create supported equal chunks; uneven chunks require the separately validated weighting and shape path. Preserve optimizer moments, counters, parameter values, and logical data position while rebuilding the schedule wrappers. Compare the next update against a reference that uses the same samples with the new chunk count. Include the monitoring interval, hysteresis thresholds, rejected proposals, reconstruction peak, and transition latency in evidence. Do not treat a favorable pre-change memory observation as guaranteed headroom for the next shape or external allocation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class AdaptiveMicrobatchSelector:
    def propose(self, stage_evidence, supported_candidates):
        ...

    def agree_at_drained_boundary(self, proposal, runtime):
        ...

    def rebuild_shape_contract(self, runtime, accepted_plan):
        ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report every proposal, accepted generation, rejection reason, predicted and observed peaks, logical batch, chunk sizes, transition cost, throughput, and update errors. Verify equivalent parameter updates across a changed microbatch count using the deterministic model. Label the selector best among tested candidates rather than globally optimal. A policy that reacts quickly but repeatedly pays reconstruction costs may lose to a fixed schedule.

Part 7 - Engineering Interpretation and Philosophy

Explain which evidence justifies adaptation and which uncertainty favors keeping the current plan. Choose a policy that preserves semantics and progress before pursuing a smaller reported bubble fraction.

19.43.19 Exercise 18

Exercise Title: Stress-Test Pipeline Parallel Training with Uneven Stage Sizes, Variable Sequence Lengths, Slow Interconnects, and Tight Per-GPU Memory Budgets

Part 1 - Exercise Contract and Why It Matters

Stress pipeline training with uneven stage costs, variable sequence lengths, constrained transport, and tight application budgets. Require correct logical updates, coherent rejection, and recoverable worker-group behavior. Produce small counterexamples before attempting larger pressure experiments.

Part 2 - System and Memory Mental Model

Shape changes affect boundaries, targets, loss denominators, saved tensors, and workspace requirements. A static framework stage may need padding, shape buckets, or reconstruction at a drained boundary; first-microbatch inference does not automatically permit arbitrary later changes. Artificial transport delays measure scheduler sensitivity, not the physical bandwidth of a different machine. Tight memory can expose progress errors as well as allocation limits. All ranks must retain matching protocol generations and microbatch identities.

Part 3 - Quantitative Prediction Before Execution

Define cases with one slow stage, a large embedding stage, long sequences, unequal valid-token counts, and a pressure limit near predicted residency. Predict outcomes and failure phases. For padded shape buckets, calculate valid loss counts and retained padded capacity separately. Model a delayed boundary as added dependency time and predict how it changes live sets and the critical path rather than simply adding its duration to every stage.

Part 4 - Experimental Design and Instrumentation

Run deterministic small-model correctness cases first. Change one factor at a time, then selected combinations with preserved seeds. Use equal static chunks for the primary path and label variable-shape support extensions. Validate metadata before communication and reject unsupported contracts coherently. Introduce bounded transport delays in a named simulation layer. Keep committed parameter, optimizer, and logical-data progress at safe boundaries. After worker failure, rebuild the group and compare resumed updates with an uninterrupted run. Record all failed and rejected cases, including those that do not reproduce consistently.

Add a variable-length case with equal sample counts but unequal valid token counts across microbatches. Derive the full-batch denominator before backward and verify masked padding contributes neither loss nor gradient. If static buckets are used, include their padded storage in

the budget. For a slow-interconnect sensitivity test, specify whether the injected delay blocks a communication resource, a dependency, or a host launch; these models can produce different overlap behavior. Do not describe an artificial delay as measured PCIe bandwidth. Include a stage imbalance case where the smallest parameter stage is the throughput bottleneck. Minimize numerical failures by returning first to serialized execution, then removing checkpointing, while preserving the same logical model and samples. Store the minimized event trace with the failure classification and reproducibility record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_pipeline_stress_cases(model_spec, protocol_caps):
    ...

def validate_shape_bucket_and_loss(case, global_batch_contract):
    ...

def run_stress_case(case, runtime, reference, evidence):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export stage map, schedule, shapes, valid/padded counts, delays, budgets, peak residency, latency, numerical errors, outcome, and failure phase. Separate simulated pressure or delay from hardware measurements. Check earliest stage gradients, not only final outputs. Preserve the smallest mismatch and its event trace. Unsupported dynamic shapes are rejected configurations, not successful stress runs. An absent OOM or deadlock in a bounded test is not proof of universal safety.

Part 7 - Engineering Interpretation and Philosophy

Explain which stress case most directly tests the runtime's core invariant. Use its result to refine supported scope, resource bounds, or recovery behavior without concealing unsuccessful experiments.

19.43.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Memory-Aware Pipeline Runtime That Jointly Optimizes Stage Placement, Micro-Batch Scheduling, Activation Residency, and Pipeline Utilization

Part 1 - Exercise Contract and Why It Matters

Integrate the validated components into an explicit memory-aware pipeline runtime. Jointly search a bounded set of stage placements, schedules, microbatch counts, and local checkpoint choices. Benchmark complete correct training under per-device budgets and preserve a capability matrix.

Part 2 - System and Memory Mental Model

The runtime combines logical parameter ownership, boundary protocols, a dependency scheduler, autograd caches, loss weighting, and a storage ledger. A legal candidate must preserve one logical update and use compatible message and shape contracts. Primary placement search uses fresh replays; online adaptation changes only supported microbatch plans at drained boundaries. Arbitrary graph cuts, cross-stage ties, stochastic behavior, and live stage migration remain unsupported until separately validated. This exercise builds an educational engine, not a claim to replace every production pipeline system.

Part 3 - Quantitative Prediction Before Execution

Before integration, predict candidate persistent bytes, activation live sets, transport buffers, workspace reserves, stage service times, and makespan. Define correctness tolerances, budget scope, progress conditions, and the selection objective. Enumerate enough candidates to compare equal-count, parameter-aware, and memory-aware partitions, plus sequential, fill/drain, and flushed 1F1B schedules where supported. Treat interleaving as an optional explicit virtual-stage configuration.

Part 4 - Experimental Design and Instrumentation

Validate a tiny model from canonical initialization against several serial full-batch Adam updates. Run correctness checks, profiling, timing, and capacity searches in separate replays. Time complete forward, backward, update, and required completion. Preserve E00's reproducibility record plus valid counts, chunk shapes, schedule, placement, checkpoint policy, and application budgets. Export CPU evidence. Verify committed stage-state restart against uninterrupted updates. Use available devices on one host; report unavailable configurations as not measured.

Publish a capability matrix with validating run IDs for each implemented component; scaffold signatures do not establish support. Preserve predicted candidate costs and rejection reasons. Count samples once across the pipeline. Commit matching stage versions, optimizer progress, data position, and configuration identity. Limit conclusions to tested shapes, device maps, schedule constraints, and measured uncertainty.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class MemoryAwarePipelineRuntime:
    def validate_candidate(self, model_spec, placement, schedule):
        ...
```

```
    def construct_local_stages(self, logical_initialization):
        ...

    def run_drained_training_update(self, logical_batch):
        ...

    def export_cpu_evidence(self):
        ...

    def checkpoint_committed_state(self, destination):
        ...

def E19(config):
    # Integrate validated components and benchmark isolated candidates.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation in separate columns. Each run needs an ID, configuration, input shapes, budgets in bytes, stage and device peaks, reserved peaks, elapsed seconds, useful throughput, numerical errors, outcome, and failure phase. Use explicit unsupported and not-measured values. Report the best tested feasible plan, its search limits, and the smallest counterexample to any universal rule, or state none was observed. Do not invent GPU results or convert a simulated quota failure into hardware evidence. Report regressions and adaptation costs alongside improvements.

Part 7 - Engineering Interpretation and Philosophy

Justify the selected plan through checked gradients, ownership, progress, and resource measurements. Identify untested workloads or hardware conditions that could change the decision.

19.44 DMM42

Chapter Title: Multi-GPU Memory Balancing
Specialization: Dynamic Memory Management and CUDA Systems

19.44.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Memory Imbalance, Compute Imbalance, Communication Cost, and Device Capacity Across Multiple GPUs

Part 1 - Exercise Contract and Why It Matters

Model balancing as a constrained placement problem with separate memory, compute, communication, and correctness objectives. Deliver explicit device budgets, ownership maps, phase lifetimes, and supported execution modes before choosing a balance metric or moving state.

Part 2 - System and Memory Mental Model

Equal byte counts do not imply equal capacity pressure on heterogeneous GPUs. Equal pressure does not imply equal stage time or low communication. Process-local allocated and reserved memory differ from driver-wide used memory, and peak values need a named measurement region. Spare capacity on another device cannot automatically satisfy a request on the constrained one. The primary placement and migration track is a deterministic single-process multi-GPU sequential model; distributed sharded compositions are separate version-checked extensions, not freely movable ordinary modules.

Part 3 - Quantitative Prediction Before Execution

Define capacity C_i, application budget B_i, phase-specific predicted live bytes $M_i(t)$, and a required workspace reserve. Calculate feasibility before minimizing imbalance. Compare a placement with equal bytes on unequal capacities against one with unequal bytes but equal pressure. Add a communication edge cost and explain why memory feasibility and throughput are distinct constraints rather than interchangeable scores.

Part 4 - Experimental Design and Instrumentation

Establish a small serial reference for outputs, gradients, and several Adam updates. Start with FP32, deterministic layers, no cross-device tied weights, no stochastic modules, and explicit copies between devices. Freeze logical parameter IDs and input/loss semantics. Record device identity, capacity, topology, process mode, software versions, allocator backend, seed, model, precision, optimizer, batch/sequence shape, and initial-state ID. Validate installed capabilities before using DeviceMesh, TP, FSDP, or pipeline APIs.

Write an ownership table for the primary single-process model and another for each distributed extension. Include logical parameters, actual representations, optimizer owners, sample identities, and communication participants. A rank is a process identity; a device is a physical execution resource; a stage or shard is a logical role. Keep those meanings distinct even when the primary mapping is one-to-one. Use a two-device paper example to show a placement that balances parameters but overloads one device during backward. Add another example where a low-memory device is the compute bottleneck. These examples should determine which measurements are required, not become fabricated local benchmark results. Define whether the task is initialization, inference, or training capacity and use complete training updates for the primary conclusions. State the loss objective and global sample coverage before evaluating any balancing policy so a smaller peak cannot be purchased by silently omitting work or changing the model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BalancingContract:
    process_mode: str
    device_budgets_bytes: tuple
    logical_parameter_registry: object
    supported_migration_units: tuple
```

```
    loss_identity: str
    measurement_region: str

def validate_balancing_contract(contract, model_spec):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Require correct useful updates and compatible communication before accepting a lower balance score. Unknown overhead remains unknown. Simulated budgets, offline topology examples, and unrun distributed experiments must not be reported as hardware measurements. Export CPU evidence without retaining live training graphs.

Part 7 - Engineering Interpretation and Philosophy

Explain which constraint makes a device limiting and which trade-offs remain after feasibility. A useful balancer preserves training semantics while making explicit, measured resource decisions.

19.44.2 Exercise 01

Exercise Title: Measure Allocated, Reserved, Peak, and Free VRAM Independently on Every CUDA Device in a Multi-GPU PyTorch Process

Part 1 - Exercise Contract and Why It Matters

Measure current allocated, reserved, peak allocated, peak reserved, and driver free/total bytes independently on every visible CUDA device used by the declared process. Deliver device-indexed measurements with explicit scope, phase, and timestamp.

Part 2 - System and Memory Mental Model

Allocator counters describe the calling process's allocator on a device. Driver free/total information has broader device scope and can reflect other processes and non-allocator allocations. Reserved capacity includes cached storage; it is not additional to allocated payload. Reading every device in one process is not equivalent to summing every distributed rank's counters. Queries can initialize contexts or perturb timing, so cold initialization and warmed observations must be distinguished.

Part 3 - Quantitative Prediction Before Execution

Predict the response of each counter to allocating, retaining, releasing, and reusing a bounded tensor on one chosen GPU. Specify whether peaks were reset and what region they cover. Calculate driver used bytes as total minus free under that API's scope, but do not equate it with this process's live tensor bytes. Predict what a second process's allocation would change.

Part 4 - Experimental Design and Instrumentation

Use explicit device arguments rather than relying on current-device state. Warm declared contexts deliberately, then reset peaks at synchronized region boundaries on each participating device. Run an allocation-only trace first and a full forward/backward/update trace separately. Record sampling order and age because readings across devices are not atomic. In one-rank-per-GPU extensions, each rank samples its owned device and exchanges CPU metadata; do not have every rank create contexts on all GPUs merely to query them. Preserve backend-specific unsupported counters.

Use stable device identity alongside the visible CUDA ordinal, since visibility settings can renumber devices. Record the process mode and whether a sample caused first use of a context. Reset peaks on every participating device before the named region; resetting a peak counter neither releases memory nor reserves future capacity. Sample a bounded retained tensor, a released tensor, and a reused allocation to distinguish current and historical values. Keep any optional empty_cache experiment separate from ordinary timing because it changes allocator reuse behavior. In a distributed run, aggregate process-local counters only with complete rank ownership metadata; several ranks sharing one device can have distinct allocator totals but repeat the same global free/total observation. Timestamp each row and reject an allegedly simultaneous comparison when its sampling skew exceeds the declared tolerance. Unknown external activity should remain context, not be subtracted from a process ledger through an unsupported assumption.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DeviceMemorySample:
    process_id: int
    device_identity: str
    phase: str
    timestamp_seconds: float
    allocated_bytes: object
    reserved_bytes: object
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    driver_free_bytes: object
    driver_total_bytes: object

def sample_explicit_device(device, measurement_contract):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw bytes, device mapping, reset boundary, timestamp, and scope. Check that a deliberate allocation appears on the intended device. Do not sum driver-wide used readings duplicated across ranks. Explain cached reserved memory after tensor release without calling it a leak automatically. An asynchronous phase sample needs a clear completion convention; a host function return is not a synchronized training boundary.

Part 7 - Engineering Interpretation and Philosophy

Choose which counter answers a live-payload, allocator-capacity, or device-headroom question. Explain why no single used-memory number covers all three scopes.

19.44.3 Exercise 02

Exercise Title: Build a Per-GPU Memory Dashboard That Tracks Parameters, Gradients, Activations, Temporary Buffers, and Free Capacity During Training

Part 1 - Exercise Contract and Why It Matters

Build a CPU-side per-GPU dashboard from validated samples and a storage ledger. Display parameters, gradients, initialized optimizer state, saved activations, communication/temporary buffers, and driver headroom with separate scopes. The learner implements the monitor and evidence export explicitly.

Part 2 - System and Memory Mental Model

Allocator APIs do not automatically classify bytes by model role. Category accounting needs a registry and lifetime instrumentation, with aliases counted once. Some backend workspace and external allocations remain unattributed. A dashboard must not subtract unrelated category peaks and label the residual activation memory. Free capacity is sampled context, not a promise that the next allocation or migration will succeed.

Part 3 - Quantitative Prediction Before Execution

Predict persistent bytes for a small two-device model after Adam is initialized. Add saved activations and transport buffers on a phase timeline. Design the display so current live categories, historical peaks, and driver-wide headroom cannot be mistaken for simultaneous additive quantities. Define unknown, unsupported, stale, and not-measured states instead of filling missing fields with zero.

Part 4 - Experimental Design and Instrumentation

Collect metadata at deliberate training boundaries and lower-frequency runtime samples. Use supported saved-tensor inspection only in a diagnostic replay, exporting storage IDs and byte counts without retaining GPU tensors. Deduplicate shared backing across categories and preserve overlap annotations. Attach process/rank and device identity to every row. Separate rendering or logging overhead from ordinary timing. Bound log retention and avoid per-layer global synchronization in the final monitor. Validate the dashboard against a tiny hand-checked allocation and training trace.

Design each dashboard row with a field for scope, observation age, and provenance. Separate current categories from maxima and show whether an entry comes from direct storage inspection, a supported instrument, or a model estimate. Parameter counts by name can duplicate tied storage; use backing identity and retain the logical alias relationship. Saved activations

can include views of parameters or larger input buffers, so record category overlap before summing. Include optimizer scalar state, not just moments, and state whether it resides on CPU or CUDA. A dashboard can present historical phase peaks without implying those phases coexist. Validate the displayed free-capacity field against its original driver sample rather than deriving it from physical capacity minus process allocations. Bound CPU history size and sampling frequency, then measure monitor overhead. Do not let the evidence log itself become the source of the apparent memory growth it is meant to diagnose.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DeviceCategoryRow:
    device_identity: str
    phase: str
    category_bytes: dict
    unattributed_status: str
    sample_age_seconds: float

def build_device_category_rows(storage_ledger, raw_samples):
    ...

def export_dashboard_cpu_rows(rows, destination):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require raw values alongside derived display fields. Include a retained view and a delayed transport buffer to test category lifetimes. Compare process-local allocated bytes with the category inventory under declared scope, preserving unexplained residuals. Verify that logs do not keep live autograd graphs or GPU references. Report the dashboard's sampling overhead and age rather than presenting stale rows as exact simultaneous state.

Part 7 - Engineering Interpretation and Philosophy

Explain which decision each field supports and which uncertainties remain. Prefer an auditable incomplete inventory to an apparently complete breakdown assembled from incompatible counters.

19.44.4 Exercise 03

Exercise Title: Create an Intentionally Imbalanced Model Placement and Quantify the Difference Between Maximum and Minimum Per-GPU VRAM Usage

Part 1 - Exercise Contract and Why It Matters

Create a deliberately imbalanced placement of the same logical model and quantify per-device memory differences. Compare it with a controlled reference placement while preserving inputs, model values, optimizer, and complete training semantics.

Part 2 - System and Memory Mental Model

A device can be overloaded by persistent parameters, long-lived activations, a large output head, or transfer staging. The primary single-process model uses explicit device transitions with autograd-aware copies. A placement change can alter both memory and communication, so classify the source of imbalance. Small local tensor shapes do not prove independent backing, and initial construction can create larger peaks than warmed execution.

Part 3 - Quantitative Prediction Before Execution

Choose heterogeneous layer widths and assign most large layers to one GPU. Predict local parameter and initialized-state bytes, boundary payload, and activation lifetimes. Calculate maximum-minus-minimum current allocated bytes at one aligned boundary and the analogous spread of region peaks. Explain why peak spread need not describe an instantaneous state when peaks occur at different times.

Part 4 - Experimental Design and Instrumentation

Use a bounded deterministic network with no ties or batch-coupled state. Construct only the planned local modules from a canonical initialization. Validate outputs, gradients, moments, and several updates against a serial oracle. Measure both intentionally imbalanced and reference placements in fresh replays. Sample each device at common completed phases and preserve sampling order. Include cold construction and warmed full-update peaks as separate regions. Record extra cross-device copies and output collection.

Use a tiny model whose layer dimensions make the intended imbalance obvious by hand. Include at least one nonzero activation and nonzero loss contribution from every sample so skipped work cannot improve the memory score unnoticed. Measure the same completed boundary on both GPUs and store the sampling timestamps with the spread. For peak comparisons, preserve the event or phase where each device reached its own maximum. An average of those maxima is an operational summary, not a reconstructed simultaneous state. Compare initialization separately because creating a whole model on one GPU and redistributing it later can dominate the apparent imbalance. Check that no old full model survives behind parameter groups or Python closures. If both placements fit, compare useful throughput; if one fails, report the phase and successful work count rather than assigning it a fictitious step time. The experiment should reveal the limiting device without assuming that every unequal placement is bad.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_intentionally_imbalanced_map(layer_inventory, devices):
    ...

def run_checked_placement_replay(placement, logical_state, config):
    ...

def quantify_device_spread(device_rows, region_contract):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-device raw bytes, category inventory, current spread, peak spread, timestamps, throughput, and numerical errors. Do not call the least allocated GPU idle without compute evidence. If activation costs reverse the predicted ranking, retain that outcome and identify the responsible phase. A lower spread produced by wasting memory on the emptier GPU is not an acceptable optimization.

Part 7 - Engineering Interpretation and Philosophy

Explain the concrete source of imbalance and which device limits feasibility. Use this reproducer to evaluate later metrics rather than assuming all unequal byte totals require migration.

19.44.5 Exercise 04

Exercise Title: Define Memory Balance Metrics from Per-GPU Used Memory, Peak Memory, Capacity, and Utilization Ratios

Part 1 - Exercise Contract and Why It Matters

Define a family of balance metrics with named accounting layers and units. Compare absolute spread, normalized pressure, peak pressure, and predicted slack. Deliver counterexamples to treating any one metric as a universal placement objective.

Part 2 - System and Memory Mental Model

Capacity and usable application budget can differ. Device-wide used memory and process-local allocated bytes answer different questions and must not be mixed inside one vector. Historical per-device peaks may occur at different times. A memory pressure ratio is not GPU compute utilization. Balance is subordinate to feasibility and useful work: making every device fuller can lower relative imbalance while reducing safety margin.

Part 3 - Quantitative Prediction Before Execution

For a declared same-scope vector U_i, define

$$\Delta_U = \max_i U_i - \min_i U_i, \qquad \rho_i = U_i / B_i \quad (B_i > 0).$$

Define predicted slack from application budget minus a phase peak and reserve, counting the reserve exactly once. If using coefficient of variation, keep zero-mean cases undefined or explicitly handled. Compare equal bytes on unequal budgets and unequal bytes on equal pressure. Add a request-size fit counterexample.

Part 4 - Experimental Design and Instrumentation

Validate formulas on synthetic two- and three-device cases before measuring hardware. Include all-zero use, missing capacity, one unavailable sample, heterogeneous budgets, and a stale driver reading. Define aggregation boundaries and timestamp tolerance. Evaluate metric rankings against observed full-update feasibility and latency in separate replays. Keep original predictions and raw vectors beside derived values. Do not infer allocator fragmentation or causal compute imbalance from a memory spread alone.

Choose one accounting layer for each metric vector and put that choice in its name or metadata. Validate budget-normalized pressure with positive budgets only; a missing or zero budget cannot silently produce zero pressure. For peak vectors, preserve each component's region and time. Add a case in which all devices have equal pressure above their application budgets, showing that perfect balance can still be infeasible. Add a case where increasing unused retained cache makes an absolute-spread statistic look better without creating any useful capacity. Request size and contiguous-fit restrictions can defeat a simplistic free-byte ranking, so keep a separate next-phase allocation estimate and unknown eligibility status. If using coefficient of variation, calculate population or sample convention explicitly and test zero mean. Do not interpret a memory-utilization ratio as SM activity or kernel occupancy. Counterexamples must accompany the formulas before those formulas are allowed to drive an automatic move.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class BalanceMetricResult:
    accounting_scope: str
    raw_usage_bytes: tuple
    budget_bytes: tuple
    absolute_spread_bytes: object
    normalized_pressure: object
    predicted_slack_bytes: object
    limitations: tuple

def calculate_balance_metrics(samples, budgets, prediction_region):
    ...
```

```
def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report undefined denominators and unknown inputs explicitly. Require a minimal counterexample for every proposed universal ranking. Distinguish current balance from worst-phase capacity risk. Show a case where a modest imbalance is preferable because it removes expensive transfers. If a predicted safe placement fails, preserve the failure phase rather than silently redefining the metric after observing the result.

Part 7 - Engineering Interpretation and Philosophy

Choose a minimal metric set for feasibility screening and investigation. Explain which decision requires byte slack, which requires normalized pressure, and which requires actual compute or communication measurements.

19.44.6 Exercise 05

Exercise Title: Partition Model Layers Across GPUs by Equal Layer Count and Demonstrate Why Equal Counts Do Not Guarantee Equal Memory Consumption

Part 1 - Exercise Contract and Why It Matters

Partition ordered layers by equal count and test whether this balances memory. Compare useful persistent bytes and complete training peaks, including activations and transfers, on the same logical model.

Part 2 - System and Memory Mental Model

Layers can differ greatly in matrix dimensions, persistent buffers, optimizer state, and saved activations. Embedding and output layers can dominate parameters while another stage dominates activation residency. A layer list is not necessarily the complete forward graph; residuals and non-module operations must remain intact. Equal-count partitioning is a baseline with explicit limits rather than a memory guarantee.

Part 3 - Quantitative Prediction Before Execution

Construct a short ordered model with equal numbers of layers per GPU but unequal widths. Calculate parameter and buffer bytes from shapes and dtypes. Add initialized gradients and Adam moments under the declared flags. Predict a boundary activation and local saved-state peak. Give a second example with similar parameter totals but different activation costs.

Part 4 - Experimental Design and Instrumentation

Choose contiguous cuts so the primary comparison has a simple device transition graph. Preserve every activation, reshape, mask, and residual operation. Use untied deterministic modules and the same initial values. Validate the partition against serial outputs, all gradients, and multiple updates. Measure cold construction and warmed full steps separately. Record layer inventory, cut positions, local capacities, transfers, and phase-specific peaks. Keep batch size, sequence length, precision, optimizer, and timing boundaries fixed while changing only the partition rule.

Keep complete logical computation units rather than assuming every module boundary is a safe device cut. A residual edge may carry an earlier activation past several counted layers, changing both transport and residency. Use contiguous complete blocks for the primary baseline and record any unavoidable extra boundary values. Count registered buffers as well as parameters; some layers contain non-parameter state whose placement matters. Compare the same number of completed optimizer updates and the same loss weighting. If a batch-dependent layer is present, either implement its intended semantics across the chosen execution grouping or exclude it from the deterministic oracle. Include a synthetic example with a large embedding or output layer and several tiny normalization layers. Its equal-count partition can be calculated without GPU execution and should predict a concrete persistent imbalance. Then measure whether activations or workspace reinforce or reverse that prediction in the supported training model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def equal_count_contiguous_partition(ordered_units, devices):
    ...

def audit_partition_forward_graph(model_spec, placement):
    ...

def compare_equal_count_memory(placement, reference, measurements):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report layer counts beside actual bytes, peak phase, compute time, communication, and correctness. Demonstrate unequal memory when observed; otherwise state the tested model did not expose the proposed effect. Include a hand-calculated heterogeneous counterexample regardless of hardware outcome. Do not fix a poor baseline by changing model width or dropping an operation. Explain any mismatch between persistent-byte predictions and training peaks.

Part 7 - Engineering Interpretation and Philosophy

Identify what equal-count partitioning ignores. State which additional cost information is necessary before using it for a capacity decision.

19.44.7 Exercise 06

Exercise Title: Build a Greedy Layer Placement Algorithm That Assigns Modules According to Their Parameter and Buffer Memory Footprints

Part 1 - Exercise Contract and Why It Matters

Build a deterministic greedy placement algorithm using parameter and persistent-buffer footprints. Deliver valid execution maps, explicit feasibility checks, and comparison with equal-count placement. Label this as a persistent- state heuristic rather than a complete training-memory planner.

Part 2 - System and Memory Mental Model

Greedy assignment can reduce predicted persistent imbalance while adding many device transitions or ignoring activation peaks. Module ownership must respect shared storage, execution dependencies, and the runtime's supported cuts. In the primary sequential model, noncontiguous device assignments are allowed only with explicit autograd-aware transfers at every changed edge. Optimizer state and gradients are additional persistent training costs whose omission must remain visible.

Part 3 - Quantitative Prediction Before Execution

Sort eligible units by a declared footprint and assign them to the feasible device with the smallest resulting chosen load score. Define tie- breaking and treatment of indivisible units. Hand-simulate unequal unit sizes and a unit that fits nowhere. Predict parameter/buffer totals and count the cross-device execution edges introduced by the resulting map.

Part 4 - Experimental Design and Instrumentation

Inventory unique parameter and buffer storage from the logical model, including dtype and alias relationships. Group tied or shared units as indivisible constraints or reject them in the primary track. Validate the algorithm on tiny cases and compare its score with exhaustive enumeration where feasible. Construct the selected map from canonical values in a fresh replay. Check complete forward and gradient semantics before benchmarking. Report the omitted activation and temporary costs explicitly. Keep the heuristic's objective and execution-order constraints fixed during comparison.

Define the placement unit independently of the order in which a framework traverses modules. Preserve a stable logical ID and an eligibility set. If two units share storage, either merge them into a constrained unit or reject the unsupported configuration; assigning their shared names independently would create an invalid byte ledger. State whether the greedy order is descending size and whether the load score is bytes or normalized budget pressure. Use deterministic tie-breaking so the same inventory produces the same map. Compare a tiny case with all legal assignments to expose the heuristic's limits. The execution engine must follow the original logical layer order, even if placement order was size-sorted. Add explicit transfers at every cross-device edge and verify their gradients. Do not execute layers in greedy assignment order. Keep the omitted activation and communication costs visible in every result row until later exercises add them to the model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PlacementUnit:
    logical_id: str
    parameter_bytes: int
    persistent_buffer_bytes: int
    eligible_devices: tuple
    alias_group: object

def greedy_persistent_placement(units, budgets, tie_break_policy):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export assignment order, candidate device scores, rejection reasons, final persistent loads, execution edges, measured peaks, and update errors. A heuristic that balances its input cost has not proved training feasibility. Check oversized units and zero eligible devices without entering a futile retry loop. Retain a case where the greedy plan is worse than the tiny exhaustive oracle, or state none was found within the enumerated range.

Part 7 - Engineering Interpretation and Philosophy

Explain what the heuristic optimizes and why its simplicity can be useful. Identify the missing cost that most plausibly invalidates its placement on the chosen workload.

19.44.8 Exercise 07

Exercise Title: Extend the Placement Cost Model to Include Activation Memory and Discover Cases Where Parameter-Only Balancing Produces GPU OOM

Part 1 - Exercise Contract and Why It Matters

Extend the placement model with schedule- and shape-dependent activation memory. Construct a bounded case where parameter-only screening accepts a plan that exceeds a declared training budget. Distinguish a simulated quota failure from an optionally observed physical CUDA OOM.

Part 2 - System and Memory Mental Model

Saved activations, copies across device boundaries, output merging, backward temporaries, and workspace can dominate weight bytes. Their lifetimes matter: adding isolated layer maxima is not an exact stage peak. In a serial forward/backward graph, many saved values can coexist across devices until backward consumes them. An application budget failure is deterministic evidence about the declared model, not proof of a hardware allocator failure.

Part 3 - Quantitative Prediction Before Execution

Define a per-unit activation function of batch size, sequence length, dtype, and checkpoint policy. Combine its intervals with persistent state, transport buffers, and workspace reserve. Construct equal parameter totals with a long-sequence or wide-intermediate activation spike on one device. Predict the first budget violation and a revised placement that reduces it. Keep the original prediction before executing the trace.

Part 4 - Experimental Design and Instrumentation

Validate the cost model on synthetic lifetime lists and a tiny training oracle. Use quota admission for the primary failure reproducer. Compare parameter-only and activation-aware plans on the same logical batch in fresh replays. Warm optimizer state, measure complete updates, and inspect the peak phase. If a physical OOM test is chosen, isolate it and restart cleanly after failure rather than continuing from partial updates. Do not retain diagnostic GPU tensors while measuring. Record unsupported workspace fields as unknown with a conservative planning allowance.

Construct one activation-heavy unit with small parameter payload and a large saved intermediate. Predict its peak using a lifetime interval rather than only its forward output shape. Include backward workspace and initialized optimizer state in the application quota. A parameter-only map should pass its own declared screening, then fail the more complete quota test at a named event. Preserve that distinction rather than calling the first heuristic incorrect for an input cost it never modeled. If real CUDA exhaustion is not observed, report the deterministic quota counterexample and the tested hardware range honestly. For failed training, no stage may be considered committed until the whole logical update is complete. Reconstruct from the last committed state before a new comparison. A revised placement must run the same model and samples, and its new transfer edges must be included in the peak and timing ledger rather than hidden outside measurement.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def estimate_activation_lifetimes(model_spec, shape, placement, schedule):
    ...

def predict_training_peak(persistent_state, lifetimes, workspace_bounds):
    ...

def compare_parameter_only_and_activation_aware(cases, evidence):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful and backing activation bytes, predicted and measured peaks, quota/hardware failure type, failure phase, and update correctness. A failed attempt must not silently advance only some local optimizers. Preserve nonreproducing hardware outcomes honestly. Show which activation intervals invalidate the parameter-only decision and whether the revised plan introduces additional transfer costs.

Part 7 - Engineering Interpretation and Philosophy

Explain why parameter balance and training feasibility are different claims. Choose the minimum activation information needed for the next placement decision without pretending to know every backend allocation exactly.

19.44.9 Exercise 08

Exercise Title: Incorporate GPU Capacity into Placement Decisions and Balance a Model Across Devices with Different Available VRAM Budgets

Part 1 - Exercise Contract and Why It Matters

Incorporate heterogeneous available budgets into placement. Compare equal byte loading with normalized-pressure and slack-aware decisions while keeping logical training work constant. Support equal physical GPUs with explicitly simulated unequal application budgets as a separate controlled experiment.

Part 2 - System and Memory Mental Model

Physical capacity, current driver free bytes, allocator cached capacity, and application allowance are different quantities. External use can change headroom between sampling and allocation. Adding driver free bytes to all reserved bytes would double-count live allocations and still would not prove request fit. A device with more total VRAM can have less usable headroom. The placement must also fit its initialization and migration transient peaks.

Part 3 - Quantitative Prediction Before Execution

Choose two unequal budgets and an indivisible unit list. Derive feasible assignments and compare maximum normalized pressure with minimum byte slack. Include a target that has enough steady-state space but insufficient temporary space for construction. State how workspace reserve is included once. Predict a rejection when no device can admit the largest required unit.

Part 4 - Experimental Design and Instrumentation

Represent budgets as explicit bytes with source and timestamp: physical capacity, configured application quota, or measured contextual headroom. Validate the policy on synthetic heterogeneous cases. Use real differing capacities only if available, otherwise label the quota experiment accurately. Construct selected placements in fresh replays and measure initialized full updates. Keep the same model, batch, precision, optimizer, and initial state. Record per-device pressure, predicted slack, actual peaks, topology, and uncertainty margins. Do not manufacture a different GPU by silently changing the reported hardware identity.

Record physical capacity, configured application limit, sampled driver headroom, and reserve as separate fields. State exactly which quantity bounds the cost model. An artificial smaller application budget on one of two identical GPUs is useful for testing capacity-aware

logic but does not reproduce every performance property of a different GPU. Do not alter clock, architecture, or link claims to match the simulated capacity. Include initialization and transaction phases because a destination can fit the eventual model yet fail while old and new copies coexist. Test an indivisible unit larger than all budgets and require a clear infeasible result. Compare equal-byte, equal- pressure, and maximum-slack assignments on the same tiny inventory. The selected metric should match the desired next-phase feasibility, not merely aesthetic symmetry. Preserve uncertainty due to external allocations and avoid treating one driver sample as a durable promise of available capacity.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class DeviceBudget:
    device_identity: str
    physical_capacity_bytes: int
    application_limit_bytes: int
    workspace_reserve_bytes: int
    evidence_source: str
    sample_timestamp: object

def place_under_heterogeneous_budgets(units, budgets, cost_model):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report physical and application capacities separately, every rejected candidate, initial and warmed peaks, and numerical errors. A normalized score below one is only meaningful within its accounted scope and reserve assumptions. Include a case where equal byte use overloads the smaller budget. Preserve unknown external activity rather than attributing a surprise allocation failure to the placement algorithm without evidence.

Part 7 - Engineering Interpretation and Philosophy

Choose a capacity-aware criterion for a named operating constraint. Explain why the least-used device in absolute bytes is not necessarily the best destination.

19.44.10 Exercise 09

Exercise Title: Measure Cross-GPU Activation Transfer Volume and Add Communication Cost to the Memory Placement Objective

Part 1 - Exercise Contract and Why It Matters

Measure cross-device activation and derivative traffic and add its cost to placement selection. Build an execution-edge ledger rather than counting only parameter bytes moved during construction.

Part 2 - System and Memory Mental Model

Every changed device edge may require activation copies in forward and derivative copies in backward. Noncontiguous tensors can add packing buffers, and skip edges can transmit more than one value. A topology link may permit peer access without delivering a guaranteed bandwidth. Logical payload is not measured bus traffic. Kernel launches, waits, staging, and overlap determine exposed communication time, which need not equal the sum of transfer durations.

Part 3 - Quantitative Prediction Before Execution

For each directed edge, calculate forward/backward payload from actual shape and dtype. Estimate transfer time under an explicitly measured or hypothetical bandwidth plus launch overhead. Compare a balanced alternating device map with a contiguous map. Predict added live copies and a case where avoiding one large activation boundary is more valuable than equalizing a small parameter imbalance.

Part 4 - Experimental Design and Instrumentation

Validate edge values and gradients with the serial oracle. Instrument cross-device copies in the single-process runtime, or P2P messages only in a separately validated distributed mode. Warm representative transfer sizes and measure completed dependent work. Record topology, peer-access capability, packing, stream dependencies, and payload. Use separate profiling and ordinary timing replays. Add communication as a latency estimate or constraint with compatible units; do not subtract milliseconds directly from byte relief. Preserve shared-link contention and unmeasured traffic as explicit uncertainty.

Build the edge ledger from the actual forward graph, including residual values and metadata that cross devices. A forward activation may need a reverse derivative even when its destination has no trainable parameters, so infer backward traffic from differentiation requirements rather than parameter ownership alone. Count packing buffers and source/destination copies under their actual lifetimes. Measure a representative tensor size and dtype instead of applying one tiny-transfer latency to all boundaries. Record whether peer access is supported, but keep that capability separate from measured bandwidth and end-to-end exposed time. A transfer can overlap compute yet remain on the critical path at a later consumer. Validate the consumer result before stopping a dependent-work timer. If host staging is used, include its RAM, pinning, and extra copy cost. Keep logical payload, estimated transport work, and actual physical traffic as three independently labeled quantities.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class PlacementEdgeCost:
    producer: str
    consumer: str
    source_device: str
    target_device: str
    forward_payload_bytes: int
    backward_payload_bytes: int
    exposed_seconds_estimate: object

def build_placement_edge_ledger(graph, placement, shape_contract):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export payload, packing capacity, completed transfer/dependent latency, overlap evidence, and total step time. Do not infer overlap solely from non_blocking flags. Check that the backward path is included in training traffic. If physical traffic is unavailable, label estimates by their algorithmic assumptions. A memory-only improvement with higher end-to-end latency is a valid trade-off that the objective must expose.

Part 7 - Engineering Interpretation and Philosophy

Explain communication as a consequence of graph cuts and ownership. Choose the edge whose placement most affects the measured critical path.

19.44.11 Exercise 10

Exercise Title: Compare Memory-Only Placement Against
Memory-and-Communication-Aware Placement on the Same Multi-GPU Model

Part 1 - Exercise Contract and Why It Matters

Compare a memory-only placement with a memory-and-communication-aware placement on the same model. Require both plans to satisfy the same resource budgets and numerical contract before judging latency or throughput.

Part 2 - System and Memory Mental Model

The most evenly loaded assignment can scatter adjacent layers and create large repeated transfers. A somewhat uneven assignment can be preferable if every device remains feasible and the critical path shrinks. Communication and memory costs interact through duplicate live boundary buffers. Compute imbalance is another independent contributor. Keep the objective explicit: minimizing normalized pressure and minimizing completed-step time are different goals, even when one is used as a constraint on the other.

Part 3 - Quantitative Prediction Before Execution

Enumerate a tiny model's feasible maps and calculate persistent load, activation peak, edge payload, and a stated latency estimate. Find a pair where a small pressure difference trades against a large boundary transfer. Define a throughput floor or an objective in seconds, with memory as a hard constraint. Predict the preferred candidate before timing.

Part 4 - Experimental Design and Instrumentation

Build both placements from identical logical state in fresh replays. Keep global batch, sequence length, dtype, optimizer, activation policy, and output collection fixed. Validate outputs, gradients, moments, and several updates. Profile representative copies and compute regions separately from ordinary timing. Warm initialization and optimizer state, then measure complete forward/backward/update regions on all devices. Report candidate search limits and any uncertainty in estimated edge bandwidth. Include a simple contiguous baseline so an alternating greedy map is not the only comparison.

Fix the finite candidate set and objective before observing its timing results. Use memory as a hard constraint with a named reserve and use seconds for a latency objective, or present a measured Pareto comparison without inventing a unitless weighted score. The communication-aware plan can remain slightly imbalanced if every phase fits. Include compute costs so moving a large layer to a slower device is not assumed free. Keep initialization and output collection comparable across plans. Validate gradients before Adam and compare moments after updates, since an optimizer can conceal some gradient- scale errors in a short parameter-only check. Report variability across fresh runs and preserve the device mapping. If the apparent speed difference is within measurement variability, state that the tested evidence does not resolve the ranking. A lower predicted communication estimate alone is not a measured throughput improvement.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def score_feasible_placement(placement, memory_model, edge_model, objective):
    ...

def compare_memory_and_joint_plans(replays, reference, evidence):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export predicted and observed pressure, allocated/reserved peaks, communication payload, service times, complete latency, throughput, and numerical errors. Do not change batch size on only one plan and attribute the result to placement. A feasible joint plan that is slower

than expected needs an explained or unknown residual, not a fabricated improvement. Preserve both successful and rejected candidate IDs.

Part 7 - Engineering Interpretation and Philosophy

Choose a placement for the stated budget and throughput target. Explain why a balance score is a diagnostic rather than the entire engineering objective.

19.44.12 Exercise 11

Exercise Title: Build a DeviceMesh and Represent Independent Data, Tensor, and Pipeline Parallel Dimensions Without Manually Managing Every Process Group

Part 1 - Exercise Contract and Why It Matters

Represent independent data, tensor, and pipeline dimensions using a named DeviceMesh. Verify rank coordinates and subgroup membership before using those submeshes with supported parallelism APIs. Deliver the mapping, not an assertion that creating a mesh automatically parallelizes a model.

Part 2 - System and Memory Mental Model

A mesh organizes ranks and communication groups. Data groups connect replicas of equivalent logical model pieces; tensor groups cooperate within a layer; pipeline coordinates own different stage positions. The APIs still need explicit plans and compatible submeshes. Logical rank order does not guarantee physical link speed. Every rank must agree on the mesh definition and group creation sequence.

Part 3 - Quantitative Prediction Before Execution

For degrees D, T, P, require DTP ranks. Enumerate a hypothetical 2 by 2 by 2 grid and the groups obtained by varying one coordinate at a time. Explain why eight ranks are needed when all three degrees exceed one. With two devices, demonstrate only valid degenerate dimensions and retain the full-grid example as an offline mapping test.

Part 4 - Experimental Design and Instrumentation

Bind devices from local rank and validate unique membership, dimension names, product, and rank order before communication. Construct named submeshes through supported DeviceMesh interfaces and pass only the relevant dimensional view to each API. Export CPU mapping records and test a tiny rank-distinct group operation. Compare logical membership with available topology evidence. Record versions and supported composition modes. Do not create inconsistent meshes as a live negative test; validate malformed specifications offline instead. One multi-GPU host can provide the required ranks if enough devices are available.

Enumerate subgroup membership by fixing every coordinate except the one being varied. Verify that a data group connects equivalent logical pieces, a tensor group owns complementary feature pieces, and a pipeline coordinate represents ordered stage position. Keep sample semantics with the map: corresponding TP ranks cooperate on matching samples, while data replicas cover their intended distinct samples. Pipeline neighbors pass the same microbatch identities downstream. A mesh constructor does not establish any of these input contracts automatically. The full hypothetical three-dimensional example needs eight ranks when every degree is two; a two-device run must retain degenerate dimensions or test only one nontrivial dimension. Check that each parallelism API receives its supported submesh rather than the whole grid blindly.

Record rank order, visibility mapping, and versions so a logical coordinate cannot be confused with a physical CUDA ordinal in later memory rows or checkpoint metadata.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.distributed.device_mesh import init_device_mesh

@dataclass
class ParallelCoordinate:
    global_rank: int
    local_device: int
    data_coordinate: int
    tensor_coordinate: int
    pipeline_coordinate: int
    dimension_group_members: dict

def build_named_parallel_mesh(spec, launch_context):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report complete membership, device bindings, subgroup sizes, capability status, and tested group results. A successful constructor does not prove correct input sampling or parameter ownership. Label unavailable nontrivial grids not measured rather than fabricating benchmarks. Verify no dimension is silently reused as an unrelated synchronization group.

Part 7 - Engineering Interpretation and Philosophy

Explain how a named mesh reduces bookkeeping while leaving parallelism semantics explicit. Identify which coordinate determines samples, tensor ownership, and stage position in the intended composition.

19.44.13 Exercise 12

Exercise Title: Combine Tensor Parallelism and FSDP on Separate Device-Mesh Dimensions and Measure the Resulting Per-GPU Memory Distribution

Part 1 - Exercise Contract and Why It Matters

Compose TP and FSDP on orthogonal named dimensions and measure per-rank memory distribution. Verify actual parameter placements at rest and during execution instead of assuming every component divides by the product of degrees.

Part 2 - System and Memory Mental Model

TP partitions layer computation; FSDP distributes state among data replicas of corresponding TP slices and temporarily gathers those slices for execution. Small replicated parameters, activations, communication buffers, and full TP-local gathers remain. Apply a version-compatible TP plan and fully_shard route in the supported order. These wrapped parameters are not eligible for the ordinary module migration path introduced later.

Part 3 - Quantitative Prediction Before Execution

Require at least four ranks for a nontrivial $D = 2, T = 2$ experiment. Enumerate both group families. Predict persistent large-parameter payload near its valid sharded extents and transient FSDP gathers of TP-local pieces. Add gradients, actual Adam state, activations, and padding by phase. Explain why two devices can provide controls but cannot demonstrate both dimensions larger than one.

Part 4 - Experimental Design and Instrumentation

Validate a tiny model and mesh before scaling. Match input samples within each TP group and distribute distinct intended samples across data groups. Derive the loss normalization and data reduction exactly once. Construct the optimizer after supported parallelization transformations. Compare outputs, gradient shards, moments, and several updates with a serial global-batch oracle. Record at-rest and transient local shapes, FSDP reshard policy, TP boundary placements, and initialization peaks. Profile communication in a separate replay and sample each rank's owned GPU only.

Audit the local physical representation at three boundaries: initialized persistent state, a parameter-gather window, and completed backward/update. A full parameter gathered inside an FSDP data group can still be one TP-local slice of the global matrix. Count it separately from the persistent shard when they coexist. Keep small replicated norm or bias parameters under their actual policy instead of dividing every byte by both degrees. Validate head/feature divisibility and TP output layouts before composition. Check data normalization with a tiny known-gradient global batch to detect double averaging. Only supported accumulation and reshard policies may be used in the benchmark. Include communication buffers and initialization copies in the cost comparison. If four devices are unavailable, the two-by-two mapping and analytical memory prediction remain useful offline checks but are not an empirical demonstration of orthogonal tensor and data sharding.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.tensor.parallel import parallelize_module
from torch.distributed.fsdp import fully_shard

def build_checked_tp_fsdp(model, named_mesh, tp_plan, fsdp_policy):
    ...

def audit_tp_fsdp_rank_storage(runtime, phase, logical_registry):
```

```
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export group maps, local storage by representation, peak phase, normalized pressure, collective ledger, latency, and numerical errors. Do not sum the same driver-wide device reading from several ranks. Preserve unavailable hardware or unsupported API combinations explicitly. A lower persistent shard total is not proof that gathered-state peaks are balanced.

Part 7 - Engineering Interpretation and Philosophy

Explain which redundancy each dimension removes and which transient asymmetry remains. Use measured rank distributions to identify the limiting phase rather than relying on a product-of-degrees memory formula.

19.44.14 Exercise 13

Exercise Title: Combine Pipeline Parallelism with FSDP and Diagnose Stage-Level Memory Imbalance from Uneven Parameters and Live Activations

Part 1 - Exercise Contract and Why It Matters

Combine pipeline stages with FSDP data groups and diagnose stage-level memory imbalance. Keep pipeline ownership and data-shard ownership distinct, and compare persistent versus live-activation bottlenecks.

Part 2 - System and Memory Mental Model

Pipeline coordinates own different submodels. Each stage's FSDP group connects equivalent submodels across data replicas, not different stages of one pipeline. Parameter gathers and gradient reductions follow compatible microbatch order within each data group. Saved activations depend on the pipeline schedule and stage position. Multiple local chunks add joint device residency. Do not add an independent DDP reducer to a path already using FSDP without a separately validated composition.

Part 3 - Quantitative Prediction Before Execution

For $D = 2, P = 2$, enumerate the four-rank groups and sample flow. Predict stage-specific persistent shards, full gathered stage units, communication buffers, and GPipe or flushed-1F1B activation sets. Compare two stages with similar persistent state but different live microbatch counts. Explain which parameter or activation component limits the worst rank.

Part 4 - Experimental Design and Instrumentation

Use an installed, supported FSDP/pipeline composition and static microbatch shapes initially. Validate the module/chunk boundary and optimizer construction order. Keep identical stage structures within each data group. Preserve sample/target identities along a pipeline and correct sampling across data replicas. Derive microbatch weighting and data averaging once, then validate several global updates against a serial oracle. Record schedule, reshard and accumulation policies, peak phase, outstanding gathers, and activation lifetimes. If four devices or

compatible support is unavailable, complete offline group and cost checks and label execution not measured.

Create a rank table with data coordinate and stage coordinate, then attach module identity and microbatch schedule. Equivalent FSDP replicas must own the same stage structure and execute compatible collective order even when their sample values differ. Different pipeline stages must not be placed in one data-sharding group as though their parameters were interchangeable. Use equal local batches and supported static shapes first. Derive the joint microbatch loss scaling and FSDP reduction convention before execution; pipeline stage count is not another averaging dimension. Trace full gathered units alongside saved microbatch graphs and their last readers. Earlier stages can have different outstanding activations under 1F1B, so persistent shards alone cannot predict balance. Keep stage/chunk wrapper construction and optimizer references under the installed API's contract. If a composition cannot be validated, reject it clearly and continue the primary ordinary-module balancing experiments without claiming distributed execution support.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.distributed.pipelining import PipelineStage, Schedule1F1B
from torch.distributed.fsdp import fully_shard

def build_checked_pipeline_fsdp(local_chunk, mesh, contracts):
    ...

def trace_stage_and_shard_residency(runtime, measurement):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report rank-to-stage maps, shard and gather capacities, peak activation sets, memory pressure, update errors, and communication by group. Distinguish one stage's compute imbalance from its memory imbalance. A wrapper constructor success is not sufficient evidence of correct accumulated gradients. Unsupported reshard or accumulation paths must remain rejected rather than patched through private internal state.

Part 7 - Engineering Interpretation and Philosophy

Explain why sharding persistent state may leave pipeline activation imbalance unchanged. Choose a supported cut, schedule, or gather-policy change that targets the observed limiting phase.

19.44.15 Exercise 14

Exercise Title: Build a Unified Per-Rank Memory Cost Model for Parameters, Shards, Activations, Communication Buffers, and Temporary All-Gathered State

Part 1 - Exercise Contract and Why It Matters

Build a unified per-rank cost model covering logical parameters, persistent shards, gradients, optimizer state, saved activations, communication buffers, and temporary gathered representations. Predict complete phase peaks with explicit uncertainty.

Part 2 - System and Memory Mental Model

Different representations of one logical parameter can coexist physically: a local shard and a gathered TP-local computation tensor are separate allocations. Views into one backing allocation are not. Representation identity, ownership, dtype, and lifetime are necessary to reconcile both cases. Global tensor size does not describe local storage. Reserved allocator capacity and driver-wide use remain observations outside the exact tensor-payload sum.

Part 3 - Quantitative Prediction Before Execution

Define the predicted peak as the maximum over phase-specific unique live backing storage plus declared workspace bounds. Apply actual local extents instead of ideal divisions for uneven shards. Include initialization, optimizer update, and migration as separate phases. Construct a case where the persistent inventory fits but simultaneous gathers violate the budget, and another where aliases make a naive sum overestimate memory.

Part 4 - Experimental Design and Instrumentation

Inventory each representation by logical ID, storage ID, device/rank, placement, dtype, capacity, first use, and final-reader completion. Calibrate only named workspace terms on a small configuration and validate on held-out shapes and parallel modes. Feed actual schedule dependencies into the lifetime sweep. Keep unexplained or backend-specific terms as bounds or unknowns. Export predictions before measurement and preserve residuals by phase and rank. Avoid gathering a full global model for diagnostics in the capacity run; use a separate small correctness replay.

Give each physical representation a kind such as persistent shard, gathered computation copy, replicated small state, saved activation, or transport buffer. Preserve a common logical parameter ID while assigning different storage IDs to actual copies. Views share backing identity and need a last- reader rule before that capacity becomes releasable. Use a common event timeline for each device, including several local virtual stages where applicable. Calibrate workspace bounds on one shape and validate on another sequence length where activation memory changes. Keep original predictions immutable in the evidence so an underestimated phase can be audited. Model current live bytes and historical peak separately from reserved allocator capacity. For migration, include source copies retained for rollback and destination initialization temporaries. An attractive post-move inventory cannot establish that the transaction itself fits. Report uncertainty explicitly before the cost model is used as an admission decision.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class RankRepresentationCost:
    logical_identity: str
    representation_kind: str
    storage_identity: str
    rank: int
    capacity_bytes: int
    first_event: object
    last_reader_event: object

def predict_rank_phase_peaks(representations, workspace_bounds, schedule):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw component bytes, predicted peak-contributing sets, measured peaks, residuals, calibration inputs, and uncertainty. Do not add all category maxima without a common timeline. Include per-rank rather than mean-only validation. A model that predicts a safe plan incorrectly must retain the failed prediction and failure phase. Distinguish application budget compliance from a guarantee against external allocations or unsupported workspaces.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest representation model that supports the next balancing decision. Explain which uncertainty instrumentation can reduce and which requires conservative reserves or explicit rejection.

19.44.16 Exercise 15

Exercise Title: Detect the Most Memory-Constrained GPU at Runtime and Migrate an Eligible Layer or Tensor Working Set to a Less-Loaded Device

Part 1 - Exercise Contract and Why It Matters

Detect the limiting device and migrate one eligible ordinary module or stateless working set at a completed update boundary. Preserve model values, optimizer state, references, and subsequent updates. Implement a transactional primary path in the single-process multi-GPU runtime.

Part 2 - System and Memory Mental Model

The limiting device is identified by predicted next-phase slack and required allocation size, not simply the largest current byte count. Migration can temporarily duplicate state. A trainable module needs parameters, buffers, Adam moments/counters, hyperparameters, and

execution-map references preserved. Calling module.to after optimizer construction is not a complete migration protocol. Wrapped DDP/FSDP/TP parameters, tied units, active graphs, pending readers, captured graphs, and hooks with untracked references are ineligible in the primary implementation.

Part 3 - Quantitative Prediction Before Execution

Predict source relief after old storage is released, target construction and migration peak, and changed future activation traffic. Include current source state retained for rollback until commit. Calculate a destination that fits steady state but cannot fit the transactional peak. Explain why source reserved bytes or driver free bytes need not improve immediately even when live allocated payload falls.

Part 4 - Experimental Design and Instrumentation

Use independent per-module Adam optimizers with identical declared hyperparameters and one shared logical update boundary; validate equivalence to the serial reference first. Drain forward/backward and transfers, complete updates, and clear gradients under the fixed policy. Reconstruct the eligible module on the target, copy values, and build its new optimizer referencing the new parameters. Map all initialized state by stable logical IDs, preserving counter dtype/device policy and hyperparameters. Validate copied state before atomically switching the application map. Retain the unchanged source until commit, then release old references after completion. Compare several subsequent updates with a no-migration reference.

Use an ordinary dense unit with no aliases, shared parameters, custom hooks, stateful randomness, scheduler dependencies, or captured execution in the first migration test. Its independent Adam optimizer uses fixed supported flags, initially without foreach or fused temporaries. Per-module optimizers must first match the intended global Adam update for this uncoupled case. Do not assume optimizer state_dict integer identifiers are stable logical parameter names; map state through the registry and validate shape, dtype, counter, and group options. Copy scalar state according to the optimizer's required device policy instead of moving every counter blindly to CUDA. Construct the destination unit without mutating the source, validate state, and switch the application registry only at commit. Failed preparation must leave the source optimizer and map usable. Subsequent training is the decisive check: compare gradients, moments, counters, and parameters after several updates, not merely the copied weight values immediately after migration.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def identify_limiting_device(samples, next_phase_prediction, budgets):
    ...

def validate_migration_eligibility(unit, runtime_state):
    ...
```

```
def prepare_migration_transaction(unit, destination, optimizer_registry):
    ...

def commit_or_rollback_migration(transaction, placement_registry):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report logical state equality, optimizer parameter references, moments, counters, transaction peak, source relief, migration time, future traffic, and next-update errors. Test a failed preparation that leaves the source unchanged. Do not discard or reinitialize moments to make migration appear cheap. If a stateless scratch unit is chosen, prove no aliases or outstanding consumers require its old storage. Preserve ineligible status explicitly.

Part 7 - Engineering Interpretation and Philosophy

Explain the difference between moving bytes and transferring ownership of a trainable state. Choose migration only when correctness and transient capacity are both established.

19.44.17 Exercise 16

Exercise Title: Implement High- and Low-Watermark Rebalancing That Prevents Repeated Tensor Migration Between GPUs

Part 1 - Exercise Contract and Why It Matters

Add high and low watermarks, persistence requirements, and cooldown to reduce repeated migration. Validate behavior on synthetic pressure traces and actual bounded training without claiming hysteresis can prevent every possible move under arbitrary workloads.

Part 2 - System and Memory Mental Model

A high threshold can trigger investigation while a lower target provides separation after a move. Noisy samples, alternating shapes, stale driver headroom, and migration-induced peaks can otherwise cause oscillation. Watermarks must use the same named pressure scope and account for next-phase workspace. A destination must pass both migration-peak and future-load checks. Cooldown cannot override imminent infeasibility; the policy needs a documented reject, pause, or replan outcome.

Part 3 - Quantitative Prediction Before Execution

Define $0 \leq \ell < h < 1$ for a chosen budget-normalized signal, a minimum number of sustained observations, and a cooldown measured in completed updates. Construct traces near h, sustained above h, and alternating large shapes. Predict trigger, rejection, commit, and cooldown events. Include a case where no feasible move exists and ensure the policy does not repeatedly attempt the same impossible transaction.

Part 4 - Experimental Design and Instrumentation

Validate the state machine offline with missing and stale samples. Run the E15 eligible runtime using one unchanged workload first, then a controlled shape/pressure sequence. Make decisions only at drained update boundaries. Record pending migration, last commit generation, post-move target, and rollback state. Compare a threshold-only controller with the hysteretic controller using the same input trace and initial state. Include monitoring and migration overhead in end-to-end timing. Preserve numerical equivalence through every accepted move.

Use a pressure trace with observations alternating just above and below the high threshold, then a sustained increase, then a destination-pressure increase after a move. Predict the complete state-machine path before running training. Keep sample-age limits and minimum dwell time explicit. A move's own transient allocation should not be mistaken for a new unrelated pressure signal that immediately reverses it. Record pending and committed placement generations and reject stale recommendations. Test the no-feasible-destination case without repeated attempts on every update. If cooldown blocks a move but the next update is predicted infeasible, the runtime must choose a named pause/reject/replan path rather than proceeding optimistically. Compare total moved bytes and end-to-end useful throughput, not only move count. Fewer moves can still be worse if the controller remains stuck on a slow or infeasible placement.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RebalanceWatermarks:
    high_pressure: float
    low_pressure: float
    sustained_sample_count: int
    cooldown_updates: int
    maximum_sample_age_seconds: float

def update_rebalance_state(policy, evidence, completed_update_id):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw pressure, sample age, thresholds, state transitions, attempted and committed moves, rejected reasons, bytes moved, latency, and update errors. Verify suppression of the specific oscillation trace rather than asserting universal stability. Show a sustained infeasible

condition that produces an explicit blocked outcome. A cooldown that silently allows an invalid next update has not met the memory contract.

Part 7 - Engineering Interpretation and Philosophy

Choose hysteresis parameters from measured noise and migration cost. Explain the responsiveness-stability trade-off and the conditions that require replanning instead of another local move.

19.44.18 Exercise 17

Exercise Title: Build a Cost-Aware Rebalancer That Moves State Only When Expected VRAM Relief Exceeds Migration and Future Communication Cost

Part 1 - Exercise Contract and Why It Matters

Build a cost-aware rebalancer that first requires useful memory relief and feasibility, then evaluates migration time and future communication. Keep byte constraints and time objectives dimensionally separate.

Part 2 - System and Memory Mental Model

A move can release source live bytes yet slow every subsequent update through new device edges. It can also be essential because the old plan cannot execute the next shape. Compare time costs only over an explicit reuse horizon and account for uncertainty. A best-fit destination by current free bytes may be poor after incoming optimizer state and activations are included. Migration eligibility and rollback conditions remain those of E15.

Part 3 - Quantitative Prediction Before Execution

Require a minimum source byte relief and feasible source/target phase peaks. For a predicted horizon of H updates, compare migration time t_m with $H(t_{\text{old}} - t_{\text{new}})$ only when both plans execute the same useful work. Include future edge traffic in the new step estimate. If the old plan is infeasible, use an explicit capacity-first objective and throughput floor instead of pretending to measure its nonexistent completed latency.

Part 4 - Experimental Design and Instrumentation

Enumerate a bounded set of eligible module/destination candidates at a drained boundary. Use E14 for transaction and future peaks, E09 for changed edges, and measured migration costs from separate calibration. Reject candidates with insufficient evidence or excessive uncertainty. Compare always-move, watermark-only, and cost-aware policies on identical deterministic traces. Preserve predicted horizon and cost before each decision, then measure realized relief and latency. Include monitoring, failed preparation, rollback, and cooldown overhead. Validate subsequent parameter and optimizer updates for every accepted candidate.

Separate a capacity-restoring move from a performance-improving move. For the former, require a feasible next update and a declared throughput floor; the old infeasible plan has no measured completed latency for the same work. For the latter, choose a finite expected residence horizon and include migration preparation, optimizer-state copies, destination validation, new edge traffic, and monitoring overhead. Retain uncertainty bounds when the horizon or bandwidth is unknown. Reject a small theoretical gain that is within those bounds instead of pretending the score is exact. Compare predicted source relief with actual live-byte reduction only after old references are released. Reserved allocator capacity may remain cached, so do not declare the transaction ineffective solely from driver free memory. Conversely, do not

claim useful capacity from a lower balance score caused by allocating extra destination buffers. Preserve failed amortization examples as policy learning evidence.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def evaluate_move_candidate(candidate, memory_model, edge_model, horizon):
    ...

def choose_feasible_profitable_move(candidates, objective, uncertainty):
    ...

def compare_rebalancing_policies(replay_specs, reference, evidence):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted/observed source relief, transaction peaks, bytes copied, migration seconds, new step time, horizon, break-even status, and numerical errors. Do not compare gigabytes directly with milliseconds in an invented unscaled score. Preserve moves that failed to amortize their cost and explain whether horizon error, bandwidth uncertainty, or changed shapes caused the miss. A no-move decision is valid when evidence does not justify a transition.

Part 7 - Engineering Interpretation and Philosophy

Select a policy for a stated workload horizon and capacity requirement. Explain when preserving the current placement is better than improving a balance statistic through expensive migration.

19.44.19 Exercise 18

Exercise Title: Stress-Test Multi-GPU Balancing with Unequal GPU Capacities, Variable Sequence Lengths, Memory Spikes, Heavy Collective Communication, and Artificial VRAM Pressure

Part 1 - Exercise Contract and Why It Matters

Stress the balancer with unequal budgets, variable sequences, transient memory pressure, and communication contention. Preserve correctness, scoped failure classifications, and recovery evidence across both the eligible migration track and static distributed extensions.

Part 2 - System and Memory Mental Model

Artificial quotas, held allocation buffers, and injected communication delays model different phenomena. A held buffer consumes real device capacity; a quota changes application admission; a delay is not a measurement of another interconnect. Variable shapes can alter activation and kernel workspace costs without changing parameter bytes. Distributed collective order and ownership remain fixed unless a supported coordinated reconstruction is performed. Ordinary migration must not alter sharded wrappers behind their runtime.

Part 3 - Quantitative Prediction Before Execution

Define cases with equal physical GPUs and unequal application budgets, a larger next sequence, a bounded pressure buffer, and contention in a separately validated distributed mode. Predict accept, reject, migrate, or restart outcomes and failure phases. Calculate transaction peaks and next-update reserves. Include a pressure spike shorter than the expected migration amortization horizon and a case with no feasible destination.

Part 4 - Experimental Design and Instrumentation

Run deterministic small-model correctness first, then change one resource factor at a time. Keep seeds and logical sample IDs. Apply actual pressure buffers only within a predeclared bound. Use fresh groups for distributed configuration changes and coordinated shutdown after worker failure. Commit checkpoints at completed boundaries and compare resumed training with an uninterrupted reference. Test missing/stale samples and failed migration preparation offline before hardware. Record whether heterogeneity is physical or simulated. Preserve optional multi-dimensional experiments as not measured when devices or version support are unavailable.

Keep a table identifying whether each condition is real hardware heterogeneity, an application quota, a retained pressure allocation, an injected delay, or an offline scenario. Record the bytes and lifetime of any real pressure buffer and release it under the same controlled schedule across policy comparisons. Variable sequence lengths should retain the same valid-token loss semantics; padding capacity remains part of memory even when padding is excluded from loss. A heavy-collective extension needs compatible rank order and a verified parallel runtime before contention is introduced. Do not migrate an FSDP parameter through the ordinary path to escape a stress failure. Use committed checkpoint reconstruction for changes to distributed ownership. Minimize numerical failures by disabling adaptation, then returning to a static serial placement while preserving model values and samples. Save the minimal case, logical parameter registry, configuration generation, and failure phase so the result can be reproduced without retaining the original GPU graph.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_balancer_stress_cases(model_spec, runtime_capabilities):
    ...
```

```
def apply_bounded_pressure(case, device_inventory, budget_contract):
    ...

def run_balancer_stress_case(case, runtime, reference, evidence):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export case configuration, physical/application capacities, shape, pressure mechanism, parallel mode, raw samples, predicted and observed peaks, moves, latency, numerical errors, outcome, and failure phase. Distinguish coherent rejection from successful execution. Preserve nonreproducing OOMs or spikes as experimental outcomes. Do not call every imbalance a leak or every failure fragmentation. Include the smallest numerical or ownership counterexample.

Part 7 - Engineering Interpretation and Philosophy

Explain which invariant each stress case tests and how its result changes supported scope or planning reserves. Prefer explicit refusal to an unsupported state migration that silently corrupts training.

19.44.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Multi-GPU Memory Balancer That Dynamically Optimizes Placement Across Heterogeneous VRAM Budgets While Preserving Throughput

Part 1 - Exercise Contract and Why It Matters

Integrate validated monitoring, placement, cost prediction, and eligible rebalancing into an explicit PyTorch runtime. Benchmark correct full updates under heterogeneous byte budgets while controlling throughput regressions. Choose the best tested feasible policy without promising a universal optimum.

Part 2 - System and Memory Mental Model

Maintain separate execution modes: the primary mutable single-process model with eligible ordinary modules, and optional statically planned distributed TP/FSDP/pipeline compositions. They share cost/evidence schemas but do not share an unrestricted migration mechanism. The runtime needs logical parameter identity, optimizer ownership, placement generation, phase lifetimes, and explicit capability checks. A lower normalized spread is useful only when training remains correct and the selected memory/latency constraints hold.

Part 3 - Quantitative Prediction Before Execution

Predict a finite candidate set's per-device phase peaks, initialization and transaction peaks, edge traffic, compute costs, and adaptation overhead. Define hard budgets, uncertainty reserves,

minimum useful relief, and a throughput floor. Include equal-count, persistent-only, activation-aware, and communication-aware static baselines, then eligible adaptive policies. State which distributed degrees are actually available before planning tests.

Part 4 - Experimental Design and Instrumentation

Validate several serial-equivalent Adam updates from canonical state. Run correctness, profiling, timing, and capacity checks separately. Measure complete training plus adaptive monitoring and migration. Preserve E00's record and all budgets, sample scopes, thresholds, cost-model versions, eligibility decisions, and placement generations. Export CPU evidence. Validate committed restart against uninterrupted updates. Report unavailable or unsupported modes explicitly.

Publish a capability matrix distinguishing measurement scope, static placement, eligible module/scratch migration, hysteresis, cost selection, distributed compositions, and restart. Every supported entry needs a validating run ID. Preserve candidate predictions and rejections. Count useful samples once across model-parallel ranks under the actual data contract. Report construction, migration, and warmed peaks separately. Check committed parameter identities, optimizer progress, and placement generation before validating resumed updates. State the selected policy's throughput cost, search limits, and unsupported cases.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class MultiGPUMemoryBalancer:
    def validate_runtime_mode(self, model_spec, capabilities):
        ...

    def construct_checked_placement(self, logical_state, plan):
        ...

    def run_training_update(self, batch):
        ...

    def rebalance_at_completed_boundary(self, evidence):
        ...

    def export_cpu_evidence(self):
        ...

def E19(config):
    # Integrate checked components and benchmark isolated candidates.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation in separate columns. Each run needs ID, configuration, shape, budgets in bytes, per-device allocated and reserved peaks, driver-headroom scope, elapsed seconds, useful throughput, numerical errors, outcome, and failure phase. Include adaptation costs, rejections, and failed predictions. Provide the smallest counterexample to any universal rule or state none was observed in the tested range. Distinguish simulated budget failures from real CUDA outcomes. Require validating run IDs for every claimed capability.

Part 7 - Engineering Interpretation and Philosophy

Justify the selected policy through ownership, correct updates, measured resource relief, and end-to-end cost. Identify untested shapes or device conditions that could change the decision.

19.45 DMM43

Chapter Title: CUDA Events and Precise GPU Timing
Specialization: Dynamic Memory Management and CUDA Systems

19.45.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Asynchronous CUDA Execution, Host Timing, Device Timing, Streams, and Event-Based Measurement

Part 1 - Exercise Contract and Why It Matters

Define a timing contract separating host submission, host-observed completion, device event intervals, and dependency stalls. Deliver a stream and event graph before interpreting any duration as operation latency.

Part 2 - System and Memory Mental Model

CUDA work is commonly queued asynchronously relative to Python. Stream order gives local sequencing; different streams need explicit dependencies when values are shared. An event marks progress at its recorded stream position, not the instant Python called record. Event intervals can include resource contention, stream waits, and host submission gaps between markers; they are not automatically exclusive kernel execution time. Host and device clocks have different meanings and cannot be subtracted as if they were one timestamp domain.

Part 3 - Quantitative Prediction Before Execution

Draw a host enqueue timeline and a device execution timeline for one matrix multiplication. Predict what an unfenced Python interval, a completed wall-clock interval, and a same-stream event pair include. Add unrelated stream work and a producer-consumer wait, then identify which completion boundary covers each dependency. State that event-pair elapsed time requires compatible same-device timing events and completed recordings.

Part 4 - Experimental Design and Instrumentation

Use a single CUDA device and one stream initially, fixed FP32 shapes, preallocated inputs, and checked numerical results. Record GPU identity, PyTorch/CUDA versions, driver, dtype, precision policy, stream IDs, shapes, seed, allocator backend, warmup, clock/load context when observable, and timing boundaries. Keep event creation and lazy initialization outside warmed

regions. Use monotonic host timing. Mark CUDA Graph capture and distributed clock alignment unsupported in the primary implementation until separately validated.

Create a synthetic timeline with a short host submission interval, a longer queued GPU operation, and a later host consumer. Add a second stream whose work is unrelated to that consumer. Label every number as a hypothetical example and derive which portions each timer observes. Then insert a host preparation gap after the start marker can execute but before the operation is enqueued. Explain why the resulting event interval can include that gap. This prevents the simplistic rule that all event times are pure GPU arithmetic and all wall times are the same arithmetic plus a fixed overhead. Define completion as a dependency property, not as the host having reached the next line of Python. Give each region an explicit unit, device, stream, generation, and validity state. Keep the primary experiment on one device with ordinary eager execution; any extension involving graphs, processes, or multiple devices must establish its own event-domain and completion contract before numbers are accepted.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TimingContract:
    region_id: str
    device_identity: str
    stream_identity: str
    host_boundary: str
    device_boundary: str
    completion_rule: str
    warmup_policy: str

def validate_timing_contract(contract, dependency_graph):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Preserve prediction, observation, and interpretation separately. Verify completion and values before accepting a sample. Unknown clocks, incomplete events, and unrun hardware measurements remain explicit. A small number is not evidence of fast GPU execution when it only measures host submission.

Part 7 - Engineering Interpretation and Philosophy

Explain which decision each timing scope supports. The goal is an honest measurement system whose dependency and completion boundaries can be audited.

19.45.2 Exercise 01

Exercise Title: Measure a CUDA Tensor Operation with Python Wall-Clock Time and Demonstrate Why Asynchronous Execution Produces Misleading Results

Part 1 - Exercise Contract and Why It Matters

Measure a CUDA operation with an unfenced Python wall clock and demonstrate what that number actually represents. Compare submission latency with independently established completion rather than assuming a small interval is execution time.

Part 2 - System and Memory Mental Model

A Python call can return while kernels remain queued. An unfenced interval can include dispatch, allocation, host-side preparation, and accidental blocking, so it is not guaranteed to be pure launch overhead either. First use may initialize CUDA or select kernels. Reading a CUDA scalar or copying output to CPU inside the interval can change the experiment by adding synchronization.

Part 3 - Quantitative Prediction Before Execution

Predict the host interval around a preallocated matrix operation with no completion wait. Draw the queued work that can remain after the timer stops. Give a counterexample where an implicit synchronization makes the interval longer than expected. Specify the numerical output check and completion wait that will occur only after the deliberately unfenced measurement.

Part 4 - Experimental Design and Instrumentation

Use a monotonic high-resolution Python clock, fixed operands, and a bounded workload. Run cold and warmed cases separately. Capture only the call interval for the unfenced case, then complete the work before validating output or recycling buffers. Avoid printing CUDA tensors or calling item inside the measured submission path. Compare against a completed reference in a separate replay with identical values and shapes. Record whether output allocation is included, and do not switch to an out variant on only one side. Drain outstanding work between isolated trials.

Compare a single isolated operation with a bounded loop that queues several operations without intermediate waits. The latter can eventually encounter host-side backpressure or allocation behavior that changes submission time. It is not a collection of completed request latencies. Keep the output policy explicit: replacing one result reference can still leave queued CUDA consumers that require storage safety. Retain the required buffers and complete them before cleanup. Record whether input creation, random generation, output allocation, and CPU validation occur inside or outside the host bracket. Use a known small result for correctness so checking it does not dominate the measured workload. If an unfenced call blocks unexpectedly, inspect the trace and surrounding operations before claiming CUDA stopped being asynchronous. A meaningful result can be a classification of what the host interval included, even when it does not display the anticipated large timing gap on the tested hardware. Preserve that outcome instead of increasing workload size without a predeclared bound.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch

def measure_unfenced_host_interval(operation, evidence):
    # Preserve output lifetime; validate completion after the host interval.
    ...

def validate_after_completion(result, reference, device):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report the host interval as submission-path time with its exact inclusions. Record completed latency separately, plus cold/warm status and result error. An unfenced measurement that happens to match completed latency is a result to investigate, not proof the operation is synchronous in every case. Do not allow work from one trial to inflate the next unnoticed. Keep failed or incomplete samples out of latency summaries without replacing them with zero.

Part 7 - Engineering Interpretation and Philosophy

Explain why the timer is not wrong; its boundary answers a different question. Identify the smallest change that would turn this measurement into completed operation latency.

19.45.3 Exercise 02

Exercise Title: Add torch.cuda.synchronize() Around Wall-Clock Timing and Compare the Result Against the Unsynchronized Measurement

Part 1 - Exercise Contract and Why It Matters

Measure completed CUDA work with device synchronization before and after a monotonic host interval. Compare with E01 while keeping operation, allocation policy, shapes, precision, and warmup identical.

Part 2 - System and Memory Mental Model

The pre-measurement synchronization drains earlier work on the selected device; the post-measurement synchronization ensures the bracketed work is complete. The measured wall interval includes host submission and the completion wait. A device-wide wait can also cover unrelated work in other streams, so its scope is broader than one operation. It does not synchronize every GPU in the machine merely because no stream was named.

Part 3 - Quantitative Prediction Before Execution

Write the required ordering: drain, start host clock, submit operation, wait for the selected device, stop host clock. Predict the bias if the first drain is omitted. Add an unrelated stream

and predict when the final wait would extend the interval. State whether the intended metric is isolated operation latency or completed workload latency on a busy device.

Part 4 - Experimental Design and Instrumentation

Start with one stream and no unrelated work. Use an explicit device argument for synchronization and a monotonic host clock. Measure bounded repeated trials after warmup, retaining outputs until complete. Validate values outside timing. Compare unfenced and fenced paths in independent replays or with complete draining between trials. Then introduce controlled unrelated stream work as a separate scope experiment. Record any intentional changes to normal overlap caused by boundary synchronization. Do not put a global wait after every layer when measuring a production overlapped pipeline.

Use an explicit selected device for both drains and verify that the operation actually executes there. A synchronization on another GPU does not complete this device's work. Keep the initial drain outside the timed interval, but report its existence and the isolated state it creates. If testing a busy-device scenario, launch the same finite unrelated workload in both comparison replays and record its dependency relationship. The final device wait can cover work that starts after the target operation was submitted, so name the resulting metric honestly. Do not insert a scalar correctness read before the intended final fence; that would add another completion path. Use a no-operation region as a diagnostic for clock and synchronization cost without assuming its value can be exactly subtracted from a real sample. When timing many updates, distinguish average completed throughput from single-update latency and keep input transfer and CPU batch preparation inclusions consistent across the runs.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch

def measure_completed_wall_time(operation, device, contract):
    # Drain, time submission plus completion, and validate outside the region.
    ...

def compare_fenced_unfenced(replay_specs, evidence):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report explicit device, pre-drain policy, measured inclusions, host time, and numerical status. Check for earlier queued work and other-stream interference before interpreting discrepancies. Synchronized timing deliberately alters scheduling; distinguish an isolated benchmark

from normal application throughput. An empty-region control estimates overhead but should not be blindly subtracted from every sample as an exact correction.

Part 7 - Engineering Interpretation and Philosophy

Choose when completed wall time is the appropriate metric. Explain why its broader scope can be useful even after event timing becomes available.

19.45.4 Exercise 03

Exercise Title: Create torch.cuda.Event(enable_timing=True) Start and End Events and Measure the Execution Time of a CUDA Matrix Multiplication

Part 1 - Exercise Contract and Why It Matters

Use timing-enabled CUDA start/end events around a matrix multiplication on a declared stream. Wait for the end recording before reading elapsed milliseconds and validate the operation separately.

Part 2 - System and Memory Mental Model

Events are recorded into a stream's ordered work. Creating an event object does not record a timestamp. The pair must have timing enabled, compatible device ownership, and the intended record order. Event resources may initialize lazily. elapsed_time computes a device interval; it is not a completion-polling substitute. A same-stream pair brackets intervening stream progress, including waits or contention that occur there.

Part 3 - Quantitative Prediction Before Execution

Predict the ordering of start marker, multiplication, end marker, end completion, and elapsed-time read. Convert reported milliseconds to seconds explicitly. For very short work, predict why one sample can be dominated by instrumentation or resolution. Derive a repeated-operation average as a separate throughput-like measurement, not a distribution of single-call latency.

Part 4 - Experimental Design and Instrumentation

Preallocate fixed operands and initialize event resources outside the warmed measurement region. Select the device and stream explicitly. Record start, enqueue the operation, record end, and establish end completion before reading the pair. Keep operands/output alive through their consumers. Use fixed dtype and precision settings, record layout/contiguity, and check output against a trusted small reference after timing. Compare a single multiplication with a bounded repeated region, documenting whether output allocation and buffer reuse differ. Do not add CPU validation inside the event-bracketed launch sequence.

Record both markers with an explicit stream argument or a verified stream context and store that stream identity in the sample. Warm their underlying resources with a completed diagnostic recording before reusing the pair for measurement. Keep event generation changes visible in the registry. Use a matrix shape whose operation is large enough to interpret, but do not claim a universal minimum measurable size. If deriving achieved arithmetic throughput, state the matrix multiplication FLOP convention and divide only by a valid completed interval. Preserve dtype, layout, TF32 or other precision settings, and output-allocation choice with the result. A repeated region can amortize marker cost, but its time divided by iteration count is an average over that region rather than independent single-call samples. Compare both designs

only under their declared meaning. Result validation occurs after completion and must not leave an extra live reference model or output that changes later memory-pressure experiments.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def create_timing_pair(device, stream):
    ...

def measure_matmul_with_events(inputs, outputs, timing_pair, stream):
    # Recording, completion, elapsed read, and unit conversion remain work.
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export event generation, device/stream, record order, completion status, elapsed milliseconds, converted seconds, shape, dtype, and result error. Reject non-timing, unrecorded, mismatched-device, or unfinished pairs explicitly. A zero-valued tiny interval is not automatically a failed event; assess resolution and region size without fabricating positive time. Preserve raw samples before aggregation.

Part 7 - Engineering Interpretation and Philosophy

Explain the precise device interval the pair observes. State which host or application costs remain outside that measurement.

19.45.5 Exercise 04

Exercise Title: Compare CUDA Event Timing Against Synchronized Python Wall-Clock Timing and Explain the Difference Between GPU and End-to-End Latency

Part 1 - Exercise Contract and Why It Matters

Compare event timing with completed Python wall-clock timing for the same CUDA region. Explain their different boundaries without requiring either number to equal the other or treating their difference as an exact overhead decomposition.

Part 2 - System and Memory Mental Model

A host interval can include dispatch, waiting, and Python work outside the device markers. An event interval can include host submission gaps after the start marker executes, stream dependencies, and resource contention. Neither automatically reports exclusive kernel duration.

Different replays can experience different clocks, load, or allocator behavior. A fair comparison needs matched region semantics and an explicit completion rule.

Part 3 - Quantitative Prediction Before Execution

Draw host and stream timelines with both clock pairs. Mark event creation, recording, CPU preparation, GPU work, and final synchronization. Predict a case with extra host preparation and another with a stream wait inside the event pair. Explain why subtracting event time from host time cannot uniquely identify Python overhead or PCIe time.

Part 4 - Experimental Design and Instrumentation

Use identical fixed operands, output-allocation policy, precision, warmup, and number of operations. Collect a nested measurement only after naming exactly what the host bracket includes; also use independent replay comparisons to assess instrumentation effects. Wait on the end event or selected completion boundary before the host timer stops. Validate results outside the region. Record external load when observable and repeat enough trials to show variability. Keep profiler-based exclusive kernel analysis in a separate instrumented replay rather than equating it with event-pair elapsed time.

Build one measurement in which the host bracket starts before both event records and stops after end-event completion. List the event-record API and synchronization costs that the host interval includes. Then build another contract that starts host timing after CPU data preparation, showing why an end-to-end claim depends on where the application boundary is placed. Keep these comparisons descriptive rather than forcing a fixed wall-minus-device identity. Concurrent GPU load can change the event interval even though the same kernel code is launched. Host scheduling can also delay enqueueing the end marker after the start has executed. Use separate instrumented traces when attributing a discrepancy to either cause. Report both distributions with identical shape and precision metadata. If two scopes are measured in different replays, do not pair their sample-by-sample differences as if they shared the same execution history. Preserve uncertainty where the available evidence cannot isolate a component.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch

def measure_host_and_device_scopes(operation, stream, timing_contract):
    ...

def compare_timing_scopes(sample_rows):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report both raw durations, boundary definitions, completion method, variability, and correctness. Flag negative inferred overhead or inconsistent scope as a diagnostic rather than clamping it silently. A mismatch may be expected from the boundaries; explain it with the timeline and preserve remaining uncertainty. Do not claim events exclude all host effects or all unrelated GPU interference.

Part 7 - Engineering Interpretation and Philosophy

Choose a metric for a kernel-region question and one for user-visible completed latency. Explain how both can be valid while answering different engineering questions.

19.45.6 Exercise 05

Exercise Title: Demonstrate Why Reading elapsed_time() Before the End Event Completes Can Fail or Produce Invalid Timing Assumptions

Part 1 - Exercise Contract and Why It Matters

Demonstrate the completion precondition for elapsed_time without assuming that an early read must always fail. Build explicit recorded/pending/complete states and accept timing only after the correct end recording completes.

Part 2 - System and Memory Mental Model

Short GPU work can finish before Python attempts the read, so an immediate call may succeed. Pending work can instead produce a not-ready error or another reported API failure. Neither outcome authorizes treating elapsed_time as a poll. Unrecorded events, disabled timing, and stale generations are separate invalid conditions. Query or synchronization establishes completion of a recorded event, while application state establishes that the intended record actually occurred.

Part 3 - Quantitative Prediction Before Execution

Predict the possible outcomes of immediate reads for short and longer bounded regions. Draw a case where a reused event object refers to a newer recording than the sample expects. Define which states are valid for reading and which must be rejected or deferred. Explain why a zero duration is not an acceptable placeholder for pending work.

Part 4 - Experimental Design and Instrumentation

Use fresh timing pairs or a generation-checked pool. Submit a controlled bounded workload, record the end, and attempt an early read only in the isolated diagnostic test. Capture the observed status rather than requiring a particular error. Then establish end completion and read again through the valid path. Test unrecorded and timing-disabled misuse in a metadata/API validation case. Avoid intentionally launching invalid kernels. Keep operand and event lifetimes intact, and record the installed versions and exact error classification without manufacturing a reproducible race.

Track event creation, first record, latest record generation, completion, and result consumption separately. A newly created event has not measured a region even if a completion query reports no pending work. An end event that belongs to a different generation must not satisfy an older sample's read precondition. Test those metadata cases deterministically before the hardware diagnostic. For an actual early read, classify success, not-ready, invalid configuration,

or another reported error without requiring a particular race outcome. Some asynchronous failures can surface at a later API call; retain the launch context and do not automatically blame the timing read for causing the original failure. After a valid completion, compare repeated reads before any re-record to check stable sample identity. Do not invent negative or random timing values to illustrate premature access. The educational failure is an invalid assumption about readiness, whether the particular attempt happened to finish early enough to succeed or not.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TimingPairState:
    generation: int
    start_recorded: bool
    end_recorded: bool
    completion_status: str
    timing_enabled: bool

def read_completed_elapsed(pair, expected_generation):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report attempted state, query result where meaningful, early-read outcome, completed elapsed time, and generation. A successful early read means the precondition happened to hold; it does not prove implicit waiting. Reject stale, unrecorded, or incomplete samples rather than converting failures into latency values. State if a pending-read failure was not observed within the bounded workload range.

Part 7 - Engineering Interpretation and Philosophy

Explain why a timing API and a completion API have different responsibilities. Choose an invariant that makes the instrument correct regardless of host/GPU relative speed.

19.45.7 Exercise 06

Exercise Title: Synchronize Only the End Event Instead of the Entire CUDA Device and Measure the Reduction in Unnecessary Global Blocking

Part 1 - Exercise Contract and Why It Matters

Compare waiting for a recorded end event with synchronizing the whole selected device. Measure host blocking scope while preserving correctness of the task and all buffers still used by unrelated work.

Part 2 - System and Memory Mental Model

An event wait covers work causally preceding that recording, including explicit dependencies it inherits. It need not wait for independent later or other-stream work. A device-wide synchronization has broader scope. Event synchronization blocks host progress until that event completes; it is different from enqueueing a stream dependency. Narrower scope does not guarantee lower measured time when resource contention or workload ordering already couples the streams.

Part 3 - Quantitative Prediction Before Execution

Construct a target task and a longer bounded independent background task on separate streams. Predict which work is required before target output can be consumed and which is required before all buffers can be released. Draw event-only and device-wide host wait intervals. Include a case where an explicit target dependency makes both waits cover the same work.

Part 4 - Experimental Design and Instrumentation

Preallocate disjoint buffers, establish their initial readiness, and warm event resources. Launch the same task set in separate replays for the two completion methods. Stop the target-latency host timer at its declared boundary, then drain background work outside that region before cleanup. Validate both outputs. Use profiling separately to inspect contention and unintended dependencies. Keep measured device, stream mapping, task sizes, and precision fixed. Do not place a hidden device-wide synchronization in the event-only path before stopping its timer.

Specify that background work is independent both mathematically and in storage: no shared mutable outputs, no reused scratch buffer, and no hidden readiness edge from the target to the background completion. Warm and prepare both streams before the trial. Keep the same finite task set across event-only and device-wide replays, and measure the target host wait at the same point in submission order. After stopping the target interval, retain background buffers until a separate cleanup fence proves them safe. Add a dependency control where the target deliberately waits for the background and predict why event synchronization now inherits that work. Actual resource scheduling can serialize independent kernels, so a narrower logical scope may show little or no latency improvement. Report that observation. Do not shorten the background workload only for the device-wide comparison or let its unfinished work leak into a later trial. The comparison should demonstrate scope and any measured benefit, not guarantee an improvement by definition.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch
```

```
def compare_event_and_device_completion(task_set, device, evidence):
    ...

def drain_remaining_work_for_cleanup(task_set):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report target completion latency, background completion, host blocked time, dependency graph, and errors. Distinguish a scope reduction from an actual observed speedup. If the background finishes first or serializes with the target, report no reduction rather than altering the result. Verify no background storage is reused while still in flight after the target event has completed.

Part 7 - Engineering Interpretation and Philosophy

Choose the narrowest completion boundary that proves the intended consumer safe. Explain why finishing one task does not imply the whole device is idle.

19.45.8 Exercise 07

Exercise Title: Use Event.query() to Poll Completion Without Blocking the CPU Thread and Build a Non-Blocking GPU Task Monitor

Part 1 - Exercise Contract and Why It Matters

Build a bounded nonblocking completion monitor using Event.query and application-owned event state. Allow the CPU to perform other work between polls and export completed timing records without waiting in every monitoring call.

Part 2 - System and Memory Mental Model

Query reports captured-work completion without waiting for it. It does not prove an intended task was submitted; an unrecorded event must be rejected by the monitor's own state. Polling consumes CPU/API time and detects completion only at sampling instants. A task can finish between polls, so host detection latency differs from device elapsed time. Re-recording pooled events before consuming their samples can corrupt task identity.

Part 3 - Quantitative Prediction Before Execution

Define pending, completed, consumed, failed, and retired states with generation IDs. Predict the detection delay bound for a fixed polling cadence under stated host-scheduling assumptions. Compare frequent polling with a coarser cadence in CPU overhead and readiness delay. State which quantity comes from device events and which from host poll timestamps.

Part 4 - Experimental Design and Instrumentation

Submit bounded tasks with unique task IDs and event generations. Poll only recorded ends, return promptly for pending tasks, and perform a small CPU-side work unit between

polling passes. Read elapsed time only after the matching pair is complete. Retain task buffers through final consumers and retire event leases only after record consumption. Implement bounded pending capacity and explicit backpressure. Compare against a blocking baseline in separate replays. Include timeout as a monitor outcome, not permission to free storage still used by CUDA.

Give the monitor a maximum number of pending records and a policy for capacity exhaustion, such as rejecting new instrumentation or applying explicit backpressure at a named boundary. Never overwrite a pending pair to maintain a prettier queue length. Bound each polling pass by task count or CPU time and return control to useful host work. Detection latency includes both polling cadence and host scheduling delay; it is not the device's execution duration. Record host submission, first observed completion, and collection timestamps alongside the event duration without subtracting across clock domains. A timed-out task remains an owner of its buffer lease until completion or safe process recovery. Test this invariant offline. Compare monitor CPU overhead, pending high-water mark, and completed useful throughput against the blocking baseline and an uninstrumented run. If the host has nothing useful to do, frequent polling may simply create busy waiting; state that behavior rather than calling it free asynchronous progress.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PendingTimedTask:
    task_id: str
    generation: int
    start_event: object
    end_event: object
    recorded: bool
    buffer_lease: object

def poll_completed_tasks(pending, host_timestamp, budget):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report polling cadence, CPU overhead, device duration, host detection delay, pending high-water mark, dropped/rejected submissions, and correctness. Do not replace pending with zero elapsed time. Test stale generations and unrecorded tasks offline. A timeout must preserve safe

cleanup or explicit process recovery. Measure monitor overhead against an uninstrumented workload rather than calling query cost-free.

Part 7 - Engineering Interpretation and Philosophy

Explain how nonblocking monitoring trades detection latency against CPU work. Choose a bounded policy suitable for feeding scheduling decisions without turning the monitor into a busy-wait benchmark.

19.45.9 Exercise 08

Exercise Title: Record Events on a Custom CUDA Stream and Verify That Timing Measures Work Executed in the Intended Stream

Part 1 - Exercise Contract and Why It Matters

Record timing events on a custom CUDA stream and verify that the measured region contains the intended work. Preserve input readiness, output consumption, and allocator lifetime across the default/custom-stream boundary.

Part 2 - System and Memory Mental Model

A stream context changes where eligible operations are enqueued, but an event recorded on another stream brackets different progress. Data created on the default stream may need an explicit dependency before custom-stream use. A later default-stream consumer also needs the correct completion edge. Ordering readiness and preventing premature allocator reuse are separate obligations; record_stream is not a substitute for a producer-consumer wait.

Part 3 - Quantitative Prediction Before Execution

Draw default-stream input production, custom-stream wait, start event, operation, end event, and consuming-stream wait. Predict which waits belong inside the timing interval under two declared contracts. Construct a wrong- stream timer example that produces a plausible duration without enclosing the target operation. Identify the validation that rejects it.

Part 4 - Experimental Design and Instrumentation

Select device and stream explicitly and preinitialize events. Use a correct readiness dependency before computation, then record both markers on the intended stream. Preserve buffer lifetime through explicit leases until completion or a validated allocator stream-recording policy. Transfer output readiness to its consumer stream before numerical checks. Run a metadata negative control with mismatched recorded-stream identity instead of depending on a race to reveal the bug. Compare with a serialized correct reference and inspect a separate profiler trace.

Make input production and first custom-stream use visible in the dependency graph. If a tensor was allocated or filled on another stream, establish the required readiness before recording the measured operation. Decide whether that initial wait belongs inside the requested metric. On output handoff, the consumer needs its own readiness edge even when the Python function has already returned. Keep explicit strong references until all consumers complete in the primary implementation; use record_stream only under a separately validated lifetime policy. Recording allocator use does not order producer and consumer values. Compare a correctly timed worker region with an offline wrong-stream annotation that the validator rejects. A tiny wrong-stream interval might look plausible, so numerical correctness of the operation alone

cannot validate the timer's placement. Export current-stream metadata at recording points and restore application stream context after instrumentation. Avoid an instrumentation helper that silently moves the operation onto the default stream and thereby changes the workload it claims to measure.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def prepare_custom_stream_inputs(inputs, producer_stream, worker_stream):
    ...

def time_on_declared_stream(operation, worker_stream, timing_pair):
    ...

def handoff_completed_output(output, producer_event, consumer_stream):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export event/operation stream IDs, dependencies, timing scope, completion, result errors, and buffer release conditions. Reject a pair that never encloses the claimed work. A correct value in one run does not prove missing dependencies safe. Record whether wait time is included or excluded by marker placement. Do not infer a cross-stream dependency from Python statement order alone.

Part 7 - Engineering Interpretation and Philosophy

Explain how stream placement defines measurement meaning. Separate value readiness from storage-lifetime safety in the final interpretation.

19.45.10 Exercise 09

Exercise Title: Measure Independent Operations on Two CUDA Streams and Determine Whether Their Execution Actually Overlaps

Part 1 - Exercise Contract and Why It Matters

Measure two independent stream workloads and test whether they actually overlap. Compare serialized and concurrent execution with a common same-device fork/join timing boundary and separate branch measurements.

Part 2 - System and Memory Mental Model

Two streams permit concurrency but hardware resources, kernel occupancy, copy engines, shared memory bandwidth, and launch behavior can prevent it. Adding branch durations does not give concurrent makespan. Establish a common start dependency and join both recorded branch completions before the common end marker. Cross-stream event endpoints on one device are meaningful only under an explicitly defined interval; events from different GPUs cannot be used as one elapsed-time pair.

Part 3 - Quantitative Prediction Before Execution

Let isolated branch durations be a and b. Compare ideal concurrent makespan $\max(a, b)$ with serialized $a + b$ under no contention and negligible overhead. State why actual branch durations may change when co-running. Predict fork/join dependencies and an example where contention makes the concurrent schedule no faster. Distinguish temporal overlap from throughput improvement.

Part 4 - Experimental Design and Instrumentation

Use disjoint preallocated inputs and outputs with valid initial readiness. Record a common start on a coordinator stream, make workers wait for it, record branch regions, and join their end events before the coordinator end. Wait for the common end before reading durations. Compare with an equivalent serialized replay and inspect a separate execution trace for actual concurrency. Keep precision and operation counts fixed. Validate both outputs and preserve buffer leases. Use multiple workload sizes rather than asserting every pair of matrix multiplications can overlap effectively.

Use a coordinator start marker as the common same-device anchor. Worker streams wait for that recording, then produce their own start/end records; the coordinator waits for both ends before recording the makespan end. Check the graph has no cycle and that all required work lies between the anchor and join. This arrangement supplies causal interval boundaries without assuming Python launch order serializes the workers. Calculate relative branch start/end offsets only from compatible same-device completed event recordings. If a profiler provides a timeline, keep its clock interpretation separate from host timestamps. Compare serialized and concurrent results for both small and resource-heavy operations. Concurrent branch durations can lengthen through contention, so do not compute speedup from isolated durations alone. Preserve the fixed useful operation count and buffer capacity across trials. A claim of overlap should cite actual interval/trace evidence, and a claim of speedup should use completed makespan or useful throughput; neither claim follows automatically from the other.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_same_device_fork_join(tasks, worker_streams, coordinator):
    ...

def compare_serialized_concurrent(replay_specs, measurements):
```

```
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report isolated and concurrent branch durations, common makespan, completion graph, trace evidence, result errors, and variability. Do not infer overlap from a nonblocking launch or two stream objects. A shorter concurrent makespan is useful evidence but still needs boundary validation. Preserve no-speedup or slowdown outcomes and identify observable contention without inventing hardware causes.

Part 7 - Engineering Interpretation and Philosophy

Explain which resource or dependency limits observed concurrency. Choose whether overlap is worth retaining for the tested workload and measurement objective.

19.45.11 Exercise 10

Exercise Title: Build Cross-Stream Dependencies with CUDA Events and Make One Stream Wait for Another Without Calling Device-Wide Synchronization

Part 1 - Exercise Contract and Why It Matters

Build producer-consumer stream dependencies with events while allowing the host to continue. Verify correct values and timing scope without inserting a device-wide synchronization into the dependency path.

Part 2 - System and Memory Mental Model

A consumer stream waiting for an event delays its future queued work; it does not wait for that work to finish on the CPU. The producer must have recorded the intended event generation before the wait is established. Dependencies do not automatically keep every buffer alive. A timing start before the consumer wait includes dependency delay; a start after that wait measures a different interval. Neither alone isolates all resource-related stall causes.

Part 3 - Quantitative Prediction Before Execution

Draw producer computation, event record, consumer wait, and consumer computation. Predict host submission order and device execution order. Place timing markers before and after the wait to define two distinct metrics. Add independent host work and state when the host must eventually fence before reading results or reusing storage.

Part 4 - Experimental Design and Instrumentation

Use a producer that fills a known tensor and a consumer that transforms it. Establish the event wait explicitly, retain storage through the last consumer, and verify against a serialized reference. Test stale or unrecorded event generations in the validator. Compare host submission and completed latency in separate regions. Drain for cleanup only after the measured asynchronous path. Capture a profiler trace to distinguish waiting, computation, and interference. Keep all event timing pairs on compatible same-device recordings even if an optional cross-device wait is supported.

Record the producer event before enqueueing the consumer wait for that generation. Re-recording the event later must not be assumed to update an already established dependency to a new task. Store generation and task ID with both ends of the edge. Keep a validation case where the consumer waits for an old completed recording and reject it before numerical benchmarking. Measure a consumer interval beginning before the wait and another beginning after it, with the difference interpreted only under the controlled experiment's assumptions. Resource contention or delayed host submission can contribute to those intervals too. The CPU can proceed after scheduling a wait, but any later CPU output read still requires the appropriate completion fence. A safe output handoff can therefore be asynchronous without being unconditionally ready. Preserve buffer ownership through the consumer's last use and keep cleanup waits outside the target host-submission region. Do not remove the wait merely because a race failed to reproduce in a short run.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def enqueue_producer_consumer(producer, consumer, buffers, event_lease):
    ...

def measure_consumer_wait_inclusions(plan, timing_contract):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report dependency generations, host return time, consumer inclusive and post-wait intervals, completion boundary, and result error. Verify no device-wide wait is hidden in the measured path. A difference between intervals is only a scoped wait estimate with stated interference assumptions; do not label it a complete causal stall decomposition. Preserve safe buffer cleanup after the host has returned.

Part 7 - Engineering Interpretation and Philosophy

Explain the distinction between scheduling a wait and blocking the host. Choose marker positions that answer the intended readiness or compute-region question.

19.45.12 Exercise 11

Exercise Title: Measure Host-to-Device Transfer Latency with CUDA Events and Compare Pageable and Pinned Memory Under Identical Tensor Sizes

Part 1 - Exercise Contract and Why It Matters

Measure H2D copies from pageable and pinned host storage using matched sizes, contents, destination reuse, and stream boundaries. Report both host submission/completion and device event intervals, with pinning cost separately identified.

Part 2 - System and Memory Mental Model

Pinned storage can support asynchronous transfer paths, but performance and overlap depend on hardware, driver, size, and execution conditions. Pageable sources can involve staging and host blocking. An event interval around a copy can reflect host submission gaps or staging-related delay and must not be called pure DMA time automatically. Pre-pinning outside a region answers a different question from pinning inside an end-to-end transfer path.

Part 3 - Quantitative Prediction Before Execution

Calculate useful bytes from element count and dtype. Predict which costs belong to preallocated-copy, pin-and-copy, and completed end-to-end contracts. Draw start/copy/end enqueue order for a host-blocking staging case and explain why GPU markers need not remove host effects. Predict buffer lifetime requirements until the copy completion event.

Part 4 - Experimental Design and Instrumentation

Create equal-valued pageable and pinned sources, preallocate CUDA destinations, and warm event resources. Measure copy_ into existing storage with identical stream and nonblocking policy where supported. Keep a separate pin-and-copy replay that includes host allocation/pinning. Never mutate or release the pinned source while a copy can still read it. Wait for the end before validating copied values. Measure isolated transfer latency first, then separately test overlap with computation. Record host submission duration, completed wall time, device interval, and pinned capacity.

Separate three cases: already-pinned source to preallocated CUDA destination, pageable source to the same kind of destination, and explicit pin-then-copy including preparation. Record the actual source pin status rather than relying on its variable name. Match tensor size, dtype, contiguity, values, stream, and destination reuse. Keep source data unchanged until the copy completion condition holds; a nonblocking request is not permission for immediate reuse of pinned host storage. Pageable staging can delay host submission and influence the time between GPU markers, so describe the device interval as the observed bracketed copy path rather than asserting a clean DMA-only measurement. Validate transfer correctness after the fence with a bounded CPU comparison. When testing overlap later, use independent compute and explicit ready events instead of inferring overlap from the faster isolated transfer. Include pinned capacity and pinning cost in the runtime's resource accounting even if those costs are excluded from the reusable-copy latency contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch

def prepare_matched_host_sources(shape, dtype, seed):
    ...
```

```
def measure_h2d_copy(source, destination, stream, contract):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export source pin status, bytes, destination reuse, allocation/pinning inclusions, stream, nonblocking request, all timing scopes, and result error. A flag does not prove overlap; use dependency and trace evidence. Do not compare an allocating to call with a preallocated copy on the other path. Preserve cases where pinned memory is slower for a small transfer. State when staging or physical bus traffic cannot be directly observed.

Part 7 - Engineering Interpretation and Philosophy

Explain which transfer contract matters to the memory-aware runtime. Choose whether pinning is reusable preparation or part of its repeated critical path, and report that choice clearly.

19.45.13 Exercise 12

Exercise Title: Measure Device-to-Host and Device-to-Device Copy Latency Separately and Convert Transfer Time into Effective Bandwidth

Part 1 - Exercise Contract and Why It Matters

Measure D2H and same-device D2D copies separately and convert completed copy intervals into useful-payload bandwidth. Treat cross-GPU peer copies as an optional separately scoped extension.

Part 2 - System and Memory Mental Model

A pinned D2H destination may remain unreadable until its transfer completes. Pageable behavior does not remove the need for an explicit correctness boundary. Same-device D2D uses device memory resources rather than PCIe by default. Useful payload per second differs from a read-plus-write traffic convention. For cross-GPU work, never form an elapsed-time pair by recording one endpoint on each device; use validated local stream intervals or completed host timing across the participating devices.

Part 3 - Quantitative Prediction Before Execution

For payload B bytes and duration $t_{\mathrm{ms}} > 0$, derive

$$\mathrm{GB/s} = \frac{B}{10^6 t_{\mathrm{ms}}}, \qquad \mathrm{GiB/s} = \frac{1000B}{2^{30} t_{\mathrm{ms}}}.$$

Keep zero or unresolved tiny durations undefined for bandwidth. State whether one payload or twice the payload defines the reported convention. Predict why small-copy effective bandwidth can be dominated by overhead.

Part 4 - Experimental Design and Instrumentation

Preallocate matched source/destination buffers and initialize sources with known values. Measure D2H into pinned storage and D2D on the selected device with explicit stream events. Wait for completion before CPU reads, validation, or buffer reuse. Keep output allocation, pinning, and data-type conversion outside the preallocated-copy region; measure those separately if relevant. Sweep a bounded size range and repeat trials. For optional peer copies, record topology and peer capability and validate the actual timing stream/device contract before making bandwidth claims.

Check the arithmetic with a synthetic payload and a synthetic positive duration before processing hardware samples. Label that calculation as a unit-conversion test, not a bandwidth measurement. Preserve raw bytes and milliseconds beside decimal GB/s and binary GiB/s. For same-device copies, one useful payload divided by time is a valid convention; counting read plus write traffic is another convention and must not be substituted silently. For D2H, wait for the recorded copy completion before inspecting a pinned destination on the CPU. For optional peer copies, identify the actual stream that owns the operation and keep both event endpoints on a compatible device. If that contract cannot be verified, use completed host timing with all required device completion and report its broader scope. Do not compare an allocating cast/copy path against a pure preallocated copy as though their only difference were direction. Zero or unresolved event durations leave bandwidth undefined rather than infinitely fast.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def measure_copy_direction(source, destination, stream, direction):
    ...

def calculate_effective_bandwidth(payload_bytes, elapsed_ms, convention):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report direction, devices, pin status, payload convention, milliseconds, GB/s, GiB/s, completion, and numerical error. Reject an unfinished D2H buffer read and cross-device elapsed-time pair in validation. Do not call same-device memory-copy bandwidth PCIe bandwidth. Preserve unknown staging and backend traffic rather than inferring physical link utilization from useful bytes.

Part 7 - Engineering Interpretation and Philosophy

Explain what effective bandwidth includes and what it omits. Choose a copy metric appropriate for transfer admission without confusing transport resources across directions.

19.45.14 Exercise 13

Exercise Title: Measure Compute and Transfer Regions Separately in an Overlapped Pipeline and Calculate the Percentage of Transfer Latency Hidden by Computation

Part 1 - Exercise Contract and Why It Matters

Instrument compute and transfer regions in a bounded overlapped pipeline. Measure component intervals and completed makespan, then estimate hidden transfer time under explicit assumptions. Distinguish temporal overlap from latency removed from the critical path.

Part 2 - System and Memory Mental Model

Concurrent region durations can overlap and can change under contention. Their sum is not the pipeline's elapsed time. A timeline intersection shows simultaneous activity, not automatically useful hiding. A serialized baseline must perform the same copies and compute with matching buffers and boundaries. Fill, drain, host staging, and launch overhead remain part of the declared end-to-end region.

Part 3 - Quantitative Prediction Before Execution

Let matched serialized and overlapped makespans be T_s, T_o, and isolated transfer time be $T_x > 0$. Evaluate $(T_s - T_o)/T_x$ only as a scoped attribution estimate under unchanged compute and overhead assumptions. Separately calculate transfer-interval overlap with the union of compute intervals. Construct a case where overlap exists but contention eliminates speedup. Keep negative or above-one raw estimates visible as assumption diagnostics.

Part 4 - Experimental Design and Instrumentation

Use bounded double buffering with pinned host sources, a transfer stream, and a compute stream. Establish readiness and final-reader dependencies before slot reuse. Record per-copy and compute intervals plus a same-device fork/join makespan; collect completed wall time as a separate metric. Run serialized, transfer-only, compute-only, and overlapped replays with identical useful work. Validate outputs and inspect a separate profiler trace. Include fill and drain in primary pipeline timing. Do not synchronize after every component in the path whose overlap is being measured.

Keep pipeline depth, useful chunks, allocation policy, and validation work fixed across serialized and overlapped replays. Record fill and drain, not only a favorable steady interval. The isolated transfer baseline can change under concurrent compute, so the difference-of-makespans fraction is an estimate with assumptions, not an exact physical decomposition. Compute temporal overlap from interval unions to avoid counting two overlapping compute regions twice. A high temporal fraction can coexist with a slower overall pipeline if kernels or copies contend. Preserve a negative raw benefit estimate and investigate the workload rather than clamping it to zero. An estimate above one can expose unmatched baseline overhead or changed compute costs; report the inconsistency explicitly. Use validated slot generations and last-reader events before overwriting double buffers. Extra staging capacity is part of the memory trade-off, so a faster overlapped path must still fit the declared application budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def instrument_overlapped_pipeline(plan, buffers, timing_pool):
    ...

def estimate_hidden_transfer(serialized, overlapped, isolated, timeline):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw component intervals, makespans, completed wall time, temporal overlap fraction, attribution estimate, assumptions, and result errors. Do not silently clamp implausible percentages. Explain scope changes or contention with traces where possible. A smaller exposed transfer wait is not proof of lower total step time if compute slowed. Missing timeline alignment remains unknown rather than invented overlap.

Part 7 - Engineering Interpretation and Philosophy

Choose the metric that helps the runtime decide whether prefetch is worth its extra residency. Explain why simultaneous activity and critical-path benefit require different evidence.

19.45.15 Exercise 14

Exercise Title: Add Warmup Iterations and Demonstrate How CUDA Initialization, Kernel Selection, and Allocator Warmup Distort First-Iteration Timing

Part 1 - Exercise Contract and Why It Matters

Measure cold and warmed behavior separately and identify how initialization, algorithm selection, allocation, event initialization, and execution state affect the first iterations. Define a reproducible warmup policy without deleting unfavorable data after seeing it.

Part 2 - System and Memory Mental Model

The first CUDA use can include host/runtime setup. New shapes or kernels can trigger distinct preparation, and allocator reuse can change subsequent behavior. Event pairs may exclude some setup while still include host submission gaps after their start. Warmup also changes device temperature, clocks, cache state, and workload history. A warmed fixed-shape result is not a universal first-request latency.

Part 3 - Quantitative Prediction Before Execution

Draw cold-start host and device regions and predict which setup terms each timing scope can observe. Define fixed warmup counts or a predeclared stability criterion with a maximum budget. Add a new-shape case after warmup and predict why earlier calibration might not transfer. Keep initialization and warmed execution as separate reported outcomes.

Part 4 - Experimental Design and Instrumentation

Use fresh processes for true process-cold comparisons and explicitly state what environmental coldness is not controlled. Warm operands, kernels, event resources, and the intended allocation policy before the steady region. Keep seed, shape, dtype, precision, thread settings, and operation count fixed. Measure shape-switch behavior in a named separate series. Record every warmup observation if used by the stability policy, but exclude it from warmed statistics only by the predeclared rule. Validate outputs outside timing and bound workload size so calibration cannot grow indefinitely.

Distinguish process-cold, new-shape, allocator-cold, and warmed fixed-shape conditions. A fresh Python process does not prove the entire machine, driver, filesystem, or GPU cache is cold. State what is controlled and what remains unknown. Warm timing-event resources as well as kernels, consuming the diagnostic record before reusing its generation. If calibration uses a stability criterion, define its window, tolerance, and maximum iterations beforehand. Do not continue warmup until a preferred number appears. Record shape changes, precision settings, allocator policy, and whether outputs are preallocated. A new shape can invalidate a prior warmed cost estimate even if the high-level operation name is unchanged. Preserve first-use costs in a separate result series and include initialization in user-visible startup timing where relevant. Compare fresh runs to distinguish within-run warmup from run-to-run variability. Avoid explaining every slow first sample as algorithm selection unless a supported trace or configuration check substantiates that particular cause.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def define_warmup_contract(workload_spec, stability_policy):
    ...

def collect_cold_and_warm_replays(config, evidence):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report process state, event initialization, warmup count/rule, shape history, allocation policy, device context, and both timing distributions. Do not call a repeated loop process-cold or infer which internal algorithm changed without supported evidence. Preserve slow warmed samples rather than reclassifying them as warmup afterward. State if stability was not reached within the bounded calibration range.

Part 7 - Engineering Interpretation and Philosophy

Explain which production scenario each distribution represents. Choose cold or warmed estimates according to the runtime decision rather than whichever looks faster.

19.45.16 Exercise 15

Exercise Title: Run Hundreds of Event-Timed Iterations and Report Median, Mean, Minimum, Maximum, and Tail Latency Instead of Relying on a Single Measurement

Part 1 - Exercise Contract and Why It Matters

Collect hundreds of valid event samples and report median, mean, minimum, maximum, and selected tail quantiles. Preserve raw data, sample identity, measurement mode, and failure counts instead of relying on one attractive iteration.

Part 2 - System and Memory Mental Model

An isolated call with a wait after each iteration has different queueing and scheduling behavior from many queued operations. Repeated-region averages are not individual request samples. Instrumentation, clocks, thermal state, concurrent work, and allocator policy can shape the distribution. The minimum is the smallest observed sample, not a guarantee or hardware lower bound. Tail quantiles need a stated finite-sample convention and adequate support.

Part 3 - Quantitative Prediction Before Execution

Define a sample count in the hundreds, warmup exclusion rule, percentile method, and outlier policy before collection. Compare isolated-latency and queued-region designs with their different boundaries. Calculate statistics by hand on a small list containing repeated values and a large outlier. Explain why p99 estimated from only a modest number of samples has limited resolution and uncertainty.

Part 4 - Experimental Design and Instrumentation

Use a bounded event pool and fixed operand/output policy. Assign each iteration an independent pair generation and do not re-record it before consuming its result. In queued mode, collect completion at declared batch boundaries rather than synchronizing every operation; in isolated mode, wait per sample deliberately. Keep modes separate. Retain CPU scalar samples and configuration IDs, not live GPU outputs. Record acquisition order and any system context available. Repeat fresh runs to expose run-to-run variability. Validate correctness outside timing and account for failed or unfinished iterations explicitly.

Use separate labels for isolated latency, queued operation intervals, and repeated-region per-operation averages. Event pairs queued back to back can observe a different scheduling environment from a request whose host waits before the next submission. Do not pool those populations. Define percentile interpolation or nearest-rank convention and preserve acquisition order so trends and bursts remain inspectable. Report finite sample count with tail statistics; a single high-order observation cannot establish a stable service level for all future requests. Keep failures and incomplete records in a parallel outcome table instead of treating them as fast samples. A predeclared invalid-record rule may exclude missing markers, but a long valid duration is not invalid simply because it is an outlier. Use bounded batches of event leases and collect them before re-recording. Track CPU collection overhead and event-pool capacity so hundreds of observations do not introduce unreported memory pressure or synchronization into the workload.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def collect_event_sample_batch(workload, pool, sampling_contract):
    ...

def summarize_valid_samples(rows, quantile_method, failure_policy):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw milliseconds, sample count, min/max/mean/median, chosen quantiles, percentile convention, and rejected/error counts. Never convert failures to zero or discard slow samples because they weaken the result. Report legitimate predeclared exclusions separately. Do not combine different shapes, timing modes, or cold/warm populations into one unexplained histogram. Preserve variation instead of reporting unsupported precision.

Part 7 - Engineering Interpretation and Philosophy

Choose summary statistics for throughput planning and latency-sensitive admission. Explain the practical limits of tail estimates from the tested sample size.

19.45.17 Exercise 16

Exercise Title: Build a Hierarchical Event Timer That Measures Prefetch, Transfer, Forward, Backward, Offload, and Eviction Regions Independently

Part 1 - Exercise Contract and Why It Matters

Build a hierarchical instrumentation system for prefetch, transfer, forward, backward, offload, and eviction. Assign host/device scope to each region and support multiple streams without falsely treating overlapping children as additive durations.

Part 2 - System and Memory Mental Model

Prefetch can contain CPU file access, pinning, allocation, and CUDA copy; CUDA events measure only an explicitly bracketed device interval. Eviction can mean a D2H copy, logical release, allocator-cache retention, or a policy decision. These need different evidence. A same-device parent makespan must join all child completion dependencies it claims to cover. Parent minus summed children is not valid exclusive time when children overlap or have different clock domains.

Part 3 - Quantitative Prediction Before Execution

Define region IDs, parent relationships, device/stream, generation, logical request, timing scope, and completion. Construct a two-stream example whose child durations sum above the parent makespan. Define exclusive time only for a validated compatible nonoverlapping/nested

timeline. Predict which prefetch and eviction components require monotonic host clocks or memory counters rather than event pairs.

Part 4 - Experimental Design and Instrumentation

Start with one-stream nested compute regions, then add transfer-stream children with explicit fork/join parents. Use distinct event leases per outstanding region and retain buffers through last consumers. Record host preparation separately. For training, include forward, backward, and optimizer update in a named completed-step boundary even if component regions are reported independently. Resolve completed event records asynchronously through a bounded collector. Export CPU rows and inspect a separate profiler trace. Avoid forcing a device synchronization at every region exit.

Define each region's clock domain before assigning a parent. CPU file read or pinning can be a host child of prefetch, while H2D is a device child with its own stream and completion. A parent completed-wall interval may cover both without allowing their timestamps to be subtracted directly. For a device parent spanning streams, establish a start anchor and join all included child completions. Exclusive time is meaningful only under verified compatible interval relationships; subtracting overlapping children can produce a meaningless negative result. Treat an eviction policy decision, a D2H copy, logical buffer retirement, and allocator release as separate events or counters. A no-op CUDA event pair around Python deletion does not measure memory reclamation. Keep optimizer update and recovery inclusions in the complete training boundary. Export region identity, dependency edges, and completion status so the memory-aware scheduler can distinguish a ready copy from an unfinished prefetch request with the same region name.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class HierarchicalTimingRegion:
    region_id: str
    parent_id: object
    request_id: str
    device_identity: object
    stream_identity: object
    scope: str
    generation: int
    completion_status: str

def begin_instrumented_region(spec, timing_pool, dependency_graph):
    ...

def finalize_completed_regions(registry, cpu_evidence):
```

```
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report inclusive durations, parent makespans, overlap relationships, host preparation, release/capacity observations, and uncertainty. Reject cross-device elapsed pairs and negative invented exclusive time. A logical eviction timestamp is not proof the driver recovered physical memory. Verify that instrumentation neither retains graphs nor serializes the pipeline it claims to observe.

Part 7 - Engineering Interpretation and Philosophy

Choose region semantics that correspond to runtime decisions. Explain why a hierarchy of names is insufficient without a hierarchy of dependencies and compatible clocks.

19.45.18 Exercise 17

Exercise Title: Detect an Unintended Synchronization Point by Comparing Expected Asynchronous Timing Against Recorded CUDA Event Dependencies

Part 1 - Exercise Contract and Why It Matters

Detect and localize an unintended host synchronization through matched host timing, event dependencies, and profiler evidence. Distinguish genuine synchronization from resource contention or deliberate stream waiting.

Part 2 - System and Memory Mental Model

A CPU scalar read, certain data-dependent operations, blocking copies, or explicit waits can make an expected asynchronous path block. Event intervals alone do not identify the cause: markers can include delayed submission, and host waiting can occur outside their scope. A GPU-side stream dependency is not the same as a blocked Python thread. Confirm the suspected boundary with an independent trace or controlled rewrite before making a causal claim.

Part 3 - Quantitative Prediction Before Execution

Draw a pipeline with expected host submission, compute, transfer, and consumer dependencies. Insert a known scalar extraction as a diagnostic synchronization case. Predict which host interval grows and how the event interval may or may not change depending on marker placement. Add a no-host- sync resource-contention counterexample with a similar total latency.

Part 4 - Experimental Design and Instrumentation

Run a small correct asynchronous reference and one version with an intentional synchronization candidate. Keep device computation and output validation consistent, moving diagnostic CPU reads outside timing in the reference. Record host call intervals and event completion graph, then profile separately for synchronization events. Remove or relocate the suspected boundary and repeat. Use supported synchronization-debug facilities only where available and

label their coverage limits. Preserve all required value and storage dependencies when rewriting the path; deleting a necessary wait is not a valid optimization.

Use a controlled scalar extraction as a known host-wait example, then move it outside the submission-critical path while preserving required output validation. Capture host call durations and the GPU timeline in separate instrumented replays. Compare a resource-contention case that contains no new host fence to show why a timing gap is not sufficient causal evidence. A GPU stream wait can delay its consumer without blocking Python, whereas a host event synchronization deliberately blocks the calling thread. Keep both categories visible. Supported debug facilities can help localize some synchronization operations, but their absence of warnings is not proof that no blocking occurred. Do not remove a necessary data dependency to improve a benchmark. Validate outputs, buffer generations, and completed work after the rewrite. If a suspected operation is outside the event markers, the event interval may remain almost unchanged while wall latency changes; use that outcome to refine the boundary explanation rather than forcing the timer readings to agree.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import time
import torch

def compare_expected_and_observed_dependencies(plan, timing_rows, trace):
    ...

def localize_sync_candidate(reference_replay, modified_replay, evidence):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export suspected operation, host blocking evidence, marker placement, trace match, rewritten result, numerical error, and remaining uncertainty. Do not claim every host/device timing gap is synchronization. A faster unsafe rewrite fails validation. Include a contention case or state if it was not observed. Report instrumentation/debug overhead separately from ordinary latency.

Part 7 - Engineering Interpretation and Philosophy

Explain the evidence linking the operation to lost asynchrony. Choose a rewrite that preserves completion requirements while moving unnecessary blocking off the critical path.

19.45.19 Exercise 18

Exercise Title: Stress-Test the Timing System with Multiple Streams, Variable Tensor Sizes, Concurrent Transfers, Memory Pressure, and Dynamic Scheduling Decisions

Part 1 - Exercise Contract and Why It Matters

Stress the timing system with multiple streams, variable shapes, concurrent copies, bounded memory pressure, and dynamic task decisions. Require correct task identity, completion, buffer safety, and honest timing scope under load.

Part 2 - System and Memory Mental Model

Dynamic shapes can change kernel choice and warmup status. Contention can lengthen event intervals without adding a new explicit dependency. Pressure can trigger allocation work or failures outside the timed device region. A task can time out at the monitor while still running on CUDA. Multiple GPUs have separate event domains; one pair cannot time a cross-device interval. A pooled event generation must survive delayed collection.

Part 3 - Quantitative Prediction Before Execution

Define bounded cases with two streams, alternating sizes, H2D/D2H competition, a retained pressure buffer, and pending-record capacity exhaustion. Predict completed, pending, rejected, and failed states. Calculate memory for instrumentation and task buffers as well as workloads. Include an offline cross-device-pair rejection and a stale-generation case. State which outcomes are synthetic policy tests versus real device observations.

Part 4 - Experimental Design and Instrumentation

Validate deterministic small tasks before applying pressure. Change one factor at a time, then selected combinations with fixed seeds. Use a bounded pool, explicit backpressure, and safe delayed collection. Drain or recover the process before freeing buffers after a timeout or asynchronous failure. Preserve a failed task's diagnostic context without inserting it as a zero-latency sample. Check numerical outputs and stream dependencies. Run profiling separately from ordinary timing. Label unavailable multi-GPU or transfer paths not measured rather than fabricating clock alignment or hardware results.

Create a record-integrity matrix for unrecorded events, timing-disabled pairs, cross-device endpoints, stale generations, delayed collectors, and capacity exhaustion. Validate deterministic rejection offline before adding CUDA load. Keep dynamic shape and cold/warm state in every record so a scheduler does not reuse a small warm cost for a larger first-use task. Memory pressure tests must be bounded and identify whether pressure is a real held allocation or an application quota. A timeout does not cancel a CUDA kernel or make its buffers safe to free. Preserve leases until a verified drain or process-recovery path resolves outstanding work. If an asynchronous error appears while querying an event, retain the originating task context and failure phase without claiming the query caused the kernel failure. For multiple GPUs, summarize local event domains and completed host intervals separately; never invent a common event clock or subtract raw timestamps from unrelated processes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_timing_stress_cases(capabilities, resource_budget):
    ...
```

```
def validate_timing_record_integrity(records, task_registry):
    ...

def run_bounded_timing_stress(case, instrumentation, evidence):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export shapes, devices, streams, pressure mechanism, event generations, pending high-water mark, overhead, raw intervals, completion status, errors, and failure phase. Separate timeout detection from actual CUDA completion. Keep nonreproducing races or slowdowns as outcomes. Do not infer allocator fragmentation from timing variability alone. Preserve the smallest record- identity or dependency counterexample found.

Part 7 - Engineering Interpretation and Philosophy

Explain which stress case invalidates the strongest naive timing claim. Use the result to refine supported scope, pool capacity, or completion policy without hiding failed samples.

19.45.20 Exercise 19

Exercise Title: Build and Benchmark a Reusable PyTorch CUDA Event Instrumentation System That Feeds Accurate Compute, Transfer, and Stall Measurements into a Memory-Aware Runtime

Part 1 - Exercise Contract and Why It Matters

Integrate a reusable CUDA event instrumentation system that supplies validated compute, transfer, completion, and scoped stall evidence to a memory-aware runtime. Keep collection bounded and preserve normal overlap while benchmarking its overhead.

Part 2 - System and Memory Mental Model

The system combines region contracts, event leases, stream dependencies, completion monitoring, buffer lifetimes, and CPU evidence. Timing values must carry shape, dtype, device, load context, and age before a scheduler uses them as cost estimates. Event intervals do not provide a complete causal stall decomposition or guarantee future latency. Host-only prefetch, logical eviction, and cross-device completion need their own clocks and evidence. Primary support excludes CUDA Graph capture and distributed timestamp alignment until separately validated.

Part 3 - Quantitative Prediction Before Execution

Predict event count, pending capacity, storage overhead, collection delay, and instrumentation time for the chosen workload. Define accepted error/tolerance checks, completion invariants, and a maximum monitoring overhead objective. Choose a finite calibration set and

held-out shapes. State how stale or missing measurements cause conservative runtime behavior rather than zero-cost predictions.

Part 4 - Experimental Design and Instrumentation

Validate tiny known dependency graphs, then instrument a deterministic transfer/compute workload and a complete training step where available. Use separate correctness, profiling, and ordinary timing replays. Compare uninstrumented, coarse-region, and fine-region instrumentation on identical useful work. Preserve E00's reproducibility record plus region schemas, pool sizes, generations, sampling modes, and completion rules. Export CPU scalars without live graph retention. Test event-pool reuse and safe cleanup. Record unavailable CUDA execution or unsupported paths explicitly instead of supplying invented timing results.

Publish a capability matrix for completed same-stream timing, custom-stream handoff, fork/join makespan, polling, copy directions, hierarchical regions, safe pool reuse, and scoped stall diagnosis. Each supported entry needs a validating run ID. Compare coarse and fine instrumentation against the same uninstrumented useful work, including memory retained by event pools and evidence queues. Feed the runtime distributions with shape, dtype, device, load context, sample count, age, and validity rather than a single universal latency constant. Missing or stale costs should trigger conservative fallback or explicit rejection, not a zero estimate. Keep CPU preparation and logical memory-release evidence outside CUDA-only claims. Record unsupported Graph capture or cross-process alignment honestly. Preserve prediction errors on held-out shapes and any overhead regression. The final result should show which measurements improve a concrete scheduling decision while retaining correct outputs and safe lifetimes, with bounded instrumentation cost and clear limits on causal interpretation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class CUDAEventInstrumentation:
    def validate_region(self, contract, dependency_graph):
        ...

    def acquire_event_lease(self, task_id, device, stream):
        ...

    def record_region_end(self, lease, completion_dependencies):
        ...

    def collect_ready_cpu_records(self):
        ...

    def retire_completed_lease(self, lease):
        ...

def E19(config):
```

```
# Assemble checked components and compare instrumentation overhead.
...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Every run needs ID, configuration, input shape, byte budgets, peak allocated/reserved memory, host and device timing scopes, raw durations, completion status, correctness, outcome, and failure phase. Report distributions, overhead, rejected records, and the smallest counterexample to a universal timing rule, or state none was observed. Preserve unsupported/not-measured values. A method signature is not capability evidence; each supported feature needs a validating run ID.

Part 7 - Engineering Interpretation and Philosophy

Justify the chosen instrumentation granularity through correct dependencies, safe lifetimes, measured overhead, and useful runtime decisions. Identify untested conditions that could invalidate its cost predictions.

19.46 DMM44

Chapter Title: Memory and Transfer Bandwidth Profiling
Specialization: Dynamic Memory Management and CUDA Systems

19.46.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Theoretical Bandwidth, Effective Bandwidth, Latency, Throughput, and Memory-Bound Execution

Part 1 - Exercise Contract and Why It Matters

Define a bandwidth measurement contract containing path, useful work, byte convention, timing scope, completion, cache state, and concurrency. Distinguish a theoretical hardware ceiling from measured effective throughput and from application latency.

Part 2 - System and Memory Mental Model

Useful-payload bandwidth for a transfer counts delivered bytes, while a device-memory copy benchmark often counts both requested reads and writes. Neither automatically equals physical DRAM or link traffic. Caches, transaction size, staging, conversion, and protocol overhead can change actual traffic. Small requests can be latency- or launch-limited even when large requests approach a sustained plateau. A high bandwidth number is meaningless without its numerator, denominator, and memory path.

Part 3 - Quantitative Prediction Before Execution

For bytes B and completed seconds $t > 0$, derive useful B/t and a copy's requested read/write rate $2B/t$ under their different conventions. Convert decimal GB/s and binary GiB/s consistently. Build the latency model $t(B) = \alpha + B/\beta$ as a scoped approximation and identify which data range could estimate its overhead and sustained rate. Give a counterexample to interpreting every slow operation as bandwidth-bound.

Part 4 - Experimental Design and Instrumentation

Start with eager inference-only copies, preallocated independent buffers, matching dtypes, fixed seeds, and verified contents. Preserve GPU identity, software/driver versions, allocator, topology, host-memory pinning, NUMA context when known, shapes, byte counts, precision, warmup, concurrency, and timing boundaries. Use completed same-device event pairs for compatible CUDA regions and monotonic host clocks for CPU/file/end-to-end work. Treat cross-device clock pairs, unsupported profiling counters, and unavailable paths explicitly.

Build a paper path diagram for a host buffer, a CUDA destination, a same-device consumer, and an optional second GPU. Label requested payload, requested reads/writes, and physical traffic as distinct accounting layers. A successful host-to-device copy can deliver one payload while touching host and device memory through several internal stages; do not add those stages to a link numerator without a defined convention. Create synthetic small- and large-message examples with the same sustained-rate assumption but different fixed overhead fractions. These are unit/model tests, not observed hardware points. Define latency as completed time for one declared request, and throughput as useful work over a declared completed region. A repeated batch can improve throughput without improving the first request's latency. State what cache state, concurrency, and resource sharing are held fixed before fitting a model. If citing theoretical bandwidth, use authoritative specifications for the exact hardware and compatible units; otherwise leave the ceiling unknown. Keep memory capacity and bandwidth separate because a fast transfer path can still require staging buffers that exceed the application budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BandwidthContract:
    path_identity: str
    byte_convention: str
    timing_scope: str
    completion_rule: str
    cache_policy: str
    concurrency_identity: str

def validate_bandwidth_contract(contract, buffer_specs):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation distinct. Export raw bytes and durations beside derived rates. Unknown traffic remains unknown; zero or unresolved durations do not imply infinite bandwidth. Do not invent hardware results or use published device figures as local measurements.

Part 7 - Engineering Interpretation and Philosophy

Explain what resource each rate describes and which runtime decision it can support. An honest path-specific cost model is more useful than one universal bandwidth constant.

19.46.2 Exercise 01

Exercise Title: Calculate Effective Bandwidth from Bytes Transferred and CUDA Event Timing for a Controlled PyTorch Memory Copy

Part 1 - Exercise Contract and Why It Matters

Calculate effective bandwidth for a controlled PyTorch copy using completed CUDA event timing. Validate the byte numerator and timing domain before summarizing throughput.

Part 2 - System and Memory Mental Model

A copy can allocate, convert dtype, broadcast, or pack strided storage unless those behaviors are excluded. Use equal-shaped, equal-dtype independent buffers for the primary pure-copy region. Event intervals include stream progress and possible interference rather than guaranteed exclusive engine time. Source and destination must remain valid through completion, and the timing pair must belong to one compatible device domain.

Part 3 - Quantitative Prediction Before Execution

For payload B bytes and elapsed $t_{\mathrm{ms}} > 0$, derive

$$\mathrm{GB/s} = B/(10^6 t_{\mathrm{ms}}), \qquad \mathrm{GiB/s} = 1000B/(2^{30} t_{\mathrm{ms}}).$$

State whether this exercise reports one delivered payload or requested reads plus writes. Calculate synthetic unit-conversion examples and preserve their synthetic status. Predict why tiny intervals need larger regions or an explicit unresolved result.

Part 4 - Experimental Design and Instrumentation

Preallocate and initialize buffers, warm event resources and the selected copy path, and record start/copy/end on the declared stream. Establish end completion before reading elapsed time. Validate copied values outside timing. Collect bounded repeated samples with generation-safe event reuse. Record allocation and dtype-conversion exclusions explicitly. Compare a single-copy latency series with repeated-region throughput only under separate labels. Retain CPU scalar evidence rather than every GPU output.

Check the byte numerator using actual tensor metadata rather than a shape label alone. Source and destination must have the same logical shape and dtype in the pure-copy case, with no overlap, broadcasting, or implicit conversion. Use known coordinate-coded contents to detect a no-op alias or wrong region. Record whether the time covers one copy or several repetitions and multiply bytes by that repetition count only when every copy actually executes. A final output equal to the source does not by itself prove all repeated requests happened; preserve the operation ledger. Initialize and consume diagnostic event records before reusing their generation

for warmed timing. Read elapsed time only after the matching end has completed. A zero-valued tiny interval can reflect resolution and must leave bandwidth undefined until a valid larger-region contract is used. Report both payload and read/write conventions if helpful, but do not silently switch them between rows. Validate decimal/binary unit conversions on a hand-calculated synthetic case before applying them to real distributions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def count_copy_payload(source, destination, byte_convention):
    ...

def time_checked_copy(source, destination, stream, timing_pair):
    ...

def calculate_completed_copy_rate(payload_bytes, elapsed_ms, convention):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report shape, dtype, useful bytes, requested-byte convention, event generation, device/stream, duration, completion, and copy error. Reject aliasing, unfinished pairs, unrecorded events, or a changing numerator. Do not replace failed samples with zero time. A bandwidth above a presumed hardware ceiling needs a scope/cache/convention investigation before any performance claim.

Part 7 - Engineering Interpretation and Philosophy

Explain the exact rate calculated and what it does not measure. Choose whether the runtime needs per-request latency, sustained useful payload, or requested memory traffic.

19.46.3 Exercise 02

Exercise Title: Benchmark CPU-to-GPU Transfer Bandwidth Across Increasing Tensor Sizes and Identify the Region Where PCIe Throughput Saturates

Part 1 - Exercise Contract and Why It Matters

Sweep H2D payload size and identify an observed large-transfer throughput plateau within the tested range. Confirm the actual host-GPU path before calling the result PCIe throughput.

Part 2 - System and Memory Mental Model

Small transfers include launch and staging overhead; larger transfers may approach a sustained rate limited by host memory, interconnect, or device conditions. A plateau is empirical evidence, not proof of the nominal bus ceiling. Pageable and pinned sources are different contracts. Preallocation, NUMA locality, contention, and warmup can change the curve.

Part 3 - Quantitative Prediction Before Execution

Choose a bounded geometric size sweep and predict latency with $\alpha + B/\beta$. Define a plateau criterion using neighboring large-size rates and variability before observing results. Explain why an unsaturated curve cannot establish the link maximum. Predict the difference between copy-only and completed end-to-end regions.

Derive a crossover payload from the fitted fixed-overhead and sustained-rate terms. For a declared acceptable overhead fraction, solve for a candidate minimum payload and test that prediction on held-out sizes. Keep a failed prediction when the simple model misses staging thresholds or implementation changes. This is a model-specific batching hint, not a hardware saturation law. Report the chosen fraction, fit interval, residual uncertainty, and whether the proposed payload remains within pinned and CUDA buffer budgets.

Part 4 - Experimental Design and Instrumentation

Use pinned sources and preallocated CUDA destinations as the primary reusable-copy path. Match contents and dtype across sizes, with no conversion. Warm each shape and time completed regions with event and host scopes recorded separately. Keep source storage unchanged until completion. Repeat sizes in an order that exposes drift, and record distributions rather than one sample. Preserve topology evidence and hardware identity; if the physical host link is unverified, label the result H2D rather than asserting PCIe. Measure pinning or allocation in separate end-to-end experiments.

Choose size limits from explicit host pinned-memory and CUDA budgets. A geometric sweep should include several points in any candidate plateau region rather than declaring saturation from the largest single sample. Repeat or interleave size order to distinguish systematic size trends from thermal/load drift. Keep source placement and host-memory locality recorded where observable. An H2D plateau can arise from host memory, staging, submission, link behavior, or another resource, so topology confirmation and traces matter before assigning the bottleneck to PCIe. Preserve raw completed times and fit residuals. If the smallest sizes are dominated by overhead, do not force a line through all sizes or interpret a negative fitted intercept as a physical latency. Restrict the model or report the fit failure. Keep an unverified host-link type in the capability record rather than guessing from the GPU model. Compare copy-only calibration with a preparation-inclusive application query so later runtime decisions do not omit a cost that their actual request must pay.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_bounded_h2d_size_sweep(resource_budget):
    ...
```

```
def fit_scoped_latency_model(size_rows, fit_range, uncertainty):
    ...

def detect_measured_plateau(rows, declared_criterion):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export sizes, pin status, raw latency distributions, effective rates, fit residuals, plateau criterion, topology evidence, and correctness. Report no plateau observed when appropriate. Do not extrapolate a fitted rate beyond its calibrated range or attribute every limit to PCIe without evidence. Preserve host staging and CPU submission contributions under their named scopes.

Part 7 - Engineering Interpretation and Philosophy

Choose a transfer-size regime for the runtime's cost model. Explain when a fixed overhead matters more than large-message bandwidth.

19.46.4 Exercise 03

Exercise Title: Benchmark GPU-to-CPU Transfer Bandwidth and Compare It Against Host-to-GPU Throughput Under Identical Buffer Sizes

Part 1 - Exercise Contract and Why It Matters

Benchmark D2H throughput using the same payload-size set as H2D and compare directions without assuming symmetric performance. Preserve matched host-memory and buffer-reuse contracts.

Part 2 - System and Memory Mental Model

A D2H copy into pinned host memory can still be unfinished when Python returns. Reading its destination requires an appropriate completion fence. H2D and D2H can differ through engine behavior, host memory, topology, and staging. Equal byte counts do not guarantee equal end-to-end costs. Device events and host timers must retain the same meanings across directions.

Part 3 - Quantitative Prediction Before Execution

Predict useful bytes and latency/rate curves for both directions under an explicit model. Derive direction ratios only for matched size and timing scope. Identify what evidence would justify an asymmetry conclusion and what variation would leave it unresolved. Include a case where host allocation would dominate a comparison if it were included on only one path.

Part 4 - Experimental Design and Instrumentation

Preallocate GPU sources and pinned CPU destinations for D2H. Match the H2D dataset's dtype, byte sizes, stream policy, warmup, repetitions, and allocation exclusions. Initialize source values before timing. Record completed CUDA regions and completed host intervals separately. Wait before checking CPU contents or reusing buffers. Alternate direction order across controlled replays to reduce drift bias. Keep validation and profiling outside ordinary timing, and record any unsupported path explicitly.

Use the same payload sequence and warmup rule for both directions, but initialize each source independently before its timed copy. A CPU destination that will receive D2H must not be read or overwritten until its actual completion. If the primary comparison uses pinned memory, ensure both the H2D source and D2H destination satisfy that policy. Keep CPU allocation outside both reusable-copy regions, and include it on both sides in any allocating comparison. Distinguish the host call's return interval from completed wall time and the event-bracketed interval. Record direction order and run-to-run variation, because sequentially benchmarking all H2D first and all D2H much later can confound direction with changing load. Compare distributions or paired configurations rather than arbitrary sample indices from separate replays. If a direction is consistently slower, state the measured difference before proposing a hardware explanation. Preserve unsupported physical traffic counters and unresolved staging effects as unknown. A later offload policy must use the appropriate direction model instead of averaging away an important asymmetry.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def benchmark_matched_directions(size_specs, host_buffers, gpu_buffers):
    ...

def compare_direction_distributions(h2d_rows, d2h_rows):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report per-direction raw bytes, distributions, pinning, completion, effective bandwidth, comparison uncertainty, and result error. Do not inspect an unfinished D2H buffer to test correctness. A direction difference is an observation to explain with supported evidence, not permission to assert a particular hardware limitation. Preserve unresolved or nonreproducing rankings.

Part 7 - Engineering Interpretation and Philosophy

Choose separate cost estimates when direction matters. Explain why CPU offloading cannot assume the reload path and eviction path have the same latency.

19.46.5 Exercise 04

Exercise Title: Compare Pageable and Pinned Host Memory by Effective H2D and D2H Bandwidth Across Small, Medium, and Large Transfers

Part 1 - Exercise Contract and Why It Matters

Compare pageable and pinned host storage for H2D and D2H across small, medium, and large payloads. Separate reusable transfer cost from allocation, pinning, and staging preparation.

Part 2 - System and Memory Mental Model

Pinning can enable useful asynchronous transfer paths but consumes a bounded host resource and can be expensive to perform repeatedly. Pageable copies can involve staging or host blocking. An event-bracketed region does not automatically isolate pure DMA because host submission delays can affect its interval. Different buffer contracts answer different application questions.

Part 3 - Quantitative Prediction Before Execution

Predict four reusable-copy curves by direction and pin status. Add separate pin-and-copy and allocating-copy contracts. Estimate how a fixed preparation cost changes small-message effective bandwidth. Construct a case where pre-pinned reuse helps while repeated pinning removes that advantage. Keep those as predictions until measured.

Part 4 - Experimental Design and Instrumentation

Use equal-valued, equal-dtype host buffers and independent preallocated GPU storage. Verify actual pin status, contiguity, and byte count. Measure reusable copies and preparation-inclusive paths in distinct replays with matched timing boundaries. Keep pinned H2D sources unchanged and D2H destinations unread until completion. Bound pinned capacity and outstanding copies. Collect host submission, completed wall time, and compatible event intervals. Inspect staging only through supported traces; preserve unknown internal behavior rather than inventing it.

Allocate equal-valued pageable and pinned buffers with matched shape, dtype, and layout. Verify pin status from the object used by the copy, not from an earlier buffer that was subsequently replaced. Distinguish already- pinned reusable storage, explicit pinning of an existing pageable tensor, and a path that allocates and fills new host storage for every request. The end-to-end application comparison must include whichever preparation its request really requires. Keep source contents stable for nonblocking H2D and preserve D2H destination ownership through the fence. Record total pinned capacity and outstanding requests so the fastest mode does not hide unbounded host residency. Small-message rankings can differ from large-message rankings; retain those observations rather than imposing one winning mode. If event and wall intervals differ, inspect their boundaries and host staging before subtracting them as an exact overhead. Include a repeated-reuse trace to measure amortization explicitly. The conclusion should name the workload and resource constraint under which pinning helps, not assert a universal speedup from the presence of a flag.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def prepare_host_memory_comparison(spec, pinned_capacity_budget):
    ...

def benchmark_host_memory_modes(cases, timing_contract):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report direction, size class, pin status, preparation inclusions, timing scopes, throughput distributions, host capacity, and copy errors. Do not compare an allocating path with a preallocated path without labeling the difference. Preserve slower pinned results where observed. A nonblocking flag is not evidence that compute-transfer overlap occurred.

Part 7 - Engineering Interpretation and Philosophy

Choose a host-buffer strategy for repeated offload under both RAM and latency constraints. Explain which costs are amortized and which remain on the critical path.

19.46.6 Exercise 05

Exercise Title: Compare Hundreds of Small Transfers Against One Batched Transfer with the Same Total Byte Count and Quantify Per-Transfer Overhead

Part 1 - Exercise Contract and Why It Matters

Compare hundreds of small transfers with one larger transfer carrying the same useful bytes. Quantify submission overhead and preparation costs without hiding packing or output reconstruction.

Part 2 - System and Memory Mental Model

Many requests can pay repeated dispatch, event, and staging costs. Batching can reduce those costs but may need CPU packing, GPU unpacking, additional storage, or longer waiting before a batch is ready. Equal payload bytes alone do not make the paths operationally equivalent. Per-copy synchronization would introduce another experimental factor and must not appear on only one side of the primary comparison.

Part 3 - Quantitative Prediction Before Execution

For n chunks of size b, compare $n(\alpha + b/\beta)$ with $\alpha + nb/\beta$ under the simple serialized model. Add packing/unpacking and batch-formation delay as separate terms. Define one copy-only comparison and one end-to-end application comparison. Predict when the added preparation could exceed the saved request overhead.

Part 4 - Experimental Design and Instrumentation

Preallocate a fixed total payload and equivalent destinations. For the small path, submit the declared chunk count under one completed batch boundary; for the large path, use one contiguous payload. Validate sample ordering and contents after completion. Add a separate fragmented-source case that requires real packing and include its cost. Keep pinning, dtype, total bytes, warmup, and stream policy matched. Measure CPU submission, completed time, event makespan, and peak staging capacity. Repeat with bounded chunk counts and preserve the full operation ledger.

Define whether the small chunks already occupy one contiguous parent or begin as independent fragmented application objects. In the first case, a larger transfer can be a fair copy-only alternative without real packing. In the second, CPU packing and any GPU unpacking belong to the application cost. Preserve the same logical order of samples and validate every destination interval. Use hundreds of requests only within the declared buffer budget, and retain completion before slot reuse. Do not synchronize after each small copy unless that is a separately named latency contract; otherwise the test would combine request granularity with a changed synchronization policy. Measure one completed batch makespan, host submission duration, and useful throughput. If estimating per-request overhead from a fitted model, retain its size range and uncertainty rather than extrapolating it to arbitrary concurrency. Add batch-formation delay for an online workload that waits for requests to accumulate. A bandwidth gain can coexist with worse response time or higher staging memory, so the final runtime decision needs both constraints.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_equal_payload_transfer_cases(total_bytes, chunk_counts):
    ...

def measure_transfer_batch(case, buffers, timing_contract):
    ...

def estimate_request_overhead(rows, preparation_contract):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report total bytes, chunks, per-chunk size, preparation, completion, latency, throughput, and memory overhead. A fitted per-request cost is scoped to its range and concurrency. Do not exclude real packing from an end-to-end batching claim. A batched path that delays readiness

or increases peak memory can be worse for a latency-sensitive runtime despite higher copy-only bandwidth.

Part 7 - Engineering Interpretation and Philosophy

Choose batching based on useful completed work, preparation, residency, and response-time constraints. Explain why equal bytes is necessary but insufficient for a fair transfer comparison.

19.46.7 Exercise 06

Exercise Title: Sweep float16, bfloat16, float32, and float64 Transfers and Determine Whether Achieved Bandwidth Depends on Element Count or Total Bytes

Part 1 - Exercise Contract and Why It Matters

Sweep float16, bfloat16, float32, and float64 copies under both fixed- element and fixed-byte controls. Determine which observed differences follow from payload and which require another explanation.

Part 2 - System and Memory Mental Model

A raw matching-dtype copy moves storage bytes without arithmetic conversion. Changing element width at fixed element count changes payload. At fixed bytes, shapes or element counts differ and may select different implementation paths. A device's support for fast bfloat16 arithmetic is not identical to support for copying bfloat16 storage. Casting during the benchmark is a different workload and must not masquerade as pure transfer.

Part 3 - Quantitative Prediction Before Execution

Calculate payload for each dtype and predict fixed-element latency from the fitted size model. Construct equal-byte cases with valid integral element counts. Predict that byte-matched large contiguous copies may be similar under a simple transport model, but leave dtype/path effects as tested hypotheses. Define numerical or exact-storage correctness checks appropriate to initialized values.

Part 4 - Experimental Design and Instrumentation

Create source/destination pairs with identical dtype within each copy. Verify element_size and total bytes from the actual tensors. Exclude random generation, conversion, and allocation from reusable-copy timing. Warm each supported case and measure the same direction, stream, pinning, and completion contract. Run fixed-element and fixed-byte sweeps separately. Record unsupported storage or transfer combinations rather than silently substituting another dtype. Keep values bounded and deterministic so copy validation does not become a test of different arithmetic precision.

Create a table of actual element widths and derive every case's byte count from numel times element_size. Fixed-element and fixed-byte sweeps must be separate result families. For the latter, choose byte targets divisible by each tested width and preserve the same logical layout class. Use matching source/destination dtypes so the path does not cast while copying. Explicitly record unsupported storage or transport behavior without assuming that missing fast arithmetic support forbids byte movement. Initialization can use simple finite values exactly representable in all selected dtypes; its CPU/GPU compute cost stays outside the reusable-copy region. Validate byte-preserving or value-preserving behavior according to the declared check. If equal-byte rates differ, investigate size, kernel path, alignment, layout, staging, and variability

before attributing the result to dtype. Do not force a byte-only conclusion merely because the simple model predicts it. Conversely, a larger fixed-element payload explains additional time without invoking slower floating-point arithmetic. Keep conversion-inclusive application requests as a different path model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_dtype_transfer_cases(element_counts, byte_targets, capabilities):
    ...

def compare_dtype_byte_controls(case_rows, latency_model):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report actual dtype, element width, numel, bytes, control policy, conversion status, timing distributions, and errors. Do not attribute a fixed-element float64 slowdown to arithmetic when it moved more bytes. Conversely, do not force equal rates if matched-byte measurements differ. Inspect path, layout, overhead, and variability before proposing a cause.

Part 7 - Engineering Interpretation and Philosophy

Choose bytes as the primary transfer-cost input while preserving dtype and layout as capability/context fields. Explain when element count alone would mislead the runtime.

19.46.8 Exercise 07

Exercise Title: Measure CUDA Device-to-Device Copy Bandwidth and Compare It Against Host-Device Transfer Bandwidth

Part 1 - Exercise Contract and Why It Matters

Measure same-device CUDA copy performance and compare it with host-device transfers using clearly labeled numerator and resource conventions.

Part 2 - System and Memory Mental Model

A same-GPU D2D copy primarily accesses device memory resources; H2D/D2H uses a host-device path and host memory. Comparing device read-plus-write bytes with host useful-payload bytes without labels creates a factor-of-two ambiguity. Repeated device copies can be served partly by caches, so the observed effective rate is not automatically sustained device DRAM bandwidth.

Part 3 - Quantitative Prediction Before Execution

Calculate one-payload and requested read/write rates for the same D2D sample, then identify the valid comparison with H2D useful throughput. Predict small-size overhead and large-size behavior without borrowing a hardware peak figure. Explain why rates from different resources need not share a common ceiling.

Part 4 - Experimental Design and Instrumentation

Use independent contiguous GPU buffers with equal shapes/dtypes and preallocated copies. Warm the path and record completed same-device intervals. Sweep sizes within a bounded memory budget and use a documented reuse/cache policy. Compare with matched host-transfer rows under both timing and byte labels. Validate contents after completion and prevent source/destination aliasing. Record whether cache-sensitive repetition or rotating buffers were used. Profile separately if attempting to identify kernel versus copy-engine behavior, and keep unsupported hardware counters unknown.

Specify same-device D2D explicitly so it cannot be confused with peer movement between GPUs. Use independent backing storage and reject a source view that aliases the destination in an overlapping way. Record source and destination strides and verify no conversion or broadcasting occurs. For comparison with host paths, present useful-payload rates under one convention and requested device read/write rates under another clearly labeled convention. The two numbers may differ by a factor of two without any measurement conflict. Run repeated-buffer and larger/rotating-working-set experiments separately, with a finite memory bound and the same completion rule. A large allocation can reduce some cache reuse but does not prove every byte reached DRAM. If supported counters are unavailable, call the result effective copy bandwidth for that working set. Keep ordinary timing free of profiler replay overhead. An apparent rate higher than a nominal device-memory figure should trigger a check of numerator, cache regime, interval validity, and specification scope, not an immediate claim that the hardware exceeded its physical limit.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def benchmark_same_device_copy(spec, buffers, timing_pool):
    ...

def compare_device_and_host_paths(rows, numerator_conventions):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export path, useful/requested bytes, cache policy, completed duration, rate, memory capacity, and correctness. Do not label same-device D2D as PCIe bandwidth or claim a repeated small-buffer result measures DRAM saturation. Preserve high apparent rates with a scoped interpretation rather than deleting them or claiming impossible hardware performance.

Part 7 - Engineering Interpretation and Philosophy

Explain which resource makes the paths different. Choose a calibration that matches the memory-aware runtime's actual access pattern.

19.46.9 Exercise 08

Exercise Title: Benchmark Peer-to-Peer Tensor Transfers Between Two GPUs and Compare Direct P2P Movement Against CPU-Staged Copies

Part 1 - Exercise Contract and Why It Matters

Benchmark GPU-to-GPU movement and an explicit CPU-staged alternative. Verify peer capability and available path evidence before labeling the GPU copy direct P2P.

Part 2 - System and Memory Mental Model

Peer access capability is not proof of the exact path selected by every high-level copy. Topology, driver, platform restrictions, and implementation can cause fallback or different transport. The explicit staged path contains D2H completion followed by H2D from valid host storage, with staging capacity and possible overlap defined. Cross-device event endpoints cannot form one valid elapsed-time pair.

Part 3 - Quantitative Prediction Before Execution

Predict one-payload delivery rate for each complete path. For serialized staging, model D2H plus H2D plus preparation rather than dividing the payload by only one leg. Include any rotating staging buffers in the memory bound. Predict a topology where the direct candidate may not be available and define an honest unsupported or unverified label.

Part 4 - Experimental Design and Instrumentation

Use two available CUDA devices with explicit identity and peer capability checks in each direction. Preallocate source, destination, and pinned staging. Time completed end-to-end movement with a monotonic host clock and all required device completions. Use local event intervals only with verified owning-stream semantics. Validate values after every path. Seek supported profiler/topology or diagnostic evidence of direct movement; otherwise call it the high-level GPU-copy candidate. Keep CPU staging explicit without changing global system peer settings. Record direction, topology, sizes, warmup, and buffer reuse.

Test capability and complete correctness for each GPU direction because a pair's observed behavior can be asymmetric. Preserve stable device identities, visible ordinals, topology evidence, and process mode. A high-level copy candidate may succeed through a path the profiler cannot distinguish; label that uncertainty instead of promoting capability to proof. The CPU-staged reference must complete D2H before H2D consumes that host buffer, and its host capacity belongs to the accounting. If double-buffering the staged path, validate slot generations and report its additional residency and changed overlap. Use complete host timing with both relevant device completions as the portable primary end-to-end metric; never subtract events recorded on different GPUs. Local leg timing is optional only with verified stream semantics.

Do not change machine-wide peer settings just to obtain a preferred comparison. An optional supported diagnostic can add path evidence, but its performance is a separate instrumented result. Preserve a not-measured outcome when the second device or reliable path evidence is unavailable.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def inspect_peer_path_capabilities(device_pair, evidence_sources):
    ...

def benchmark_gpu_copy_and_cpu_staging(spec, buffers, completion_contract):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report capability versus observed-path evidence separately, complete latency, staging leg times, useful bytes, host capacity, and errors. Do not invent a direct path from a fast rate or a successful capability query. If only one GPU is available, retain offline protocol checks and mark execution not measured. Preserve asymmetric direction results and unsupported diagnostics.

Part 7 - Engineering Interpretation and Philosophy

Choose a path based on measured complete cost and verified support. Explain why the runtime should retain path identity and uncertainty instead of assuming all GPU pairs communicate equally.

19.46.10 Exercise 09

Exercise Title: Build a PyTorch GPU Memory-Copy Benchmark and Estimate Effective Device-Memory Bandwidth from Total Bytes Read and Written

Part 1 - Exercise Contract and Why It Matters

Build a GPU copy benchmark that reports requested device-memory bytes read and written. Estimate effective memory bandwidth while preserving the distinction from measured physical DRAM traffic.

Part 2 - System and Memory Mental Model

For an independent equal-dtype copy of N elements of width s, requested traffic is $2Ns$ bytes. Caches, write behavior, transaction granularity, and implementation choices can make physical traffic differ. Reusing a small working set can measure a cache-influenced regime.

Unsupported performance counters do not justify relabeling requested bytes as actual DRAM bytes.

Part 3 - Quantitative Prediction Before Execution

Derive the requested numerator for one copy and a repeated region. Calculate how counting one payload instead changes the reported number. Choose a bounded range and rotation policy intended to explore cache and larger-working-set behavior. State that a larger buffer does not alone prove caches had no effect. Predict the evidence needed for a physical-traffic claim.

Part 4 - Experimental Design and Instrumentation

Preallocate independent buffers and use matching shape/dtype, no broadcasting, no conversion, and no autograd graph in the primary memory benchmark. Warm copies and timing resources. Measure completed event regions and raw distributions. Compare repeated-buffer and rotating-buffer cases as separate contracts, recording total resident capacity. Validate all touched outputs. If supported, collect memory-traffic counters in a separate Nsight Compute replay and record metric names, device, version, and collection limitations. Keep those instrumented results separate from ordinary timing.

Count requested traffic for the exact operation sequence, not only the final output's size. A copy of independent storage requests a read and a write, whereas aliasing can turn an intended benchmark into a no-op or another unsupported case. Include repeated-region count and buffer-rotation policy in the numerator record. Cache-influenced effective rates are useful observations when labeled, but they cannot establish sustained external-memory bandwidth. If hardware counters are collected, record the specific memory level and whether the tool replayed kernels or adjusted cache behavior. Counter availability and permissions can vary; unsupported metrics remain unsupported rather than being reconstructed from elapsed time. Compare requested and physical bytes only under compatible workload and memory-level assumptions. Avoid summing load/store counters that refer to different scopes or double-counting transactions already included in an aggregate metric. Use held-out working sets to test the calibration's portability. Preserve the raw scalar timings, copy result checks, resident capacity, and peak allocation alongside the bandwidth estimate so the runtime can reject an otherwise fast calibration that would exceed its memory budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def requested_copy_traffic_bytes(source_spec, repeat_count):
    ...

def benchmark_device_memory_copy(case, buffers, timing_contract):
    ...

def reconcile_requested_and_profiled_traffic(rows, hardware_metrics):
    ...
```

```
def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report requested reads/writes, useful payload, elapsed time, cache policy, working-set capacity, effective rate, actual-counter status, and correctness. An apparent rate above a nominal DRAM figure may reflect caches or conventions; investigate before claiming hardware violation. Do not copy theoretical specifications into the measured column or confuse kernel replay counters with uninstrumented application timing.

Part 7 - Engineering Interpretation and Philosophy

Explain when requested-byte bandwidth is useful despite incomplete physical-traffic knowledge. Identify the uncertainty that prevents a stronger DRAM utilization claim.

19.46.11 Exercise 10

Exercise Title: Compare Contiguous and Noncontiguous Tensor Copies and Measure the Bandwidth Lost to Strided Memory Access and Extra Materialization

Part 1 - Exercise Contract and Why It Matters

Compare contiguous and strided copy paths while separating useful payload, backing capacity, index work, and explicit materialization. Verify that both paths deliver the intended logical values.

Part 2 - System and Memory Mental Model

A noncontiguous view can retain a larger parent allocation, and a backend may choose a specialized kernel or temporary. Calling contiguous before timing changes the measured contract; calling it inside adds materialization work. A strided tensor alone does not establish how warp lanes access memory. Do not attribute every difference to coalescing without lower-level evidence.

Part 3 - Quantitative Prediction Before Execution

Define matched logical shapes with distinct strides and derive useful copied bytes, parent backing capacity, and requested extra materialization bytes where known. Compare direct strided copy with materialize-then-copy including and excluding preparation under separate labels. Predict a case where preparation amortizes across repeated consumers and another where it does not.

Part 4 - Experimental Design and Instrumentation

Construct coordinate-coded inputs and independent destinations. Record shape, stride, storage offset, contiguity, dtype, and backing capacity. Avoid source/destination overlap and broadcasting. Warm supported paths and measure completed intervals with matched allocation policy. Profile separately for extra kernels or copies. Validate logical ordering after completion, including sliced and transposed cases. Preserve unsupported layouts as rejected rather than silently converting them before the supposedly strided benchmark.

Use coordinate-coded tensors to verify logical order after transposition or slicing. Record shape, stride, storage offset, source backing capacity, destination layout, and any temporary representation. A view with few logical elements can retain a much larger parent storage. Do not include that backing span in useful copied bytes unless the path actually moves it, but do include it in residency. Compare direct strided copy, explicit materialization, and repeated reuse of a materialized representation as three named contracts. If materialization is outside the copy-only interval, retain its measured cost for end-to-end analysis. Profile extra kernels and copies without assuming the high-level API uses one implementation on every shape. A noncontiguous source and noncontiguous destination can produce different work from a strided source copied into contiguous output, so do not combine them into one unexplained category. Keep storage overlap excluded. The resulting performance difference is a layout-path effect unless lane mapping and transaction evidence support a narrower claim about coalescing.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_matched_layout_copy_cases(spec):
    ...

def measure_layout_and_materialization(case, timing_contract):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report useful bytes, backing capacity, preparation inclusions, stride, extra materialization, duration, effective rate, and copy error. Do not infer physical traffic from view size alone. A faster prepared path must include its one-time cost in an end-to-end reuse analysis. Explain remaining kernel or cache uncertainty rather than calling all lost bandwidth strided access.

Part 7 - Engineering Interpretation and Philosophy

Choose a layout strategy according to consumer count, capacity, and measured complete cost. State which evidence would be needed to attribute the result specifically to warp-level access efficiency.

19.46.12 Exercise 11

Exercise Title: Design Coalesced and Poorly Localized GPU Memory-Access Workloads and Measure Their Effective Bandwidth Difference

Part 1 - Exercise Contract and Why It Matters

Design controlled GPU access patterns that differ in locality, and establish when the evidence supports a coalescing claim. Keep a PyTorch-level locality comparison separate from an optional explicit-lane kernel experiment.

Part 2 - System and Memory Mental Model

Coalescing concerns addresses requested by lanes of a warp, not merely the printed stride of a Python tensor. High-level gathers can include index reads, bounds work, allocation, and implementation-dependent thread mapping. A custom CUDA or supported kernel-language extension can control lane mapping, but it adds a separate capability and validation requirement. Timing alone cannot prove the number of physical memory transactions.

Part 3 - Quantitative Prediction Before Execution

Specify adjacent versus dispersed lane addresses for a hypothetical kernel and derive requested data bytes separately from index bytes and backing span. Construct a high-level gather experiment with the same number of outputs but different index locality. Explain why its rate includes indexing overhead. Predict which profiler transaction or traffic evidence could support the coalescing interpretation.

Part 4 - Experimental Design and Instrumentation

Start with deterministic PyTorch access workloads and label them locality tests. Preallocate outputs where supported and exclude index construction from the access region while recording its cost separately. If implementing the optional explicit-lane kernel, validate bounds, output equality, lane mapping, and supported launch configuration before benchmarking. Keep useful values and operation counts matched. Collect supported traffic metrics in a separate replay and preserve unknowns. Use bounded working sets and distinguish cache reuse from access-transaction effects.

Define the access pattern independently of the Python operator name. For the optional controlled-lane experiment, specify which lane requests which element, alignment assumptions, bounds, and whether reads, writes, or both are dispersed. Keep the same useful output count and validate every value. For the high-level PyTorch experiment, include index-array reads and other known requested bytes separately from useful data bytes. Advanced indexing may allocate or use a different kernel, so its slowdown cannot be assigned solely to memory transactions. Exclude index generation from the access-only region and retain it in an end-to-end path if the application regenerates indices. Test cache reuse and working-set size under bounded capacity. Use supported profiler metrics to compare requested work with physical traffic where possible, preserving version and device scope. Do not invent a custom-kernel implementation hidden inside the scaffold. If that capability is unavailable, complete the locality experiment honestly and mark direct warp-level coalescing verification unsupported.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_access_pattern_cases(spec, index_policy):
    ...
```

```
def launch_validated_access_case(case, output, kernel_capabilities):
    # Optional controlled-lane kernel remains learner implementation work.
    ...

def evaluate_locality_evidence(rows, traffic_metrics, lane_mapping):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report pattern, useful/index bytes, working set, output validation, latency, effective convention, lane-mapping status, and hardware evidence. Do not call a gather slowdown a pure coalescing penalty without sufficient control. Mark the custom-kernel path unsupported if unavailable and retain the valid high-level locality result. Preserve cases where caching changes the expected ranking.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest conclusion justified by the experiment. Distinguish a useful locality signal from a proven microarchitectural cause.

19.46.13 Exercise 12

Exercise Title: Measure Simultaneous H2D Transfer and GPU Compute and Calculate How Much PCIe Traffic Is Hidden Behind Computation

Part 1 - Exercise Contract and Why It Matters

Measure simultaneous H2D transfer and GPU compute with a validated bounded pipeline. Report temporal overlap and completed latency benefit as separate quantities.

Part 2 - System and Memory Mental Model

Independent streams and pinned sources permit useful overlap but do not guarantee it. Compute and copies can contend for device memory or other resources. Total bytes delivered do not decrease merely because transfer latency is hidden. A serialized baseline must perform the same useful work and include the same fill, drain, preparation, and output requirements.

Part 3 - Quantitative Prediction Before Execution

Let matched serialized and overlapped times be T_s, T_o, and isolated transfer time be $T_x > 0$. Treat $(T_s - T_o)/T_x$ as an attribution estimate only under unchanged-compute/overhead assumptions. Separately calculate overlap of transfer intervals with the union of compute intervals. Predict a case with temporal overlap but no end-to-end speedup. Preserve negative or above-one raw estimates as diagnostics.

Part 4 - Experimental Design and Instrumentation

Use pinned sources, preallocated double buffers, one transfer stream, and one compute stream. Establish data-ready and final-reader events before slot reuse. Record compatible component intervals plus a fork/join makespan, and completed host time separately. Run transfer-only, compute-only, serialized, and overlapped replays with identical shapes and useful chunks. Validate results after completion. Profile in a separate replay and do not synchronize after each component in the overlapped timing path. Record actual path evidence before describing the host link as PCIe.

Keep the serialized and overlapped pipelines identical in useful copies, compute, output collection, and preparation policy. Double buffering adds capacity and slot-lifetime constraints even if it shortens the critical path. Use a common same-device anchor and joined completion for makespan, plus separate component intervals and completed wall time. Compute temporal overlap from interval unions so simultaneous compute regions are not counted twice. The difference-of-makespans estimate assumes compute and overhead do not change; contention can violate that assumption. Preserve negative benefit or an estimate above one and investigate unmatched baselines rather than clamping the report. Include fill and drain, especially when only a few chunks are processed. Useful transfer bytes remain delivered even when their latency overlaps compute; do not describe the percentage as bytes eliminated from the link. Record the confirmed host-link type or retain a generic H2D label. A faster overlap policy must still satisfy the pinned and CUDA staging budget and output correctness requirements.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_safe_transfer_compute_pipeline(spec, buffers, stream_plan):
    ...

def compare_overlap_and_latency_benefit(replays, timeline):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export component durations, makespan, useful payload, overlap fraction, benefit estimate, assumptions, memory overhead, and correctness. Do not claim PCIe traffic vanished or silently clamp an implausible hidden percentage. If compute slowed under contention, include that cost. A faster pipeline still needs to satisfy its extra staging-capacity budget.

Part 7 - Engineering Interpretation and Philosophy

Choose whether overlap is worthwhile for the tested workload. Explain why transfer activity, exposed wait, and total throughput answer different runtime questions.

19.46.14 Exercise 13

Exercise Title: Run Concurrent H2D and D2H Transfers on Separate CUDA Streams and Determine Whether Bidirectional Transfer Engines Can Operate Simultaneously

Part 1 - Exercise Contract and Why It Matters

Run simultaneous H2D and D2H on separate CUDA streams and test bidirectional progress under the available hardware. Compare aggregate useful throughput with per-direction latency and a serialized reference.

Part 2 - System and Memory Mental Model

Two stream objects do not prove independent copy engines or full-duplex performance. Host memory, topology, staging, and device resources can limit concurrency. Aggregate throughput sums delivered bytes over a common completed makespan; summing two independently calculated rates can misrepresent the same interval. D2H destinations and H2D sources require separate safety rules.

Part 3 - Quantitative Prediction Before Execution

For payloads B_h, B_d and common duration T, define aggregate useful rate $(B_h + B_d)/T$ and retain each direction's completion latency. Compare ideal independent and serialized bounds under explicit assumptions. Predict a case where aggregate rate rises but one direction's tail latency worsens. State what trace evidence would establish simultaneous activity.

Part 4 - Experimental Design and Instrumentation

Preallocate disjoint pinned host and CUDA buffers with known contents. Use a common start anchor and join both stream completions before the end marker on the same device. Measure equivalent serialized and concurrent replays after warmup. Wait before CPU validation or buffer reuse. Capture a separate timeline to inspect overlap, not just launch order. Sweep matched sizes and preserve per-direction distributions. Do not infer exact copy-engine count solely from timing; use supported device evidence where available.

Use disjoint H2D sources and D2H destinations so the two directions do not create accidental data dependencies through one host buffer. Pin and initialize storage before the reusable-copy region. A common fork/join boundary defines aggregate useful rate, while each branch retains its own start/completion interval. Validate CPU results only after the D2H branch has completed. Record whether direction workloads are equal or deliberately asymmetric, and keep total work matched in the serialized control. An aggregate rate can exceed a single-direction rate because it includes both directions; it is not evidence that one direction exceeded the link's unilateral ceiling. Conversely, separate streams may still serialize or contend. Use traces and supported capability data before claiming simultaneous engine execution. Do not infer exact engine count from one timing curve. Preserve per-direction tail latency because an offload scheduler can maximize aggregate traffic while delaying the next required reload. Include host-memory bandwidth and staging as possible shared constraints without assigning causality unsupported by the measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_bidirectional_fork_join(case, buffers, streams):
    ...

def calculate_direction_and_aggregate_rates(case, completed_rows):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report direction bytes, individual completion, common makespan, aggregate rate, temporal overlap, host pinning, and errors. Keep unsupported hardware capability fields unknown. A throughput improvement without simultaneous trace evidence needs a cautious interpretation. Preserve no-overlap or slowdown outcomes and explain what the observed evidence can and cannot attribute.

Part 7 - Engineering Interpretation and Philosophy

Choose direction-specific and aggregate costs for concurrent offload. Explain why maximizing aggregate rate alone may violate a latency-sensitive reload requirement.

19.46.15 Exercise 14

Exercise Title: Saturate the Host-GPU Link with Multiple Concurrent Transfers and Determine the Point Where Additional Streams Stop Increasing Aggregate Bandwidth

Part 1 - Exercise Contract and Why It Matters

Sweep concurrent transfer streams and identify the tested point where additional streams cease improving aggregate completed throughput. Include memory capacity and per-request latency, not only a peak aggregate rate.

Part 2 - System and Memory Mental Model

More streams can expose concurrency or merely divide a fixed resource among more requests. Shared host memory and link bandwidth can saturate, while staging and queueing increase latency. Fixed total payload and fixed per-stream payload are different experiments. A plateau within a tested range does not establish a universal optimal stream count.

Part 3 - Quantitative Prediction Before Execution

Define a fixed-total-byte sweep first and a separate fixed-per-stream series. Calculate aggregate bytes over one fork/join makespan. Predict how per-request latency and outstanding capacity can grow even if aggregate rate stops increasing. Set a plateau criterion and maximum concurrency before collecting results.

Part 4 - Experimental Design and Instrumentation

Use bounded pinned and GPU buffer pools with distinct task/slot generations. Launch matched copies across candidate stream counts, establish a common start and joined completion, and validate every output. Keep direction, dtype, size distribution, warmup, preparation, and topology fixed within each series. Record host submission overhead, common completed time, per-request latency, and peak staging capacity. Profile separately for contention. Apply backpressure when pool capacity is reached rather than silently overwriting an in-flight buffer.

Define fixed total bytes before constructing the concurrency sweep. If each extra stream instead receives another full payload, report that as a separate growing-work experiment. Use a bounded stream/event/buffer pool and preserve a generation for each outstanding slot. Aggregate bytes are divided by one completed common makespan, not by summed branch times. Record CPU submission duration, queueing, and per-request completion so a throughput plateau does not hide rising latency. Predeclare the criterion for insignificant rate improvement, the maximum tested streams, and the latency/memory constraints. Repeat nearby candidate counts to assess variability. Host staging, link resources, and device memory can be shared even across different transfer streams. Preserve topology and pinning with the curve, because a calibrated concurrency point is contextual rather than universal. If the largest tested count still improves rate, report that the tested range did not locate a plateau. A stream count rejected for insufficient buffer capacity is not a measured bandwidth failure and should retain its own outcome.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_stream_concurrency_sweep(total_payload, resource_limits):
    ...

def benchmark_transfer_concurrency(case, buffers, timing_registry):
    ...

def select_tested_concurrency(rows, latency_and_memory_constraints):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export stream count, total/per-stream bytes, common makespan, aggregate rate, latency tails, host overhead, pool capacity, and correctness. Do not sum overlapping durations to compute aggregate time. Report unresolved plateaus or variability honestly. If a higher stream count improves rate but exceeds the memory or latency bound, classify it infeasible for the declared objective.

Part 7 - Engineering Interpretation and Philosophy

Choose a concurrency limit from the joint rate, latency, and residency measurements. Explain why a modest limit can be preferable to the largest available stream count.

19.46.16 Exercise 15

Exercise Title: Build a Roofline-Style Experiment That Distinguishes Memory-Bound and Compute-Bound PyTorch Operations from Arithmetic Intensity and Measured Bandwidth

Part 1 - Exercise Contract and Why It Matters

Build a Roofline-style experiment with explicit arithmetic and byte models. Distinguish evidence consistent with memory limits from compute, launch, latency, and implementation bottlenecks.

Part 2 - System and Memory Mental Model

Arithmetic intensity is operations per byte at a named memory level. Requested device-memory bytes, cache traffic, and host-transfer bytes are not interchangeable denominators. A matrix multiplication can reuse data far more than a pointwise operation. Precision, Tensor Core policy, fusion, and actual kernel selection affect achievable compute. A point below a roof is not automatically bandwidth-bound.

Part 3 - Quantitative Prediction Before Execution

For F FLOPs and bytes Q, define $I = F/Q$ and the scoped roof

$$P \leq \min(P_{\text{compute}}, I\,\beta_{\text{memory}}).$$

Derive a pointwise add's requested reads/writes and a matrix product's ideal input/output byte model under stated reuse assumptions. Count fused multiply-add consistently. Compare empirical sustained ceilings with theoretical ones and preserve their different provenance.

Part 4 - Experimental Design and Instrumentation

Choose a bounded pointwise workload and matrix-multiplication sweep with known shapes, dtype, precision, and allocation policy. Validate numerical outputs. Measure warmed completed intervals and useful FLOPs; collect supported memory counters in a separate profiling replay if available. Calibrate an empirical bandwidth and compute reference under matching precision/resource conditions. Keep eager and compiled/fused paths separate. Vary working set, shape, and reuse to test the predicted limiting region. Do not use H2D bandwidth as a device-DRAM roof or count ideal minimum bytes as measured traffic.

Choose the memory level for each Roofline point before calculating intensity. Requested minimum bytes from a mathematical operation can differ from actual DRAM bytes because of tiling, cache reuse, temporary tensors, and fusion. Label analytical intensity accordingly. Keep compute ceilings matched to dtype and precision policy, including any Tensor Core or TF32 behavior, and separate vendor theoretical values from empirical sustained references. For an eager pointwise chain, account for intermediate passes rather than assuming it was fused. For a compiled version, establish the actual kernel/traffic evidence separately. Small operations can be dominated by launch or latency and remain far below both simple roofs. Use a shape or reuse sweep and a controlled intervention before assigning a cause. A copy bandwidth calibration is an empirical reference for its resource and pattern, not a universal ceiling for every kernel. If performance counters are unavailable, retain a model-based classification with uncertainty and

avoid claiming an exact physical-memory utilization percentage. Preserve numerical checks after precision or implementation changes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def model_workload_flops_and_bytes(spec, memory_level, fusion_policy):
    ...

def construct_scoped_roofline(reference_measurements, workload_rows):
    ...

def classify_supported_bottleneck_evidence(point, uncertainty, trace):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report FLOP convention, byte model, memory level, precision, ceilings, measured performance, counters, residuals, and correctness. Include a small launch-limited case that neither simple roof explains well. Use counterfactual shape/reuse changes to test a proposed bottleneck rather than assigning it from one chart point. Mark unknown actual traffic and unsupported metrics.

Check calibration compatibility before comparing a point with its roof. A matrix shape that exposes little parallelism can have a lower empirical compute reference than a larger shape of the same dtype. A cache-sensitive copy reference can also misrepresent a DRAM-limited kernel. Preserve these scope differences and report a classification as unresolved when the ceilings are not comparable. Do not strengthen a model-based classification into a causal claim merely because a plotted point lies near a line.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest bottleneck conclusion supported by the experiment. Choose whether reducing traffic, increasing reuse, changing granularity, or another measured intervention is the next useful test.

19.46.17 Exercise 16

Exercise Title: Measure the Transfer Cost of CPU Offloading and Calculate the Minimum Parameter Reuse Required to Make Keeping a Tensor in VRAM More Efficient

Part 1 - Exercise Contract and Why It Matters

Measure CPU offload/reload cost and derive a workload-specific residency break-even rule. Include authoritative-value policy, dirty writeback, reuse horizon, and the opportunity cost of occupying VRAM.

Part 2 - System and Memory Mental Model

An immutable parameter can retain a valid CPU copy after a reload; it does not require a fresh D2H writeback on every use. Modified state needs a version-aware dirty policy. With free VRAM and no adverse effect on other work, avoiding any unnecessary reload already saves latency; there is no universal positive reuse threshold. A meaningful threshold needs explicit admission cost, future misses, competing residency, or a throughput objective.

Part 3 - Quantitative Prediction Before Execution

Let resident incremental cost be $A + O(k)$ for admission and opportunity cost over k uses. Let the offloaded alternative cost $E + q(k)R$ for required eviction/writeback and reload misses. Compare these time quantities after canceling common compute. Derive a break-even only under a declared model for O and q. Keep memory feasibility as a separate byte constraint, not seconds subtracted from gigabytes.

If a threshold is derived, specify integer rounding and strict versus non-strict break-even. Evaluate the neighboring reuse counts explicitly on a synthetic trace before hardware testing. Include a trace with several uses per reload so reuse count and miss count differ. A policy that reloads once for an entire burst has a different threshold from one that evicts after every use, even when both bursts contain the same number of parameter accesses.

Part 4 - Experimental Design and Instrumentation

Use a small deterministic inference workload with read-only weights first. Measure complete offload/reload paths with reusable pinned staging and validated contents. Replay fixed access traces with different reuse counts and capacity pressure. Record which host version remains authoritative and which reloads are actually needed. Add a separately validated dirty-state case if implemented. Compare retained versus offloaded policies on identical useful work, including admission, writeback, staging, and future communication. Preserve next-use predictions before observing the trace outcome.

State the authoritative value at every transition. Immutable weights can keep a valid CPU backup and need only reloads after eviction; modified weights or KV-like blocks need a dirty/version policy. Count actual dirty writeback bytes rather than forcing a full D2H on every access. Define whether the resident and offloaded alternatives start from the same initial location and include their distinct admission costs. If both are feasible with free VRAM and no opportunity cost, retaining a tensor avoids any unnecessary reload, so a universal minimum reuse count is not implied. A finite break-even can arise when initial placement, displaced competing state, or different future misses create explicit extra costs. Keep those costs in seconds and capacity in bytes. Replay a known access trace and preserve the predicted reuse horizon before observing it. Compare complete useful execution, staging, and induced future communication. If the assumed horizon is wrong, report the policy miss rather than revising the prediction retrospectively. Safe version and buffer lifetimes remain mandatory even when the transfer-cost model recommends eviction.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def measure_offload_policy_trace(trace, buffers, authority_contract):
    ...

def derive_residency_break_even(costs, miss_model, opportunity_model):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export uses, misses, versions, dirty bytes, copied bytes, measured path times, staging capacity, opportunity assumptions, and outcome correctness. Report no finite threshold or no useful threshold when the model implies it. Do not invent a universal reuse count. A resident policy that displaces more valuable state must include that induced cost rather than claiming all avoided transfer time is free benefit.

Part 7 - Engineering Interpretation and Philosophy

Choose a residency rule for a specified trace and budget. Explain which assumption would change the break-even and which uncertainty requires a conservative no-move decision.

19.46.18 Exercise 17

Exercise Title: Build a Runtime Bandwidth Model for NVMe-to-RAM, RAM-to-VRAM, GPU Memory, and GPU-to-GPU Paths and Predict the Bottleneck of a Three-Tier Offload Pipeline

Part 1 - Exercise Contract and Why It Matters

Build a path-specific cost model for file/NVMe-to-RAM, RAM-to-VRAM, device memory, and GPU-to-GPU movement. Predict a bounded three-tier pipeline's bottleneck and validate on held-out transfer sizes and schedules.

Part 2 - System and Memory Mental Model

Disk reads, page-cache hits, host staging, H2D, and device consumption have different resources and clocks. Ordinary PyTorch copies do not establish direct NVMe-to-GPU access. A file-to-RAM result may be dominated by OS cache rather than physical NVMe. GPU peer paths need the evidence from E08. Shared host memory, PCIe roots, or storage resources can invalidate an independent- stage overlap model.

Part 3 - Quantitative Prediction Before Execution

Fit scoped latency functions $t_j(B) = \alpha_j + B/\beta_j$ where data support them. Compare serial completion as a sum of required stages with an ideal steady pipeline bound based on the maximum resource service time per chunk. Add fill, drain, finite buffers, and shared-resource contention. Predict a case where the bottleneck shifts when chunk size or concurrency changes.

Part 4 - Experimental Design and Instrumentation

Use a bounded benchmark-owned file and verify storage identity before calling the path NVMe. Measure completed file reads with a monotonic host clock, recording cache-control limits. Do not flush global system caches or modify unrelated files. Calibrate CPU staging and CUDA paths separately, then validate the complete pipeline with checksums and explicit buffer leases. Use bounded pinned/CUDA pools and held-out sizes. Record actual edges, service times, resource sharing, bytes, versions, and cold/warm status. Unavailable paths remain unsupported/not measured.

Use benchmark-owned bounded files and validate offsets, lengths, and integrity before reading. Record whether storage identity is verified as NVMe and whether cache state is controlled, merely observed, or unknown. A warm page-cache read is a RAM-backed path even if the file resides on NVMe; do not label its measured rate physical storage throughput. Avoid global cache-flush actions and unrelated file mutation. File I/O and CPU packing use monotonic host timing, while CUDA legs use compatible completed events or broader host completion contracts. Keep one path model per direction, size range, layout, pinning, and concurrency. A serial sum and a steady-state pipeline maximum answer different questions and require fill/drain corrections for finite work. Include shared-resource constraints: two nominal stages can compete for one host-memory subsystem or interconnect root. Validate on held-out chunk sizes and bounded buffers, retaining checksum results and prediction residuals. Missing path support should produce a capability gap or conservative fallback, not a fabricated universal NVMe-to-GPU bandwidth.

Separate path latency from a pipeline's first-result and steady-throughput metrics. Record read submission, completed host-buffer readiness, CUDA-buffer readiness, and final consumer completion as distinct events. Validate partial final chunks with their actual byte counts; padding belongs to copied payload only when the path really transfers it. If a stage model assumes a full chunk while the measured last chunk is smaller, preserve that discrepancy rather than adjusting the denominator silently. Include finite-buffer stalls in the pipeline model and identify whether they arise from capacity or a shared resource.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MemoryPathModel:
    source_tier: str
    destination_tier: str
    size_range_bytes: tuple
    context_identity: str
    overhead_seconds: object
    sustained_bytes_per_second: object
    uncertainty: object
```

```
def predict_three_tier_pipeline(path_models, schedule, resource_graph):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw path samples, fit ranges/residuals, file-cache evidence, complete pipeline makespan, memory bounds, correctness, and bottleneck prediction errors. Do not equate page-cache throughput with NVMe bandwidth or sum isolated bandwidths to obtain a pipeline rate. Preserve shared-resource uncertainty and distinguish initial latency from steady useful throughput.

Part 7 - Engineering Interpretation and Philosophy

Choose the chunking and prefetch decision supported by the calibrated resource graph. Explain why the slowest isolated path is not always the observed pipeline bottleneck.

19.46.19 Exercise 18

Exercise Title: Stress-Test the Bandwidth Profiler with Concurrent Prefetching, Eviction, KV Transfers, Multi-GPU Communication, and GPU Compute and Identify Link Contention

Part 1 - Exercise Contract and Why It Matters

Stress the profiler with prefetch, eviction, KV-like copies, optional multi-GPU communication, and compute. Identify contention through matched replays and supported trace evidence while preserving data validity.

Part 2 - System and Memory Mental Model

Concurrent tasks can share host memory bandwidth, interconnect roots, copy resources, device DRAM, or CPU submission capacity. Slowdown alone does not uniquely identify the shared link. KV or dirty-state transfers need stable versions and buffer lifetimes; moving mutable data without an ownership protocol can corrupt results. Heavy collectives require a validated rank/group contract and must not be introduced by mismatched launch order.

Part 3 - Quantitative Prediction Before Execution

Define isolated, pairwise, and combined bounded cases with fixed useful bytes and compute. Predict which resource may be shared and what measurement would distinguish it from another cause. Include a case with rising aggregate rate but worse reload-tail latency. Calculate staging and event-pool capacity before launching contention tests.

Part 4 - Experimental Design and Instrumentation

Validate each component independently, then change one concurrent load at a time. Use disjoint versioned buffers, explicit ready/last-reader events, and fixed seeds. Keep optional collective groups and operation order consistent. Measure completed per-path and common makespan distributions, with profiling in separate replays. Record topology, directions, sizes, pinning, shape, dtype, concurrency, and pressure mechanism. Use bounded application quotas or retained buffers with honest labels. Recover safely after failure before another comparison, preserving failed samples and configurations.

Create isolated calibrations, then matched pairwise and combined replays with fixed useful work. Keep tensor versions stable while a transfer reads them; mutable KV data requires a snapshot or an explicit producer-consumer handoff before offload. Use separate slots for incoming prefetch and outgoing eviction, with generations and final-reader events before reuse. Record whether a slowdown affects one direction, all transfers, compute, or host submission. That pattern can guide investigation but does not alone identify a physical shared link. Optional collectives require consistent rank groups and launch order before adding contention; unavailable multi-GPU execution remains not measured. Distinguish actual retained pressure allocations from application quotas or injected delays. Preserve latency tails and aggregate rate because a high total throughput can coexist with unacceptable reload stall. After asynchronous failure or timeout, do not free in-flight storage until a safe completion or recovery path resolves it. Minimize counterexamples by removing one concurrent load at a time while keeping shapes, values, and the remaining dependency graph unchanged.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_bandwidth_contention_cases(capabilities, resource_limits):
    ...

def validate_versioned_transfer_lifetimes(case, task_registry):
    ...

def compare_isolated_and_contended_paths(replays, evidence):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export useful bytes, path/context, isolated and contended distributions, aggregate rate, tails, pressure, peaks, errors, and failure phase. Do not call every slowdown PCIe saturation or fragmentation. Include a minimal counterexample to an independence assumption, or state none was observed. Unavailable devices and unsupported counters remain explicit rather than borrowed hardware results.

Part 7 - Engineering Interpretation and Philosophy

Explain the strongest supported contention attribution and its remaining uncertainty. Choose a scheduling or residency change that targets the observed resource conflict without violating data lifetimes.

19.46.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Bandwidth-Aware Runtime Profiler That Measures Every Memory Path and Feeds Transfer-Cost Estimates into Dynamic Placement and Offloading Decisions

Part 1 - Exercise Contract and Why It Matters

Integrate a reusable path-aware bandwidth profiler that supplies latency and transfer-cost estimates to placement/offload decisions. Benchmark complete correct useful work and instrumentation overhead under explicit resource limits.

Part 2 - System and Memory Mental Model

A runtime model needs direction, size, dtype, layout, pinning, topology, cache policy, concurrency, timing scope, and age. One scalar bandwidth cannot represent every memory path. Supported paths require validating runs; unavailable NVMe, peer copies, custom kernels, counters, or collectives remain explicit capability gaps. A prediction is a scoped estimate rather than a reservation of bandwidth or future completion time.

Part 3 - Quantitative Prediction Before Execution

Predict pool capacity, pending tasks, event overhead, and calibration cost before integration. Define held-out sizes, acceptable error, timing validity, and a concrete decision such as batch size, prefetch distance, or residency choice. Compare fixed-rate and path-aware models on identical traces. Keep feasibility in bytes and latency/throughput objectives in compatible units.

Part 4 - Experimental Design and Instrumentation

Validate unit conversions, copy correctness, event domains, and lifetimes before collecting calibration data. Use separate correctness, profiling, ordinary timing, and contention replays. Preserve E00's record plus path schemas, fit ranges, generations, capacity limits, and authority policies. Export bounded CPU evidence. If testing training, time complete forward, backward, optimizer update, and required completion rather than only the favorable transfer region. Include calibration/monitoring overhead in adaptive throughput. Reject stale or unsupported cost queries conservatively.

Publish a capability matrix for H2D/D2H, same-device D2D, verified or unverified peer candidates, CPU-staged copies, file/RAM paths, layout tests, optional controlled-lane kernels, traffic counters, concurrency, and Roofline analysis. Each supported entry needs a validating run ID. A method signature or available import is not proof that every path was measured. Store model fit range, timing scope, byte convention, sample count, context, uncertainty, and age with each cost estimate. Test held-out queries and preserve residuals rather than silently expanding a calibration's validity. Compare the concrete runtime decision against a fixed-rate baseline on the same trace, including monitoring and calibration overhead. Keep memory feasibility separate from latency objectives and reject unsupported or stale queries conservatively. A requested-byte rate, temporal overlap percentage, and physical traffic counter answer different questions and should remain separately labeled. The final conclusion should identify the best tested decision, its complete cost, and its capability limits without promising that every memory path shares one bandwidth model or that theoretical ceilings predict application throughput exactly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class BandwidthAwareRuntimeProfiler:
    def validate_path(self, path_spec, capabilities):
        ...

    def collect_completed_samples(self, workload, contract):
        ...

    def fit_scoped_path_model(self, sample_rows):
        ...

    def predict_transfer_cost(self, request, execution_context):
        ...

    def export_cpu_evidence(self):
        ...

def E19(config):
    # Integrate validated profiling and test a concrete runtime decision.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Each run needs ID, configuration, shapes, bytes/convention, path, budgets, peak allocated and reserved memory, raw timing scopes, distributions, correctness, outcome, and failure phase. Report rejected records, model residuals, overhead, and the smallest counterexample to a universal bandwidth rule, or state none was observed. Do not invent hardware outcomes. Every supported feature needs a validating run ID, not merely a scaffold method.

Part 7 - Engineering Interpretation and Philosophy

Justify the selected runtime decision through correct values, completed measurements, scoped cost models, and end-to-end benefit. Identify untested conditions that could change its prediction.

19.47 DMM45

Chapter Title: CUDA Memory Leak Detection and Root-Cause Analysis
Specialization: Dynamic Memory Management and CUDA Systems

19.47.1 Exercise 00

Exercise Title: Build a Precise Mental Model of True Memory Leaks, Tensor Retention, Allocator Caching, Autograd Graph Retention, and Non-PyTorch CUDA Allocations

Part 1 - Exercise Contract and Why It Matters

Define a leak investigation contract that separates unintended retention, allocator caching, graph structure, saved tensors, pending CUDA work, and allocations outside the PyTorch allocator. Deliver hypotheses and falsifiable tests rather than diagnosing every rising VRAM graph as a true leak.

Part 2 - System and Memory Mental Model

A reachable Python container retaining tensors is unintended application retention when the workload no longer needs them; it is not necessarily an unreachable native allocation leak. Reserved cache can remain after live storage is released. Backward normally releases saved tensors when their retention is not requested, even if a Python tensor still references graph structure. External libraries and other processes can affect device-wide readings outside PyTorch's allocator visibility.

Part 3 - Quantitative Prediction Before Execution

Draw reference ownership, storage aliases, autograd nodes, saved tensors, and stream readers for one iteration. Predict current live bytes, reserved capacity, and historical peak under steady training, growing history, and one-time optimizer initialization. Define a matching completed measurement phase and a bounded test range. Explain why a peak counter alone cannot establish a persistent growth trend.

Part 4 - Experimental Design and Instrumentation

Use a small deterministic FP32 model and fixed input shape. Choose supported Adam settings and include forward, backward, and optimizer update. Freeze gradient-clearing and loss semantics. Record GPU identity, versions, allocator backend, seed, shape, optimizer, warmup, phase, stream completion, process mode, and initial state. Keep diagnostic CPU histories bounded and avoid GPU objects in evidence logs. Pin history/snapshot APIs to installed capabilities, including documented underscore-prefixed diagnostic interfaces whose schemas can change.

Create a classification table for reachable tensor history, a reference cycle, an intentionally bounded cache, pending stream release, first-update optimizer state, and an external allocator. For each, state what remains owned, which counter can see it, and which intervention would test the hypothesis. Keep the word leak qualified until ownership and intended lifetime are established. A Python object can disappear while another view keeps the backing allocation alive, and a native allocation can remain without a visible Python tensor. Draw those cases separately. Choose one fixed completed training phase for trend detection and preserve unsynchronized samples only under an explicit pending-work contract. The investigator must not change loss weighting, batch size, or completed update count to obtain a flatter curve. Keep memory limits and stop conditions independent of whether the expected bug has appeared. The strongest conclusion is a scoped causal explanation supported by a minimal repair and matched useful work, with unknown visibility left unresolved rather than assigned to a convenient allocator or operator name.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LeakInvestigationContract:
    measurement_phase: str
    warmup_policy: str
    resource_limit_bytes: int
    iteration_limit: int
    allocator_backend: str
    expected_persistent_state: object

def classify_memory_growth_evidence(samples, contract, ownership):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Require same-phase evidence, owner or lifetime clues, and a controlled intervention before claiming root cause. Unknown fields and unrun GPU cases remain explicit. A diagnostic system must not retain the graphs it is trying to investigate.

Part 7 - Engineering Interpretation and Philosophy

Explain the distinction between allocation origin and the object that keeps it alive. Choose the smallest evidence set that can distinguish the competing explanations without overstating certainty.

19.47.2 Exercise 01

Exercise Title: Build a Stable PyTorch Training Loop and Establish the Expected Allocated, Reserved, and Peak VRAM Pattern Across Hundreds of Iterations

Part 1 - Exercise Contract and Why It Matters

Establish a stable fixed-shape training baseline over a bounded run of hundreds of iterations. Measure expected allocated, reserved, and peak patterns at named phases before injecting retention bugs.

Part 2 - System and Memory Mental Model

Adam state can appear lazily, gradients can be allocated or cleared, and kernels or allocators can warm up. A stable baseline is phase-dependent, not a requirement that every reading remain

identical from process start. Historical peaks are nondecreasing unless reset. Reserved cache can plateau above live payload. Variable shapes, compilation, distributed initialization, and legitimate caches need separate baselines.

Part 3 - Quantitative Prediction Before Execution

Inventory initialized parameters, gradients, moments, buffers, and expected transient activations. Predict first-update changes and a warmed post-update/post-clear range. Define the interval used for each peak and the evidence needed for a plateau. Predict a legitimate staircase or one-time jump that a naive positive-slope detector could misclassify.

Part 4 - Experimental Design and Instrumentation

Use fixed seeded batches, model dimensions, precision, optimizer flags, and gradient-clearing policy. Run a small numerical reference first. Sample current counters at a common completed phase and record per-iteration region peaks separately. Reset peaks only for the declared interval. Warm all used optimizer state before the primary steady window. Export CPU scalar rows, not tensors. Measure monitoring overhead against an uninstrumented replay. Repeat fresh processes and a secondary seed while preserving the primary initial-state identifier.

Use a small model whose parameters and initialized Adam moments can be counted from shapes and actual dtypes. Include a first iteration where those moments do not yet exist and a warmed window where they do. State whether gradients are set to None or zeroed in place, and keep that choice fixed. Sample before forward, after backward, after update, and after clearing in a diagnostic replay, then select one common phase for ordinary monitoring. The peak for an iteration must have a declared reset boundary; the process- lifetime peak cannot fall and should not be fitted as live use. Bound CPU sample history even when hundreds of iterations are requested. A fresh process helps isolate retained Python state but does not guarantee identical external GPU load. Record that context. Validate gradients and updates before introducing diagnostic changes, because a lower memory footprint obtained by skipping backward is not a stable training control. Report any legitimate state initialization that falls outside the chosen warmup rather than erasing it from the raw trace.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def run_stable_training_baseline(config, measurement_contract):
    ...

def sample_completed_iteration(runtime, iteration_id, phase):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw current/peak allocated and reserved bytes, initialized-state inventory, reset boundaries, sample age, update count, and numerical checks. Do not fit startup and warmed samples as one unexplained trend. If no stable window is reached, retain that result and investigate shape/state assumptions before labeling a leak. Include the expected allocator noise range and unsupported backend counters.

Part 7 - Engineering Interpretation and Philosophy

Explain what stable means for this declared workload. Preserve the baseline as the control for every later leaking and repaired replay.

19.47.3 Exercise 02

Exercise Title: Introduce a Deliberate CUDA Tensor Leak by Appending GPU Tensors to a Python List and Detect the Linear Memory Growth

Part 1 - Exercise Contract and Why It Matters

Introduce bounded unintended retention by appending independent CUDA tensors to a Python list. Detect same-phase live-memory growth and verify the container's ownership with a controlled release.

Part 2 - System and Memory Mental Model

A list can keep tensor storage reachable after the iteration's computation ends. Appending views or the same object repeatedly does not necessarily add independent storage, so the expected slope depends on actual backing ownership. Allocator rounding and segment growth affect counters differently. This is a deliberately bounded reproducer, not a request to exhaust the GPU.

Part 3 - Quantitative Prediction Before Execution

For n independent retained tensors with payload b bytes, predict useful retained bytes nb before rounding and metadata. Compare with repeated references to one tensor and small views of a larger parent. Define a stop limit below the declared resource budget. Predict current allocated and reserved trajectories and what changes after clearing the only owner.

Part 4 - Experimental Design and Instrumentation

Start from E01's stable training. Inject independent allocation retention at a named diagnostic point with fixed size and a hard iteration/byte cap. Record list length, unique backing identities, useful capacity, and same-phase memory. Validate numerical training is unchanged. In a separate intervention, remove the container ownership and complete required stream work, then observe live and cached counters. Keep ownership metadata on CPU without adding another strong GPU reference. Compare baseline, leaking, and release replays from the same logical initial state.

Choose a retained tensor size that produces a detectable payload trend without approaching physical exhaustion. Derive a hard maximum list length from the application budget before the run. Each appended object should have independently allocated storage in the primary reproducer; record that fact rather than assuming a new Python wrapper means new bytes. Add controls that append the same tensor repeatedly and that append small views of one large parent. Their list lengths can grow while their unique backing behavior differs. Release the

list under a named intervention and remove other diagnostic strong references before sampling. A remaining loop variable can retain the last item legitimately, so account for it rather than requiring the counter to return to an impossible exact baseline. Complete pending readers before interpreting reclamation. Keep training values and optimizer progress matched between leak and release variants. The result should identify owner-driven live storage growth even if reserved capacity changes only in coarse steps or remains flat during the bounded test.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def inject_bounded_tensor_history(history, tensor_spec, budget):
    ...

def audit_history_backing_ownership(history, observation_contract):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted payload slope, observed live slope, reserved steps, unique storage count, ownership intervention, and correctness. Do not require reserved bytes to drop immediately after release. A remaining alias can invalidate the expected release and needs investigation. Preserve cases where rounding masks a short-window slope or the tested range does not reach an allocator growth boundary.

Part 7 - Engineering Interpretation and Philosophy

Explain why reachable retention is sufficient to cause operational memory failure without proving a native unreachable leak. Identify the owner whose lifecycle the repair must change.

19.47.4 Exercise 03

Exercise Title: Fix the Leaking Tensor History with detach(), CPU Transfer, or Scalar Extraction and Prove That VRAM Usage Stabilizes

Part 1 - Exercise Contract and Why It Matters

Repair GPU history according to the diagnostic requirement and prove same-phase live memory stabilizes within the tested range. Compare detachment, CPU export, scalar extraction, and bounded retention under explicit contracts.

Part 2 - System and Memory Mental Model

detach severs gradient history but shares the original storage. Appending large detached CUDA tensors indefinitely still retains GPU bytes. A detached view can also keep a large backing allocation. For CPU diagnostics, use a graph-free export such as detach followed by CPU transfer, or a scalar extraction when only one value is needed. CPU history itself needs a retention budget; relocating an unbounded history changes the resource problem rather than making it disappear.

Part 3 - Quantitative Prediction Before Execution

Predict graph and storage ownership for original outputs, detached CUDA outputs, detached CPU copies, and CPU scalars. Define an expected plateau for a bounded GPU ring and growing host storage for an unbounded CPU archive. Identify which repairs satisfy the chosen diagnostic semantics rather than merely lowering one memory counter.

Part 4 - Experimental Design and Instrumentation

Replay the same workload and history insertion site with each policy. Keep detach-only as a negative control for independent large CUDA payloads. Use bounded CPU summaries or a bounded detached GPU ring for valid repairs. Wait appropriately before consuming asynchronous host copies and preserve source lifetime. Measure both CUDA and relevant host capacity, logging latency, and result equivalence. Complete hundreds of bounded warmed iterations where feasible. Record same-phase current bytes and distinguish retained cache from live payload after old GPU references are released.

State the diagnostic requirement before selecting a repair. If only a scalar metric is needed, storing a whole output tensor is unnecessary; if images or embeddings are needed, a bounded archive or streaming export has a different resource cost. Keep detach-only on a list of independent large CUDA values as a negative control. A clone of a detached CUDA tensor can create additional independent storage and does not solve unbounded history. For CPU export, sever unwanted gradient history and verify destination lifetime and completion before consuming it. CPU memory must also be bounded or intentionally archived; a flat CUDA curve with unbounded RAM is not a complete resource repair. Scalar extraction may block the host, so measure its logging overhead separately from ordinary GPU work. Confirm metric values and model updates still match the reference. Report the plateau only for the tested fixed-shape range and name the retention policy that makes it plausible, instead of claiming the absence of every possible leak from one flat graph.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def export_graph_free_diagnostic(value, policy, history_budget):
    ...

def verify_repaired_history_plateau(replay_rows, baseline, contract):
    ...
```

```
def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report storage/graph policy, history bounds, CUDA slope, host retention, logging cost, and numerical checks. Do not claim detach alone frees storage or that CPU transfer alone necessarily removes gradient references. Scalar extraction can synchronize the host; include its performance cost. State plateau evidence for the tested range rather than proving universal absence of leaks.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest diagnostic representation that preserves needed information. Explain whether the repair removes ownership, removes graph history, bounds retention, or moves data to another resource.

19.47.5 Exercise 04

Exercise Title: Create an Accidental Autograd Graph Leak by Accumulating Loss Tensors and Explain Why Every Iteration Retains Previous Computation Graphs

Part 1 - Exercise Contract and Why It Matters

Reproduce loss-accumulation graph retention with explicit backward timing. Distinguish retained graph structure from retained saved activations and identify which lifecycle produces the measured CUDA growth.

Part 2 - System and Memory Mental Model

Accumulating differentiable losses links iterations through autograd. If backward is deferred over a growing sum, saved tensors can remain live until that backward. If ordinary backward already ran each iteration without retention, saved buffers are normally released; keeping loss graph references does not imply every previous activation remains resident. A later backward through those freed graphs can fail. The title's growth hypothesis therefore needs a declared execution variant, not a universal claim.

Part 3 - Quantitative Prediction Before Execution

Draw graphs for deferred aggregate backward and for per-iteration backward followed by logging-style accumulation. Predict nodes, scalar storage, and saved tensors separately. Define a bounded window for the deferred case and compare one aggregate gradient with correctly normalized sequential accumulation. Explain why resetting only the Python variable can leave other references alive.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic model and fixed data. Run separate bounded variants: deferred loss-sum backward, ordinary per-step backward with retained loss references, and graph-free logging. Keep optimizer updates only at the correct objective boundary for each valid training comparison. Measure same-phase CUDA counters plus graph/owner metadata and supported saved-tensor evidence. Validate gradients and updates against the matching serial objective. Do not execute a second backward through freed graphs as if it were a valid repair; classify its expected failure separately.

Define two different valid objectives rather than mixing them in one training comparison. Deferred aggregate loss over a bounded batch/window needs a corresponding normalized full-window reference and an optimizer step after its required backward. Ordinary per-iteration training computes and backpropagates each loss before the next update; retaining its output for logging is a separate ownership decision. In the latter case, graph nodes can remain referenced while default backward has released saved intermediates. A later backward on the accumulated logging total can therefore fail instead of providing a valid aggregate gradient. Do not use that failure as a reason to add retain_graph everywhere. Measure graph metadata and saved CUDA storage under their different scopes. Reset the aggregate and release all owners at the bounded-window end, checking aliases and pending work. Preserve cases where host metadata grows more visibly than CUDA bytes. The exercise should show which lifecycle retains which objects, not repeat the false universal claim that every surviving loss keeps every previous activation alive.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_bounded_loss_accumulation_case(config, backward_policy):
    ...

def inspect_loss_graph_and_saved_state(case, observation_contract):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report backward order, retain policy, objective, graph references, current live bytes, host growth, and gradient correctness. Avoid attributing all CUDA growth to graph nodes without storage evidence. Preserve a per-step case with little CUDA growth if that is observed. Show the intervention that releases the relevant owner and compare with graph-free metrics.

Part 7 - Engineering Interpretation and Philosophy

Explain precisely which objects survive and why. A useful diagnosis must distinguish an expanding differentiation history from full saved-activation retention.

19.47.6 Exercise 05

Exercise Title: Compare running_loss += loss, running_loss += loss.item(), and running_loss += loss.detach() by Graph Retention and CUDA Memory Growth

Part 1 - Exercise Contract and Why It Matters

Compare the three running-loss expressions under one explicit logging contract. Measure graph references, live CUDA bytes, host state, and synchronization cost without assuming every differentiable accumulation retains all activations.

Part 2 - System and Memory Mental Model

A Python numeric accumulator updated with loss.item stays graph-free and does not retain a CUDA loss tensor, but extraction can synchronize. An in-place scalar accumulator updated with detached losses can remain a constant-sized CUDA tensor if no history stores each detached value. Updating with differentiable losses can extend graph structure. After ordinary per-step backward, saved buffers may already be freed even though the accumulation still links nodes. These behaviors differ from a list of large outputs.

Part 3 - Quantitative Prediction Before Execution

Define accumulator initialization, dtype, device, in-place behavior, and reset boundary. Predict graph connectivity and persistent scalar storage for each expression. Separate a fixed scalar accumulator from an append-only history. Include a graph-retaining deferred-backward variant only as a separately named experiment. Predict host synchronization differences without inventing measured speedups.

Part 4 - Experimental Design and Instrumentation

Use the same model, data, per-step backward, optimizer, and clearing policy across the primary logging variants. Never backpropagate the running logging sum as an extra training loss. Inspect requires_grad/grad_fn and supported owner metadata without retaining new GPU objects. Measure warmed same-phase bytes and logging latency separately. Compare gradients and several updates to confirm logging has not changed training. Reset accumulators at a named epoch or window boundary and preserve valid scalar totals.

Initialize each running accumulator explicitly so the comparison does not depend on an accidental Python-to-tensor promotion. Record its device, dtype, requires_grad state, and update form. A constant-sized detached CUDA scalar updated in place differs from a Python list that stores every detached loss. Likewise, a Python float total has no CUDA payload but an external history of Python objects still has a host-memory lifecycle. Use per-step loss backward in the primary logging comparison and never backpropagate the running diagnostic total afterward. Verify accumulated scalar values under a declared tolerance, since reduction order and scalar dtype can differ. Inspect model gradients before Adam and moments after several updates to ensure the logging variants did not change the objective. Keep item-related host synchronization visible in end-to-end timing. If differentiable accumulation extends graph structure but saved activations were already released, report that exact result rather than forcing the expected large CUDA slope. The repair choice should follow the needed diagnostic representation and performance budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def define_running_loss_case(expression_policy, reset_contract):
    ...
```

```
def compare_running_loss_variants(cases, reference, measurements):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report initialization, expression, graph state, scalar capacity, history policy, CUDA/host trend, logging time, and numerical totals. Do not call detached scalar accumulation an unbounded CUDA leak without evidence. Do not claim item is free. If graph metadata grows mainly on the host, record that scope rather than inventing large retained activation bytes.

Part 7 - Engineering Interpretation and Philosophy

Choose the logging policy according to required diagnostics and acceptable synchronization. Explain why graph-free and storage-free are different properties.

19.47.7 Exercise 06

Exercise Title: Leak Model Outputs Through a Metrics or Debug Dictionary and Trace the Retained CUDA Storage Back to the Owning Python Container

Part 1 - Exercise Contract and Why It Matters

Retain model outputs through a metrics/debug dictionary and identify the owning application path. Repair the lifetime while preserving required metrics and numerical training.

Part 2 - System and Memory Mental Model

A fixed dictionary key overwritten each iteration differs from a key per iteration or a nested append-only list. Values can share backing with large tensors, and aliases elsewhere can survive dictionary cleanup. Allocation traces locate creation but do not enumerate Python owners automatically. Introspection can itself create references, so ownership evidence needs a bounded, nonretaining design.

Part 3 - Quantitative Prediction Before Execution

Construct fixed-key, growing-key, and nested-history cases. Predict unique backing bytes rather than summing every tensor name. Add a small-view case that retains a large output backing. Define the exact application owner path and a repair that bounds or exports the needed diagnostic. Predict why clearing one container might not release storage if another alias exists.

Part 4 - Experimental Design and Instrumentation

Instrument insertion with logical output IDs, owner path strings, iteration, and storage metadata exported to CPU. Use bounded weak-reference or application-registry checks where appropriate, recognizing wrapper lifetime is not identical to backing lifetime. Compare baseline, leak, and repaired replays with the same training objective. Release diagnostic traversal locals

before sampling. Use controlled container removal and an alias negative control. Avoid printing whole CUDA values or retaining gc/referrer results inside the investigation report.

Instrument the actual ownership path: a top-level debug dictionary can contain a nested list, a callback closure, or a per-request object that outlives training. Record path strings and logical output generations at insertion rather than storing another tensor in the registry. A fixed-key overwrite can be bounded even though the tensor object changes every iteration, while an iteration-keyed dictionary can grow. Count unique backing capacity and preserve alias relationships. In a small controlled case, remove one owner while keeping another alias to show why one cleanup is insufficient. Weak references can help observe a Python wrapper's lifetime, but their expiry does not prove a shared storage has no remaining owners. Referrer tools can expose their own temporary frames and containers; release traversal results before measuring and avoid retaining them in reports. Keep value formatting on CUDA outside ordinary timing. The causal test is a bounded/exported ownership policy that removes the cohort's growth while preserving the same metrics and training updates.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def record_container_insertion(owner_path, value, iteration, registry):
    ...

def inspect_declared_container_ownership(container_spec, registry):
    ...

def repair_metrics_retention(policy, diagnostic_contract):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report owner paths, key/history growth, unique backing, graph policy, release intervention, same-phase trend, and update errors. Do not infer all owners from a snapshot address. If introspection is incomplete, mark the unresolved path. Verify the investigation's registry contains metadata rather than the retained GPU values themselves.

Part 7 - Engineering Interpretation and Philosophy

Explain how a correct metric implementation can become an ownership bug. Choose a diagnostic representation whose retention is intentional and bounded.

19.47.8 Exercise 07

Exercise Title: Create a Forward Hook That Accidentally Retains Activations Across Iterations and Repair the Hook Without Losing Required Diagnostics

Part 1 - Exercise Contract and Why It Matters

Create a forward hook that retains activation storage across iterations, then repair its diagnostics and hook lifecycle. Demonstrate numerical equivalence and bounded retention after the change.

Part 2 - System and Memory Mental Model

A hook can capture outputs in a closure, append them to external history, or be registered repeatedly. Removing one handle does not clear already retained values or other registered hooks. Detaching a captured CUDA activation removes graph history but still retains its backing. Hooks should not accidentally return a replacement output or modify training values while attempting to observe them.

Part 3 - Quantitative Prediction Before Execution

Predict history and registration growth for one persistent hook versus one new hook per iteration. Calculate retained payload for independent activations and shared-view cases. Define a bounded CPU summary or bounded activation policy that preserves the intended diagnostic. Specify registration, handle removal, history cleanup, and last-reader completion as separate lifecycle events.

Part 4 - Experimental Design and Instrumentation

Register the controlled hook once and record owner metadata at insertion. Use a fixed deterministic model and hard run/memory limits. Validate the leak pattern, then repair capture/export and guarantee handle cleanup under the runtime's lifecycle. Test repeated setup/teardown to catch duplicate registration. Compare outputs, gradients, and several updates with the no-hook reference. Measure hook overhead separately from ordinary training. Ensure asynchronous CPU exports use safe completion before consumption and bounded staging capacity.

Separate hook registration count from captured-value count. A single correctly registered hook can leak through an unbounded closure history, and repeatedly registering even a bounded hook can multiply work and owners. Keep handles in an explicit lifecycle registry and test cleanup on normal and exceptional exit paths. Removing a handle prevents future callbacks; it does not automatically clear old captured values. The primary hook observes output and returns no replacement, avoiding accidental modification of forward semantics. Record a tiny view case that keeps a larger activation backing alive. Compare bounded graph-free CPU summaries with detached CUDA history under their real storage costs. If asynchronous export is supported, retain the source until copy completion and bound staging as well as history. Run repeated setup/teardown to expose duplicate hooks and verify callback counts. Report diagnostic overhead and numerical equivalence. Do not accept a flat curve obtained by removing a hook that was required for actual model computation; the primary diagnostic hook must be observational.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def install_bounded_diagnostic_hook(module, diagnostic_policy, registry):
    ...

def remove_hook_and_owned_history(handle, owner_registry, completion):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export handle identities, registration count, owner history, storage policy, CUDA trend, overhead, and numerical checks. Removing a hook without clearing its retained history is not a complete repair. A detached CUDA-history variant is a negative control, not proof of released storage. Preserve any untracked closure ownership as unresolved.

Part 7 - Engineering Interpretation and Philosophy

Explain the hook's ownership chain and cleanup proof. Choose diagnostics that observe the model without extending activation lifetimes unnecessarily.

19.47.9 Exercise 08

Exercise Title: Reproduce Memory Growth from Repeated retain_graph=True Usage and Determine When Retaining the Graph Is Actually Necessary

Part 1 - Exercise Contract and Why It Matters

Reproduce bounded graph retention using retain_graph=True together with an explicit surviving owner. Determine when repeated differentiation genuinely requires retention and when normal graph release or recomputation is preferable.

Part 2 - System and Memory Mental Model

retain_graph preserves saved state for another traversal of a graph; it does not by itself prove an indefinitely growing leak if no references survive and the graph becomes unreachable. Fresh graphs stored each iteration with retained saved tensors can accumulate substantial memory. create_graph is a different higher-order differentiation choice with its own reference risks. Parameters must not be updated while a later backward still requires their old graph version.

Part 3 - Quantitative Prediction Before Execution

Compare one graph traversed twice with bounded lifetime, fresh retained graphs held in a growing container, and fresh graphs released normally. Predict saved-tensor and graph-structure lifetimes. Define a legitimate multi-loss derivative calculation and its final releasing backward. Contrast with the accidental use of retention to suppress an unrelated autograd error.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic model with a hard graph-count budget. Validate required gradients against a matching reference before timing memory. Keep the optimizer step after all necessary backwards for that parameter version. For the accumulating case, preserve explicit owners and measure same-phase state; for the release control, remove owners and complete pending work. Do not use in-place mutation or a second backward through freed state as a valid training path. Treat higher-order cases as optional separately validated support.

Use one legitimate graph with two required derivative traversals as a bounded control. Preserve its parameter version until both traversals are finished, then use the appropriate release and remove its Python owners. Compare with a case that stores a fresh graph each iteration after requesting saved-state retention. Both the flag and the surviving ownership policy belong in the report. If no references remain, do not assume retain_graph alone creates an infinite collection of graphs. create_graph introduces higher-order differentiation semantics and possible cycles that need separate validation; it is not merely another spelling of retain_graph. Inspect saved state through supported diagnostics rather than private grad_fn fields treated as a universal schema. Never update a weight between backwards that still need the old value, and do not mask a version-counter error by disabling checks. Preserve the exact gradient objective and compare multiple updates. A successful repair removes unnecessary retention or recomputes deliberately, while retaining any derivative the algorithm genuinely requires.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_retained_graph_case(config, ownership_policy):
    ...

def validate_required_backward_lifecycle(case, reference):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report graph count, surviving owners, retain/create settings, saved state, parameter version, live bytes, and derivative correctness. Include a control where retain_graph does not yield unbounded growth. Do not recommend retention as a generic fix for an autograd error. Verify final release of the legitimate multi-traversal case separately from the leaked-container case.

Part 7 - Engineering Interpretation and Philosophy

Explain which differentiation requirement justifies retention and which application owner makes it persist. A useful repair changes that lifecycle without discarding a required derivative.

19.47.10 Exercise 09

Exercise Title: Build an Iteration-Level Leak Detector That Fits a Memory-Growth Trend and Flags Persistent VRAM Growth Above Expected Allocator Noise

Part 1 - Exercise Contract and Why It Matters

Build an iteration-level detector for persistent same-phase memory growth. Fit scoped trends, flag candidate anomalies, and evaluate false alarms against legitimate initialization, cache growth, and variable shapes.

Part 2 - System and Memory Mental Model

A positive slope can reflect intended state, pending work, changing shapes, or instrumentation. Reserved-memory steps and historical peaks do not equal live leaks. Short noisy windows can hide small retention or overreact to one jump. The detector identifies suspicious growth, not root cause or proof of future OOM.

Part 3 - Quantitative Prediction Before Execution

For warmed current bytes A_k at a fixed phase, define a trend model $A_k \approx \alpha + \beta k$. Keep bytes per iteration distinct from bytes per second. Compare a persistent linear trace, a one-time step then plateau, a sawtooth, and a noisy stationary trace. Declare window length, minimum effect, persistence rule, and uncertainty policy before evaluation.

Part 4 - Experimental Design and Instrumentation

Validate on synthetic traces with known labels, then on E01, E02, and repaired controls in fresh replays. Preserve sample phase, shape, update count, backend, and completion convention. Use multiple windows or a stated robust method rather than blindly accepting one fitted line. Record warmup exclusions and missing samples. Calibrate thresholds on named traces and test held-out growth rates and patterns. Bound history and alert frequency so the detector does not become another retention source.

Build synthetic traces with known byte units and iteration IDs before fitting hardware data. Include a slow linear trend hidden by noise, a one-time jump, a bounded growing cache, and a missing-sample interval. Keep current allocated bytes separate from reserved capacity and nonreset peaks. Define minimum sustained effect and sample-window requirements so a short startup step does not automatically trigger a leak alert. If the shape changes, stratify by shape or establish a new expected-state contract rather than fitting incompatible populations. Preserve fit residuals and an indeterminate status when evidence is weak. Evaluate false positives and false negatives on held-out patterns instead of choosing thresholds after seeing each test. A time-based slope requires actual elapsed timestamps and is not interchangeable with bytes per update. Conditional OOM extrapolation needs capacity, continued growth, unchanged workload, and allocator assumptions; report it as a hypothesis rather than a deadline. Bound retained sample history and alert artifacts so detection overhead remains measured and finite.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
```

```
@dataclass
class GrowthTrendDecision:
    window_identity: str
    phase: str
    slope_bytes_per_iteration: object
    uncertainty: object
    classification: str
    limitations: tuple

def fit_and_classify_growth(cpu_samples, detector_contract):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw samples, slope, fit range, residuals/uncertainty, threshold, label, detection delay, and false positives/negatives. Do not insert zero for missing readings or fit nonreset peaks as current use. A predicted OOM iteration is at most a conditional extrapolation with explicit assumptions. Preserve indeterminate classifications where evidence is insufficient.

Part 7 - Engineering Interpretation and Philosophy

Choose a detector for investigation triage rather than automatic blame. Explain which extra ownership or lifetime evidence the alert should trigger.

19.47.11 Exercise 10

Exercise Title: Compare memory_allocated(), memory_reserved(), and torch.cuda.device_memory_used() to Distinguish Live PyTorch Tensors from Cached and External CUDA Memory

Part 1 - Exercise Contract and Why It Matters

Compare process-local allocated/reserved counters with device-level used memory. Distinguish live PyTorch storage, cached allocator capacity, external-library use, and unrelated process activity without an exact residual claim unsupported by the measurement scopes.

Part 2 - System and Memory Mental Model

memory_allocated and memory_reserved describe the calling process's allocator on the selected device. device_memory_used reports global device use through supported management interfaces, not this process's tensor total. The gap can include contexts, libraries, other processes, rounding, sampling skew, and retained cache. Reserved bytes already encompass allocated capacity; they must not be added as independent categories.

Part 3 - Quantitative Prediction Before Execution

Predict readings for a live tensor, its release into cache, an optional bounded external allocation, and another process using the same GPU. Define sampling order and timestamp

tolerance. Compare device use against allocator reserved capacity only as contextual evidence, not a precise external-allocation inventory. Explain why device use minus allocated bytes also includes PyTorch cache and cannot identify a culprit.

Part 4 - Experimental Design and Instrumentation

Warm contexts deliberately and use explicit device identity. Sample all three counters at matching completed phases, recording backend and management- API availability. Run isolated allocator cases first and controlled external or second-process cases only if available. In distributed mode, collect owned- device CPU rows and avoid duplicating a global device reading when summarizing. Keep unknown external activity explicit. Measure the effect of cache release only in a separate diagnostic intervention, not in every baseline iteration.

Use explicit device identity and record whether the first query initialized another context or management interface. Current allocator counters belong to the calling process and selected device, while global device usage can include unrelated processes. Capture sampling timestamps because subtracting values taken during different phases can create a false residual. Include a cache-retention control where live allocated bytes fall after release but reserved bytes remain. A separate optional cache-release intervention can show unused capacity returning, yet it cannot release live references or identify an external library. Do not add allocated and reserved bytes as independent use. If several ranks share a physical GPU, their process-local allocator inventories may differ while their global readings repeat the same device state; avoid summing that global number several times. Preserve backend and API availability, including management-library failures. A growing visibility gap should trigger more specific evidence, not an immediate native-leak label. Explain which part of the observation is exact API scope and which part remains a hypothesis about ownership.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def sample_allocator_and_device_scopes(device, phase, capabilities):
    ...

def compare_memory_scopes(rows, process_inventory, sampling_contract):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw counters, timestamps, device identity, process scope, API support, and residual interpretation. Do not treat a positive difference as proof of a native leak. If management data is unavailable, report unsupported rather than substituting reserved or zero. A cache intervention cannot free live objects or prove external ownership.

Part 7 - Engineering Interpretation and Philosophy

Choose the next investigation step from the visibility gap. Explain which claims require per-process library evidence beyond these three counters.

19.47.12 Exercise 11

Exercise Title: Record CUDA Allocation History and Capture Baseline and Leaking memory_snapshot() States at Matching Training Iterations

Part 1 - Exercise Contract and Why It Matters

Enable bounded allocation history and capture baseline/leaking snapshots at matching completed training phases. Preserve versioned schema and trace coverage so later diffs can distinguish observation from missing history.

Part 2 - System and Memory Mental Model

Allocator snapshots show managed segments/blocks and, when recorded, allocation origins and event history. They do not automatically identify Python retaining owners or all native CUDA allocations. Public memory_snapshot and documented underscore-prefixed history/snapshot helpers can expose different structures depending on version. History ring buffers can overwrite older events; missing allocation/free records are not evidence those events never occurred.

Part 3 - Quantitative Prediction Before Execution

Choose warmup, recording start, capture iteration IDs, phase, maximum history entries, and artifact bounds. Predict which E02 retained blocks should survive between two captures. Define requested versus rounded block size and pending-free states separately. Estimate diagnostic host/storage overhead and identify the history coverage needed for lifetime reconstruction.

Part 4 - Experimental Design and Instrumentation

Check installed API signatures and normalize the actual returned schema through a versioned adapter. Enable bounded recording before the allocation window of interest. Capture baseline and leaking fresh replays at equivalent post-update/post-clear boundaries, with initialization and data held fixed. Record stream-completion policy and history truncation. Export snapshot artifacts from the learner runtime with run/phase metadata; disable recording at the declared end. Keep ordinary memory/timing runs separate from heavy diagnostics and avoid retaining all snapshots in an unbounded Python list.

Enable history early enough to include the cohort of interest and record its start boundary. A bounded ring can overwrite old allocation events, so the adapter must expose coverage and truncation instead of pretending every lifetime is complete. Capture the same iteration and completed phase in fresh baseline, leak, and repair replays, with the same model/data state. Preserve requested size, rounded capacity, block state, device, frames, and any supported allocation-generation evidence. Public snapshot output and richer diagnostic snapshot dictionaries should not be parsed through one assumed structure. Validate the installed schema and fail clearly on unsupported fields. Keep recording limits, capture frequency, and artifact retention bounded. Heavy diagnostic runs may change timing and host memory, so compare them with a minimally instrumented replay. Stop recording at the declared boundary and export CPU summaries. The learner's system should retain references to capture artifacts and metadata, not an indefinitely growing list of raw snapshots inside the training loop. Missing stacks remain missing rather than invented source lines.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def configure_bounded_allocator_history(capabilities, capture_contract):
    ...

def capture_matching_snapshot(runtime, run_id, iteration, phase):
    ...

def normalize_snapshot_schema(raw_snapshot, version_identity):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report API/version, schema, capture phase, trace range, truncation, segment/block states, bytes, and instrumentation overhead. Preserve unsupported fields and incomplete coverage. A snapshot file's existence is not proof that stack recording was enabled early enough. Do not label allocations outside visibility as absent from the real device.

Part 7 - Engineering Interpretation and Philosophy

Explain which questions the capture can answer and which need ownership or external-library evidence. Choose the smallest diagnostic window that preserves the required allocation history.

19.47.13 Exercise 12

Exercise Title: Diff Two Memory Snapshots and Identify Allocations That Persist or Grow Only in the Leaking Workload

Part 1 - Exercise Contract and Why It Matters

Diff normalized snapshots and identify suspicious persistent or growing allocation cohorts. Distinguish within-run allocation identity from cross-run semantic comparison.

Part 2 - System and Memory Mental Model

An address can be freed and reused for a different allocation. Exact within-run persistence needs generation/event evidence where available. Two states alone can only show endpoint presence under their limits. Fresh baseline and leaking runs need not share addresses; compare cohorts by supported stack, size, role, phase, and workload identity rather than pointer subtraction. Persistent parameters and moments are expected survivors.

Part 3 - Quantitative Prediction Before Execution

Define new, freed, surviving, reused/ambiguous, and pending-free classifications. Hand-diff synthetic records containing address reuse, rounding, and missing history. Calculate useful requested bytes and actual block capacity separately. Predict the E02 cohort's growth after removing expected persistent state, while preserving uncertainty when allocation generations are unavailable.

Part 4 - Experimental Design and Instrumentation

Use E11's matching captures and a bounded history window. Normalize backend/schema fields before comparison. Match within-run generations only with adequate trace evidence and classify truncation honestly. Build cross-run cohort summaries under the same model, shape, seed, and phase. Compare baseline, leak, and repair. Export compact CPU suspect rows and stack references rather than copying every tensor. Validate the diff on synthetic cases before interpreting real captures. Keep inactive cache and active-awaiting-free blocks distinct from live allocated blocks.

Test the diff on an address allocated, freed, and reused between captures. The address can appear in both endpoint states without continuous lifetime. When event/generation evidence is missing, classify identity as ambiguous. For separate runs, compare semantic cohorts using supported creation stacks, requested sizes, logical roles, and phase; different raw addresses are expected. Do not remove all repeated stacks as baseline state, because an operator can create both expected parameters and unintended retained outputs. Preserve cohort counts and byte deltas alongside expected persistent ownership. Separate inactive cache, active allocation, and awaiting-free states before ranking. A pending free that completes after a deliberate reader boundary has a different explanation from a list retaining tensors. Include trace coverage and schema version in every diff result. Validate a proposed suspect against the repaired replay and owner evidence. The output should distinguish what is observed at endpoints, what is reconstructed from event history, and what is inferred from semantic matching across runs.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class AllocationDiffRow:
    cohort_identity: str
    identity_evidence: str
    classification: str
    requested_byte_delta: object
    block_capacity_delta: object
    lifetime_status: str

def diff_normalized_snapshots(before, after, trace_coverage, baseline):
    ...
```

```
def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report match rules, coverage, expected survivors, suspect cohorts, byte changes, ambiguity, and intervention outcome. Do not infer continuous lifetime merely because an address appears twice. A large survivor is not a leak without an unnecessary-retention hypothesis. Preserve a small counterexample where naive pointer diff misclassifies reused storage.

Part 7 - Engineering Interpretation and Philosophy

Explain what makes a cohort suspicious and what further evidence would confirm its retaining owner. Prefer honest ambiguity to a false exact lifetime.

19.47.14 Exercise 13

Exercise Title: Trace Persistent CUDA Allocations to Their Python Stack Frames and Locate the Exact Source Line Responsible for Retention

Part 1 - Exercise Contract and Why It Matters

Trace suspicious allocations to their creation stack and locate the application retention site with separate ownership evidence. Produce a minimal validated repair rather than blaming an allocating operator automatically.

Part 2 - System and Memory Mental Model

Allocation frames identify where storage was created. The line appending an existing tensor to a list can be elsewhere and may not allocate any CUDA bytes itself. Native/library frames can obscure the application origin. Debuggers and referrer inspection can add references or expose only part of the ownership chain. Exact retention-line attribution requires a supported application trace and a controlled intervention.

Part 3 - Quantitative Prediction Before Execution

Construct a tensor created in one helper and stored by another helper. Predict the allocation stack versus insertion line. Define an evidence chain from allocation cohort to logical output ID, owner path, insertion iteration, and repair. Add an alias case where fixing only one owner leaves the storage alive. Distinguish exact, candidate, and unresolved attribution statuses.

Part 4 - Experimental Design and Instrumentation

Capture allocation stacks with E11 and instrument candidate container/hook insertions using bounded CPU metadata. Correlate logical storage generations within one run; do not match pointers across fresh runs. Rank application frames but preserve native frames and missing stacks. Remove or bound the suspected ownership in a fresh replay while keeping useful training unchanged. Verify the cohort and slope disappear within the tested range and gradients/ updates still match. Release introspection locals before measuring and avoid storing live referrer objects in the report.

Use two helpers in the minimal example: one creates an output and another adds it to a diagnostic owner. The creation stack should point to the former; the retention instrumentation should identify the latter. Preserve both in the evidence chain. A container insertion can

allocate no CUDA bytes itself, so a memory snapshot may never list that retaining line as an allocation origin. Rank suspects by unexplained surviving bytes, cohort growth, lifetime, and owner evidence rather than by stack depth alone. Keep a confidence or coverage status with each source location. If compiled or native frames obscure the application line, retain that limitation and seek a smaller eager reproducer. Controlled removal of the suspected owner must leave useful forward/backward/update work unchanged. Test an extra alias so the investigator cannot declare the first removed reference the only owner without checking. Do not retain referrer objects, frames, or tensors in the final report. Exact attribution is earned by correlated ownership and a matched repair, not by a plausible stack string.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def correlate_allocation_origins_and_owner_events(suspects, owner_registry):
    ...

def rank_retention_site_candidates(evidence_chain, coverage):
    ...

def verify_retention_site_intervention(replay_spec, reference):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report creation frame, retaining line/path evidence, confidence/coverage, remaining aliases, intervention, byte trend, and numerical checks. Do not claim snapshots alone expose the exact Python owner. If only an allocation site is known, retain that limited result. A causal repair needs matched training and a restored ownership lifecycle, not simply a lower allocation count after deleting computation.

Part 7 - Engineering Interpretation and Philosophy

Explain why origin and retention are complementary clues. Choose the smallest repair that removes unnecessary ownership without changing the computation being debugged.

19.47.15 Exercise 14

Exercise Title: Use PyTorch Profiler Memory Records to Find an Operator or Abandoned Debug Path Responsible for Unexpected Long-Lived Allocations

Part 1 - Exercise Contract and Why It Matters

Use profiler memory records to localize unexpected allocation activity and correlate it with longer-lived suspect state. Keep allocation cost and retention cause distinct.

Part 2 - System and Memory Mental Model

Operator memory tables attribute allocation/deallocation activity within a capture, not every object's final Python owner. Large temporary operators can be healthy; a tiny debug insertion can retain their outputs without allocating. Shape/stack tracing adds overhead and can hold tensor references, changing behavior. Profiler evidence therefore needs comparison with a minimally instrumented baseline and snapshots/owner events.

Part 3 - Quantitative Prediction Before Execution

Predict a large temporary allocation that is released each iteration and a smaller operator whose output is retained. Define which profiler events and lifetime evidence distinguish them. Specify capture range and enabled features, and estimate whether their diagnostic overhead could affect the observed trend. Keep net memory, peak memory, and cumulative allocated traffic as different measures.

Part 4 - Experimental Design and Instrumentation

Profile a bounded warmed interval with named training and debug regions. Enable supported memory/stack/shape options deliberately and record their settings. Compare baseline, leaking, and repaired fresh replays under the same workload. Correlate operator frames with E12 cohorts and E13 owner metadata. Run ordinary timing/memory measurement separately without profiler reference retention. Validate outputs and several updates. Export tables, trace references, and unknown mappings to CPU rather than retaining captured GPU objects in the investigation system.

Record the profiler configuration and its capture phase with every memory table. Shape recording can temporarily hold references and add copies, and stack tracing adds overhead; use a separate minimally instrumented run to check whether the apparent trend survives. A large positive allocation event may be a healthy temporary and a negative event may occur outside the chosen capture. Net operator memory is therefore not a complete lifetime map. Correlate named debug regions with snapshot cohorts and insertion metadata. Include one large temporary that releases normally and one small retained output to test whether ranking follows evidence rather than raw size. Preserve unsupported event-to-cohort mappings. If a repair changes the operator graph, explain the changed expected memory baseline instead of claiming a pure ownership fix. Compare numerical gradients and several optimizer updates. Report profiling overhead and capture artifacts separately from ordinary training throughput. The profiler should narrow the origin/activity question, while owner events and interventions resolve why a particular allocation survived.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.profiler import profile, record_function
```

```
def profile_bounded_memory_regions(workload, capture_contract):
    ...

def correlate_operator_activity_with_survivors(profile_rows, cohorts, owners):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report operator activity, capture options, relevant phase, persistent cohort evidence, owner hypothesis, overhead, and repair validation. Do not call the largest allocating operator the leak automatically. Preserve mismatches introduced by instrumentation and mark unmatched stack/owner relationships unknown. A profiler's net memory column alone cannot prove continuous allocation lifetime.

Part 7 - Engineering Interpretation and Philosophy

Choose whether operator traces, snapshots, or owner instrumentation should guide the next step. Explain how each narrows a different part of the causal chain.

19.47.16 Exercise 15

Exercise Title: Build a Binary-Search Leak Isolation Tool That Enables and Disables Training-Loop Sections to Locate the Smallest Memory-Growing Code Region

Part 1 - Exercise Contract and Why It Matters

Build a controlled section-isolation tool for memory-growing behavior. Use binary search only when its independence and monotonicity assumptions hold; otherwise use a bounded delta-debugging search and report the smallest tested reproducer.

Part 2 - System and Memory Mental Model

Training sections depend on each other. Disabling backward or optimizer changes legitimate memory behavior and can invalidate the original baseline. Two individually harmless logging paths can leak through an interaction. A binary split is not guaranteed to find a globally minimal region when effects are nonmonotonic. Start with optional metrics, debugging, and hook sections whose removal preserves the primary training update.

Part 3 - Quantitative Prediction Before Execution

Define a growth predicate from E09 and a capability/dependency graph for toggled sections. Construct one independent-retention case suitable for binary elimination and one interacting case that violates it. Count the replays required under the declared search strategy and hard budget. Distinguish smallest tested subset from a proof of global minimality.

Part 4 - Experimental Design and Instrumentation

Create fresh matched replays for each valid configuration from the same logical initialization, data, and shape. Toggle optional side effects first and verify outputs, gradients, and updates.

If core computation is replaced, construct a new explicit expected-memory baseline rather than interpreting lower memory as leak removal. Preserve configuration IDs, predicate uncertainty, search decisions, and rejected invalid combinations. Bound run count and instrumentation storage. Confirm the final suspect through an ownership intervention and repair replay rather than relying on search ranking alone.

Define which sections can be toggled without changing the mathematical training update. Logging, optional visual diagnostics, and observational hooks are suitable initial candidates; removing loss computation is not. Validate the dependency graph before launching a replay. For an independent single retention site, binary elimination can be efficient. For interacting sections, include a case where one creates a container and another inserts values so neither half alone reproduces the original behavior. Use a bounded delta- debugging strategy or report the unresolved interaction rather than asserting binary-search monotonicity. Every replay needs fresh state, matching samples, phase, and a growth-predicate uncertainty. Preserve invalid configurations as rejected, not negative leak tests. Confirm the smallest tested reproducer through ownership evidence and a repair. Do not claim global minimality without an exhaustive or otherwise justified search. If core training work is replaced by a stub, create a new explicit expected-memory contract and keep it separate from the final causal repair comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class IsolationConfiguration:
    enabled_sections: tuple
    dependency_validity: str
    expected_memory_contract: str
    replay_identity: str

def isolate_growth_region(section_graph, predicate, replay_budget):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export valid/rejected configurations, search order, growth decisions, uncertainty, numerical checks, and final reproducer. Do not claim exact source minimality from a heuristic search. Preserve an interacting-section counterexample and indeterminate predicate cases. A deleted forward pass is not a valid repair of an output-history bug.

Part 7 - Engineering Interpretation and Philosophy

Explain which assumptions make the isolation result trustworthy. Choose a final experiment that separates a causal retention repair from a workload reduction.

19.47.17 Exercise 16

Exercise Title: Detect a Memory Leak Hidden Behind Stable Reserved Memory by Tracking Active Allocation Count, Live Bytes, and Allocation Lifetimes Instead of VRAM Usage Alone

Part 1 - Exercise Contract and Why It Matters

Detect growing live storage while reserved capacity remains flat. Track supported current allocation counts, live/requested bytes, and allocation lifetimes under a declared allocator backend.

Part 2 - System and Memory Mental Model

Existing cached segments can absorb new retained allocations without increasing reserved memory initially. Cumulative allocation totals naturally grow in healthy training and are not current live counts. Active allocator state can include blocks awaiting completion on another stream; that is not automatically reachable Python retention. Counter availability and meaning can differ by backend.

Part 3 - Quantitative Prediction Before Execution

Construct a bounded trace that first establishes reusable reserved capacity and then retains new independent payload within it. Predict a flat reserved interval with rising current live bytes. Compare current allocation count with cumulative allocations and a pending-free control. Estimate the maximum test range before another segment could be needed without assuming a particular allocator rounding pattern.

Part 4 - Experimental Design and Instrumentation

Use synthetic traces to validate metric selection, then a bounded native-allocator replay where supported. Prewarm the declared capacity in a separate phase and record it. Sample same-phase current counts/bytes and use E11 history to inspect lifetimes. Keep pending stream work explicit and repeat after deliberate completion to distinguish pending frees from retention. Do not force a reserved plateau by altering the leaking workload's useful computation. Validate the repaired owner policy against baseline training. Preserve unsupported statistics as unknown rather than substituting cumulative counters.

Choose supported current fields by backend and keep their full semantic names in the evidence. A cumulative count of allocations grows whenever a healthy training loop repeatedly creates temporaries; it cannot substitute for the current number of live blocks. Requested bytes and rounded allocator capacity answer different questions. Prewarm a bounded arena or reusable capacity before the synthetic/controlled retention phase, recording that setup separately. New live tensors can consume inactive blocks within already reserved segments, exposing growth without a reserved increase. Do not require this exact allocator pattern to occur on every backend or size range. Add a separate cross-stream pending-free case and sample again after its readers complete. That backlog can temporarily increase active state without an unnecessary Python owner. Combine current bytes, supported counts, and lifetime history rather than declaring a leak from one field. Validate the owner repair against the fixed baseline. Preserve a not-observed hardware plateau with the synthetic counterexample instead of manipulating the test until the expected picture appears.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def select_supported_current_allocation_metrics(backend, capabilities):
    ...

def detect_growth_under_reserved_plateau(rows, lifetime_evidence):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report current and cumulative metric names, live bytes, reserved bytes, backend, lifetime states, completion boundaries, and intervention result. A flat device graph is not proof of no retention. Conversely, pending-free blocks that retire after readers complete are not sufficient evidence of a leak. If the plateau does not appear within the tested range, retain that outcome and the synthetic counterexample.

Part 7 - Engineering Interpretation and Philosophy

Explain why reserved capacity can hide a real live-storage trend. Choose the additional counter or lifetime observation that exposes the issue without creating false alarms from normal allocation traffic.

19.47.18 Exercise 17

Exercise Title: Diagnose CUDA Memory Growth Invisible to the PyTorch Allocator by Comparing PyTorch Statistics Against Device-Level Memory Consumption

Part 1 - Exercise Contract and Why It Matters

Investigate device-memory growth not explained by PyTorch allocator statistics. Use scoped comparisons and optional bounded external-allocation controls without claiming visibility into every library or process.

Part 2 - System and Memory Mental Model

CUDA contexts, communication libraries, third-party allocators, and other processes can consume device memory outside PyTorch-managed segments. Another allocator may cache released tensors, producing its own plateau. A global device counter cannot attribute all growth to the current process. PyTorch snapshots cannot reconstruct stacks for allocations they never observed.

Part 3 - Quantitative Prediction Before Execution

Predict PyTorch counters and device-level use for a healthy external cache, a deliberately retained external allocation, and unrelated process activity. Define evidence needed to distinguish them. Keep device use minus reserved capacity as a visibility-gap indicator with timing/context

limits, not exact external leak bytes. Predict cleanup behavior under the external allocator's actual ownership/cache policy.

Part 4 - Experimental Design and Instrumentation

Run the stable PyTorch control first. If a supported third-party or native allocation interface is available, use a small explicitly bounded allocation lifecycle with documented cleanup and completion. Record its library, version, process identity, owner, cache policy, and sample timestamps. Do not install or assume an external backend merely to fill a result table. Compare fresh isolated replays and a release intervention. For optional distributed cases, initialize communication separately and distinguish one-time buffers from repeated growth. Preserve unsupported per-process visibility.

Identify the optional external allocator before running its control. Its tensor deletion, pool release, and actual driver release can be different operations, just as PyTorch has caching. Use a documented bounded allocation and cleanup lifecycle with explicit stream completion; do not leave an unowned raw allocation to simulate a permanent failure. Record whether the library allocates through PyTorch's allocator, its own pool, or a direct CUDA interface, because visibility follows that choice. A driver-level rise can also come from another process, so preserve process context and timestamp skew. Compare initialization-only growth with repeated growth after warmup. If no external interface is installed, retain the analytical scope test and mark the hardware control not measured. Do not install dependencies or infer NCCL behavior simply to fill every row. An unresolved global-minus-allocator gap is a valid investigation result until library-specific owner, cache, or process evidence narrows it. Absence of allocation frames in PyTorch's snapshot cannot prove a native allocation was never made.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def collect_external_visibility_evidence(device, process_context):
    ...

def run_bounded_external_allocator_control(adapter, resource_contract):
    ...

def classify_unexplained_device_growth(rows, external_evidence):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw scopes, external adapter status, owner/cache evidence, cleanup, initialization, device trend, and remaining uncertainty. Do not label an unexplained gap a proven native leak. If no external interface is available, report the control not measured while retaining the scope analysis. Never treat absence from snapshots as absence from the device.

Part 7 - Engineering Interpretation and Philosophy

Choose the next library/process-specific diagnostic based on actual visibility. Explain where automated PyTorch-only attribution must stop.

19.47.19 Exercise 18

Exercise Title: Stress-Test the Leak Detector with Graph Retention, Python Containers, Hooks, External CUDA Allocations, Fragmentation, and Legitimate One-Time Memory Growth

Part 1 - Exercise Contract and Why It Matters

Stress the detector and investigation pipeline with retention, hooks, external visibility gaps, cache behavior, fragmentation-like patterns, and legitimate one-time growth. Evaluate false positives as carefully as true retention detection.

Part 2 - System and Memory Mental Model

Different causes can share a rising reserved-memory curve. Variable shapes can change caching and fit, while one-time optimizer or communicator state can create a step. Fragmentation concerns reuse/fit and cannot be proved from a reserved-minus-allocated gap alone. Graph structure, saved activations, pending frees, and external allocations need separate labels. Diagnostic overhead can create its own growth.

Part 3 - Quantitative Prediction Before Execution

Build a labeled synthetic matrix with linear retention, one-time jump, noisy plateau, sawtooth collection, pending-free backlog, stable-reserved live growth, and external-only growth. Add bounded hardware cases when supported. Predict detector label, required follow-up, and ambiguity for every case. Define detection delay, false-alarm rate, evidence coverage, and resource limits before testing.

Part 4 - Experimental Design and Instrumentation

Validate individual cases before combining them. Preserve seed, shape schedule, phase, allocator backend, and expected persistent state. Use bounded list/hook/graph controls and explicit external capability checks. Change one cause at a time, then selected combinations that test interacting ownership. Record instrumentation host memory and timing. After failure, restart from a clean state before comparing policies. Keep numerical training checks for valid workload variants. Preserve nonreproducing OOM or fit outcomes without inventing fragmentation evidence or a universal allocator diagnosis.

Create separate expected labels for reachable payload retention, graph- structure retention, saved-activation retention, pending frees, cache growth, external visibility, and legitimate persistent initialization. Some cases can be indeterminate with the available counters; do not force one exact cause. Use synthetic histories to test address reuse and trace truncation without requiring an unreliable hardware race. Keep bounded real list, hook, and retained-graph reproducers with explicit owners. For variable shapes or fragmentation-like workloads, record

the request sequence and actual outcomes; a gap between reserved and allocated bytes is not causal fragmentation proof. Include diagnostic self-retention as a test: an evidence logger that stores GPU tensors must be detected or rejected. Track host overhead from history and profiler records as well as CUDA memory. Evaluate detection, localization, and successful repair separately, since an alert can be correct while its top-ranked suspect is wrong. Preserve all rejected and unsupported cases with their reasons, and validate that repaired training still performs the intended updates.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def make_leak_investigation_stress_matrix(capabilities, budget):
    ...

def evaluate_detector_and_attribution(case, evidence, expected_labels):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export raw traces, labels, predicted/observed diagnoses, false positives/ negatives, capture overhead, bytes, outcome, and failure phase. Include the smallest counterexample to a naive rule or state none was observed. A valid unsupported/indeterminate result must not be counted as a correct exact diagnosis. Verify clean repairs preserve outputs and optimizer updates.

Part 7 - Engineering Interpretation and Philosophy

Explain which stress case most limits the system's claims. Refine supported scope, phase contracts, or follow-up policy without hiding unsuccessful cases.

19.47.20 Exercise 19

Exercise Title: Build and Benchmark an Automated PyTorch Memory Leak Investigation System That Detects Growth, Captures Snapshots, Diffs Allocations, Ranks Suspect Stack Traces, and Produces a Root-Cause Report

Part 1 - Exercise Contract and Why It Matters

Integrate growth detection, bounded capture, schema normalization, allocation diffs, owner evidence, and candidate ranking into an automated investigation system. Produce a root-cause report whose confidence follows from validated evidence and controlled repairs.

Part 2 - System and Memory Mental Model

The system must distinguish alerts from diagnoses and creation stacks from retaining owners. It needs run/phase identity, allocator visibility, trace coverage, expected state, and a bounded evidence lifecycle. Automatic ranking can propose suspects but cannot guarantee exact attribution for external allocations or missing histories. Preserve unresolved status rather than forcing every investigation into a confident leak label.

Part 3 - Quantitative Prediction Before Execution

Predict monitoring, history, snapshot, and report storage overhead. Define trigger thresholds, capture limits, maximum replay count, phase alignment, and numerical acceptance. Choose a finite set of known retention and healthy controls plus held-out cases. Specify report fields that separate facts, hypotheses, interventions, results, and unsupported visibility.

Part 4 - Experimental Design and Instrumentation

Build from E01's deterministic baseline and validate controlled leaks and repairs. Use separate ordinary measurement, profiler, and capture replays. Preserve E00's reproducibility record plus detector version, API/schema, history coverage, owner registry, and configuration IDs. Time complete training and investigation overhead separately. Export bounded CPU summaries and learner-generated capture references without live graph retention. Confirm candidate repairs through matched gradients and several updates. Unavailable GPU or external paths remain not measured.

Define the root-cause report schema before integration. It should include workload/phase contract, raw counter scopes, growth decision, capture coverage, suspect cohorts, creation frames, retaining-owner evidence, intervention, numerical validation, and unresolved alternatives. Keep facts separate from ranked hypotheses. A system can successfully detect suspicious growth yet remain unable to prove an exact retaining line, especially with external allocations or missing event history. Bound automatic capture count, artifact retention, replay budget, and diagnostic host memory. Include collection and analysis overhead in the benchmark rather than reporting only the stable training loop. Use known cases for development and held-out cases for evaluation. Every supported feature needs a validating run ID; imports and method names do not establish capability. Preserve minimal counterexamples to universal rules and failures to reproduce. The final report should recommend the next smallest discriminating experiment or a validated repair, with an honest confidence/coverage statement rather than automatic blame assigned to the largest allocation stack.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class MemoryLeakInvestigationSystem:
    def monitor_completed_iteration(self, runtime, phase):
        ...

    def capture_bounded_diagnostic_state(self, trigger):
        ...

    def diff_and_rank_candidates(self, captures, ownership_evidence):
```

```
        ...

    def validate_candidate_intervention(self, replay_spec):
        ...

    def export_root_cause_report(self):
        ...

def E19(config):
    # Assemble checked diagnostics and evaluate known/held-out cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep prediction, observation, and interpretation separate. Each run needs ID, configuration, shape, byte budgets, current/peak allocated and reserved bytes, device-level scope, elapsed time, correctness, outcome, and failure phase. Report raw growth, suspect cohorts, origin/owner distinction, coverage, intervention results, overhead, and remaining uncertainty. Include minimal counterexamples and unsupported/not-measured values. A scaffold method is not capability evidence; every supported feature needs a validating run ID. Never invent GPU results or declare a suspected line proven without ownership and repair evidence.

Part 7 - Engineering Interpretation and Philosophy

Justify the final diagnosis or unresolved classification through scoped counters, lifetimes, ownership, and matched interventions. Identify the next smallest experiment that would resolve remaining uncertainty.

19.48 DMM46

Chapter Title: Autograd Graph Memory Analysis
Specialization: Dynamic Memory Management and CUDA Systems

19.48.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Autograd Nodes, Saved Tensors, Gradient Edges, Tensor Lifetimes, and Backward-Time Memory Release

Part 1 - Exercise Contract and Why It Matters

Construct a vocabulary and an accounting contract for the entire exercise sequence. Distinguish a backward node, a gradient edge, a saved tensor slot, a Python Tensor wrapper, and an underlying storage allocation. Deliver a small annotated computation, predicted lifetime transitions, and counterexamples to simplistic memory rules. The objective is to explain what must remain available for the requested derivatives before proposing any memory optimization.

Part 2 - System and Memory Mental Model

Autograd records differentiable operations during forward execution and uses the resulting dependencies during backward. Nodes may save inputs, outputs, or other values needed by

their derivative formulas. Several saved slots can reference one storage, while a tiny view can keep a large backing allocation alive. Ordinary backward usually releases saved intermediates as they become unnecessary; graph structure can remain reachable through an output afterward. Allocator caching and asynchronous pending frees are separate phenomena.

Part 3 - Quantitative Prediction Before Execution

For distinct observed storages with capacities c_j and conservative live intervals $[a_j, b_j)$, predict a storage occupancy envelope:

$$M_{\text{observed}}(t) = \sum_j c_j \, \mathbf{1}[a_j \le t < b_j].$$

Compare this with the sum of logical saved-slot bytes. Construct one example with repeated saves and another with a small slice of a large tensor. Explain why neither node count nor saved-slot sum alone equals the total CUDA peak.

Part 4 - Experimental Design and Instrumentation

Begin with a deterministic eager model using smooth operations, fixed shapes, and one scalar loss. Draw forward consumers separately from backward dependency edges. Mark parameters, gradient buffers, optimizer states, temporary workspace, and cached capacity as different accounting categories. Follow the same state through forward, backward, gradient clearing, and owner deletion. Record the installed PyTorch version and restrict claims to the inspected operations; unsupported fields must remain explicitly unknown.

Create a reproducibility record containing hardware identity, allocator backend, PyTorch and CUDA versions, seeds, dimensions, precision, optimizer, and initial state identifier. Keep cold-start and warmed behavior separate. For each experiment preserve an ID, configuration, input shape, byte budget, timing scope, outcome, and failure phase when applicable. Do not imply that logical zero-data metadata means zero host memory. Use explicit unsupported and not-measured values throughout the sequence. A CPU-only analytical control can validate accounting and graph invariants when CUDA is unavailable, but it cannot supply a measured GPU peak or establish real asynchronous release behavior.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class StorageRecord:
    generation: object
    capacity_bytes: object
    owners: tuple
    completion_status: str

def classify_autograd_objects(loss, scope):
    ...
```

```
def E00(config):
    # Draw dependencies and predict release boundaries first.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a counterexample to the claims that every node saves a tensor, every saved slot owns distinct memory, and deleting one wrapper frees its storage. Validate derivative values against an analytical toy case. Keep predictions, observations, and interpretations in separate columns. Do not retain CUDA values inside the evidence logger. A CPU metadata record can describe an allocation without proving that the corresponding GPU kernel has completed.

Part 7 - Engineering Interpretation and Philosophy

Memory analysis is a study of obligations: which future computation still needs a value, which owner preserves it, and which execution dependency permits reuse. A useful model admits uncertainty about opaque workspaces and backend behavior. State which decisions can already be justified from the graph and which require a controlled measurement. Carry this distinction into every later recommendation rather than treating a diagram as a complete allocator or execution trace.

19.48.2 Exercise 01

Exercise Title: Inspect grad_fn and next_functions to Trace the Autograd Graph of a Multi-Layer PyTorch Computation

Part 1 - Exercise Contract and Why It Matters

Build an iterative traversal of the backward graph rooted at a declared loss. Export node records and dependency edges without recursively duplicating shared subgraphs. Deliver a readable adjacency representation, an explicit coverage statement, and a demonstration involving a branch that rejoins. The traversal should support investigation without quietly becoming a new long-lived owner of the objects it investigates.

Part 2 - System and Memory Mental Model

A tensor's grad_fn identifies its producing backward node when applicable. The next_functions interface exposes backward dependencies and edge metadata; it does not enumerate every forward tensor or reconstruct the complete source program. Some entries have no node. Accumulator nodes and shared dependencies need distinct treatment. Identities are meaningful within the diagnostic traversal and must not be compared as permanent identifiers across replays.

Part 3 - Quantitative Prediction Before Execution

Predict the unique node count and edge count for a chain and for a shared branch before inspecting them. If a shared dependency is encountered twice, count the node once while preserving both incoming relationships. Explain why a walk that sums descendants independently overestimates the DAG size. Keep node counts separate from byte estimates: a small number of nodes can retain very large tensors.

Part 4 - Experimental Design and Instrumentation

Use a short multi-layer model with named application regions and an explicit shared intermediate. Traverse all requested roots with a visited set and a bounded work queue. Preserve

edge positions and null entries rather than inventing missing computation. Run traversal on a diagnostic replay, export CPU-only labels, then discard node references before the ordinary memory measurement. Test whether enabling the analyzer changes the post-run memory baseline.

Choose traversal depth and event limits before inspection. Test a deep chain that would overflow a naive recursive walker, a diamond with a shared node, and multiple roots sharing an ancestor. Distinguish repeated discovery from a graph cycle: the backward representation of a normal eager computation is not made cyclic merely by a shared edge. Keep application labels stable while allowing internal node names to vary by version. If the implementation keeps strong references to nodes for identity stability during traversal, release that collection after export and before judging cleanup. Include traversal overhead and the completeness of the visited roots in the final record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def walk_backward_roots(roots, traversal_id):
    # Deduplicate nodes within this traversal; preserve edge slots.
    ...

def export_adjacency(nodes, edges, output_path):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that the branch is represented as shared structure rather than two independent copies. Include a constant input with no gradient requirement and a disconnected auxiliary computation outside the chosen root. Mark those coverage boundaries explicitly. Avoid assigning bytes to a node simply because its name resembles a known operator. If holding traversal objects changes release behavior, report that observer effect and use a separate measurement replay.

Part 7 - Engineering Interpretation and Philosophy

A backward graph is a dependency view for a particular differentiation task. It is valuable because it narrows which paths can explain a retained value, but it cannot independently prove ownership or execution timing. Explain what the adjacency export establishes, what the application labels add, and what must wait for saved-tensor or allocator evidence. Prefer an incomplete graph with honest boundaries over a complete-looking reconstruction assembled from unverified assumptions.

19.48.3 Exercise 02

Exercise Title: Compare Leaf and Non-Leaf Tensors and Determine Which Objects Store Gradients and Which Only Participate in the Graph

Part 1 - Exercise Contract and Why It Matters

Classify leaf and non-leaf tensors, gradient requirements, and gradient storage as separate properties. Produce a table before and after backward, then repeat with retain_grad enabled on one intermediate. Include direct CUDA creation, a differentiable device or dtype conversion, a detached tensor, and a tensor that never requires gradients. Explain each outcome from the construction history rather than from whether the .grad field happens to be populated.

Part 2 - System and Memory Mental Model

Leaf tensors requiring gradients normally receive accumulated gradients from backward. Non-leaf tensors participate in differentiation without retaining their own .grad by default; retain_grad opts into that storage. A tensor that does not require gradients can also be a leaf. The autograd.grad interface returns derivatives instead of following the same accumulation contract. The words leaf, trainable, and currently holding a gradient are therefore not interchangeable classifications.

Part 3 - Quantitative Prediction Before Execution

Predict which .grad fields are None, which have the tensor's logical shape, and which add retained CUDA bytes. For a retained intermediate with n elements and gradient element size s, use ns as a logical payload estimate, not a guarantee about rounded allocator capacity. Predict how the next iteration changes when gradients are set to None rather than filled with zeros.

Part 4 - Experimental Design and Instrumentation

Use a small differentiable expression whose derivative is analytically known. Record is_leaf, requires_grad, grad_fn status, device, dtype, and the chosen gradient policy as CPU scalars or strings. Compare ordinary backward with a fresh replay using autograd.grad. Clear gradients at matching phase boundaries. Avoid probing non-leaf .grad repeatedly in a way that confuses expected warnings with execution failures. Never infer a missing derivative from None without checking the API contract.

Use an explicit construction table rather than mutating one tensor through all role tests. A Parameter created directly on its target device is a useful leaf reference; a real differentiable conversion demonstrates a different history. State whether a detached value is made into a new differentiated leaf and which earlier derivatives are intentionally absent in that case. Compare retained intermediate gradients at matching points after backward, not against a baseline already cleared for the next step. For sparse or nonstandard layouts, narrow the supported scope instead of applying a dense payload formula without checking its meaning. Preserve the distinction between no gradient requested and a computed zero.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def classify_tensor_role(tensor, construction_label):
    ...

def compare_gradient_retention(config):
    # Separate retain_grad from retain_graph.
```

```
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check derivative values and accumulation over two backward calls on freshly constructed graphs. A conversion test must actually change device or dtype; a no-op conversion may return the original tensor. Report gradient-buffer memory separately from saved activations. Include a leaf that is unused by the loss and document the chosen unused-input behavior. Distinguish a valid None result from a numerical zero gradient that was computed and stored.

Part 7 - Engineering Interpretation and Philosophy

The distinction matters when evaluating optimizations: removing unnecessary retained intermediate gradients can reduce memory without altering the model, whereas detaching an intermediate changes the differentiation path. Explain which experiment changes observation policy and which changes mathematical work. Keep the gradient storage contract visible in every later comparison, so apparent savings are not merely the consequence of comparing different sets of requested or accumulated derivatives.

19.48.4 Exercise 03

Exercise Title: Measure CUDA Memory Before Forward, After Forward, During Backward, and After Graph Release to Reconstruct the Autograd Memory Lifecycle

Part 1 - Exercise Contract and Why It Matters

Measure the autograd memory lifecycle at matching boundaries and reconstruct where the high-water mark occurs. Include the first optimizer update so lazy optimizer state creation is visible. Deliver a phase table and a separate backward-region peak measurement. Endpoint measurements alone cannot locate a temporary peak inside backward, so the design must distinguish boundary occupancy from a high-water mark observed during an interval.

Part 2 - System and Memory Mental Model

Forward can retain values for backward; backward can allocate gradient buffers and workspace while releasing saved state. The maximum may occur before either phase endpoint. memory_allocated tracks allocator-visible live tensor memory, while memory_reserved includes cached capacity. Device-level use has a broader scope. Deleting the loss after ordinary backward may remove remaining graph structure without causing a second release of already-freed saved tensors.

Part 3 - Quantitative Prediction Before Execution

Build an accounting prediction with persistent parameters, gradients, optimizer state, saved activations, and temporary workspace. Do not add independently measured category peaks as if they occurred simultaneously. Predict a range for the backward peak using overlap assumptions, then state which assumption the experiment can test. Compare a cold first step with warmed repeated steps and explain why their optimizer and allocator baselines differ.

Part 4 - Experimental Design and Instrumentation

Define deliberate synchronization points, reset peak statistics for each measurement region, and record both allocated and reserved bytes. Use a separate diagnostic replay with bounded history to inspect events during backward without synchronizing after every operator. Keep input dimensions, precision, optimizer, gradient clearing, and initial state identical across replays. Record transfer and setup timing separately when excluded from the measured region, and state every inclusion explicitly.

Give every sample an initial-state identifier and a precise phase name. An allocation-only control needs its own declared region; a training measurement includes forward, backward, and optimizer update. Resetting a peak counter does not free memory or restore the initial graph. Use independent replays when a probe changes ownership or execution order. If recording CPU memory, name the metric and process scope rather than adding unrelated RSS and CUDA values. Keep transfer, collation, calibration, and recovery time explicit in the timing contract. Repeat fixed-seed comparisons first, then use additional seeds to check whether the observed pattern depends on particular values.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def sample_boundary(device, phase, run_id):
    ...

def measure_backward_region(loss, device, evidence):
    # Reset the declared peak region and wait at its boundary.
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a stable warmed baseline before interpreting growth. Compare sampled endpoints with the interval peak and explain any gap using supported evidence. Do not claim exact tensor ownership from a counter alone. Export numeric scalars without preserving live loss tensors or gradients in the log. A missing CUDA device produces a not-measured result rather than an invented lifecycle trace. Report synchronization and instrumentation costs alongside the minimally instrumented runtime.

Part 7 - Engineering Interpretation and Philosophy

The lifecycle is a set of overlapping allocations and obligations, not four universal monotonic phases. Identify which phase dominates the tested workload and whether a proposed intervention can affect that phase. A forward saving that shifts the peak into backward can still be useful, but it must be judged using the full step's high-water mark and validated updates rather than a single favorable endpoint.

19.48.5 Exercise 04

Exercise Title: Inspect Saved Tensors Required by Backward and Estimate Their Contribution to Peak VRAM

Part 1 - Exercise Contract and Why It Matters

Inspect saved values in a few controlled derivative formulas and estimate their memory contribution without equating logical tensor size with exclusive VRAM. Deliver a saved-slot inventory, a storage-sharing inventory, and a prediction of the minimum backing capacity those observations can keep alive. Restrict internal attribute inspection to small version-checked examples; the exercise must not depend on a universal parser for private node fields.

Part 2 - System and Memory Mental Model

An operation saves only what its backward implementation needs for the chosen gradient requirements. Addition may need no input values, while multiplication or nonlinear derivatives can need inputs or outputs. Packed saved tensors can be unpacked into a different Python object sharing the same storage. Parameters may already belong to the persistent baseline, so saving their references does not necessarily allocate another parameter-sized CUDA block.

Part 3 - Quantitative Prediction Before Execution

Calculate logical saved bytes as a sum over slots, and separately calculate unique observed backing capacities. Consider two overlapping views of one large tensor and a parameter saved by several operations. Predict the amount of double counting and identify which storage was already resident. Bound the incremental saved-state footprint without pretending that unobserved workspace or allocator rounding has been measured.

Part 4 - Experimental Design and Instrumentation

Compare a small set of scalar and matrix operations in isolated eager replays. Vary which inputs require gradients while holding shapes constant. Record supported saved attributes or hook observations, strides, storage offsets, and storage capacities without storing inspected CUDA tensors in the report. Release temporary inspection results promptly. Recheck the ordinary run without inspection to detect whether accessing saved objects or retaining wrappers changed their lifetimes.

Build a synthetic storage catalog before relying on runtime pointers. Include one allocation saved twice, two views with different offsets, a zero-element view, and a small slice that pins a large backing capacity. Compare these with independent clones having identical values. Preserve device and generation in every identity record. A tensor's data pointer can include its offset; it is not a universal backing-storage identifier. Conversely, identical numeric addresses in separate lifetimes do not establish a shared allocation. Explain how empty tensors and unsupported layouts are represented without inventing capacity or collapsing distinct records. These controls validate bookkeeping without claiming any particular allocator rounding policy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def inspect_supported_saved_fields(node, version_scope):
```

```
    # Private illustrative fields require explicit support checks.
    ...

def summarize_slots_and_storages(slot_rows, persistent_catalog):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Include a small view whose backing allocation is much larger than its logical payload and an operation with no observed saved tensor. Unknown inspection coverage must remain unknown rather than zero. Validate outputs and gradients against an uninstrumented replay. A storage pointer match is useful within a controlled live interval but is insufficient across allocation generations. Report logical bytes, unique capacity, and persistent overlap in adjacent columns so the reader can audit the estimate.

Part 7 - Engineering Interpretation and Philosophy

Saved-state analysis explains one reason a storage remains necessary. It does not establish exclusive ownership by one operation or guarantee immediate release at backward. Explain how the inventory narrows optimization candidates and where aliases or pre-existing persistent state limit possible savings. The most useful estimate distinguishes removable capacity from bytes that would remain resident even if the saved reference disappeared.

19.48.6 Exercise 05

Exercise Title: Use torch.autograd.graph.saved_tensors_hooks to Log the Shape, Dtype, Device, and Size of Every Tensor Saved for Backward

Part 1 - Exercise Contract and Why It Matters

Instrument supported saved-tensor events with saved_tensors_hooks and export shape, stride, dtype, device, logical size, and scoped storage metadata. Every means every covered save callback inside the declared context, not every possible tensor retained by Python, a custom extension, or an opaque backend. The logging mechanism must preserve the values needed by backward and must not become an unbounded GPU history.

Part 2 - System and Memory Mental Model

The pack hook receives a tensor and returns a payload that the unpack hook can reconstruct into the required value. A metadata dictionary alone cannot satisfy that contract. The packed payload must not hold the original input Tensor object, which can create a reference cycle. Use a validated detached representation for a first-order logging experiment while keeping report rows CPU-only. This representation choice is not permission to detach the forward computation.

Part 3 - Quantitative Prediction Before Execution

Predict pack count, possible repeated unpack calls, and logical bytes for a small known expression. Do not assume a one-to-one relationship between pack and unpack counts. Estimate host log size under a fixed event limit, and distinguish payloads required for backward from

optional diagnostic rows. Predict what a nested hook context records, then verify the installed version's innermost-hook behavior.

Part 4 - Experimental Design and Instrumentation

Start with first-order gradients and compare an instrumented replay against an uninstrumented oracle. Preserve values, shape, dtype, and original device through pack and unpack; do not mutate hook arguments or payloads. Include a repeated backward case to test idempotent reconstruction while the payload is needed. Keep counters and copied metadata separate from payload ownership. Test higher-order differentiation separately before claiming that the same representation supports it.

Set an event budget with an explicit truncation marker. A partial log cannot support an assertion that every save in the entire run was recorded. Avoid formatting full tensor values, converting whole tensors to lists, or reading CUDA scalars inside each callback; such actions can add transfers and synchronization. Test nested contexts using distinguishable metadata tags and restore the previous context even when the workload raises. If a payload is shared across retrievals, keep its ownership valid until all uses end. Treat unpack failures as correctness failures, not as missing observations that can be ignored. Report whether instrumentation changes supported higher-order behavior.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PackedValue:
    representation: object
    event_id: object

def pack_saved_value(tensor, scope, recorder):
    ...

def unpack_saved_value(payload):
    ...

def E05(config):
    # Install hooks only around the declared forward scope.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify numerical outputs and requested gradients, including a case that unpacks the same save more than once. Report context, nesting, thread assumptions, unsupported retention paths, and logging overhead. The callback does not provide the owning autograd node, so do not fabricate node attribution from its timestamp. Validate that disabling optional logging removes report data without changing required payload ownership or the final memory baseline.

Part 7 - Engineering Interpretation and Philosophy

An observation interface is useful only when its correctness contract is preserved. Explain why returning metadata instead of a value is not a memory optimization, and why retaining the original tensor inside a report is a self-inflicted retention path. Carry callback coverage and attribution uncertainty forward into rankings; callback availability alone does not make the instrumented view complete.

19.48.7 Exercise 06

Exercise Title: Rank Autograd Operations by Total Saved-Tensor Bytes and Identify the Most Memory-Expensive Backward Dependencies

Part 1 - Exercise Contract and Why It Matters

Rank application regions or supported operations by saved-state burden while separating logical save traffic from unique retained storage. Deliver multiple rankings and a counterexample where the operation with the largest saved-slot sum is not the best memory-saving target. Establish the attribution method before labeling rows as operator costs; ambiguity must be represented rather than resolved through guesses about callback order.

Part 2 - System and Memory Mental Model

A pack callback receives a tensor but no universally reliable owning-node identifier. Controlled module scopes, explicit application regions, or tagged custom functions can provide partial attribution. Shared values can be saved under multiple regions, so region totals are not additive exclusive memory. Call count and tensor size describe save activity; lifetime overlap and alternative owners determine whether eliminating one save releases capacity.

Part 3 - Quantitative Prediction Before Execution

For each region predict slot bytes, unique referenced capacity, persistent capacity overlap, and a removable-capacity bound. Construct two regions that save the same parameter and one that saves a short-lived independent tensor. Predict how rankings change when using byte-time rather than byte totals. State whether a storage shared by several regions receives shared attribution or an explicitly non-additive reference in each row.

Part 4 - Experimental Design and Instrumentation

Instrument named regions in separate diagnostic replays and retain the same workload order. Include nested modules, shared parameters, and a repeated operation. Export unresolved attribution with its candidate scopes. Use a small known custom function as an attribution control if supported, while keeping its mathematical derivative checked. Compare the strongest ranked candidate with a correctness-preserving intervention in an independent replay; ranking alone is not causal evidence.

Provide a ranking table with columns for attribution scope, observed save count, logical bytes, unique referenced capacity, persistent overlap, lifetime coverage, and ambiguity. Record the aggregation rule next to each column. Include a deliberately misleading module-level example where nested scope totals double count the same save events. Compare flat exclusive application regions with hierarchical inclusive reporting, labeling their semantics. If a region is called several times, preserve invocation IDs before aggregating. A candidate's rank should not become more confident merely because several ambiguous callbacks were assigned the same guessed label. Validate the claimed saving through one controlled intervention and record a null result honestly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def attribute_save_events(events, application_scopes):
    ...

def rank_saved_state(attributions, storage_catalog, lifetime_bounds):
    # Export non-additive shared capacity and ambiguous ownership.
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit whether totals count aliases, repeated saves, or persistent parameters multiple times. A zero-byte row must mean proven absence under the stated coverage; otherwise use unknown. Compare proposed savings with measured whole-step peak changes and explain differences in concurrency or workspace. Report rank stability across repeated runs without claiming statistical certainty from a small sample. Include the smallest counterexample that invalidates the largest-save-means-largest-saving rule.

Part 7 - Engineering Interpretation and Philosophy

Ranking is a prioritization aid, not an automatic deletion policy. A region can have many saved bytes yet be cheap to keep because its values overlap with unavoidable state. Another can retain modest bytes across the actual peak and become a better target. Explain how the selected ranking supports the next experiment and where incomplete attribution limits its interpretation.

19.48.8 Exercise 07

Exercise Title: Reproduce Graph Retention by Storing a Tensor with grad_fn Across Iterations and Measure the Resulting CUDA Memory Growth

Part 1 - Exercise Contract and Why It Matters

Construct bounded examples of graph retention through stored outputs and measure which memory actually persists. Compare storage before backward, ordinary completed backward, and backward with retained state. The title's hypothesis must be tested: storing a tensor with grad_fn does not universally preserve all saved activations after ordinary backward has released them. Deliver distinct outcomes for output storage, graph structure, and saved state.

Part 2 - System and Memory Mental Model

A Python container can keep an output and its reachable graph structure alive. Before backward, or when saved state is explicitly retained, that reachability can also preserve large

backward dependencies. After ordinary backward, many saved buffers have already been released even though grad_fn remains visible. A detached output still occupies its own CUDA storage; CPU graph metadata and GPU saved activation storage are different resources.

Part 3 - Quantitative Prediction Before Execution

Predict growth over a bounded number of iterations for three cases: storing outputs without backward, storing outputs after ordinary backward, and storing outputs after retained backward. Separate output bytes from expected saved capacity and avoid counting shared parameters per iteration. State which case should show materially steeper growth and which operator-specific saved-state assumptions make that prediction conditional.

Part 4 - Experimental Design and Instrumentation

Use independent replays with identical shapes, loss, seeds, and container limits. Stop before a configured allocation budget rather than seeking a physical OOM. Sample at matching completed boundaries and delete all stored roots at the end. Compare diagnostic graph records with allocator-visible bytes and host metadata growth. Keep evidence rows free of tensor objects, and verify that the reporter itself does not retain each iteration's loss.

Keep the stored values identical across cases, including shape and dtype, so output payload is a fair control. Compare list storage with a bounded ring buffer to distinguish unbounded ownership from a fixed diagnostic window. Before-backward retention should use deferred work intentionally, while the after-backward cases must complete the selected backward policy before sampling. Do not accumulate multiple losses inadvertently while constructing the test. Release local loop variables and diagnostic roots as well as the container when testing cleanup. If host graph metadata grows after ordinary backward while CUDA saved-state capacity does not, report that split outcome explicitly rather than calling the entire retained graph absent.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def run_retention_case(config, backward_policy, owner_policy):
    ...

def compare_retained_categories(case_rows):
    ...

def E07(config):
    # Bound iterations and release diagnostic graph references.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A non-reproducing growth pattern is an outcome to explain, not permission to invent a trace. Verify that container length, stored output sizes, and selected backward policy match the design. Compare cleanup after container clearing with a fresh baseline while allowing cache retention. Do not interpret stable reserved memory as proof that no new live outputs were retained, or a remaining grad_fn as proof that all saved tensors survived.

Part 7 - Engineering Interpretation and Philosophy

The important question is which obligation remains, not whether a single attribute exists. Explain why the stored-output experiment distinguishes legitimate diagnostics, unnecessary CUDA payload retention, and preserved backward work. A good repair removes an unwanted owner while preserving the intended derivative computation; it need not force the allocator to return cached segments to the driver.

19.48.9 Exercise 08

Exercise Title: Break an Unwanted Autograd History with detach() and Prove Which Graph Nodes and Saved Tensors Become Eligible for Release

Part 1 - Exercise Contract and Why It Matters

Remove an unwanted differentiation history from a diagnostics branch and identify which release conditions actually change. Compare detach, CPU export, and removal of the original owner. Deliver a proof of preserved training gradients for the diagnostic repair, plus a deliberately invalid intervention that detaches a required activation. Keep that invalid case as a counterexample, not as an optimization with equivalent training semantics.

Part 2 - System and Memory Mental Model

detach creates a tensor without the original differentiation history while sharing underlying storage. Keeping the original output, another graph root, or an alias can preserve the same backing allocation. Release eligibility requires all relevant owners and future consumers to disappear, and actual reuse must respect asynchronous completion. Detaching a forward activation needed by the loss changes which derivatives are computed; it cannot be justified merely by observing a lower peak.

Part 3 - Quantitative Prediction Before Execution

Predict graph reachability and storage ownership for an original output, a detached alias, a detached CPU copy, and a scalar diagnostic. Include a small view backed by a larger allocation. Estimate which CUDA capacity remains in each case and when removing the original root can matter. State why the prediction differs before backward and after ordinary backward has already released saved dependencies.

Part 4 - Experimental Design and Instrumentation

Use the bounded retention cases from E07 and move only the optional metrics path across the differentiation boundary. Record every remaining application owner, then clear them in a controlled order. Compare the required parameter gradients and optimizer updates with the original loop. Perform the invalid required-activation detach in a separate labeled replay and demonstrate its derivative mismatch. Do not hide that semantic change behind an apparently successful forward-value comparison.

For the valid diagnostic repair, compare at least several complete parameter updates from the same initial state, samples, and optimizer configuration. A matching loss in the first forward pass cannot prove unchanged gradients. Keep CPU export completion explicit before inspecting its values, and note that scalar extraction can introduce synchronization. Compare full diagnostic retention with a bounded summary rather than assuming every analysis needs all historical values. If the only way to meet the memory budget is truncating required history, classify that proposal as a different algorithm with its own validation criteria. Do not present it as an exact implementation repair of the original differentiation task.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def export_diagnostic(value, export_policy):
    ...

def test_release_after_owner_removal(config, owner_sequence):
    ...

def E08(config):
    # Validate the training derivative contract before accepting detach.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A disappearing Python wrapper is not proof of released CUDA storage. Combine owner removal, scoped graph reachability, and matching allocator samples while preserving unknown native owners. Compare shared-storage identities only within controlled generations. Export derivative errors and not just output errors. If cleanup leaves a detached CUDA payload in a list, classify the remaining footprint as payload retention rather than claiming that detach failed to break the gradient edge.

Part 7 - Engineering Interpretation and Philosophy

A differentiation boundary is a mathematical decision. It is appropriate for metrics and explicitly nondifferentiated branches, but it must be reviewed against required gradient paths. Explain which evidence establishes safe history removal and which only establishes shared storage. Later analyzers may suggest detach as a candidate for such boundaries, but they must never automatically truncate required training derivatives to satisfy a budget.

19.48.10 Exercise 09

Exercise Title: Compare backward() with backward(retain_graph=True) and Measure the Memory Cost of Preserving the Graph for Reuse

Part 1 - Exercise Contract and Why It Matters

Compare ordinary backward with backward retaining saved state under identical forward computation and gradient requirements. Measure the post-backward footprint, full-step peak, and cleanup after roots are released. The experiment must distinguish preserving reusable saved values from creating a derivative graph. A single boolean should not be treated as a universal leak switch without considering which graph owners remain reachable.

Part 2 - System and Memory Mental Model

retain_graph controls whether the graph's saved state is freed for the relevant backward traversal. It does not by itself construct the differentiable graph of the derivative; create_graph addresses that separate requirement. Retaining one graph for a legitimate subsequent traversal

differs from retaining a new graph every iteration in a container. Gradient accumulation also remains a separate source of live buffers and changing numerical results.

Part 3 - Quantitative Prediction Before Execution

Predict retained saved capacity using the unique storage inventory, excluding unavoidable parameter overlap. Compare a one-graph retained replay with a bounded multi-graph history. Explain why the retained-state difference may appear after backward yet not change a forward-dominated overall peak. Predict the effect of a final non-retaining backward and of dropping every root without another traversal.

Part 4 - Experimental Design and Instrumentation

Generate fresh inputs and model state for each policy. Match gradient clearing and include an identical completed sampling point after backward. Preserve only the roots required by the chosen experiment; ensure the diagnostic traversal is not another hidden root. Use operators with saved values and a trivial no-save control. Record selected options explicitly rather than relying on implicit defaults that may depend on create_graph.

Record the number of retained graphs and the intended future use of each. A single graph intentionally reused twice is a different workload from many abandoned retained graphs. Include a control that deletes all roots without a second backward, and distinguish logical release eligibility from actual completion-dependent allocator reuse. If measuring retained state after backward, keep gradient and optimizer state identical between cases. Do not use a fresh optimizer in one case and a warmed optimizer in the other. Report whether the output itself is large enough to dominate the remaining memory, so a modest saved-state difference is not mistaken for a failed experiment.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def compare_backward_retention(config, retain_policy):
    ...

def measure_after_final_use(state, sampling_scope):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check gradients against the same reference before interpreting memory savings. Repeated backward accumulates gradients unless cleared; account for that numerical contract. A no-save graph can show little retained CUDA difference, which is valid. Report output storage and residual graph metadata separately from saved activations. Treat allocator reservation as retained cache unless other evidence establishes live ownership; empty_cache is not a substitute for releasing a reachable graph.

Part 7 - Engineering Interpretation and Philosophy

Retention is justified by future derivative work, not by habit. Explain which subsequent computation requires the preserved state and when that obligation ends. Compare retaining, recomputing the forward, and combining losses in a later exercise. The preferred policy minimizes unnecessary residency while preserving all requested derivatives, and its benefit must be evaluated at the actual whole-step peak.

19.48.11 Exercise 10

Exercise Title: Perform Multiple Backward Passes Through the Same Graph and Determine Exactly When retain_graph=True Is Required

Part 1 - Exercise Contract and Why It Matters

Perform multiple vector-Jacobian products through a shared forward graph and establish when earlier traversals must preserve saved dependencies. Compare retention, recomputation, and a combined-loss traversal. Deliver gradients, memory, and runtime for each valid strategy. The word exactly applies to the chosen graph and requested derivative task; it must not become a universal claim that every repeated backward always fails without retention.

Part 2 - System and Memory Mental Model

A later traversal needs retained state if it revisits backward operations whose required saved values were already freed. Some trivial derivative formulas require no saved values and may permit repetition without an error. Such behavior is not a general programming guarantee. Independent forward graphs do not require shared retention. For scalar losses, combining objectives can compute the sum of gradients without separately traversing a shared subgraph twice.

Part 3 - Quantitative Prediction Before Execution

Predict the parameter gradient for two losses sharing an intermediate, including the weighting and accumulation convention. Compare two retained traversals with one combined traversal and two independently recomputed forwards. Estimate how long saved capacity persists under each schedule. Include a nonlinear saved-value case and a simple no-save control; predict different failure behavior without using the control as a universal rule.

Part 4 - Experimental Design and Instrumentation

Keep parameters unchanged until all derivative work using their forward values has completed. Avoid optimizer steps or in-place mutations between traversals. Use explicit retain settings for the nonfinal and final uses, then clear accumulated gradients consistently. If computing separate gradients with autograd.grad, compare each requested result rather than only their sum. Track forward count and timing so recomputation cost is not excluded from an allegedly equivalent benchmark.

Write the derivative requests in advance: individual loss gradients, a weighted sum, or multiple vector-Jacobian products. These are related but not identical outputs. Document any normalization by batch size and the effect of gradient accumulation. Recomputing requires matching input values and relevant random or mutable state; start with a pure deterministic function before introducing those complications. Include a test where two losses share only parameters but come from independent forwards, so the learner does not infer graph sharing from parameter identity alone. Treat an attempted optimizer update between shared traversals as a rejected schedule and preserve the reason in the evidence record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def execute_derivative_schedule(config, schedule):
    ...

def compare_requested_gradients(results, oracle):
    ...

def E10(config):
    # Reject parameter mutation before all old-value consumers finish.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Record whether a repeated traversal fails, the failure phase, and the installed operator behavior. Do not depend on exact exception wording. Confirm that the final use permits saved-state release and that logging has not retained roots. Check the combined-loss gradient against the weighted sum while recognizing that it does not return individual gradients by itself. Validate memory and runtime using the same total requested work for each comparison.

Part 7 - Engineering Interpretation and Philosophy

Scheduling derivative work is a memory decision. Retaining the graph may be appropriate for separate derivative queries; a combined objective or fresh forward can remove that need in other tasks. Explain the smallest valid schedule for the application and the evidence that its release boundary is correct. An optimization is meaningful only after the required outputs of differentiation have been specified.

19.48.12 Exercise 11

Exercise Title: Reproduce a Memory Explosion from Repeated create_graph=True Usage and Explain How Higher-Order Gradient Graphs Expand Memory Requirements

Part 1 - Exercise Contract and Why It Matters

Demonstrate bounded growth caused by retained higher-order derivative work without asserting that create_graph always causes an explosion. Compare fresh independent graphs that are released with a differentiable unroll or stored derivative history that remains reachable. Deliver the derivative dependency map, memory trend, and explicit stopping policy. A large measured increase is an outcome; no physical allocation failure is required.

Part 2 - System and Memory Mental Model

create_graph records operations used to compute derivatives so that later derivatives can flow through them. The resulting derivative graph has its own saved values and owners. Repeated use can remain bounded when old work is released. Using backward with create_graph can create parameter-gradient reference cycles; autograd.grad is the preferred starting point for this exercise, with explicit ownership and cleanup of returned derivative tensors.

Part 3 - Quantitative Prediction Before Execution

Choose a smooth nonlinear objective with a nonzero second derivative. Predict which derivative outputs still require gradients and how an unroll of depth k extends dependencies. Do not assume linear or exponential memory growth without deriving the chosen construction's retained work. Include a constant derivative example to explain why create_graph does not force every returned gradient to carry further differentiable structure.

Part 4 - Experimental Design and Instrumentation

Sweep a modest unroll depth under both host and CUDA budgets, starting from fresh state per depth. Separate retained derivative outputs from CPU-only trend records. Use an analytic scalar or small-vector oracle before scaling. If including backward-created gradient cycles as a secondary control, specify how .grad references are removed during cleanup. Stop on configured admission limits and record budget rejection separately from CUDA OOM.

Choose both a released independent-iteration control and a deliberately connected unroll. Track whether each new state depends differentiably on the previous state and whether returned gradients are appended to a history. These are separate mechanisms and should be changed one at a time. In the optional backward-based cycle case, document clearing .grad references to None after use, rather than assuming numeric zeroing breaks object relationships. Restrict the highest depth using predicted storage and a safety margin. If a budget stops the sweep, report the largest admitted depth and measured trend without extrapolating a hardware failure that was never observed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_bounded_derivative_unroll(config, depth):
    ...

def release_derivative_owners(state, gradient_policy):
    ...

def E11(config):
    # Compare retained unrolls with independent released graphs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate first and second derivatives before trusting the memory experiment. Report graph ownership, retained depth, logical saved bytes, unique capacity, and measured peak as different quantities. A failure because a derivative is constant is not evidence of corrupted autograd. Compare cleanup with a fresh baseline and inspect lingering gradient references. Reject any conclusion that attributes unbounded growth to create_graph alone when the reproducer also stores an ever-growing history.

Part 7 - Engineering Interpretation and Philosophy

Higher-order differentiation requests more mathematical work, so its memory cannot be judged against a first-order task as if both obligations were the same. The useful question is whether retained history is necessary for the chosen derivative. Explain where a truncation would change the algorithm, where release is safe, and which growth pattern the bounded experiment actually supports.

19.48.13 Exercise 12

Exercise Title: Compare First-Order and Second-Order Gradient Computation by Node Count, Saved Tensor Memory, Peak VRAM, and Runtime

Part 1 - Exercise Contract and Why It Matters

Compare a first-order gradient task with a precisely defined second-order task, using graph structure, saved-state estimates, peak VRAM, and runtime. Use a Hessian-vector product as the primary higher-order result so that the experiment does not accidentally allocate a dense Hessian. Each task needs its own numerical oracle; the second-order run performs additional required work and is not simply an inefficient version of the first-order run.

Part 2 - System and Memory Mental Model

A first gradient computed with create_graph can support differentiation of its dot product with a fixed direction. That procedure produces a Hessian- vector product for a smooth scalar objective. Dense Hessian construction has a different output-size and memory contract. Node counts reflect observed backward dependencies and host graph metadata; they are not direct byte measurements and can change with implementation details.

Part 3 - Quantitative Prediction Before Execution

For n differentiated scalar inputs, compare the output payload sizes of a gradient, one Hessian-vector product, and a dense Hessian. Predict which saved values must survive until the second derivative is evaluated. Estimate a range for peak overlap rather than summing independently observed peaks. Use a quadratic or another smooth analytic objective to predict exact reference derivatives before any CUDA measurements.

Part 4 - Experimental Design and Instrumentation

Match model state, input values, precision, device, and warmup policy. Measure full task latency including the first gradient required by the second-order run. Keep the direction fixed and nondifferentiated unless an additional mixed derivative is explicitly requested. Count graph nodes only in separate diagnostic replays. Export derivative errors as CPU scalars and release all derivative roots at the stated final-use boundary.

Use a fixed normalized direction for the Hessian-vector product and preserve its seed. Validate the gradient of the scalar objective and the directional second derivative independently. Count nodes with the same traversal coverage for each task and avoid retaining the counting result's live node objects. If adding a dense Hessian experiment, bound its dimension and include output storage in the cost rather than comparing only internal graphs. Distinguish higher-order support failures of a chosen operator from a general autograd failure. Report whether timing includes graph construction, derivative execution, and result transfer, since excluding different components can reverse an apparently favorable runtime comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def request_first_order(objective, inputs, policy):
    ...

def request_hessian_vector_product(objective, inputs, direction):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare both requested derivatives with their own oracles and check finite differences on a small well-conditioned case where appropriate. Report dtype and error tolerances rather than demanding bitwise equality across different kernels. A zero Hessian can be mathematically valid. Include current allocation, peak allocation, reserved capacity, and cleanup results. Explain any graph count difference without claiming that twice as many nodes implies twice the GPU memory.

Part 7 - Engineering Interpretation and Philosophy

The comparison should reveal the incremental residency and execution cost of a declared derivative task. It should also identify unnecessary ownership that can be removed without changing that task. Explain why switching from a dense Hessian to a Hessian-vector product is a change in requested output, while releasing finished diagnostic records is an implementation improvement within the same mathematical contract.

19.48.14 Exercise 13

Exercise Title: Analyze a Residual Network and Determine Why Skip Connections Extend Activation Lifetimes Beyond Their Producing Layer

Part 1 - Exercise Contract and Why It Matters

Analyze activation lifetimes in a residual network using both forward consumers and backward requirements. Deliver a branch-aware timeline and a counterexample to the claim that every skip addition saves its entire input for backward. Distinguish architectural comparisons from correctness-preserving rewrites: a plain chain and a residual network generally compute different functions, so their outputs are not interchangeable equivalence references.

Part 2 - System and Memory Mental Model

A skip value must survive until its forward merge consumer has read it. The backward formula for an addition often does not need the input values, while operations within the branch may save substantial state. Aliases, repeated uses, normalization, and gradient requirements can extend lifetimes further. The producing layer's end is therefore not a universal release point, but the skip edge alone does not prove backward-time retention of that value.

Part 3 - Quantitative Prediction Before Execution

Draw a residual block with a long branch and identify the last forward reader of the skip tensor. Then add an operation whose derivative saves a related value and predict the new lifetime. Calculate unique live storage at several cuts through the schedule. Explain how branch overlap can move the memory peak even when the total logical number of produced activation elements is unchanged.

Part 4 - Experimental Design and Instrumentation

Use a deterministic residual model with named branch boundaries. Compare forward-use metadata with saved-tensor observations and completed memory samples. Include an addition-only control and a nonlinear branch that saves values. Validate any proposed early release or offload within the same residual function. Track whether a view or another consumer still owns the backing storage before declaring the skip tensor reclaimable.

Mark branch creation, merge submission, merge completion, and saved backward reads as separate observations. Forward submission order does not establish that the skip storage is safe to overwrite. Include a case where an intermediate is reused twice within the branch and another where the skip is a view. For an offload candidate, retain a valid restoration route and account for source lifetime through the copy. Compare the proposed interval against actual last readers and aliases. The residual's existence may explain a longer forward lifetime, but only observed derivative requirements justify extending the same value through backward. Preserve both kinds of evidence in the annotation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def trace_residual_obligations(config, region_labels):
    ...

def predict_branch_overlap(storage_records, consumer_events):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check outputs and parameter gradients against the original residual model for all interventions. Compare observed forward lifetime extension with saved backward lifetime extension separately. Report cases where the skip shares storage with another activation or where a compiler changes the operation representation. Keep eager execution as the primary controlled scope. A higher memory peak than the chain does not by itself identify the exact residual value responsible.

Part 7 - Engineering Interpretation and Philosophy

Residual connections illustrate why a local layer view can miss future users. The correct release boundary follows every required consumer, including those outside the producing branch.

Explain which lifetime extension belongs to the architecture and which belongs to an implementation or an accidental owner. That distinction determines whether optimization requires recomputation, transport, ownership cleanup, or a change in model semantics.

19.48.15 Exercise 14

Exercise Title: Build a Tensor Lifetime Timeline from Forward Creation Through Last Backward Use and Identify Opportunities for Early Release or Offloading

Part 1 - Exercise Contract and Why It Matters

Build a timeline from value production through the last required consumer and identify conservative release or offload opportunities. Represent uncertainty between host observations and actual device completion. Deliver both a host event log and a dependency-aware GPU interpretation. A hook callback timestamp must not be presented as an exact CUDA execution timestamp or a proof that storage is immediately safe to reuse.

Part 2 - System and Memory Mental Model

A saved tensor can be unpacked before the consuming kernel finishes reading it. Several consumers, aliases, or streams can share the backing allocation. Python last-use observations therefore provide only part of the lifetime argument. GPU events and explicit stream dependencies can bound completion; multiple streams form a partial order rather than one universally comparable sequence of wall-clock events. Pending frees also separate owner disappearance from allocator reuse.

Part 3 - Quantitative Prediction Before Execution

For each observed storage, predict production, forward last use, backward retrievals, and final completion bounds. Calculate a conservative byte-time measure over the chosen observation clock, documenting its limits. Include a cross-stream reader that outlives the last Python unpack event. Predict why reclaiming at that callback would be unsafe and how an explicit completion dependency changes the admissible reuse boundary.

Part 4 - Experimental Design and Instrumentation

Use bounded CPU metadata records with event IDs and causal links. Place CUDA events on the relevant streams in a separate timing replay and join only where the measurement contract requires completion. Preserve shared save payloads until all required consumers finish. Avoid device-wide synchronization after every callback because it would destroy the overlap being studied. Record timestamp domains and distinguish measured intervals from inferred or conservative bounds.

Define interval endpoints and inclusion conventions in the exported schema. If using half-open intervals for completed ownership, explain how simultaneous events and unresolved completion are represented. Never subtract timestamps from different devices or clock domains without a supported relationship. On multiple streams, use causal dependencies to justify ordering and retain incomparable events as such. Include a payload unpacked twice and verify that the first retrieval does not close its lifetime. If callback events are missing, keep the upper bound open. Validate the byte-time calculation on synthetic intervals, including overlapping aliases that must contribute only one backing capacity to the unique live envelope.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def record_lifetime_observation(kind, storage_id, causal_links):
    ...

def derive_completion_bounds(host_records, stream_events):
    ...

def E14(config):
    # A final unpack callback is not final device-read completion.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate the timeline against a small serial case with deliberately completed boundaries, then add shared and asynchronous cases. Reject negative durations caused by mixing clocks instead of silently clipping them. If the final reader is unknown, retain an open lifetime bound. Compare peak estimates with allocator measurements while accounting for missing workspace. Report the timeline's collection overhead and any scheduling changes introduced by timing events or hooks.

Part 7 - Engineering Interpretation and Philosophy

A conservative timeline is useful even when exact physical release is unknown. It can rule out unsafe reuse and identify intervals long enough to consider offloading. Explain which opportunity remains valid under the uncertainty bounds and what additional observation would narrow them. An early-release recommendation must satisfy both ownership and execution dependencies, rather than relying on a visually convenient gap in a host trace.

19.48.16 Exercise 15

Exercise Title: Build an Autograd Memory Graph That Annotates Every Node with Saved-Tensor Bytes, Lifetime, and Downstream Consumers

Part 1 - Exercise Contract and Why It Matters

Integrate observed backward nodes, saved slots, and underlying storages into an auditable memory graph. Annotate every observed node with coverage status, attributed saves where supported, and lifetime bounds. Preserve shared and ambiguous relationships instead of assigning each allocation to one apparent owner. Deliver a schema and a small validated export that can support later policy recommendations without claiming complete visibility into all autograd or allocator internals.

Part 2 - System and Memory Mental Model

A node-to-slot-to-storage model separates computational dependency from memory ownership. Several nodes can save references to one backing allocation, and one node can need several saves. Reverse dependency edges describe consumers within the observed graph, not

every possible application consumer. Some node attributes are unsupported or unmapped; zero is appropriate only when absence is established under the declared inspection coverage.

Part 3 - Quantitative Prediction Before Execution

Predict graph records for a shared parameter, overlapping views, and a saved activation used by two branches. Compute logical slot totals and unique live storage envelopes separately. State why summing per-node reference totals does not reconstruct the peak. Add persistent state and unobserved workspace as separate categories, and predict how an unresolved attribution changes a confidence statement without altering the raw observation.

Part 4 - Experimental Design and Instrumentation

Define run IDs, traversal IDs, storage generations, scope labels, and nullable fields before integration. Link hook observations only through supported application attribution or controlled examples; callback order alone is not a node mapping. Build reverse edges with coverage annotations. Export scalar metadata and bounded adjacency records, then release diagnostic objects. Compare an analyzer-enabled replay with a clean replay to detect observer retention and instrumentation costs.

Version the export schema and attach field provenance. Distinguish observed capacity, derived logical size, inferred association, and unsupported data. Use stable application labels to compare replays, while keeping pointer and node identifiers local to their run. Provide a synthetic graph with an unmapped save so downstream aggregation must propagate uncertainty. Check that removing a node reference from the export does not erase a still-shared storage record. Keep a separate persistent-state catalog for parameters and gradients. Reports should expose both per-node references and storage-level occupancy without presenting either as a complete measurement of context, communication, or opaque backend workspace.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MemoryGraph:
    nodes: tuple
    saved_slots: tuple
    storages: tuple
    relations: tuple
    coverage: object

def build_memory_graph(traversal, save_events, lifetime_bounds):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate schema invariants on synthetic graphs before collecting CUDA data. Every relation must reference an existing record, shared storage must remain shared, and unknown capacity must never become zero through aggregation. Test an allocation address reused in another generation. Compare a known small computation with its exported graph and explain remaining mismatches. Record whether a lifetime is measured, inferred, bounded, or unresolved in the exported field itself.

Part 7 - Engineering Interpretation and Philosophy

The integrated graph should preserve distinctions needed for decisions rather than conceal them behind a single attractive number. Explain how a recommendation can trace back to observations, assumptions, and missing evidence. Completeness is scoped to the inspected roots and supported save paths. An explicit unknown is more valuable than a fabricated node attribution that could lead to an unsafe detach or premature storage reuse.

19.48.17 Exercise 16

Exercise Title: Compare Normal Backpropagation, Activation Checkpointing, and Saved-Tensor CPU Offloading Using the Same Autograd Memory Graph

Part 1 - Exercise Contract and Why It Matters

Compare normal backpropagation, activation checkpointing, and saved-tensor CPU offloading for the same model and derivative task. Deliver a memory-time-host RAM comparison and explain the different obligations each technique changes. Use the memory graph as a common application-level reference, while allowing the observed backward representation and number of recomputation events to differ. Numerical validation is a requirement before any memory-saving claim.

Part 2 - System and Memory Mental Model

Checkpointing retains enough inputs and state to recompute selected forward work instead of keeping all intermediate saved values. CPU offloading preserves values in another memory tier and restores them for backward. Neither makes all activation memory disappear. Transfers need host capacity and completion dependencies; recomputation consumes time and can move the peak. Hook contexts can override rather than automatically compose with one another.

Part 3 - Quantitative Prediction Before Execution

Predict saved CUDA capacity avoided, checkpoint input residency, CPU payload, transfer volume, and recomputation work for one selected region. Include the possibility of temporary coexistence during transport. Estimate latency from measured transfer and compute costs without assuming perfect overlap. Predict which region is the best candidate under a fixed host budget, then state what observation could reverse that prediction.

Part 4 - Experimental Design and Instrumentation

Use version-checked non-reentrant checkpointing with use_reentrant=False as the primary checkpoint policy. Start with deterministic pure region functions and explicit inputs. Use supported save_on_cpu or a validated pack/unpack implementation for offloading, preserving values and restoration device. Collect diagnostic save graphs in separate passes when hook composition is not validated. Measure ordinary execution without heavy tracing and include backward plus optimizer update in the full-step region.

For CPU offloading, cap pageable and pinned host use and test restoration before scaling. With asynchronous pinned transfers, do not inspect CPU payload contents or recycle source and destination buffers before the relevant copy completes. Use completion dependencies appropriate to the actual streams. For checkpointing, include recomputed work in runtime and distinguish original and recomputation event generations. Compare application roles rather than requiring identical internal node graphs. If a logging hook overrides an offload hook, the run is not a valid offload measurement. Verify the active policy or use separate collection passes, and record the installed version's composition behavior in the reproducibility evidence.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.checkpoint import checkpoint

def execute_memory_policy(model, batch, policy, host_budget):
    ...

def compare_policy_correctness(reference, candidates, tolerances):
    ...

def E16(config):
    # Validate hook/checkpoint composition for the installed version.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare losses, required parameter gradients, and several optimizer updates from identical initial state. Report host peak, CUDA peak, reserved bytes, latency, and transfer volume. If adding randomness, preserve and test the relevant RNG behavior; if adding mutable state, prove recomputation safety. Higher-order support requires its own validation. A missing feature or unsupported hook combination is a reported limitation, not an equivalent fallback silently inserted into the result.

Part 7 - Engineering Interpretation and Philosophy

Keep, offload, and recompute move different costs across time and memory tiers. Explain which policy addresses the measured peak and which merely lowers a noncritical endpoint. Compare at the same derivative contract and host budget. The best policy is workload-specific: storage lifetime, transfer readiness, and recomputation cost matter more than assuming that a particular technique always reduces whole-step memory or improves throughput.

19.48.18 Exercise 17

Exercise Title: Detect an Unexpected Long-Lived Activation by Combining Autograd Graph Traversal, Saved-Tensor Hooks, and CUDA Memory Snapshots

Part 1 - Exercise Contract and Why It Matters

Investigate one unexpectedly long-lived activation using graph dependencies, saved-tensor observations, and CUDA allocator snapshots. Deliver a causal hypothesis, a minimal discriminating intervention, and a report separating allocation origin from retaining ownership. The three observation sources have different scopes and timestamps; matching them must preserve uncertainty rather than forcing a complete one-to-one identity from an address alone.

Part 2 - System and Memory Mental Model

A snapshot describes allocator-visible blocks and states, while a graph traversal describes differentiation dependencies and hooks describe covered save activity. A creation stack can locate where storage originated without explaining why it survives. Pending stream readers and cached inactive blocks can resemble retention in coarse samples. Diagnostic tools themselves can keep tensors or node objects alive, creating the behavior they are meant to explain.

Part 3 - Quantitative Prediction Before Execution

Predict the expected lifetime of a chosen activation and the boundary after which its continued residency would be surprising. Construct alternative hypotheses: legitimate saved state, a Python diagnostics owner, an alias, pending completion, or analyzer self-retention. State which measurement would distinguish each pair. Estimate the unique capacity recoverable by removing one owner, including a case where another owner makes that estimate zero.

Part 4 - Experimental Design and Instrumentation

Use bounded, version-checked allocation history in a diagnostic replay and capture matching completed phase boundaries. Preserve allocation generations when correlating addresses. Record container insertions and removals with CPU metadata, and avoid storing suspect tensors in the evidence report. Compare an intervention removing only the optional owner against the original workload. Keep model math, gradients, and input schedule unchanged throughout the causal comparison.

Make the suspected owner optional so its removal does not alter the loss or gradient path. A debug list or hook-owned history is a useful controlled starting point. Preserve allocation-history bounds and note whether earlier events were overwritten before the snapshot. Include an address-reuse synthetic case so correlation cannot silently equate two generations. When a snapshot shows a block awaiting completion, compare a later deliberate completion boundary before classifying it as unnecessary retention. If creation frames are absent, keep the allocation origin unresolved. The final report must state which owner intervention was tested and whether its predicted unique-capacity relief was actually observed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def correlate_retention_evidence(graph, saves, snapshots, owner_events):
    ...

def test_owner_intervention(config, intervention):
    ...

def E17(config):
```

```
# Preserve ambiguity and snapshot capture coverage.
...
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that the suspected storage persists across the declared boundary and that its generation is not a reused address. Compare numerical results after the intervention and require repeated evidence of the ownership effect. If the suspected allocation remains, check aliases and pending work before rejecting the hypothesis. Missing frames or truncated history limit the report's coverage. Do not turn correlation between a large save and a peak into a causal proof.

Part 7 - Engineering Interpretation and Philosophy

A useful investigation narrows alternatives and identifies the smallest next experiment. It may conclude that a value is legitimately live or that the current evidence cannot identify an owner. Explain which finding is established, which remains a ranked hypothesis, and what change was validated. Attribution confidence should follow the evidence chain, not the apparent precision of a stack trace or storage pointer.

19.48.19 Exercise 18

Exercise Title: Stress-Test Autograd Memory with Long Sequences, Residual Connections, Higher-Order Gradients, Retained Graphs, and Selective Checkpointing

Part 1 - Exercise Contract and Why It Matters

Stress-test the analyzer across long sequences, residual branches, higher-order derivatives, retained graphs, and selective checkpointing. Include healthy controls and instrumentation-induced retention. Deliver a coverage matrix, correctness outcomes, overhead measurements, and minimal counterexamples to unsupported universal rules. Stress means exploring difficult interactions under explicit budgets, not deliberately exhausting a shared machine until it becomes unusable.

Part 2 - System and Memory Mental Model

Interactions can invalidate assumptions that held in isolated exercises. Checkpoint recomputation changes save-event sequences; higher-order graphs introduce new derivative obligations; shared storage couples release decisions; and asynchronous readers extend completion bounds. Dynamic shapes change capacity without implying a leak. A single memory trend or node count cannot distinguish these causes without the workload's ownership and derivative contract.

Part 3 - Quantitative Prediction Before Execution

Predict expected categories for each test: bounded healthy residency, intentionally retained state, ambiguous attribution, unsupported feature, or invalid semantic rewrite. Estimate admission limits from conservative live storage and host logging budgets. Design a pair of cases with similar peak VRAM but different ownership causes, and another pair with similar saved-slot totals but different unique backing capacity. State what the analyzer should and should not infer.

Part 4 - Experimental Design and Instrumentation

Build a deterministic small test matrix before scaling sequence length or unroll depth. Add dimensions one at a time, then selected interacting pairs. Use fresh initial state and separate diagnostic and ordinary measurement replays. Put deadlines, event limits, and memory admission bounds around every case. Validate checkpoint and hook interactions against the installed version. Record explicit not-supported and not-measured statuses instead of silently omitting difficult combinations.

Maintain separate expected labels for saved-state retention, output payload retention, graph metadata retention, asynchronous pending use, and legitimate persistent state. A case can have multiple causes. Add a bounded dynamic-shape sequence where memory stabilizes after reaching its maximum shape, and a fixed-shape case with an expanding diagnostics container. Keep an intentionally incorrect hook payload as a rejected correctness control. Evaluate the system on cases not used to choose ranking thresholds. Report collection slowdown, host log size, and unsupported feature interactions alongside successful detections. A refusal to recommend under missing evidence can be correct behavior and should not be scored as a false negative automatically.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_stress_matrix(config, feature_support):
    ...

def run_admitted_case(case, budgets, evidence_sink):
    ...

def E18(config):
    # Separate healthy, invalid, unsupported, and retained cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Score graph coverage, storage deduplication, lifetime bounds, and recommendation correctness separately. An accurate alert with a wrong owner is not successful root-cause analysis. Validate all claimed equivalent outputs and gradients; invalid detach rewrites must be rejected even when memory improves. Report false positives on warmup, caches, and legitimate retained derivative work. Keep failures to reproduce and budget rejections in the results, with their actual reasons.

Part 7 - Engineering Interpretation and Philosophy

The stress suite should expose the analyzer's boundary of competence. Explain which assumptions survived interaction and which require narrower support claims. A counterexample improves the system when it becomes an explicit eligibility rule or an uncertainty field. The goal is not to produce a recommendation for every case, but to make valid recommendations traceable and prevent unsupported ones from being mistaken for safe optimizations.

19.48.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Autograd Memory Analyzer That Maps Saved Tensors, Graph Dependencies, Lifetimes, and Peak VRAM to Recommend Keep, Offload, Recompute, or Detach Decisions

Part 1 - Exercise Contract and Why It Matters

Integrate a bounded PyTorch autograd memory analyzer that connects observed saved values, graph dependencies, ownership, lifetime bounds, and measured whole-step peaks. Produce candidate keep, offload, recompute, or detach decisions with explicit eligibility checks and validating replays. Deliver an auditable report and benchmarks against simpler policies. The runtime must be allowed to return insufficient evidence instead of automatically modifying an uncertain gradient path.

Part 2 - System and Memory Mental Model

Correctness constraints precede cost ranking. Keep preserves the value in place; offload changes residency with restoration obligations; recompute requires a reproducible region and its inputs; detach changes differentiation and is eligible only for declared nondifferentiated branches or an explicitly different algorithm. Shared storage, future consumers, transport buffers, and incomplete attribution constrain the savings available from each action. A graph annotation is evidence for a decision, not execution authorization by itself.

Part 3 - Quantitative Prediction Before Execution

Predict a candidate's reduction at the actual peak rather than its isolated logical size. Compare expected time costs for transport, recomputation, and waiting, with host and CUDA capacity constraints. Include shared capacity that would remain after the action. Rank only eligible candidates and preserve uncertainty intervals. Define success as validated required derivatives within budget, accompanied by measured latency and analyzer overhead.

Part 4 - Experimental Design and Instrumentation

Integrate the previous schemas, supported collectors, scope-aware deduplication, and conservative lifetime analysis. Separate collection, recommendation, and validation stages. Use known small cases for development and held-out workloads for evaluation. Benchmark normal execution, analysis overhead, and the selected policy independently. Bound capture frequency, host log size, replay count, and optional intervention attempts. Keep all automatic actions inside explicitly validated capability and correctness limits.

Define the final report before running integration. Each candidate needs a run ID, application target, derivative contract, evidence coverage, unique-capacity estimate, timing assumptions, host requirement, eligibility decision, and validating replay. Keep predicted effects separate from measurements and interpretation. Preserve rejected actions with reasons, particularly required-gradient detach, unsafe asynchronous reuse, and unsupported hook composition. Measure end-to-end analysis and validation cost rather than only the resulting optimized step. Do not claim global optimality from a greedy candidate search. Report the best validated policy in the tested range, remaining uncertainty, and the smallest next experiment that could improve the decision.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class Recommendation:
    action: str
    target: object
    prerequisites: tuple
    predicted_effect: object
    uncertainty: tuple

def propose_actions(memory_graph, derivative_contract, budgets):
    ...

def validate_candidate(config, recommendation, reference):
    ...

def E19(config):
    # Refuse unsafe detach and unsupported release assumptions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require an evidence chain from each recommendation to observations, assumptions, eligibility rules, and an independent validation result. Report losses, gradients, updates, peak bytes, host footprint, runtime, and unsupported cases. Compare against always-keep and one simple eligible policy rather than only favorable handpicked examples. Measure prediction error separately from diagnostic value. A recommendation that saves memory while changing required derivatives is a correctness failure, regardless of its apparent capacity benefit.

Part 7 - Engineering Interpretation and Philosophy

The finished analyzer should help an engineer decide what to investigate or change with confidence proportional to the evidence. Explain remaining uncertainty about opaque state, execution timing, and hidden owners. Prefer a small supported policy set with clear counterexamples over broad automatic claims. The strongest result combines validated savings, preserved mathematical obligations, bounded instrumentation, and an honest statement of cases where keeping the existing computation is the only justified action.

19.49 DMM47

Chapter Title: Detach, No-Grad, and Inference Mode Memory Control
Specialization: Dynamic Memory Management and CUDA Systems

19.49.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Gradient Tracking, Graph Construction, Tensor History, and Memory Saved When Autograd Is Disabled

Part 1 - Exercise Contract and Why It Matters

Define gradient tracking as a requirement of the workload rather than a switch chosen from memory pressure alone. Distinguish default grad execution, no-grad execution, inference execution, parameter freezing, output detachment, and module evaluation behavior. Deliver a decision table with required parameter and input derivatives, future output consumers, ownership, and mode eligibility. Every later exercise must preserve this declared derivative contract before interpreting any reduction in memory.

Part 2 - System and Memory Mental Model

Graph construction depends on execution mode, differentiable operations, and input gradient requirements. Disabling recording avoids corresponding backward state but still allocates outputs, temporary workspace, parameters, and caches. model.eval changes behavior of relevant modules without disabling autograd. A detached result shares storage with its source. Inference execution removes additional tracking overhead but imposes stronger restrictions on tensors it creates, especially when later autograd work would need those values.

Part 3 - Quantitative Prediction Before Execution

Predict memory as persistent state plus concurrently live payload, saved backward state, and temporary capacity. Avoid summing peaks observed at different times. For a saved view, compare logical bytes with unique backing capacity. Construct a workload with no trainable inputs or parameters and predict why default execution may already construct no backward graph. Explain why disabling autograd does not imply zero CUDA allocation or a fixed percentage saving.

Part 4 - Experimental Design and Instrumentation

Begin with a deterministic eager model and explicit derivative requirements. Create separate training and evaluation contracts, recording model behavior mode independently from grad mode. Name the future consumers of each exported tensor. Include one evaluation result used only for metrics and one feature used by a later trainable layer. Mark unsupported layouts or differentiation features explicitly. Use synthetic accounting examples before attempting real CUDA measurements.

Preserve GPU identity, installed software versions, allocator backend, seed, model dimensions, optimizer, precision, and initial state identifier. Separate cold setup from warmed measurements and use additional seeds only after a fixed-seed comparison is stable. State whether timing includes transfers, collation, calibration, metric finalization, and recovery. Use deliberate completion boundaries and reset peaks for the declared region. A training comparison includes forward, backward, and optimizer update; allocation-only or forward-only experiments need their own explicit regions. Record host and CUDA budgets separately, and never retain live graphs in the evidence log merely to simplify later reporting.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DerivativeContract:
    parameter_targets: tuple
```

```
    input_targets: tuple
    output_consumers: tuple
    forward_ad_required: bool

def classify_mode_eligibility(contract, tensor_provenance):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require counterexamples to the claims that evaluation disables graph recording, that detachment creates independent storage, and that inference allocates no payload. Validate the requested derivatives on a small analytic case. Keep predictions, observations, and interpretations separate. Every measured row needs a run ID, configuration, shape, byte budget, timing scope, outcome, and failure phase when applicable. Unknown capacity or unsupported behavior must not silently become zero. Report a missing CUDA measurement honestly rather than supplying representative hardware numbers.

Part 7 - Engineering Interpretation and Philosophy

The purpose of mode control is to remove obligations the application never requested while preserving those it did. Explain which distinction changes a real decision: graph history, storage ownership, module behavior, or later consumer compatibility. Carry that explanation into the controller design. A lower peak obtained by silently removing a required derivative is a correctness failure, even when forward values still look plausible.

19.49.2 Exercise 01

Exercise Title: Compare a Normal Forward Pass, torch.no_grad(), and torch.inference_mode() by Peak VRAM, Allocations, and Runtime

Part 1 - Exercise Contract and Why It Matters

Compare the same forward workload under default grad, no-grad, and inference execution. Measure whole-region peak allocation, supported allocation activity, reserved capacity, and latency. Deliver an output equivalence check and a scoped interpretation of memory differences. Forward-only comparisons should not include backward in only one candidate; a separate training reference can explain additional costs without becoming a misleading benchmark baseline.

Part 2 - System and Memory Mental Model

Default execution can save values for backward when differentiable inputs or parameters require gradients. No-grad suppresses reverse graph recording for the scoped computations. Inference execution additionally avoids some tracking work. These changes do not necessarily remove parameter storage, output payload, workspace, or allocator caches. Similar reserved memory between modes can coexist with different live allocations, while allocation counts depend on the instrument's accounting layer and backend support.

Part 3 - Quantitative Prediction Before Execution

Predict which tensors remain live at the forward endpoint and which disappear when its output is released. Estimate saved-state savings from a diagnostic inventory, deduplicating shared storage. Define latency and memory improvement using the same reference scope and units. Predict a case with little additional inference benefit and another with many small eager operations where tracking overhead could matter; these are hypotheses rather than guaranteed outcomes.

Part 4 - Experimental Design and Instrumentation

Hold model.eval status, inputs, weights, shapes, precision, and output lifetime constant across modes. Warm each candidate independently, separate cold setup, and reset peaks around the declared forward region. Use completed CUDA event intervals and a synchronized end-to-end region with explicit inclusion rules. Collect allocation diagnostics in separate replays. Do not call empty_cache inside one measured candidate or retain every output merely to make another candidate appear memory intensive.

Choose an ordinary dense eager workload before testing compilation or alternative backends. Preserve the same output-retention boundary, since deleting one candidate's output before sampling would invalidate the comparison. Define allocation activity using supported fields and take cumulative-counter deltas only over matching regions. An increasing lifetime allocation counter is normal for repeated temporary creation and is not a live allocation count. Report GPU event milliseconds and wall-clock seconds with explicit units. If the device timer and wall time disagree, investigate launch overhead, waiting, and scope differences before declaring one measurement incorrect.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def run_forward_mode(model, batch, mode, measurement_scope):
    ...

def compare_forward_evidence(rows, reference_outputs):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check output values at declared tolerances before comparing performance. Report current and peak allocated bytes separately from reserved bytes. State whether an allocation metric counts tensor creations, allocator requests, or driver segment growth; these are not interchangeable. Repeat trials and report latency distributions with instrumentation overhead. A null or negative measured benefit is valid. Preserve unsupported counters rather than approximating them from an unrelated byte difference.

Part 7 - Engineering Interpretation and Philosophy

Choose a mode based on both eligibility and measured benefit. A large graph- recording reduction can coexist with negligible runtime change in a compute- dominated forward. Explain whether the experiment addresses latency, capacity, or both, and which later consumers limit inference eligibility. The result should support a workload-specific decision rather than establish a universal ranking of the three execution modes.

19.49.3 Exercise 02

Exercise Title: Inspect requires_grad, grad_fn, and Version-Counter Behavior Under Normal, No-Grad, and Inference Execution

Part 1 - Exercise Contract and Why It Matters

Inspect tensor metadata and mode state without collapsing them into one boolean. Record requires_grad, grad_fn presence, leaf status, inference status, and supported version-counter behavior. Include tensors created before the context, tensors created inside it, and views. Deliver a provenance-aware table and explicit expected exceptions, demonstrating why the current mode alone does not describe every tensor visible in that scope.

Part 2 - System and Memory Mental Model

Entering no-grad does not retroactively clear requires_grad on existing tensors. Factory functions accepting a requires_grad argument are an important exception to the simple no-grad result rule. Inference tensors do not track version counters; inspecting _version on one can raise. Existing normal tensors and views require separate classification rather than an assumption that entering inference converts everything. The _version field is a diagnostic detail, not a stable public memory-management interface.

Part 3 - Quantitative Prediction Before Execution

Predict metadata for a differentiable input, a computed result, an explicit factory-created leaf, and a view in each context. Mark version access as supported, unsupported, or expected failure instead of substituting zero. Compare an actual mutation of a normal tensor with an inference tensor created in scope. State which predictions concern reverse AD and which require separate forward-mode AD testing.

Part 4 - Experimental Design and Instrumentation

Use fresh small tensors per case so one mutation cannot invalidate another test. Record the queried grad and inference context states alongside tensor provenance. Use the supported inference-status query to classify tensors independently. Catch only the expected diagnostic failure and preserve its phase. Test context restoration after exit and exception. Avoid reading full CUDA values during metadata collection, and do not use pointer equality as a proxy for gradient history or tensor kind.

Include an ordinary tensor allocated before inference, a fresh allocation inside inference, and a view of each. Verify their actual tensor kind; normal inputs are not converted retroactively. For supported diagnostic mutations, normal tensors retain normal versioning obligations even when used inside an inference scope. A view can also preserve relationships not captured by a simplistic all-results-are-false rule. Add a no-grad factory leaf with explicit requires_grad and distinguish that exception from recorded differentiable operations. Catch expected version-inspection errors without suppressing unrelated exceptions, and record whether each field is public or diagnostic.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def inspect_tensor_state(tensor, provenance, version_policy):
    ...

def probe_mode_metadata(config, cases):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify each prediction against the installed version and keep actual exceptions in the evidence. Do not infer absence of a graph merely because one output is nondifferentiable. Include a pre-existing trainable parameter whose flag remains true inside no-grad while its newly computed ordinary result has no recorded reverse history. Distinguish factory behavior from differentiable operation recording. A successful metadata probe does not prove that later training consumption of an inference tensor is safe.

Part 7 - Engineering Interpretation and Philosophy

Tensor provenance and dynamic execution state answer different questions. The audit must preserve both if it is to explain unexpected graphs or compatibility errors. Explain which fields describe current context, intrinsic tensor properties, or version-sensitive implementation details. Use those boundaries to prevent the final controller from classifying tensors solely from a region label such as validation or preprocessing.

19.49.4 Exercise 03

Exercise Title: Use detach() on an Intermediate Tensor and Trace Exactly Where the Autograd Graph Is Cut

Part 1 - Exercise Contract and Why It Matters

Detach one selected intermediate and trace the derivative paths removed by that boundary. Compare a required activation path with an optional diagnostics branch. Deliver forward values, input and parameter derivatives, storage-sharing evidence, and a graph sketch. The experiment must make clear that matching forward results does not establish equivalent training after a graph cut.

Part 2 - System and Memory Mental Model

detach creates a new wrapper without the source differentiation history while sharing backing storage. Upstream graph state can remain reachable through other roots and consumers. Later operations on a detached value can create a new graph for their own trainable inputs, but that does not reconnect the original history. Calling requires_grad on a suitable detached value creates a new differentiation boundary rather than recovering the removed connection.

Part 3 - Quantitative Prediction Before Execution

Use a smooth two-stage scalar expression and predict derivatives for the uncut computation, a cut between stages, and a detached diagnostics-only branch. Identify exactly which requested derivatives disappear or change. Predict storage ownership before and after removing the original root. Include a shared branch so the learner can explain why one detach does not necessarily release the upstream graph or its saved values.

Part 4 - Experimental Design and Instrumentation

Run each variant from fresh identical input and parameter values. Keep the required derivative contract fixed for the equivalence tests, labeling deliberate contract changes separately. Traverse only diagnostic replays and export CPU metadata so graph inspection does not retain the measured roots. Check storage sharing within a live generation. Preserve all aliases until their planned release points and test whether cleanup changes the observed allocation baseline.

Keep a small reference expression whose chain rule can be checked by hand. Use separate roots for the main objective and diagnostics, then show how retaining the main root limits cleanup after detaching the diagnostic alias. When constructing a new detached leaf, distinguish its derivative from the derivative with respect to the original input. Include a constant derivative case so absent history is not confused with numerical zero. A candidate that passes forward checks but removes one requested gradient must remain explicitly rejected, even when the downstream trainable layer continues to receive plausible gradients.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def compare_cut_locations(config, derivative_contract):
    ...

def export_cut_dependencies(roots, traversal_scope):
    ...

def E03(config):
    # A new detached leaf does not reconnect the original history.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate analytical derivatives, not just loss values. Reject the required-path cut as an equivalent optimization even if it lowers VRAM. Verify that a metrics-only detach preserves every required parameter update. Report surviving aliases and graph roots before claiming release. Include a case where the source output remains stored and therefore preserves history despite another detached alias. Distinguish lost gradient connectivity from a computed gradient whose numerical value is zero.

Part 7 - Engineering Interpretation and Philosophy

A detach boundary should express an intended mathematical separation. It is useful for observation and explicit truncated algorithms, but automatic placement requires knowledge of

the workload's derivative targets. Explain why a memory controller cannot infer that intention solely from tensor size, lifetime, or a low observed gradient magnitude. The safest useful recommendation names the contract that authorizes the cut.

19.49.5 Exercise 04

Exercise Title: Compare detach(), detach_(), and clone().detach() by Storage Sharing, Allocation Cost, and Gradient Semantics

Part 1 - Exercise Contract and Why It Matters

Compare detach, detach_ and clone().detach using wrapper identity, storage sharing, allocation cost, and derivative semantics. Deliver a mutation-based alias test and expected failures for unsupported in-place detachment. Treat clone().detach as the requested comparison while also considering detach().clone as an independent-copy alternative. No case should imply that removing history alone produces an immutable snapshot of the source values.

Part 2 - System and Memory Mental Model

detach shares backing storage through a new tensor wrapper. detach_ changes the tensor's autograd relationship in place and cannot detach views in place. Other Python names referencing the same tensor object observe that object change; distinct aliases need separate analysis. clone creates independent storage and is differentiable in ordinary grad execution, so cloning before detaching can perform transient tracking work that is absent when detachment precedes the independent copy.

Part 3 - Quantitative Prediction Before Execution

Predict wrapper and backing identities, logical payload bytes, and surviving gradient paths for each operation. Include a contiguous tensor, a view with a nonzero offset, and a small view pinning a large allocation. Estimate copy payload from element count and dtype while distinguishing allocator rounding and nonstandard layout. Predict which source mutations affect the detached result and which leave an independent clone unchanged.

Part 4 - Experimental Design and Instrumentation

Use fresh owned tensors for each case and isolate mutation tests from derivative validation. Do not mutate a source needed by an unfinished backward. Record shape, stride, storage offset, supported backing capacity, and scoped identities. Attempt detach_ on a view only as a labeled failure control. Measure allocation and runtime in separate clean replays, with clone setup and output lifetime included consistently. Do not retain inspected tensor objects in metadata exports.

Add a second Python name referencing the exact source object and a distinct view sharing its storage. Compare how detach_ affects object metadata versus how later value mutations propagate through aliases. Do not attempt unsupported in-place detachment as a production fallback. Restrict storage accounting to supported dense layouts and scope identities to one allocation generation. For a small view, compare a detached alias with an independent compact copy, including temporary overlap while both exist. Explain when copying fewer logical elements can reduce long-term backing residency after the original owners are removed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def compare_detachment_variants(config, cases):
    ...

def test_alias_mutation(source, candidate, mutation_contract):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check values before mutation, changes after mutation, and required derivatives where applicable. A successful pointer match does not prove immutable data, and a different tensor data pointer does not by itself prove different backing storage for offset views. Report expected view-detachment failures distinctly from allocation failures. Compare cleanup with all source and alias owners accounted for. Any measured transient clone history should be reported with its scope rather than generalized to a fixed overhead.

Part 7 - Engineering Interpretation and Philosophy

Choose sharing when the ownership and mutation contract permit it, and copying when an independent value snapshot is required. The choice affects both memory and semantics. Explain why a cheap detach can retain a large backing allocation, while a small independent copy may release it once all original owners vanish. The best option follows required values and lifetimes rather than a blanket preference for in-place operations.

19.49.6 Exercise 05

Exercise Title: Reproduce a Hidden Memory Leak by Storing Validation Outputs with Active Autograd History Across Many Batches

Part 1 - Exercise Contract and Why It Matters

Reproduce validation memory growth caused by storing outputs from a graph- tracked forward across batches. Bound the retained history and compare it with controls that store only payload or nothing. Deliver an ownership explanation, a memory trend, and cleanup evidence. Call the behavior unwanted retention when Python still owns the values; do not imply a defect in the allocator or that every validation loop necessarily leaks.

Part 2 - System and Memory Mental Model

Calling model.eval does not stop graph construction when differentiable parameters or inputs still require gradients. Storing an output before any backward can keep its graph and saved state reachable. Even without a graph, retaining CUDA predictions consumes memory. If ordinary backward has already run, much saved state may be released despite grad_fn remaining visible, so that case has a different retention contract from the primary validation reproducer.

Part 3 - Quantitative Prediction Before Execution

Predict growth for stored tracked predictions, stored detached predictions, and outputs released each batch. Separate output payload from unique additional saved state and shared persistent parameters. Derive a bounded trend expectation using fixed batch shape, then explain why allocator reservation can plateau while live bytes increase. Predict what happens after clearing the history and all remaining roots at a completed measurement boundary.

Part 4 - Experimental Design and Instrumentation

Use a deterministic model in eval behavior mode, with grad mode deliberately left enabled for the faulty primary case. Perform no optimizer updates during validation. Record history length, batch shape, output size, and supported allocated and reserved counters. Use fresh replays for controls, enforce a memory admission limit, and stop before exhaustion. Make the evidence logger CPU-only so it is not a second hidden owner of every output.

Track history insertion and removal as application events with CPU metadata. Use a fixed number of batches and identical output sizes in the primary case, then a bounded ring-buffer control to demonstrate intentional limited retention. Sample before and after deleting container contents, local output variables, and diagnostic traversal references. Compare after deliberate stream completion to avoid misclassifying pending use. If the model has no relevant gradient requirements, treat the failure to create history as a configuration finding. Do not force growth by changing the workload until it matches the expected picture.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def run_validation_retention_case(config, output_policy, mode):
    ...

def release_validation_owners(state, completion_policy):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that saved outputs actually have recorded history in the faulty case. Compare post-batch growth and post-cleanup state with matching controls. A failure to reproduce the predicted slope is a legitimate result to investigate. Do not add empty_cache as a substitute for removing reachable owners. Report host graph metadata separately from CUDA payload and saved state. Verify that an increasing reserved counter alone is insufficient to identify the retained Python container.

Part 7 - Engineering Interpretation and Philosophy

The root cause is the mismatch between intended evaluation work and retained ownership. Explain which part of the growth comes from unnecessary history and which part is the deliberately stored prediction dataset. The repair must address both if bounded validation residency is the requirement. This distinction prevents a successful no-grad change from being overstated as eliminating all epoch-length output memory.

19.49.7 Exercise 06

Exercise Title: Fix Validation Memory Growth with torch.no_grad() and Prove That the Computation Graph Is No Longer Retained

Part 1 - Exercise Contract and Why It Matters

Repair the unwanted validation graph construction with no-grad and prove the scope of the repair. Deliver output equivalence, covered saved-state observations, and an ownership-bounded memory comparison. The exercise must preserve the counterexample where graph-free CUDA outputs still accumulate in a list. Absence of a backward graph does not establish constant total validation memory unless output retention is also bounded.

Part 2 - System and Memory Mental Model

No-grad suppresses reverse-mode recording for operations in its scope while leaving ordinary tensor payload and existing external graphs intact. The context does not delete previously stored tracked outputs, and it does not switch Dropout or BatchNorm behavior to evaluation. Factory-created leaves can retain explicit requires_grad settings. Proving that a selected forward creates no covered saved state is narrower than proving that no graph exists anywhere in the process.

Part 3 - Quantitative Prediction Before Execution

Predict the saved-state reduction for fresh validation batches after entering no-grad. Compare an empty history, a previously populated tracked history, and a new list of graph-free predictions. Estimate the irreducible output payload for the latter. State which observations establish suppressed recording and which establish released ownership. Predict why switching modes halfway through an epoch does not reclaim graphs retained from earlier batches.

Part 4 - Experimental Design and Instrumentation

Compare clean replays of the faulty loop, no-grad with unchanged output storage, and no-grad with bounded CPU summaries. Keep module behavior, weights, input order, and metrics identical. Use diagnostic saved-tensor hooks only in separate supported first-order replays, counting coverage without retaining values. Inspect selected output metadata and completed memory samples. Explicitly clear the old history when testing recovery rather than crediting the context manager with that cleanup.

Use an eligibility control where evaluation intentionally requests an input gradient, such as a small saliency calculation. That region must keep required tracking even though it uses eval behavior. The repaired ordinary-validation case should clear only phase-owned diagnostics, preserving persistent training state and any explicitly retained gradients. Compare no-grad output storage with a bounded metric accumulator and record the different information contracts. If hooks are unavailable or interact with another feature, retain output metadata and coverage limitations rather than inventing a complete graph-free proof from an unsupported zero save count.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
```

```
def validate_without_reverse_history(config, output_budget):
    ...

def compare_graph_suppression(reference, repaired, coverage):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check validation metrics and outputs against the original computation. Confirm no grad_fn on covered freshly computed ordinary outputs and no covered backward saves, while documenting nondifferentiable outputs and factory exceptions. A zero hook count is scoped evidence, not universal proof about opaque extensions or previously existing roots. Report continuing payload growth separately. Verify that grad mode is restored for the next training batch and that its required gradients still match the training reference.

Part 7 - Engineering Interpretation and Philosophy

A good repair removes the unwanted obligation and verifies the next legitimate one. Explain why graph suppression and output-budget enforcement are two related but separate controls. This separation makes the eventual runtime policy reviewable: each rule names the state it changes, the evidence supporting it, and the training derivatives or validation metrics that remain required.

19.49.8 Exercise 07

Exercise Title: Replace torch.no_grad() with torch.inference_mode() and Measure the Additional Memory and Runtime Differences

Part 1 - Exercise Contract and Why It Matters

Benchmark inference execution as a replacement for an already-correct no-grad evaluation region. Establish that its outputs do not need incompatible later autograd consumption. Deliver performance and memory distributions, compatibility checks, and a case with no meaningful additional benefit. The exercise tests the additional effect beyond no-grad; it must not attribute all graph suppression savings to inference mode alone.

Part 2 - System and Memory Mental Model

Both contexts suppress ordinary reverse graph recording. Inference mode additionally avoids some view and version tracking for inference tensors and disables forward-mode AD. It is thread-local and does not imply model.eval. Gains depend on the workload and may be predominantly host execution overhead rather than CUDA payload savings. Existing normal tensors are not all retroactively converted merely because the dynamic context changes.

Part 3 - Quantitative Prediction Before Execution

Predict which memory categories should remain similar between no-grad and inference execution and which overhead could differ. Compare a large matrix workload with a sequence of small eager operations. State that GPU peak reductions may be negligible while end-to-end

timing differs. Include any output conversion required by later consumers in the cost estimate rather than assuming an inference tensor can always cross the boundary unchanged.

Part 4 - Experimental Design and Instrumentation

Use identical eval behavior, initial state, inputs, precision, output policy, and measurement boundaries. Alternate or randomize benchmark order across independent warmed trials to reduce systematic drift. Record host wall time and completed device timing with clear scopes. Validate downstream consumers before declaring the region inference eligible. Keep allocation profiling separate from latency trials and record the installed version and active mode inside the actual execution thread.

Use paired trials with a consistent warmup criterion and report sample count, median, and tail behavior. Do not present tiny differences below measurement resolution as decisive improvements. Keep model behavior identical, particularly when testing Dropout or BatchNorm, and distinguish model evaluation from context selection. If forward-mode derivatives are required, inference is ineligible; no-grad alone does not disable forward AD. Document this separately from reverse-mode results so a controller trained on first-order backward examples does not generalize its policy to every differentiation mechanism without additional support checks.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def benchmark_inference_replacement(config, consumer_contract):
    ...

def summarize_incremental_effect(no_grad_rows, inference_rows):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate output values and metrics while separately testing boundary compatibility. Report absolute bytes and time along with relative differences, using undefined ratios where denominators are invalid. If confidence intervals overlap or trials are too noisy, report an inconclusive advantage. Do not promise a positive saving. Include context-entry, conversion, and cleanup costs when part of production use. A fast isolated forward is insufficient if its output needs an expensive independent copy before the next stage.

Part 7 - Engineering Interpretation and Philosophy

Inference mode is a measured specialization for regions with stricter lifetime and consumer assumptions. Explain whether the tested gain survives the complete application boundary, and whether that gain justifies the additional compatibility rules. A correct no-grad region can remain the better choice when interoperability or forward AD matters. The controller should preserve that option instead of enforcing inference execution wherever backward is absent locally.

19.49.9 Exercise 08

Exercise Title: Reproduce an Error Caused by Reusing an Inference-Mode Tensor in a Later Gradient-Tracked Computation and Explain the Restriction

Part 1 - Exercise Contract and Why It Matters

Reproduce a controlled failure when a newly created inference tensor is later needed as saved data by a gradient-tracked operation. Repair the boundary with a normal independent copy created outside inference mode, or choose no-grad for the producer. Deliver a compatibility matrix and numerical gradient checks. Do not claim every conceivable arithmetic use outside inference must raise; use an operation whose derivative actually requires saving the inference value.

Part 2 - System and Memory Mental Model

Inference tensors lack normal version-counter guarantees required by autograd saved-value checks. A constant feature multiplied by a trainable input is a useful failure case because the input gradient needs that feature. Addition can be a misleading control because its derivative may not need the constant. A detach alias does not turn an inference tensor into an ordinary independent tensor. Enabling grad alone inside active inference mode does not remove the inference context.

Part 3 - Quantitative Prediction Before Execution

Predict the output and trainable-input gradient for a constant feature used in multiplication. Mark the inference-to-tracked boundary invalid when the value must be saved. Compare no-grad-produced features and an outside-context clone of inference features. Estimate the extra copy payload and transient overlap. Include a no-save arithmetic control as a version-checked observation, not a general guarantee that inference output can safely enter training.

Part 4 - Experimental Design and Instrumentation

Create fresh values inside each producer context and record their inference status. Exit inference mode before allocating the normal repair copy; verify its status and expected storage independence. Preserve the original producer's lack of differentiation history, since copying cannot reconstruct it. Exercise the later tracked operation and backward in separate labeled cases. Catch the expected compatibility error without depending on its exact wording, and retain the failure phase.

Make the failing value a newly allocated inference tensor rather than an ordinary tensor merely passed through the context. Test a multiplying consumer with a trainable ordinary input and compare it with a no-save control. The repair copy must be created with inference disabled; a context that only enables reverse grad is insufficient while inference remains active. Verify normal provenance after copying and budget for both source and copy during the transition. If a future consumer needs the original producer's gradient, reject both graph-free producer policies because no conversion can reconstruct the missing computation history.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
```

```
def test_inference_training_boundary(config, producer_policy):
    ...

def prepare_normal_consumer_value(value, boundary_contract):
    # Allocate an independent normal copy outside inference mode.
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check the repaired trainable-input gradient against an analytical oracle and confirm that upstream producer gradients remain intentionally absent. Include a clone mistakenly made inside inference as a rejected repair. Do not assume .to or contiguous creates a new normal tensor when it can return the same object. Report conversion time and peak overlap. Distinguish expected boundary failure from a general claim that inference mode corrupts tensor values or that all later operations are unsupported.

Part 7 - Engineering Interpretation and Philosophy

The boundary is governed by future derivative requirements, not only the producer's local intent. Explain when no-grad avoids unnecessary conversion and when inference plus an explicit normal copy is justified. The repair must preserve value semantics, required downstream gradients, and the intended absence of upstream gradients. This exercise supplies a concrete eligibility rule for mixed pipelines and the final execution controller.

19.49.10 Exercise 09

Exercise Title: Build a Training Loop with Periodic Evaluation and Ensure Evaluation Allocations Do Not Accumulate into the Training Memory Budget

Part 1 - Exercise Contract and Why It Matters

Integrate periodic evaluation into a training loop without allowing evaluation owners to accumulate across phases. Preserve training gradients, optimizer state, and module behavior on return. Deliver per-phase memory baselines, validation metrics, and several matched training updates. The memory budget must include legitimate persistent training state during evaluation rather than pretending the model starts from an empty device at each phase.

Part 2 - System and Memory Mental Model

Evaluation changes module behavior independently of gradient recording. Training state such as gradient buffers and optimizer moments can remain resident through evaluation. New caches, predictions, and diagnostic owners can increase that residency. Returning to training must restore the actual prior module flags and context, including heterogeneous submodule states when relevant. Allocator reservation can remain high after validation even when its live payload has been released.

Part 3 - Quantitative Prediction Before Execution

Predict the pre-evaluation live baseline, temporary evaluation peak, post- evaluation baseline, and next training peak. Separate intentional retained training state from evaluation-only

owners. State how gradient accumulation changes the baseline and why evaluating between micro-batches must not clear partial training gradients. Predict a bounded plateau for repeated evaluation phases and a growth pattern when a phase-owned history is accidentally kept.

Part 4 - Experimental Design and Instrumentation

Begin with evaluation only at completed optimizer-step boundaries, then add a controlled accumulation case. Snapshot behavior flags and enter the selected gradient context explicitly. Bound validation output retention and release phase-owned references after required metrics finish. Restore state in exception- safe cleanup. Use fresh matched training replays with and without periodic evaluation, controlling random state and any mutable buffers that could change the next update.

Preserve per-submodule behavior flags if the model intentionally mixes training and evaluation behavior. Blindly calling train on the entire model afterward can change previously frozen evaluation submodules. Test restoration after an expected evaluation error without skipping cleanup. If evaluation consumes random numbers, control or record that state when comparing subsequent stochastic training updates. Include retained optimizer moments in the baseline even if validation never touches them. Report a one-time high-water mark separately from a continuing increase across repeated evaluation phases, using matching completed boundaries and the same gradient-clearing policy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def evaluate_phase(model, validation_batches, phase_contract):
    ...

def restore_phase_state(saved_state, exception_status):
    ...

def E09(config):
    # Preserve partial accumulated gradients when the contract requires them.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare losses, required gradients, and parameter updates after returning to training. Verify behavior flags, gradient mode, and selected buffer values. Check completed post-evaluation live bytes rather than insisting reserved capacity returns to its old level. Include an evaluation exception to test restoration and cleanup. Report changed RNG consumption or stochastic trajectories as confounders until explicitly controlled. A harmless one-time cache warmup must not be mislabeled as repeated evaluation retention.

Part 7 - Engineering Interpretation and Philosophy

A phase boundary is a state-management contract as well as a memory boundary. Explain which objects must survive evaluation, which must be released, and which contexts must be

restored. The strongest integration reduces unnecessary residency while leaving the next training update correct. A lower isolated validation peak cannot compensate for silently discarding accumulated gradients or leaving parts of the model in the wrong behavior mode.

19.49.11 Exercise 10

Exercise Title: Compare Keeping GPU Predictions, Detached GPU Predictions, CPU Predictions, and Scalar Metrics Across an Entire Validation Epoch

Part 1 - Exercise Contract and Why It Matters

Compare four epoch-level result policies: tracked GPU predictions, detached GPU predictions, CPU predictions without retained history, and streaming scalar metrics. Deliver CUDA and host memory growth, transfer cost, and metric correctness. Specify which outputs the consumer actually requires. A scalar summary is not a drop-in replacement when later analysis genuinely needs every prediction, and moving values to CPU without detaching can still preserve graph history.

Part 2 - System and Memory Mental Model

Detached CUDA predictions remove their own history edge but retain payload and possibly a larger shared backing allocation. A CPU copy can carry a differentiable transfer edge when made in grad mode; export must intentionally remove unwanted history. Keeping all CPU predictions shifts epoch storage to host RAM rather than eliminating it. Streaming sufficient statistics can bound storage for suitable metrics, while nonlinear global metrics may require different algorithms or retained data.

Part 3 - Quantitative Prediction Before Execution

For fixed prediction shape and batch count, estimate raw output payload on each memory tier. Compare that with the unique backing capacity of stored views. Derive a streaming sum and count for an additive metric and identify why averaging batch means is incorrect for unequal batch sizes. Predict transfer volume, scalar synchronization cost, and the asymptotic storage of each policy under the same declared consumer requirement.

Part 4 - Experimental Design and Instrumentation

Run independent epoch replays from identical model state and batch order. Keep tracking mode explicit so tracked and detached policies differ intentionally. Export CPU predictions from detached values or graph-free execution and verify that no source graph owner is hidden in the export object. Use bounded device aggregation for scalar metrics and transfer summaries at deliberate boundaries. Record all conversion, synchronization, and metric-finalization work in the chosen timing scope.

Define which metrics admit exact streaming sufficient statistics. Counts, sums, and denominators must preserve masking and valid-item semantics. For global ranking metrics or later per-example analysis, keep the necessary information or use a separately validated algorithm; do not claim that a scalar average replaces every prediction dataset. If buffering CPU outputs, set a host budget and report its growth. Asynchronous copies require completion before CPU consumption or buffer reuse. Include a small slice that pins large CUDA storage to show why logical prediction size alone can underestimate the retained GPU footprint.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def export_predictions(predictions, retention_policy, consumer_contract):
    ...

def update_streaming_metric(state, predictions, targets, valid_count):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare final metrics with an exact small retained-data reference and test an unequal final batch. Report host memory as well as CUDA memory and identify whether the whole prediction dataset remains stored. Verify source ownership cleanup and copy completion before CPU inspection. Do not equate a detached alias with an independent value snapshot. Mark unsupported streaming metrics as such rather than quietly replacing them with a biased batch-average approximation.

Part 7 - Engineering Interpretation and Philosophy

Output policy often matters as much as execution mode. Explain which representation is sufficient for the actual downstream question and which information each reduction discards. The controller can choose a bounded scalar path only when the metric contract permits it. Memory savings are meaningful when their information and synchronization costs are visible alongside the resulting capacity and runtime measurements.

19.49.12 Exercise 11

Exercise Title: Selectively Disable Gradient Tracking for a Frozen Submodule While Preserving Gradients Through the Trainable Remainder of the Model

Part 1 - Exercise Contract and Why It Matters

Disable unnecessary recording around a frozen submodule only when required derivatives do not need to pass through it. Compare a frozen feature extractor before a trainable head with a frozen middle block after a trainable upstream module. Deliver gradient checks for all required parameters and inputs, a mode-eligibility table, and memory measurements for valid policies. The middle- block counterexample must prevent a misleading frozen-means-no-grad rule.

Part 2 - System and Memory Mental Model

Freezing weights removes those parameter derivative targets; it does not remove the mathematical dependence of outputs on inputs. A frozen middle block may still need autograd recording to propagate gradients to earlier trainable layers or a differentiated input. A frozen prefix fed nondifferentiated data can often run graph-free and supply normal features to a

trainable head. Inference-produced features require additional compatibility analysis if the head needs to save them.

Part 3 - Quantitative Prediction Before Execution

Write the chain rule for a trainable upstream mapping, a frozen block, and a trainable downstream loss. Identify the derivative factor removed by wrapping the frozen block in no-grad. Predict which parameter gradients remain and which incorrectly vanish. Compare with the prefix case where upstream input gradients are explicitly not requested. Estimate saved-state reduction only for policies that satisfy their respective derivative contracts.

Part 4 - Experimental Design and Instrumentation

Construct both topologies with deterministic smooth operations and a scalar loss. Freeze selected parameters explicitly, clear stale gradients, and keep optimizer participation consistent with the intended update policy. Use no-grad only for eligible prefixes. Test required input gradients separately, since saliency or adversarial objectives can make the same prefix ineligible. Compare against an ordinary-grad frozen reference rather than against a fully trainable model with different derivative work.

Add a trainable adapter before a frozen linear block and a trainable head after it. Compare required adapter gradients with and without an invalid no-grad middle region. Then move the frozen block to an eligible prefix fed nondifferentiated data. Keep these as distinct topologies with separate reference gradients. Include an input-gradient requirement as another reason a frozen prefix may need recording. A module's lack of parameter updates does not establish that its input Jacobian is irrelevant. Record this counterexample in the policy table before optimizing any larger transfer-learning model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def classify_frozen_region(region, upstream_targets, consumers):
    ...

def compare_frozen_topologies(config, derivative_contracts):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate gradients for upstream and downstream trainable modules and any requested input derivative. A matching downstream gradient alone is insufficient. Reject the middle-block no-grad rewrite under the original contract. Confirm that frozen weights do not update and that stale optimizer state is handled explicitly. Report saved-state and peak differences without claiming that freezing removes all activation memory. Retain the counterexample as an eligibility test for later automation.

Part 7 - Engineering Interpretation and Philosophy

Frozen is a statement about parameter updates, while graph-free is a statement about computation recording. Their overlap depends on the complete derivative path. Explain how a policy can exploit the eligible prefix without breaking the middle block. This distinction is essential for transfer learning, adapters, and input-gradient applications, where local parameter flags do not describe all the derivatives the workload requires.

19.49.13 Exercise 12

Exercise Title: Freeze Parameters with requires_grad_(False) and Compare Its Memory Behavior Against Wrapping the Same Module in torch.no_grad()

Part 1 - Exercise Contract and Why It Matters

Compare parameter freezing with no-grad around the same module under explicitly different input-gradient requirements. Deliver a matrix showing when the two policies perform equivalent requested work and when they do not. Include parameter gradients, input gradients, saved state, optimizer ownership, and peak VRAM. Do not compare policies with silently different derivative targets and then call the lower-memory result an equivalent optimization.

Part 2 - System and Memory Mental Model

requires_grad_(False) on parameters excludes their derivative accumulation, but operations can still be recorded when another input requires gradients. No-grad suppresses recording for the scoped operations, including paths needed for input derivatives. Freezing does not automatically delete stale .grad buffers or optimizer moments. An optimizer holding stale gradients can still update a nominally frozen parameter under its own update rules, so update eligibility must be managed separately from graph recording.

Part 3 - Quantitative Prediction Before Execution

Predict cases with frozen parameters and ordinary data inputs, frozen parameters and differentiated inputs, and unfrozen parameters inside no-grad. Specify which derivative targets each case can satisfy. Estimate parameter-gradient storage avoided and separate it from retained optimizer state and activation saves. Predict why a frozen linear layer may still need its weight values to compute an input gradient even though no weight gradient is requested.

Part 4 - Experimental Design and Instrumentation

Use a small module with analytically or independently checked input and weight gradients. Freeze only leaf parameters, clear stale gradients to None where appropriate, and configure optimizer participation explicitly. Match behavior mode and output lifetimes. Sample before freezing, after gradient cleanup, after forward, and after the declared derivative task. Track optimizer state without assuming a flag change releases its tensors. Reject input-gradient queries after an ineligible no-grad rewrite.

Create stale-state controls deliberately and safely: run one ordinary update, then freeze the selected weights while recording existing gradient buffers and optimizer state. Configure the intended frozen update policy before resuming. Do not assume zero gradients are equivalent to None for momentum or weight-decay behavior. Releasing optimizer moments is a separate decision that may affect later unfreezing and must be labeled. Compare actual parameter values across several steps, not merely their requires_grad flags. Separate memory released by explicit state removal from memory never allocated because those derivatives were not requested.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def configure_frozen_parameters(module, optimizer, freeze_contract):
    ...

def compare_freeze_and_no_grad(config, derivative_targets):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate all required derivatives and parameter updates. Test a parameter with existing gradient and optimizer state before freezing so cleanup behavior is observable. Record zero gradients and None gradients distinctly because optimizer handling can differ. Compare equivalent subsets separately from intentionally different tasks. A remaining optimizer allocation is not evidence that freezing failed, and a missing input gradient after no-grad is not a harmless performance trade-off under the original contract.

Part 7 - Engineering Interpretation and Philosophy

A parameter flag controls participation in differentiation, not the complete lifecycle of parameter-related state. Explain the savings attributable to reduced derivative work, explicit gradient cleanup, and optimizer-state policy separately. That accounting allows a controller to preserve frozen-layer input derivatives while avoiding unwanted parameter updates. A single module-level label cannot replace the required input, parameter, and optimizer contracts.

19.49.14 Exercise 13

Exercise Title: Build a Mixed Training-Inference Pipeline Where Only Selected Branches Construct Autograd Graphs

Part 1 - Exercise Contract and Why It Matters

Build a mixed pipeline with a trainable student branch, a nondifferentiated teacher or auxiliary branch, and shared inputs or features. Select execution modes per region while preserving the exact student objective. Deliver a boundary map, target and input derivative checks, memory evidence, and a case where an inference-produced teacher value needs conversion before the student loss can safely save it.

Part 2 - System and Memory Mental Model

Teacher parameters can be frozen while student gradients depend numerically on teacher outputs. Those outputs need values but usually not teacher history for ordinary distillation. A no-grad teacher result remains an ordinary tensor that downstream backward may save. An inference tensor can violate that saved-value requirement unless a normal independent copy

is prepared outside inference. Shared upstream features require careful contracts when both branches should contribute gradients.

Part 3 - Quantitative Prediction Before Execution

Write a small distillation objective and predict which teacher and student parameters receive gradients. Compare teacher targets created under no-grad with inference targets crossing an explicit normal-copy boundary. Estimate copy payload and lifetime overlap against saved teacher-state savings. Add a joint-training variant requiring teacher gradients and predict why the same graph-free policy becomes invalid despite identical forward target values.

Part 4 - Experimental Design and Instrumentation

Use deterministic teacher and student modules with fixed initial state and simple dense outputs. Set behavior flags separately for each branch. Freeze teacher parameters and control optimizer membership only for the declared nondifferentiated case. Keep the student and loss in required grad execution. Verify the tensor kind at each crossing and account for copy completion. Use fresh replays when comparing target policies, with identical loss scaling and batch ordering.

Use a teacher loss whose backward needs target values, so an inference-target boundary is exercised rather than accidentally bypassed. Check teacher target ownership after the student step, including caches and logging containers. A normal copy resolves tensor-kind compatibility but does not guarantee bounded retention. For shared features, state whether teacher, student, or both should contribute to upstream gradients and validate each requested component. If the teacher changes through an exponential moving average, keep that update outside gradient recording under its own contract and compare the same update schedule across memory policies.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def execute_branch_pipeline(batch, branches, contracts, boundary_policy):
    ...

def validate_branch_gradients(results, required_targets, reference):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare student losses, required input gradients, and several parameter updates against a valid no-grad-teacher reference. Confirm teacher gradients are absent only when authorized. Record incompatible inference-target failures distinctly from numerical errors. Include shared-feature cases where detaching one branch changes upstream gradients. Report end-to-end memory and runtime including conversions, teacher work, and loss evaluation rather than only the fastest isolated branch.

Part 7 - Engineering Interpretation and Philosophy

A region can be locally inference-like yet produce values that participate in later differentiation. Explain how boundary contracts capture that distinction and how sharing complicates automatic selection. The policy should minimize unneeded history without changing the role of teacher targets or shared features. Every boundary needs both a derivative decision and a value-lifetime decision; neither can be inferred solely from the module's name.

19.49.15 Exercise 14

Exercise Title: Detect Unnecessary Gradient Tracking in Data Preprocessing, Teacher Models, Metrics, and Auxiliary Inference Modules

Part 1 - Exercise Contract and Why It Matters

Audit preprocessing, teacher models, metrics, and auxiliary modules for graph tracking that the declared workload does not require. Deliver a suspect list, justified eligibility rules, and validating interventions. Include legitimate exceptions such as differentiable augmentation, input optimization, and jointly trained auxiliary objectives. The word unnecessary requires an application contract; a module category alone cannot establish that its gradients are irrelevant.

Part 2 - System and Memory Mental Model

Graph recording can arise from trainable parameters, differentiated floating inputs, or captured intermediate values even when a region looks observational. Integer data paths and nondifferentiable operations have different behavior. A metric may intentionally contribute a regularizer, and a teacher may be jointly trained. Detaching only the final logged value can remove retention without avoiding upstream recording, whereas graph-free execution is valid only when no required path crosses the region.

Part 3 - Quantitative Prediction Before Execution

Predict required gradients for four explicit use cases and list the runtime observations that would suggest a mismatch. Separate the benefit of preventing a graph from the benefit of releasing a stored output. Estimate candidate saved-state savings and include a case where the audit finds tracking but correctly recommends keeping it. Define false positives as recommendations to remove required derivative work, not merely regions with large graphs.

Part 4 - Experimental Design and Instrumentation

Add named application scopes and collect mode state, input and output metadata, and covered save events in a diagnostic replay. Export no live tensors. Compare findings with declared derivative targets and consumer paths before ranking candidates. Apply one eligible intervention at a time in fresh matched runs. Validate gradients beyond the candidate region, including upstream inputs when requested. Report unsupported native or compiled scopes rather than asserting complete tracking coverage.

Separate three findings: recording happened, a graph-owning output escaped, and the recording was unnecessary under the declared objective. Any one can occur without the others. For example, detaching a final metric can stop history retention even when recording occurred earlier, while a differentiable regularizer legitimately needs the graph. Preserve application scope and invocation IDs, and include multiple calls to the same helper under different contracts. A repair recommendation needs a validating run ID; recognizing a suspicious function name or observing a requires_grad flag is not sufficient evidence of removable work.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def find_tracking_mismatches(region_rows, derivative_contracts):
    ...

def validate_audit_intervention(config, candidate, reference):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Include an ordinary diagnostics region with unwanted history and a differentiable preprocessing region that must retain it. Score finding tracking separately from deciding it is unnecessary. Compare output values, metrics, and required gradients after each accepted change. Report unchanged saved-state or memory when an apparently promising candidate has persistent aliases. Check that an auditing hook does not create its own retained activation history or introduce a synchronization-heavy per-tensor reporting path.

Part 7 - Engineering Interpretation and Philosophy

An audit combines runtime facts with human-specified intent. Explain which part of each finding is observed and which depends on the derivative contract. The report should recommend a small testable change or ask for a missing contract in its output, rather than treating uncertainty as authorization to detach. A good negative finding preserves a legitimate gradient path and is as valuable as discovering removable tracking.

19.49.16 Exercise 15

Exercise Title: Build an Autograd-Tracking Audit That Reports Which Runtime Regions Create Graphs and Which Execute Without Gradient State

Part 1 - Exercise Contract and Why It Matters

Build a bounded runtime audit that distinguishes active mode state, observed graph creation, tensor provenance, and saved-state coverage by region. Deliver structured CPU metadata and a report with explicit unknowns. The audit must not claim that grad-enabled means every operation creates a graph, or that one graph-free output proves an entire region executed without autograd activity. Include nested contexts and execution in another thread.

Part 2 - System and Memory Mental Model

Grad and inference contexts are thread-local. Default grad mode permits recording but still needs differentiable operations with relevant requirements. A region can return an integer index while creating differentiable intermediates internally. A no-grad region can receive an already

tracked tensor without erasing its history. Hooks expose selected events and module boundaries, not a complete universal record of every native allocation, derivative transformation, or compiled operation.

Part 3 - Quantitative Prediction Before Execution

Predict audit rows for nested no-grad and enable_grad scopes, factory-created leaves, non-differentiable outputs, and pre-existing tracked inputs. Treat inference state separately: enable_grad alone is not an escape from active inference restrictions. Define which fields can be observed directly and which require event coverage. Estimate report memory from event count and metadata size, including an explicit truncation policy before scaling the workload.

Part 4 - Experimental Design and Instrumentation

Instrument named regions with exception-safe context handling and bounded records. Query actual mode state in the thread executing each region. Collect supported saved-tensor diagnostics in independent replays where composition is validated. Tag input provenance without preserving tensors in the report. Record nesting and invocation IDs so a module called under different policies is not collapsed into one label. Compare minimally instrumented execution with the audited replay to quantify overhead.

Keep region entry and exit records even when computation fails. A nested context may restore grad permission while inference state remains active; record both fields rather than deriving one from the other. Thread-local contexts do not automatically configure separate workers, so test mode state inside their execution functions. Register diagnostic hooks with bounded lifetimes and remove them after collection. If a hook returns or stores an activation, it can change behavior or ownership; require observational CPU metadata only. Treat compiled or custom opaque regions as separate support scopes instead of extending eager coverage claims automatically.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RegionAudit:
    region_id: object
    mode_state: object
    tensor_metadata: tuple
    graph_observations: tuple
    coverage: object

def audit_region(region, inputs, recorder, scope):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate the report against synthetic known scopes, including a graph created internally whose returned value has no grad_fn. Confirm mode restoration after an exception and independence of a deliberately configured worker thread. Use distinct statuses for observed no recording, no covered save, and unknown. Test truncation and missing hooks without replacing unknown values with zeros. Verify that disabling the audit removes its records and does not change the next iteration's live CUDA baseline.

Part 7 - Engineering Interpretation and Philosophy

The audit should describe evidence rather than pronounce every region safe for conversion. Explain the difference between permission to record, actual recorded paths, and the obligation to preserve them. Those distinctions make its output useful to the policy engine while protecting against simplistic rules based on output flags or module labels. Coverage and observer cost belong in the report, not in a hidden implementation assumption.

19.49.17 Exercise 16

Exercise Title: Compare Long-Sequence LLM Generation Under Normal Grad Mode, No-Grad Mode, and Inference Mode by KV Memory, Temporary Allocations, and Decode Throughput

Part 1 - Exercise Contract and Why It Matters

Compare controlled autoregressive decoding under default grad, no-grad, and inference execution while separating required KV payload from unnecessary history. Deliver per-token KV accounting, temporary-allocation evidence, decode throughput, and output checks. Use an explicit low-level decoding loop whose mode can actually change; a high-level generation entry point may already be decorated to disable tracking and would not establish a genuine default-grad baseline.

Part 2 - System and Memory Mental Model

KV storage remains necessary for the selected cached attention algorithm regardless of autograd mode. Default grad can additionally retain differentiable history through cache values when the implementation permits it. Integer sampling does not itself carry a differentiable token-selection path. Static, detached, or inference-only cache implementations can change which comparisons are supported. Attention workspace, logits histories, and model weights must not be mislabeled as KV payload or eliminated merely by changing execution mode.

Part 3 - Quantitative Prediction Before Execution

For uniform dense KV geometry, predict payload from active token counts:

$$M_{\mathrm{KV}} = 2\,L\,H_{\mathrm{KV}}\,D\,s\sum_i T_i.$$

State assumptions about dtype, layers, KV heads, head dimension, and sequence lengths. Add reserved capacity, padding, metadata, and temporary copies separately. Predict graph-related growth conditionally on connected cache history rather than assuming every grad-enabled cache has the same behavior. Explain why no-grad cannot remove the required KV term.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic causal model first and a cache representation compatible with the intended comparison. Force identical token sequences for the primary replay so divergent sampling does not change shapes or work. Keep attention backend, context lengths, precision, batch policy, and output retention fixed. Measure prefill and decode separately and include per-token or end-to-end scopes explicitly. Inspect actual mode state inside the model rather than assuming an outer context overrides a decorated generation helper.

Avoid an in-place cache implementation that forbids autograd and then calling its failure evidence that default grad is slower. Use a compatible functional cache for the primary controlled comparison or mark the mode unsupported. Account for old and new cache coexistence when concatenation grows storage. Disable optional histories of logits or hidden states unless they are part of every compared contract. In grouped-query attention use KV head count, not query head count, in the payload formula. Record active sequences and actual token lengths, and avoid claiming sampled integer decisions preserve a differentiable generation path.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def decode_explicitly(model, token_trace, cache_policy, grad_policy):
    ...

def account_kv_payload(cache_metadata, model_geometry):
    ...

def E16(config):
    # Verify the generation entry point does not mask the intended mode.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare logits at declared tolerances and generated tokens in a separate sampling replay. Report KV logical bytes, unique backing capacity, saved history, temporary peak, and reserved memory independently. Mark unsupported cache-mode combinations rather than silently switching cache algorithms. Count throughput using a stated token numerator and completed elapsed time, including or excluding prefill explicitly. Do not attribute a result caused by retaining all logits to the cache alone.

Part 7 - Engineering Interpretation and Philosophy

Autograd control removes derivative work, while KV management preserves the state required by attention. Explain which dominates the measured long-context peak and whether mode changes improve capacity or mostly overhead. The lesson should connect to earlier paged and offloaded KV designs without claiming that graph suppression replaces them. A valid comparison preserves both the decoding algorithm and the actual execution-mode distinction.

19.49.18 Exercise 17

Exercise Title: Build a Memory-Aware Execution Policy That Automatically Chooses Gradient-Tracked, No-Grad, or Inference Execution for Different Runtime Phases

Part 1 - Exercise Contract and Why It Matters

Build an execution policy that selects grad-tracked, no-grad, or inference regions from declared derivative and consumer contracts. Use memory estimates only after establishing eligibility. Deliver policy decisions, rejection reasons, mode restoration tests, and independent validation of selected actions. The controller must be allowed to report an infeasible memory budget instead of silently disabling a gradient that the workload requires.

Part 2 - System and Memory Mental Model

A phase name is insufficient: validation can require input gradients, preprocessing can be differentiable, and teacher outputs may be saved by student backward. Mode selection must consider future consumers, tensor kind, forward AD, shared owners, and nested context. Inference is not a stronger universally safe substitute for no-grad. New mode contexts do not erase pre-existing graphs or control output-retention policies automatically.

Part 3 - Quantitative Prediction Before Execution

Define a decision table with hard derivative constraints, tensor-boundary compatibility, and measured costs. Predict outcomes for training, ordinary evaluation, saliency evaluation, teacher targets, and terminal reporting. Estimate complete boundary costs including conversions and retained payload. Add a case where no eligible policy meets the byte budget. Preserve that infeasibility rather than ranking an invalid graph-free choice as the best memory option.

Part 4 - Experimental Design and Instrumentation

Start with an explicit phase registry and small supported dense eager regions. Validate contracts against the audit evidence from E15. Implement exception- safe context entry and restoration, recording actual mode state in the executing thread. Keep model.train or eval behavior changes as separately declared state transitions. Cache policy decisions only while their shapes, consumer requirements, and derivative targets remain valid. Use fresh replays to validate any newly selected policy.

Validate nested-policy precedence and invalidate decisions after changes to shapes, derivative targets, or consumers. Record actual mode and tensor kind. Restore state after exceptions. Report infeasibility with raw estimates when no eligible mode fits; silently changing batch size, precision, or history length changes the workload contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ModeDecision:
    mode: object
    eligible: bool
    prerequisites: tuple
    rejection_reasons: tuple
    predicted_cost: object
```

```
def choose_execution_mode(phase_contract, tensor_provenance, costs):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare decisions with a manually reviewed eligibility matrix and validate all required derivatives after execution. Include nested contexts and an exception path; check restoration and later training updates. Reject inference tensor crossings lacking a valid conversion or consumer proof. Report prediction error separately from correctness. A successful low-memory result with a missing required input gradient is a failed policy, even if its loss values match the reference.

Part 7 - Engineering Interpretation and Philosophy

The controller should automate choices whose semantic prerequisites are known, not infer the intended mathematics from current VRAM pressure. Explain which decisions are proved eligible, which depend on measured cost, and which remain unsupported. When no valid mode satisfies the budget, the report can identify other memory techniques for a future experiment while preserving the original derivative contract and declaring the current request infeasible.

19.49.19 Exercise 18

Exercise Title: Stress-Test Gradient-Control Policies with Training, Validation, Frozen Modules, Teacher-Student Inference, Cached Outputs, and Shared Tensor Storage

Part 1 - Exercise Contract and Why It Matters

Stress-test mode control across training, evaluation, frozen prefixes and middle blocks, teacher-student losses, cached outputs, and shared storage. Deliver a coverage matrix with numerical checks, memory results, expected rejections, and overhead. Include adversarial cases that expose policies based only on module names or output flags. A stress test should explore interactions under bounded resources rather than require an uncontrolled physical OOM.

Part 2 - System and Memory Mental Model

Interactions can invalidate isolated assumptions. A graph-free producer can feed a later backward that needs its values; a detached cache can still pin large storage; a frozen middle block can be necessary for upstream derivatives. Context state is local to a thread, while module behavior flags and Python owners are different shared state. Restoration, tensor provenance, and derivative requirements must therefore be checked together.

Part 3 - Quantitative Prediction Before Execution

Predict expected classifications before execution: valid graph suppression, required tracking, incompatible inference boundary, bounded payload retention, or unsupported observation. Construct pairs with similar memory but different derivative obligations and pairs with matching forward values but different gradients. Estimate admission bounds for each case from peak overlap and host output storage. Define scoring so correct rejection of an unsafe optimization counts as success rather than lack of aggressiveness.

Part 4 - Experimental Design and Instrumentation

Build deterministic small cases first, then vary shape, sequence length, output-history length, and selected context nesting. Add a no-grad factory exception, a view that cannot detach in place, and a reused inference value requiring saved data. Include a separate worker-thread case. Match initial state and batch traces across replays, bound event logging and runtime, and preserve unsupported feature combinations explicitly. Do not silently repair an invalid candidate before recording its rejection.

Include changed input-gradient requirements, teacher values saved by backward, and detached aliases modified through another owner. Test exception restoration and worker contexts separately before combining cases. Keep unsupported AD features explicit. Growing graph-free prediction histories must still trigger output-budget diagnostics, while correctly rejected unsafe conversions count as successful policy decisions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_mode_stress_cases(config, support_matrix):
    ...

def evaluate_policy_case(case, controller, oracle, budgets):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Score derivative correctness, boundary compatibility, mode restoration, memory prediction, and overhead separately. Check parameter and requested input gradients, not only scalar loss. Keep legitimate cache warmup and graph-free payload growth as distinct controls. Report false safe recommendations prominently. A missing CUDA device or unsupported differentiation feature produces an explicit status rather than a fabricated pass. Preserve minimal counterexamples and cases where predicted savings do not appear in the observed whole-step peak.

Part 7 - Engineering Interpretation and Philosophy

The suite establishes the supported boundary of automation. Explain which rules survived interaction and which need a narrower contract or additional measurement. A trustworthy controller can refuse a mode change while still explaining the memory bottleneck. The goal is reliable removal of unnecessary autograd state, not the largest percentage reduction obtained by changing the mathematical workload or discarding required results.

19.49.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Gradient-Tracking Memory Controller That Minimizes Autograd State While Preserving Exactly the Gradients Required by the Workload

Part 1 - Exercise Contract and Why It Matters

Integrate a PyTorch gradient-tracking memory controller that selects supported execution modes and output policies while preserving the workload's exact derivative targets. Deliver an auditable report, eligibility decisions, validating replays, and benchmark comparisons. Every saving must be attributed to graph suppression, history removal, output ownership, or another explicit state change. Do not bundle several interventions into an unexplained before-and-after memory number.

Part 2 - System and Memory Mental Model

The controller combines region contracts, tensor provenance, observed graph activity, memory costs, and consumer compatibility. Grad mode is required where derivatives must cross a region; no-grad can produce normal values for later tracked use; inference is eligible only under validated restrictions. Detached aliases still share payload, and frozen parameters may leave input derivatives necessary. Module behavior, optimizer updates, and output-retention budgets remain independent parts of the execution contract.

Part 3 - Quantitative Prediction Before Execution

Predict complete phase peaks and latency using unique backing capacity and measured boundary costs. Include persistent training state, validation outputs, conversion overlap, and required caches. Rank only eligible policies and preserve unknown estimates. Define success as correct required gradients and metrics within the admitted resource budget, with measured overhead. Include an infeasible case to demonstrate that the controller never satisfies a memory target by silently narrowing derivative requirements.

Part 4 - Experimental Design and Instrumentation

Integrate the audit and policy schemas with bounded collection and exception- safe phase handling. Use known cases to develop rules and held-out cases to evaluate them. Compare always-grad, manually selected valid modes, and the controller, keeping output contracts explicit. Measure collection, decision, conversion, and validation costs as well as steady execution. Limit retries, capture frequency, and host report size. Export CPU metadata and release diagnostic owners after their declared use.

Report phase IDs, derivative targets, behavior flags, actual modes, tensor provenance, output contracts, memory counters, timing boundaries, and validation results. Separate predictions from observations and interpretation. Include analysis and conversion overhead, rejected actions, unsupported features, and infeasible budgets. Claim only the best validated policy within the tested range, preserving unresolved consumer requirements.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ControllerReport:
    decisions: tuple
    derivative_checks: tuple
```

```
    memory_measurements: tuple
    timing_measurements: tuple
    limitations: tuple

def execute_controlled_phase(phase, contract, controller, evidence):
    ...

def validate_controller(config, policy, reference):
    ...

def E19(config):
    # Refuse mode changes that remove required derivatives.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a traceable chain from each accepted action to its contract, observed state, prerequisites, prediction, and independent validation. Compare losses, all required gradients, parameter updates, metrics, memory, and runtime. Preserve unsupported, rejected, and not-measured outcomes. Evaluate false safe choices separately from missed savings. Report whether measured gains survive complete consumer boundaries and subsequent training, rather than only an isolated forward whose outputs were never used.

Part 7 - Engineering Interpretation and Philosophy

The final controller should make intended differentiation explicit and remove only work that intention does not require. Explain remaining uncertainty about opaque scopes, hidden owners, dynamic consumers, and unsupported AD features. The strongest result is a small validated policy set with known counterexamples, bounded overhead, and honest infeasibility reporting. Preserving the required mathematics is the condition for calling a lower-memory execution an optimization at all.

19.50 DMM48

Chapter Title: Custom Memory Manager in PyTorch
Specialization: Dynamic Memory Management and CUDA Systems

19.50.1 Exercise 00

Exercise Title: Design the Architecture of a Custom PyTorch Memory Manager with Budgets, Residency States, Policies, Events, and Runtime Decisions

Part 1 - Exercise Contract and Why It Matters

Design an application-level memory manager with explicit managed handles, budgets, ownership, residency, transfer events, and policy decisions. Deliver component contracts, invariants, a supported-workload boundary, and a synthetic execution trace. The manager coordinates registered values through controlled access; it is not automatically a replacement for the PyTorch CUDA allocator and cannot transparently migrate every arbitrary tensor, operator workspace, or external CUDA allocation in the process.

Part 2 - System and Memory Mental Model

Separate logical tensors from physical storage replicas and allocation generations. Several views can share one backing allocation, while one logical value can have CPU and GPU replicas simultaneously. Residency, validity, transfer progress, and in-use leases are related but distinct state dimensions. A raw tensor reference held outside the manager can defeat release or observe stale data; controlled access and mutation contracts are therefore architectural requirements, not optional bookkeeping refinements.

Part 3 - Quantitative Prediction Before Execution

Predict resource occupancy for a value promoted from CPU to GPU, used, demoted, and released. Include simultaneous source and destination capacity, staging, and pending reservations. Define which budgets bound managed backing storage and which include an external safety allowance. Construct an example where the registry's logical byte sum understates retained storage and another where adding logical aliases overstates it. Explain why neither sum equals driver-level device use.

Part 4 - Experimental Design and Instrumentation

Start with deterministic dense inference values and immutable registered storage, then introduce controlled mutations and training-aware adapters later. Specify registry, accounting, admission, transition engine, transfer scheduler, policy plugins, and telemetry responsibilities. Define failure outcomes before integration. Use an event-driven simulator with deterministic completion order as the primary invariant oracle, followed by bounded CUDA replays when available. Every decision should name its prerequisites and the evidence that permits commit or rejection.

Define the supported operation boundary before choosing policies. Initial experiments should use manager-owned immutable dense values accessed through leases, with no hidden writes or raw references escaping the scope. Training, compiled graphs, capture, distributed collectives, and external allocators need separate adapters and support declarations. A Python registry cannot rewrite every existing reference when a tensor migrates. State whether access returns a short-lived tensor borrow or a managed operation, and reject consumers that cannot honor that contract. Preserve an explicit derivative and precision contract so later residency choices cannot silently become graph cuts or approximate arithmetic.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ManagerContract:
    managed_scope: object
    derivative_requirements: object
    budgets: object
    external_allowance: object

def design_manager_components(contract):
```

```
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require counterexamples to the claims that each tensor owns one allocation, that zero manager references establish safe reuse, and that admitted requests are guaranteed to succeed in CUDA. Record hardware, versions, allocator backend, seeds, shapes, precision, and initial-state identifiers. Keep predictions, observations, and interpretations separate. An unavailable CUDA device produces not-measured hardware fields, not fabricated benchmark results. Reject unsupported raw aliases or mutation paths explicitly rather than promising transparent management that the access interface cannot enforce.

Part 7 - Engineering Interpretation and Philosophy

The design succeeds when every byte and transition has a clear scope and every unsafe decision can be refused. Explain which uncertainty belongs to unmanaged work, allocator behavior, or future execution. The manager should preserve required values and derivatives while optimizing eligible residency. Reducing its internal counters is not a success if a caller still holds the old CUDA storage or receives a value from an obsolete generation.

19.50.2 Exercise 01

Exercise Title: Build a Global Tensor Registry That Tracks Tensor Identity, Shape, Dtype, Bytes, Device, Owner, Lifetime, and Current Residency

Part 1 - Exercise Contract and Why It Matters

Build a registry for all values within the declared managed domain. Track logical identity, tensor metadata, backing identity, owner leases, generation, and replica state. Deliver registration, lookup, controlled mutation, and retirement contracts. Global means global to this manager instance or explicitly coordinated process scope, not automatic discovery of every tensor in Python, other processes, native libraries, or opaque autograd state.

Part 2 - System and Memory Mental Model

Python object identity, tensor data pointer, backing storage identity, and logical handle identity answer different questions. Views can have different data pointers because of offsets while sharing storage. Numeric addresses can be reused across lifetimes. Strong registry references deliberately keep storage alive; weak wrapper references alone cannot prove device-read completion. A manager-owned handle should resolve the current valid replica rather than allow callers to cache an untracked raw tensor indefinitely.

Part 3 - Quantitative Prediction Before Execution

Predict records for a base tensor, two overlapping views, an independent clone, and a retired handle whose address is later reused. Count logical objects and distinct backing allocations separately. Estimate host registry size as records grow and specify a retirement policy. Include a mutation that invalidates a CPU replica while retaining GPU authority, identifying which generation and validity fields must change before another consumer can read.

Part 4 - Experimental Design and Instrumentation

Begin with supported contiguous dense tensors and explicitly register view relationships when extending scope. Preserve shape, stride, dtype, offset, device, capacity status, and provenance as CPU metadata. Define whether callers borrow raw tensors only inside leases. Add duplicate registration and stale- handle controls. Keep registry retirement separate from optional historical telemetry so diagnostic records do not retain live tensors or resurrect retired ownership. Mark unobservable owners as unsupported or unknown.

Include base storage capacity even when a registered view spans only a small region. Do not merge unrelated allocations because their addresses look adjacent. Use allocation generations and logical handle versions to distinguish retirement, reuse, and mutation. Keep descriptive owner metadata separate from strong owning references, labeling both when the registry intentionally owns values. A weak reference becoming dead describes a wrapper, not the final GPU reader. Test idempotent registration and retirement, and make stale handle lookup fail clearly. If a raw alias escapes, record that loss of coverage and prevent unsupported release guarantees.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TensorHandle:
    logical_id: object
    generation: int

@dataclass
class RegistryEntry:
    metadata: object
    storage_links: tuple
    replica_records: tuple
    active_leases: tuple

def register_managed_value(registry, tensor, ownership_contract):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that aliases share a backing record without collapsing distinct logical metadata. Reject stale generations and handle reuse. Test that an external borrowed tensor cannot silently outlive its lease under the supported contract; otherwise narrow the release guarantee. Compare registry-enabled and clean runs for self-retention. Do not use sys.getrefcount as a complete native ownership oracle. Export only CPU descriptions of owners, not containers holding the tensors being investigated.

Part 7 - Engineering Interpretation and Philosophy

Identity design determines whether later accounting and safety claims are meaningful. Explain why a stable logical handle can survive migration while a physical pointer cannot serve as permanent identity. A registry is useful when its coverage and ownership rules are enforceable. Honest rejection of untracked aliases is preferable to an apparently comprehensive registry whose release decisions ignore real consumers.

19.50.3 Exercise 02

Exercise Title: Implement Exact Tensor Memory Accounting and Compare the Manager's Internal Bookkeeping Against PyTorch CUDA Memory Measurements

Part 1 - Exercise Contract and Why It Matters

Implement exact accounting within a supported registered-storage domain, then reconcile it with broader PyTorch CUDA counters. Deliver logical payload, unique backing capacity, per-tier replica charges, pending commitments, and a coverage-aware residual. Exact must describe an explicit accounting boundary; it cannot mean perfectly predicting total process VRAM, allocator rounding, workspace, context allocations, or memory owned by other libraries from registered tensor shapes alone.

Part 2 - System and Memory Mental Model

Logical dense payload is element count times element size, but views, offsets, capacity, and nonstandard layouts complicate backing occupancy. Multiple logical values can reference one storage, while replicas on separate tiers consume separate capacity. memory_allocated and memory_reserved describe different allocator scopes. An allocator snapshot has its own visibility limits. Registry capacity cannot simply be added to memory_allocated when those bytes are already represented in that counter.

Part 3 - Quantitative Prediction Before Execution

For supported dense tensors calculate logical payload and unique backing capacity separately:

$$B_{\text{logical}} = \sum_i n_i s_i, \qquad B_{\text{backing}} = \sum_{j \in \mathcal{U}} c_j.$$

Define the unique set by tier and allocation generation. Add a large base with small views and a CPU-GPU replica pair. Predict differences from allocator live bytes and reservation, identifying which residual terms are expected rather than labeling all disagreement an accounting defect.

Part 4 - Experimental Design and Instrumentation

Validate arithmetic using synthetic catalogs before runtime measurements. Include overlapping views, independent clones, zero-element tensors, and capacity larger than current logical shape. Restrict unsupported sparse, quantized, or external layouts instead of forcing a dense formula. Sample at deliberate completed boundaries with matched timestamps. Record persistent unmanaged state and backend-specific unsupported fields. Compare deltas in a controlled arena rather than demanding absolute equality with all device memory.

Keep pinned host bytes as a subset of total managed host occupancy when that is the chosen RAM definition, rather than adding overlapping categories into an invented total. File size, virtual mappings, resident pages, and page cache also need separate labels. For a tensor serialized as a small view, verify the actual stored backing extent instead of assuming logical

payload determines file size. Record timestamp and completion state for runtime comparisons. A zero-element tensor may have nontrivial backing through an alias; validate its supported storage relationship before assigning zero capacity. Include unsupported layouts in the coverage table.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def account_registered_storage(registry, accounting_scope):
    ...

def reconcile_with_cuda(ledger, cuda_sample, coverage):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact synthetic totals and explain every supported-domain mismatch. Use explicit unknown capacity instead of zero. Keep requested payload, backing capacity, allocator block size, and reserved segment capacity in separate columns. A positive residual can reflect unmanaged tensors or opaque allocations; a negative residual can reflect timestamp skew or double counting. Investigate before assigning a cause. Report host metadata and file-backed capacity independently from resident host pages.

Part 7 - Engineering Interpretation and Philosophy

Accounting is reliable when it states what it measures and why quantities differ across layers. Explain which ledger is suitable for admission and which counters provide external context. A scoped exact result can coexist with uncertain whole-process use. The manager should reconcile these boundaries without inventing a universal conversion from tensor payload to guaranteed available CUDA capacity.

19.50.4 Exercise 03

Exercise Title: Define VRAM, RAM, and Optional NVMe Memory Budgets and Reject Unsafe Allocations Before They Reach the CUDA OOM Boundary

Part 1 - Exercise Contract and Why It Matters

Define independent VRAM, pageable RAM, pinned RAM, and optional NVMe capacity budgets with admission rules. Reject requests that exceed the manager's known safe commitments before issuing their allocations. Deliver a budget ledger, safety margins, and accepted, rejected, or uncertain decisions. The title's preventive goal is scoped: external allocations and allocator eligibility can still cause CUDA OOM after a request passes application-level checks.

Part 2 - System and Memory Mental Model

A migration can require destination capacity, retained source, temporary conversion workspace, and staging simultaneously. Driver free memory is context, not an atomic reservation for this process. Cached allocator space and application logical free capacity are different resources. NVMe capacity is storage space rather than a device accepted by Tensor.to; file serialization, metadata, integrity checks, and host staging form an explicit optional path.

Part 3 - Quantitative Prediction Before Execution

Define a conservative per-tier admission condition:

$$C_r + P_r + \Delta_r + H_r \leq B_r.$$

Name committed capacity, not-yet-materialized reservations, incremental request cost, and headroom separately. Ensure already materialized bytes are not counted in both committed and pending terms. Predict a request that fits its destination payload but fails because staging and overlap exceed another tier's budget. Keep undefined estimates explicitly unresolved.

Part 4 - Experimental Design and Instrumentation

Use a controlled inference arena and synthetic near-limit requests before bounded hardware tests. Estimate worst supported overlap, reserve all affected tiers atomically, and release reservations on rejected preparation. Validate file capacity and host staging before optional NVMe operations. Keep a separate allowance for unmanaged workspace and measurement uncertainty. Do not claim a public API reports the largest CUDA allocation that would certainly succeed at the next instant.

Give every budget a resource name, unit, version, and enforcement scope. If total RAM includes pinned staging, enforce the total and pinned subset constraints without double counting their occupancy. Distinguish known managed bytes from a conservative unmanaged allowance. If broader measured use already includes managed bytes, do not add the same registry capacity again. Budget rejection should return required incremental resources and the limiting tier. For optional NVMe, reserve file and metadata space, validate path ownership, and clean incomplete artifacts after failure. Do not interpret a successful filesystem allocation as proof that future I/O latency is acceptable.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BudgetDecision:
    admitted: bool
    tier_charges: object
    uncertainty: tuple
    reasons: tuple

def admit_operation(operation, ledger, budgets, allowances):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Test exact-fit, over-budget, unknown-size, and concurrent-request cases. Report manager admission rejection separately from an actual CUDA allocation failure. Check that a rejected request leaves no leaked reservation or partial destination. A successful allocation does not validate all future workload headroom. Record budget values in bytes, current samples, timestamps, and safety assumptions. If optional NVMe support is absent, mark it unsupported rather than replacing it with an unbounded host copy.

Part 7 - Engineering Interpretation and Philosophy

Budgets are enforceable promises about controlled resources, not guarantees about an entire shared machine. Explain which safety assumptions make a request admissible and which external risks remain. The admission system should fail clearly when information is insufficient. Its value is preventing known overcommit and making residual failures diagnosable, while preserving an honest distinction between policy approval and allocator success.

19.50.5 Exercise 04

Exercise Title: Build Explicit Tensor Residency States for GPU-Resident, CPU-Resident, NVMe-Resident, Prefetching, Evicting, and In-Use Memory

Part 1 - Exercise Contract and Why It Matters

Define explicit residency records covering GPU, CPU, optional NVMe, prefetching, evicting, and in-use values without forcing incompatible facts into one enum. Deliver a state model, legal combinations, replica authority rules, and transition examples. In-use should normally be an orthogonal lease or activity state: a GPU-resident tensor can be in use, while CPU and GPU replicas can both exist during a transfer.

Part 2 - System and Memory Mental Model

Location, validity, authority, transfer progress, and active consumers are separate dimensions. A destination allocation may exist before its contents are ready. A completed CPU replica can become stale after a GPU write. Eviction can mean dropping a redundant clean GPU copy or copying dirty authoritative values first. Optional file residency needs a committed versioned record, not merely a pathname or an incomplete write.

Part 3 - Quantitative Prediction Before Execution

Predict the full record after promotion starts, after copy completion, after a GPU mutation, and after demotion commits. Count every occupied tier during overlap. Construct a stale CPU replica case and identify why its existence does not permit immediate GPU release. Predict which fields remain valid if a transfer fails before completion and which source copy must preserve the latest value.

Part 4 - Experimental Design and Instrumentation

Write a transition table with preconditions, acquired reservations, submitted events, completion rules, and failure cleanup. Begin with immutable inference values, then add a versioned writer lease. Use a simulator to exercise delayed completion and simultaneous replicas. Restrict unsupported external mutation. If implementing NVMe, keep temporary files distinct from committed records and require validated shape, dtype, length, and value integrity before making a file version authoritative.

Model replica versions independently from allocation generations: an unchanged allocation can hold newly written values, while migration can create another allocation holding the same value version. A reader must request the expected version and wait for its readiness. Test a clean redundant replica, a stale replica, and the sole authoritative copy. For optional files, define whether commit promises process-local recoverability or durable persistence and implement the corresponding protocol; do not imply durability from a host write call alone. Unknown transfer completion keeps a replica pending, even when its memory has already been charged to the ledger.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ReplicaState:
    tier: str
    value_version: int
    ready_event: object
    valid: bool
    capacity_bytes: object

@dataclass
class ValueState:
    replicas: tuple
    authoritative_version: int
    reader_leases: tuple
    writer_lease: object
    pending_transitions: tuple

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject contradictory states such as no valid recoverable value with a live handle, two conflicting authoritative write versions, or a ready flag set before completion. Preserve transfer errors explicitly. Check that a clean replica drop and a dirty writeback have different costs and safety conditions. Never read an incomplete CPU destination simply because the host copy call returned. Validate the state record against actual values in small completed replays.

Part 7 - Engineering Interpretation and Philosophy

A state model is useful when it makes unsafe assumptions difficult to express. Explain why orthogonal activity and residency fields represent asynchronous work better than a single GPU-or-CPU label. The model should support a conservative answer when transfer progress or mutation provenance is unknown. Future policy plugins may choose actions, but only the transition engine can authorize state changes that preserve the latest required value.

19.50.6 Exercise 05

Exercise Title: Implement Safe Residency State Transitions and Detect Illegal Transitions Such as Evicting a Tensor Still Used by CUDA Work

Part 1 - Exercise Contract and Why It Matters

Implement a transactional transition engine that validates state, schedules safe work, and commits only after required completion. Detect requests that would discard a value still needed by CUDA work or publish an incomplete replica. Deliver illegal-transition cases, failure cleanup, and an auditable state log. A policy suggestion must not directly mutate residency records or bypass the engine's ownership and completion checks.

Part 2 - System and Memory Mental Model

An asynchronous copy submission is not a completed state transition. The source must remain valid through its last reader, and the destination must remain reserved and unavailable to incompatible users until ready. Existing read leases, writer leases, aliases, and stream events constrain release. A clean read-only copy may overlap other reads when dependencies permit it; an unsafe source release or conflicting write remains forbidden.

Part 3 - Quantitative Prediction Before Execution

For a promotion and a dirty demotion, predict prepare, submit, complete, commit, and abort stages. Identify the point at which destination bytes are materialized and when reservations change category. Construct a late-completion case where an old operation attempts to commit after the logical value has advanced to another generation. Predict rejection without corrupting the new record or releasing its valid storage.

Part 4 - Experimental Design and Instrumentation

Use operation IDs and expected generations for every transition. Reserve resources before submission, preserve the source, and make commit idempotent. Inject failures before allocation, after destination creation, and before publication. Simulate event completion deterministically, then validate supported CUDA dependencies in bounded replays. Keep state locks short and avoid waiting for device completion while holding a lock needed by another completion handler.

Write a failure table for each stage with retained source, destination charge, reservation ownership, published metadata, and retry eligibility. Submission can leave real work in flight even after a caller cancels. Keep an operation record until cleanup is safe, and make late completion unable to mutate a newer generation. A synchronous state lock does not serialize CUDA execution; explicit device dependencies remain necessary. Test two writers competing for a value and a reader arriving during eviction. Reject or safely wait according to the declared access contract rather than returning an unready destination or silently dropping a required version.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def prepare_transition(registry, request, ledger):
    ...
```

```
def commit_transition(registry, operation, completion_evidence):
    ...

def abort_transition(registry, operation, failure):
    ...

def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that every failed operation preserves a valid source or reports an unrecoverable value explicitly. Test double completion, stale operation IDs, and cancellation after submission. Releasing a reservation cannot free a buffer still used by an in-flight copy. Compare values and generations after all admitted transitions. Export CPU-only event descriptions and distinguish submission time from completion time. No illegal transition should silently become a forced device-wide synchronization fallback.

Part 7 - Engineering Interpretation and Philosophy

Safety belongs in one enforceable mechanism. Explain how the engine separates a policy's preference from the proof that a transition is legal. Transactional metadata cannot undo arbitrary external writes, so the supported access contract must remain explicit. The strongest implementation refuses stale or unsafe operations, preserves authoritative data through failures, and makes both successful and rejected transitions reviewable.

19.50.7 Exercise 06

Exercise Title: Add Reference Counting and Last-Use Tracking So the Manager Knows When Tensor Storage Can Be Released, Reused, or Evicted

Part 1 - Exercise Contract and Why It Matters

Track manager leases and completed last uses so storage can be released, reused, or evicted only when all required obligations permit it. Deliver reader and writer accounting, generation-safe retirement, and shared-storage controls. Reference counting applies to the manager's controlled ownership model; it is not a complete count of all Python wrappers, autograd saves, native holders, or outstanding GPU readers in an arbitrary PyTorch program.

Part 2 - System and Memory Mental Model

A zero manager-reader count can coexist with pending CUDA work submitted under an earlier lease. Several logical handles can share one allocation, so backing release requires resolving all relevant owners. Python garbage collection and device execution proceed on different timelines. record_stream helps the allocator handle cross-stream lifetime, but it does not decide application data dependencies or authorize overwriting a value still needed by another consumer.

Part 3 - Quantitative Prediction Before Execution

Predict lease and pending-event counts for two handles sharing storage and two streams reading at different times. Identify the earliest legal wrapper retirement, backing release, and

overwrite boundaries separately. Include a planned future reuse and explain why it can favor keeping data without necessarily making a zero-current-reader value impossible to evict. Distinguish a policy prediction about future use from an active correctness obligation.

Part 4 - Experimental Design and Instrumentation

Use scoped acquisition and release tokens rather than raw integer increments scattered throughout application code. Associate each submitted use with its completion evidence and generation. Test double release, forgotten release, and an external alias that violates the supported borrowing contract. For training extensions, integrate supported saved-tensor or checkpoint adapters; do not assume ordinary autograd references are automatically represented by manager leases.

Separate a borrowing lease from a future scheduling hint. A current reader can prevent overwrite or release, while a future reader can often tolerate eviction followed by reload. For shared backing, track obligations at both logical-value and storage levels. Include an autograd-saved value only through a supported adapter that preserves its semantics; never infer its native ownership from Python reference counts. On shutdown, stop new borrows, settle or safely retain pending operations, then retire storage. A garbage-collection pass is not a substitute for completing the relevant stream dependencies and resolving managed leases.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def acquire_value(registry, handle, access_mode, execution_scope):
    ...

def release_lease(registry, token, completion_event):
    ...

def retire_backing_if_safe(registry, storage_id, evidence):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate shared backing is never released after only one alias retires. Include a CPU wrapper disappearing while a CUDA reader remains pending, and a completed-reader case whose caching allocator retains reservation. Report unknown external ownership rather than treating it as zero. Detect lease imbalance with bounded diagnostics that do not retain raw tensors. Verify values after reuse to expose premature overwrites that might otherwise appear only as intermittent numerical corruption.

Part 7 - Engineering Interpretation and Philosophy

Correct release is the intersection of ownership and execution safety. Explain which counts are exact within the manager and which obligations require external adapters or conservative

refusal. A future-use estimate helps optimize residency, while a current reader determines legality. Keeping those concepts separate allows policy flexibility without turning a mistaken reuse prediction into a correctness failure.

19.50.8 Exercise 07

Exercise Title: Build High- and Low-Watermark Memory Pressure States That Change Runtime Behavior Before VRAM Becomes Critically Full

Part 1 - Exercise Contract and Why It Matters

Build pressure states using distinct high and low watermarks, pending commitments, and bounded reaction rules. Deliver transition traces showing when admission, prefetch, and eviction behavior changes. The policy should respond before known commitments exceed its capacity, while avoiding repeated promotion and demotion around a single noisy threshold. A smaller configured budget must not authorize unsafe release of values currently required by computation.

Part 2 - System and Memory Mental Model

Allocated, reserved, managed backing, and driver free bytes describe different pressure views. The manager's admission pressure should use its consistent committed-plus-pending ledger with allowances, while external counters provide context. Hysteresis reduces oscillation by requiring a lower threshold before returning to relaxed behavior. A budget decrease can leave existing obligations above the new target; that is a draining or infeasible state, not proof that immediate eviction is legal.

Part 3 - Quantitative Prediction Before Execution

Choose low and high thresholds with units and a clear denominator. Predict state changes for a trace hovering near the high threshold, a transfer burst, and a sudden budget reduction. Include pending destinations so pressure is visible before allocation completion. Estimate how much eligible capacity must be released to return below the low threshold, and preserve the possibility that pinned or in-use state prevents that target.

Part 4 - Experimental Design and Instrumentation

Validate the policy on deterministic byte traces before CUDA integration. Define cooldown, sampling cadence, and separate emergency admission rejection. Change one pressure input at a time to understand behavior. When entering pressure, reduce optional prefetch and select only eligible eviction candidates. On a budget decrease, stop incompatible new commitments and drain safely. Record state transition reasons, effective budget versions, and actions rejected because the required storage cannot yet be released.

Use a budget version in every pressure decision so a delayed action cannot apply thresholds from an obsolete capacity target. Test a falling budget below unavoidable persistent residency and report the deficit without deleting live state. Optional prefetch may be canceled before submission, but in-flight copies retain their cleanup obligations. Distinguish pressure relief promised by an eviction proposal from capacity actually released after completion. Settle the ledger only at the corresponding lifecycle boundary. Report the number of state flips and migration cost when comparing hysteresis settings, not just whether the final counter is below a threshold.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def update_pressure_state(previous, ledger, budgets, thresholds):
    ...

def plan_pressure_response(state, eligible_values, pending_operations):
    ...

def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check threshold equality conventions and ensure hysteresis does not mask an actual overcommit. Test zero or changing budgets and invalid threshold ordering. Measure oscillation count, time under pressure, rejected admissions, and stalled work. Do not force an apparent recovery by dropping required values. Compare managed pressure with broader CUDA samples without treating a high reserved cache as identical to live data demand. Report a failure to reach the low target honestly.

Part 7 - Engineering Interpretation and Philosophy

Pressure states translate accounting into predictable behavior. Explain which actions are optional performance changes and which are mandatory admission constraints. Hysteresis is useful only when its scope and response costs are visible. The manager should preserve correctness while acknowledging that some workloads cannot fit a newly reduced budget without changing the workload or waiting for existing obligations to end.

19.50.9 Exercise 08

Exercise Title: Implement Pluggable FIFO, LRU, Size-Aware, and Cost-Aware Eviction Policies Behind a Common Memory-Manager Interface

Part 1 - Exercise Contract and Why It Matters

Implement FIFO, LRU, size-aware, and cost-aware candidate ranking behind one policy interface. Deliver deterministic decisions, tie-breaking rules, and comparisons on identical access traces. The interface must rank only actions already permitted by ownership, replica validity, and completion rules. A policy cannot make an in-use authoritative value evictable merely by assigning it a favorable score.

Part 2 - System and Memory Mental Model

FIFO uses an explicitly defined admission age; LRU uses a defined application access event. Size-aware ranking can favor large recoverable capacity but must account for aliases that prevent actual release. Cost-aware ranking balances expected reuse, reload, writeback, and stalls. These are imperfect future-use estimates, not correctness facts. Full-attention KV blocks can all be reused each step; low attention weight alone does not make their lossless deletion valid.

Part 3 - Quantitative Prediction Before Execution

Predict each policy's choice for a shared backing allocation, a dirty large value, and a small value needed soon. Compute expected recoverable unique GPU capacity rather than logical tensor size. State the units of the cost score and how ties are broken. Construct a trace where LRU is worse than FIFO and another where largest-first causes expensive immediate reload, showing that no ranking is universally best.

Part 4 - Experimental Design and Instrumentation

Use an immutable candidate snapshot from the transition engine and return ranked proposals with reasons, never direct mutations. Revalidate eligibility at commit because state can change after ranking. Replay the same deterministic trace under each policy with matching budgets and initial state. Measure writebacks, reloads, hit rate, stalls, and end-to-end runtime. Include a no- eviction baseline when capacity permits and preserve cases where no eligible victim exists.

Define LRU's access event as an application use or completed demand, rather than a telemetry inspection that accidentally makes every value recent. Choose whether FIFO age resets on reload and document it. Size-aware scores must use unique capacity recoverable after all aliases and obligations are considered. For dirty values, include host destination admission and writeback cost before ranking them as victims. Compare policy decisions on a frozen candidate snapshot, then revalidate the selected version. Preserve shared-prefix or shared-parameter cases where removing one handle cannot release the backing allocation, even when that handle has the largest logical size.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class EvictionProposal:
    handle: object
    expected_generation: int
    recoverable_bytes: object
    score: object
    reasons: tuple

def rank_eviction_candidates(candidates, policy, cost_model):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that all policies preserve identical required values and derivatives in their supported workload. Test stale proposals, shared replicas, and dirty writeback costs. A hit-rate improvement without reduced stall or runtime is a valid mixed result. Distinguish policy miss

from incorrect eligibility. Report counterexamples and unsupported cost estimates rather than claiming global optimality. A deterministic tie rule should make identical synthetic traces reproducible.

Part 7 - Engineering Interpretation and Philosophy

The common interface makes policy differences reviewable without weakening safety. Explain which ranking suits the tested access pattern and which assumptions made it effective. A robust manager can change heuristics while keeping the same transition invariants. The best tested policy is a measured choice within a workload range, not a replacement for ownership and completion proofs.

19.50.10 Exercise 09

Exercise Title: Implement a Prefetch Planner That Selects Future Tensors from Execution Order, Reuse Distance, Transfer Cost, and Available VRAM

Part 1 - Exercise Contract and Why It Matters

Build a prefetch planner that predicts future needs, admits destination capacity, and schedules transfers before demand. Deliver deadlines, confidence, reservations, and observed useful or wasted prefetch outcomes. The planner must work within the same budget as foreground allocations rather than treating prefetched bytes as free. A future execution estimate can be wrong, so cancellation and fallback demand loading need explicit contracts.

Part 2 - System and Memory Mental Model

Prefetch advances a necessary transfer in time and increases early residency. Its benefit depends on available overlap, source readiness, link contention, and consumer dependencies. A request selected from predicted execution order is not guaranteed to execute on a conditional path. A ready destination still needs generation and validity checks at use. Prefetch cannot conceal transfer time that exceeds the available independent work, nor create extra physical capacity.

Part 3 - Quantitative Prediction Before Execution

Estimate a transfer deadline from expected consumer time, measured copy cost, and a safety margin. Predict when limited capacity forces a shorter prefetch horizon even if distant data is certain to be used. Compare useful bytes ready before demand, late bytes, and unused speculative bytes. Construct a case where prefetch improves transfer overlap but evicts a more valuable resident value and increases total runtime.

Part 4 - Experimental Design and Instrumentation

Begin with a fixed execution trace and known sizes, then add conditional branches with recorded predictions. Reserve destination and staging capacity before scheduling. Track operation IDs, value versions, predicted consumer, and completion evidence. Limit outstanding requests and prioritize mandatory demand over optional speculation under pressure. Replay with identical access traces and compare against demand-only loading, including planning and cancellation costs in the benchmark.

Record whether each future need is known from a fixed trace or inferred from a conditional path. Use measured size-dependent transfer costs rather than one constant bandwidth for every request. Demand loading should not wait behind unlimited speculative work; bound

queue depth and define priorities. If a prefetched version becomes stale after a write, invalidate it before counting a hit. Cancellation can prevent publication without undoing an already submitted copy. Measure speculative traffic and occupancy as well as demand stalls, and include a case where disabling prefetch is the best validated choice under the tested budget.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def plan_prefetch(trace_hint, registry, ledger, bandwidth_model):
    ...

def reconcile_prefetch_demand(operation, consumer, actual_state):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that a prefetch hit refers to the correct value version ready before its actual demand. Separate late completion, unused speculation, and canceled work already in flight. Do not release buffers merely because the consumer prediction disappeared. Report host and CUDA occupancy peaks, useful overlap, link traffic, and stalls. A prediction failure should degrade performance through a safe fallback, not expose incomplete or stale tensor data.

Part 7 - Engineering Interpretation and Philosophy

Prefetch is a trade between earlier residency and less waiting. Explain which horizon is justified by measured costs and which uncertainty limits it. The planner should remain optional: refusing speculative work under pressure can improve stability. Its strongest result is reduced demand stalls without budget violations or a hidden increase in migration traffic that overwhelms the benefit.

19.50.11 Exercise 10

Exercise Title: Add Pinned CPU Staging Buffers and Non-Blocking CUDA Transfers for Asynchronous Tensor Promotion and Demotion

Part 1 - Exercise Contract and Why It Matters

Add reusable pinned CPU staging buffers and non-blocking transfers for promotion and demotion. Deliver separate host and CUDA budgets, buffer leases, readiness events, and transfer correctness tests. Pinned memory is a constrained host resource, not free bandwidth. Non-blocking submission does not mean the destination is immediately readable or that the source can be overwritten before the copy completes.

Part 2 - System and Memory Mental Model

Pageable and pinned host paths have different staging and synchronization behavior. A GPU-to-CPU destination must not be consumed before completion; a pinned CPU source must remain unchanged through an asynchronous host-to- device read. Reusing a staging slot requires its transfer and consumers to finish. Calling pin_memory can itself allocate and copy, so repeatedly pinning inside the critical path is different from using a bounded reusable pool.

Part 3 - Quantitative Prediction Before Execution

Predict simultaneous occupancy for a two-slot transfer pipeline, including pinned slots, source values, GPU destinations, and temporary conversion if present. Estimate transfer cost from measured directional bandwidth and launch overhead. Compare one large transfer with many small transfers of the same payload. Identify when additional slots cannot improve overlap because the link or compute path is already saturated.

Part 4 - Experimental Design and Instrumentation

Start with same-dtype dense contiguous copies and fixed slot capacities. Reserve each slot and destination before submission, retain source leases, and record completion on the actual transfer stream. Verify CPU values only after the required event boundary. Add variable-size requests and reject or safely grow insufficient slots through the admission system. Keep transfer-only measurements separate from the complete producer-transfer-consumer pipeline and report both.

Treat a pinned buffer's capacity, valid region, transfer direction, and lease generation as explicit fields. Prevent a late completion from freeing a slot already assigned to another generation. Keep source and destination alive until their actual readers finish, even when library allocator mechanisms also help track lifetime. Repeatedly allocating pinned tensors can change host behavior and must not be hidden in setup for only one candidate. Compare pageable and reusable pinned paths at the same payload and timing scope. Report any host-side pinning, packing, dtype conversion, or noncontiguous materialization included in the complete transfer path.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def acquire_staging_slot(pool, request_bytes, reservation):
    ...

def submit_residency_copy(source, destination, slot, stream, operation):
    ...

def release_staging_after_completion(pool, slot, completion):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate round-trip values, slot reuse, source lifetime, and destination readiness. Use deterministic delayed-completion simulation for unsafe-reuse rejection rather than relying on a nondeterministic corruption race. Measure pinned host footprint, CUDA peak, transfer volume, and latency. Do not infer complete pipeline overlap from a short host submission time. Preserve unsupported async paths and quantify pinning or conversion costs that the chosen timing scope includes.

Part 7 - Engineering Interpretation and Philosophy

Staging is a resource with a lifetime, not a transfer flag. Explain how pool capacity and leases make overlap safe and predictable. The best pipeline balances host residency, destination admission, and actual useful concurrency. A lower host call duration is not sufficient evidence of higher throughput if the consumer still waits for the same copy or a prematurely reused slot corrupts its data.

19.50.12 Exercise 11

Exercise Title: Coordinate Prefetch, Compute, and Eviction Through CUDA Streams and Events Without Using Global Device Synchronization

Part 1 - Exercise Contract and Why It Matters

Coordinate prefetch, compute, and eviction through explicit stream dependencies and events, avoiding device-wide synchronization in the steady-state pipeline. Deliver a causal execution graph, safe lifetimes, and measured overlap. Bounded validation can use deliberate completed boundaries, but routine operation should not serialize all streams after every request. Removing global waits must preserve producer readiness, last-reader completion, and allocator safety.

Part 2 - System and Memory Mental Model

CUDA streams order their own work; cross-stream consumers need explicit relationships. Event waits establish device-side readiness, while record_stream or an equivalent correctly implemented lifetime protocol informs safe reuse. These solve different problems: allocator lifetime tracking alone does not make a consumer wait for the producer. Host callback order is not proof of GPU completion. A cycle in dependency waits can deadlock an otherwise valid allocation plan.

Part 3 - Quantitative Prediction Before Execution

Draw dependencies for one prefetched value, one compute consumer, and one writeback. Predict which operations may overlap and which must wait. Calculate a lower bound on pipeline latency from the critical path rather than summing all event durations. Add a second reader stream and identify the extra completion obligation before release. Predict how a misplaced early wait eliminates potential overlap without changing value correctness.

Part 4 - Experimental Design and Instrumentation

Use dedicated streams with recorded operation IDs and value generations. Record readiness after production or copy, then make each consuming stream wait before use. Preserve source and destination ownership through all readers. Use supported allocator lifetime tracking or a fully explicit creation-stream handoff protocol. Validate dependency acyclicity in simulation and instrument actual streams in separate timing replays. Keep steady-state global synchronization out of the implementation contract.

Choose fresh or safely reusable event generations for each dependency. Recording a new event state while another operation still interprets the old one can invalidate the logical dependency model. Include a two-reader case where one stream finishes late and a canceled consumer whose already submitted work still requires completion handling. Distinguish CPU waiting on an event from a device stream waiting on an event. Use the least broad wait that satisfies the contract, but validate correctness before optimizing overlap. A record_stream call informs allocator reuse and cannot replace explicit readiness waits between producer and consumer streams.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def connect_stream_dependencies(operation, producer, consumers, events):
    ...

def finalize_cross_stream_lifetime(storage, reader_events, owner_stream):
    ...

def E11(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare numerical results with a deliberately serial reference. Test multiple readers, delayed copies, event reuse, and a rejected cyclic dependency graph. Report overlap from completed event intervals with clock and device scope, not host launch proximity. Distinguish readiness waits from allocator lifetime handling. Check that telemetry does not insert hidden synchronization into every operation. Unsupported cross-device timing must remain explicitly unresolved rather than mixed into one absolute timeline.

Part 7 - Engineering Interpretation and Philosophy

Concurrency is safe when dependencies are explicit enough to justify every read and release. Explain which waits are essential and which only reduce parallelism. The manager should expose its causal graph so performance changes can be audited without weakening lifetimes. A fast submission loop is meaningful only when the completed pipeline remains correct and its true critical path has improved.

19.50.13 Exercise 12

Exercise Title: Build a Memory Reservation System That Prevents Multiple Pending Operations from Overcommitting the Same Future VRAM

Part 1 - Exercise Contract and Why It Matters

Build atomic memory reservations so concurrent pending operations cannot each spend the same apparent free capacity. Deliver reservation tokens, materialization and commit rules, cancellation, and a race-controlled simulator test. The reservation system protects the manager's

logical budget; it does not reserve physical VRAM against other processes or guarantee that the CUDA allocator will satisfy a later request.

Part 2 - System and Memory Mental Model

A free-memory sample followed by an allocation is not an atomic admission protocol. Pending destinations, staging, and workspace allowances must be charged before submission. Once destination memory is materialized, its charge must move consistently from unmaterialized pending capacity to committed capacity. Counting it in both categories overstates pressure; releasing it from both during a transition creates an overcommit window. Source capacity cannot be reclaimed before its own safe release.

Part 3 - Quantitative Prediction Before Execution

Predict the result when two requests individually fit but jointly exceed a budget. Model interleavings of check, reserve, allocate, complete, and release. Compute a conservation invariant for each tier and test an allocation failure between reservation and commit. Include a cancellation after CUDA submission: the reservation's ownership must follow the actual pending work rather than vanish because a caller no longer wants its result.

Part 4 - Experimental Design and Instrumentation

Use one coordinated ledger or a clearly defined transactional lock discipline for all affected tiers. Assign unique tokens, operation generations, requested amounts, and lifecycle states. Avoid blocking transfers while holding admission locks. Test deterministic concurrent interleavings and idempotent cleanup before real asynchronous execution. Reconcile actual materialized capacity with the estimate, rejecting unsupported underestimated growth or acquiring additional capacity before proceeding where possible.

Define one conservation equation for every reservation lifecycle transition. A materialized destination moves from pending to committed without a gap or double charge. Aborted preparation returns only unmaterialized commitments; live partial allocations remain charged until safe release. Reserve multiple tiers in one transaction or use ordered locking with complete rollback. Never hold a host lock while waiting for a completion path that needs that lock. Test two requests using the same initial free-capacity observation, and require only the admissible combination to receive tokens. Record actual capacity adjustments if allocator-visible backing differs from the initial supported estimate.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ReservationToken:
    operation_id: object
    generation: int
    tier_amounts: object
    lifecycle: str

def reserve_atomically(ledger, request, budgets):
```

```
    ...

def settle_reservation(ledger, token, materialized, completion):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert that accepted commitments never exceed the declared ledger limit under tested interleavings. Test double settlement, expired tokens, stale generations, and partial multi-tier preparation. Report admission rejection separately from an allocator OOM after valid reservation. Verify cancellation does not release live transfer buffers. Use exact synthetic invariants and bounded hardware measurements; neither a successful single-thread run nor a momentarily high free-memory sample proves concurrency safety.

Part 7 - Engineering Interpretation and Philosophy

Reservations turn future occupancy into explicit present commitments. Explain which race they prevent and which external allocations remain beyond their control. The ledger should expose why capacity is unavailable even before all destinations appear in CUDA counters. This makes prefetch, eviction, and recovery share one budget instead of competing through independent optimistic estimates.

19.50.14 Exercise 13

Exercise Title: Detect and Prevent Thrashing by Monitoring Tensor Migration Frequency, PCIe Traffic, Reuse Distance, and GPU Stall Time

Part 1 - Exercise Contract and Why It Matters

Detect repeated migrations that consume bandwidth and stall work without providing useful residency. Deliver migration cohorts, a thrashing predicate, and validated mitigation policies. Distinguish necessary streaming of a working set larger than capacity from avoidable oscillation caused by poor prefetch or eviction decisions. High transfer volume alone is not a proof that the manager is malfunctioning.

Part 2 - System and Memory Mental Model

Thrashing depends on reuse, cost, and available alternatives. A value evicted just before reuse can require immediate reload; speculative prefetch can cause that eviction. Cooldowns, minimum residency, reduced prefetch horizons, and admission throttling can help, but also constrain useful eviction. A full-attention working set may require every KV block repeatedly, so a hot/cold classification cannot invent lossless unused data or bypass a fundamentally insufficient capacity budget.

Part 3 - Quantitative Prediction Before Execution

Define windowed migration bytes, repeated round trips per generation, demand stall fraction, and useful computation between migrations. Compare two traces with the same transfer

volume but different stall and reuse behavior. Predict a case where a cooldown improves runtime and another where it blocks a necessary eviction. State thresholds, observation windows, and the evidence needed before calling a pattern avoidable thrashing.

Part 4 - Experimental Design and Instrumentation

Replay alternating working sets, predictable layer streaming, and speculative wrong-path prefetch under identical budgets. Collect per-value migrations and causal waits as CPU metadata. Apply one mitigation at a time and compare completed runtime, useful prefetch, rejected admissions, and memory peaks. Use measured transfer cost under contention rather than assuming an isolated bandwidth result remains constant. Keep correctness eligibility unchanged when adjusting the heuristic.

Use rolling windows tied to workload progress and preserve tensor generations in round-trip counts. A repeatedly reused logical ID may refer to different values, so migration frequency alone can misidentify a healthy replacement stream. Compare useful computation completed per transferred byte and direct consumer wait time. Include contention from simultaneous promotions and demotions when calibrating costs. Mitigation may reduce speculation, delay admission, or change victim ranking, but cannot delete required data or bypass leases. If the working set fundamentally exceeds budget, report necessary streaming and its measured cost instead of claiming a heuristic eliminated the capacity constraint.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def identify_thrashing(telemetry_window, workload_contract, thresholds):
    ...

def propose_thrashing_mitigation(findings, eligible_controls):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that alerts distinguish predictable necessary streaming from avoidable back-and-forth motion on controlled traces. Report ambiguous cases and false positives. Check that mitigation does not violate deadlines, budgets, or value requirements. Compare the number of migrations with transferred bytes and stalls; fewer copies can still mean more waiting. Preserve a case with no effective mitigation under the current budget rather than claiming every working set can be made resident through better policy.

Part 7 - Engineering Interpretation and Philosophy

Thrashing diagnostics should explain a cost pattern and test an alternative, not blame transfers in isolation. Explain whether the root limitation is capacity, link throughput, speculative scheduling, or victim choice. A useful manager can recognize when policy tuning is exhausted and report that the workload needs another capacity or computation strategy, while maintaining correct values throughout.

19.50.15 Exercise 14

Exercise Title: Integrate Activation Policies So the Manager Can Choose Keep, CPU Offload, or Recomputation Under Changing Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Integrate activation keep, CPU offload, and recomputation as eligible alternatives under pressure. Deliver derivative-aware region contracts, cost estimates, and matched training benchmarks. Use supported autograd integration rather than pretending the registry can replace arbitrary tensors already saved inside backward nodes. The manager must preserve the requested model function, gradients, and update sequence for policies labeled equivalent.

Part 2 - System and Memory Mental Model

Keeping preserves residency; offloading preserves values in another tier; recomputation preserves a recipe and its required inputs or state. A valid recipe needs reproducible execution and cannot ignore mutable buffers, randomness, or parameter versions. Saved-tensor hooks and supported checkpointing provide specific integration points with their own contracts. Hook nesting and selective checkpoint behavior are version-sensitive, so logging and offload do not automatically compose into complete coverage.

Part 3 - Quantitative Prediction Before Execution

Predict unique activation capacity avoided at the actual peak, retained checkpoint inputs, host offload bytes, restoration overlap, and recomputation time. Include a shared backing allocation that remains resident through another owner and therefore offers no immediate capacity relief. Compare costs under a fixed host and CUDA budget. State when no eligible intervention can reduce the peak enough without altering required derivatives.

Part 4 - Experimental Design and Instrumentation

Begin with deterministic pure regions and first-order gradients. Use explicit non-reentrant checkpoint configuration and supported save_on_cpu or validated saved-tensor adapters. Do not mutate saved inputs or replace parameter storage through .data. Collect diagnostic graphs separately when hook composition is not proven. Compare fresh identical initial states, data, precision, optimizer, and full-step timing. Validate higher-order or stochastic extensions separately before claiming support.

Preserve checkpoint inputs, parameter versions, and any RNG or mutable state needed to replay a region correctly. A recipe that reads changed weights during backward is not equivalent to the original forward. Keep transport buffers within host and device reservations, including restoration overlap. Validate hook composition in the installed version or collect diagnostics in separate passes. If compression is added to saved values, move that case to a declared approximate derivative contract rather than treating it as lossless offload. Report both prediction error and measured full-step savings, including cases where recomputation creates a different temporary peak.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.checkpoint import checkpoint
```

```
def classify_activation_options(region, derivative_contract, state):
    ...

def schedule_activation_policy(region, choice, manager, reservations):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check losses, required gradients, and several optimizer updates against normal backpropagation. Measure host peak, CUDA peak, runtime, transfer volume, and instrumentation overhead. Confirm a requested offload actually occurred under the active hook contexts. A shifted backward peak is part of the result, not an excuse to report only forward savings. Mark unsupported composition or stateful recomputation explicitly and reject any hidden detach that removes required history.

Part 7 - Engineering Interpretation and Philosophy

Activation policies exchange residency for transport or repeated computation. Explain which obligation each choice preserves and which prerequisites permit it. The manager should use measured cost after correctness eligibility, with budgets that include transient overlap. A policy that only reduces an internal saved-byte estimate without reducing the measured whole-step peak still needs an honest, limited interpretation.

19.50.16 Exercise 15

Exercise Title: Integrate Precision Policies So Selected Tensors Can Be Stored at Reduced Precision When Capacity Is More Important Than Accuracy

Part 1 - Exercise Contract and Why It Matters

Add optional reduced-precision storage policies for explicitly eligible tensors. Deliver precision contracts, representation metadata, error budgets, conversion costs, and end-to-end quality checks. Unlike lossless residency changes, lossy storage generally changes values and potentially gradients. It must be opt-in under a declared accuracy contract, not silently presented as exact equivalence when memory pressure rises.

Part 2 - System and Memory Mental Model

Storage dtype, compute dtype, accumulation dtype, and quantization metadata are different choices. A cast can allocate a destination while the original remains alive. Quantization requires scales, grouping, packing, and restoration rules; nominal bit width alone does not specify resident capacity. Autocast selects operation execution dtypes and does not automatically compress every existing stored tensor. Shared aliases and parameter or optimizer ownership can make arbitrary storage replacement unsafe.

Part 3 - Quantitative Prediction Before Execution

Predict compressed payload plus metadata, padding, staging, and conversion overlap. For a fixed tensor compare floating casts and a declared quantized representation, preserving its

scale overhead. Estimate reconstruction and downstream output errors on a bounded reference set. Include an outlier case that violates the accuracy budget and must be rejected even when compression would satisfy the byte target.

Part 4 - Experimental Design and Instrumentation

Start with immutable inference values and independent versioned representations. Require an explicit eligible-tensor list and accuracy tolerance. Validate restoration and consumers before retiring the original version. Add training saved-state compression only as a separately validated approximate policy with gradient and update checks. Do not alter live parameter or alias storage in place. Reserve both representations and workspace during conversion, and account for rollback or rejected calibration results.

Define whether a precision change is reversible from a retained master or only approximately reconstructible. Retaining an original master consumes capacity and must appear in every claimed saving. Include scale metadata, packing tails, alignment, and host copies when measuring effective compression. Reject mutable shared aliases unless all consumers observe an authorized versioned representation. Never use .data replacement as a shortcut around autograd or optimizer ownership. Test extreme values and a task-sensitive tensor that exceeds its tolerance. A representation accepted for inference must not automatically become eligible for parameter updates or higher-order derivatives.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PrecisionContract:
    allowed_representations: tuple
    value_error_budget: object
    task_quality_budget: object
    derivative_tolerance: object

def plan_precision_change(handle, contract, calibration, ledger):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report effective resident bytes, metadata, conversion latency, value error, task metrics, and required derivative error where applicable. A valid numerical tolerance must be chosen before selecting favorable examples. Preserve precision policy rejections and degradation failures. Check NaNs, infinities, extreme magnitudes, and repeated conversion effects. A lower measured footprint is not sufficient if consumers read a stale version or quality exceeds the declared loss budget.

Part 7 - Engineering Interpretation and Philosophy

Precision is a resource and accuracy trade, while lossless migration changes location. Explain that distinction in reports and policy decisions. The manager should preserve an exact mode and refuse approximate fallback unless authorized by the tensor's contract. A useful compression option states its representation, measured capacity, quality limits, and conversion costs rather than offering a universal promise based on nominal bits.

19.50.17 Exercise 16

Exercise Title: Build Automatic OOM Recovery That Rolls Back an Unsafe Operation, Changes Memory Policy, and Retries Without Restarting the Process

Part 1 - Exercise Contract and Why It Matters

Implement bounded recovery for explicitly retryable allocation failures within a declared transactional region. Deliver prepare, abort, cleanup, policy change, and retry records, plus cases that must fail without retry. The title does not authorize universal rollback of arbitrary PyTorch execution. A manager can safely recover only when required values, mutable state, randomness, and external side effects are preserved or restored under a supported contract.

Part 2 - System and Memory Mental Model

An OOM can occur after temporary allocations or state changes. Python exception tracebacks can retain failed-frame tensors, so cleanup and retry must not keep those frames alive. empty_cache releases unused allocator cache rather than live values or partially modified application state. Illegal memory access, device assertions, or corrupted execution context are not ordinary recoverable allocation failures. Partial optimizer updates and distributed collectives require stronger coordination than local retry.

Part 3 - Quantitative Prediction Before Execution

Predict state before a pure retryable operation, after an injected allocation failure, and after an admitted lower-memory retry. Account for retry workspace and retained rollback state. Compare an unchanged exact-policy retry with an optional precision change that has a separate accuracy contract. Set maximum attempts and define a decreasing resource requirement or other progress criterion so repeated failure cannot become an unbounded loop.

Part 4 - Experimental Design and Instrumentation

Begin with deterministic inference regions that have no external side effects. Catch the version-supported CUDA OOM type specifically, record scalar failure metadata, exit the exception scope, and release failed temporaries before retry. Use deterministic fault injection as the primary rollback oracle, then a bounded real allocation-failure test if appropriate. Snapshot only state required by the declared region and include its storage cost. Reject unsafe mutation or optimizer-step boundaries.

Use fault injection at known stages to validate cleanup without requiring an unpredictable real OOM. Keep injected failure labels distinct from hardware allocation failures. Catch only the supported allocation exception and preserve other failures for normal error handling. Move retry outside the exception scope and avoid storing exception tracebacks in telemetry, since they can retain failed-frame tensors. Include a pure region that retries successfully and a stateful or partially updated operation that is rejected. Optional batch-size or precision changes require an explicitly different workload contract; do not hide them as an exact retry of unchanged work.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def classify_retry_safety(operation, side_effect_contract, failure):
    ...

def abort_failed_attempt(transaction, manager, failure_metadata):
    ...

def retry_with_admitted_policy(operation, transaction, retry_budget):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare the successful result with a failure-free oracle, including RNG, mutable buffers, required gradients, and update count when supported. Verify all failed reservations and live temporaries are settled without prematurely reusing pending buffers. Report injected failure, admission rejection, actual OOM, and fatal CUDA error distinctly. In distributed extensions, refuse uncoordinated rank-local retries around collectives. Preserve nonrecoverable outcomes honestly; the same-process goal applies only to supported recoverable cases.

Part 7 - Engineering Interpretation and Philosophy

Recovery is a transaction contract, not an exception handler that blindly repeats work. Explain what was restored, why retry is safe, and which state lies outside the supported boundary. A good manager avoids known overcommit, recovers bounded eligible failures, and stops clearly when correctness or progress cannot be established. It should never trade an apparently completed request for duplicated updates or silently changed values.

19.50.18 Exercise 17

Exercise Title: Add Runtime Telemetry for Allocated Memory, Reserved Memory, Residency, Transfers, Evictions, Prefetch Hits, Stalls, and Policy Decisions

Part 1 - Exercise Contract and Why It Matters

Add bounded telemetry for manager commitments, allocator use, residency, transfers, policy proposals, prefetch outcomes, stalls, and failures. Deliver a schema with units, clocks, coverage, and operation identifiers. The observer must not retain live tensors or synchronize every event, changing the memory and concurrency behavior it reports. Collection and analysis overhead are part of the benchmark, not invisible implementation costs.

Part 2 - System and Memory Mental Model

Manager backing capacity, pending reservations, allocator allocated bytes, allocator reserved bytes, and driver-level usage have different scopes. Submission and completion timestamps

differ, and multiple streams form a causal partial order. Transfer bytes can include repeated migrations of the same logical data. A prefetch hit must specify whether the correct version was ready before demand, while a policy proposal is distinct from a committed state transition.

Part 3 - Quantitative Prediction Before Execution

Predict telemetry for one useful prefetch, one late prefetch, one canceled in-flight copy, and one failed eviction proposal. Define transfer bandwidth using stated directional payload and completed time. Calculate stall fractions with a declared denominator and avoid adding overlapping intervals twice. Estimate host log size and dropped-record behavior under an event budget. State how incomplete telemetry limits conclusions without changing raw measurements into invented zeros.

Part 4 - Experimental Design and Instrumentation

Use CPU scalars, IDs, generations, state versions, and event references with bounded retention. Sample broad CUDA counters at deliberate boundaries and record timestamp skew. Instrument detailed event timing in diagnostic replays, then compare minimally instrumented execution. Preserve workload IDs, seeds, hardware, software, allocator backend, precision, shapes, budgets, and initial state. Separate cold setup, warmed operation, calibration, and recovery timing with explicit inclusion rules.

Give every measurement a unit, scope, timestamp domain, and sampling coverage. Distinguish payload bytes from estimated physical link traffic and avoid labeling an effective copy rate as raw hardware bandwidth. For overlapping work, define whether utilization and stall fractions use a union of intervals or per-consumer totals. Keep dropped-record counts and truncation markers. Provide raw resource counters beside derived pressure values so aggregation can be audited. A report row can reference an event ID without retaining the CUDA tensor. Confirm that optional detailed tracing can be disabled without changing the manager's correctness decisions or persistent ownership.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TelemetryRow:
    operation_id: object
    generation: object
    event_kind: str
    timestamp_domain: str
    measurements: object
    coverage: object

def record_manager_event(recorder, event, scalar_metadata):
    ...

def E17(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate schemas on deterministic event traces and audit every aggregate's scope. Reject negative durations caused by mixed clocks rather than silently clipping them. Test dropped records, reused addresses, and repeated operation completion. Compare output values and memory baselines with telemetry disabled. Report overhead, capture coverage, and unsupported fields. A discrepancy between registry and device use is a diagnostic observation, not automatic evidence of a leak, fragmentation, or accounting corruption.

Part 7 - Engineering Interpretation and Philosophy

Telemetry should make decisions explainable without creating a false sense of completeness. Explain which counters describe controlled resources and which provide broader context. The report should connect a proposal, its eligibility, actual transition, and observed effect while preserving failed predictions. This gives an engineer enough evidence to improve policy rather than merely display a smooth memory chart.

19.50.19 Exercise 18

Exercise Title: Stress-Test the Memory Manager with Variable Tensor Sizes, Long Transformer Sequences, Concurrent CUDA Streams, Changing VRAM Budgets, and Deliberate Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Stress-test the manager across variable sizes, long-sequence workloads, concurrent streams, changing budgets, and deliberate bounded pressure. Deliver an invariant matrix, correctness outcomes, policy behavior, and resource and runtime measurements. Include simulated faults and unsupported cases. Pressure should be created through admitted budget limits and controlled workloads, not by relying on a dangerous race or exhausting the entire host to obtain a dramatic failure.

Part 2 - System and Memory Mental Model

Interactions can expose bugs hidden by individual features: prefetch reservations compete with demand, demotion needs pinned capacity, writes invalidate replicas, and delayed readers postpone release. Changing shapes alter capacities without implying leaks. Long Transformer sequences can exceed both saved-activation and KV budgets under different workload contracts. A smaller runtime budget may require safe draining or rejection rather than immediate success through more aggressive eviction.

Part 3 - Quantitative Prediction Before Execution

Predict outcomes before execution: admitted completion, safe waiting, admission rejection, retryable failure, unsupported operation, or irreducible budget infeasibility. Construct traces with equal logical bytes but different alias capacity and traces with equal transfer volume but different stalls. Estimate worst supported overlap and event-log size. Define failure as an invariant or correctness violation, keeping legitimate rejection separate from manager malfunction.

Part 4 - Experimental Design and Instrumentation

Build a deterministic simulator suite first, including late completion, stale generations, cancellation, dirty replicas, partial allocation failure, and duplicate callbacks. Add small real CUDA cases one feature at a time, then selected interactions. Use fixed traces and initial state,

deadlines, resource admission limits, and bounded capture. Test exact and approximate precision contracts separately. Preserve every case's supported feature matrix and actual stopping reason.

Include budget reduction below active commitments, no eligible victim, wrong-path prefetch, exhausted pinned staging, stale replica reads, and duplicated completion notifications. Add variable shapes with a healthy eventual plateau and an intentional registry-owner leak as distinct cases. Optional NVMe tests need short writes, corrupted records, and capacity rejection in a controlled private area. Stop before unbounded host growth and retain actual stopping reasons. Evaluate policies on traces not used to tune thresholds. Score invariants, numerical correctness, prediction quality, recovery, and overhead separately so an aggressive but unsafe policy cannot win through throughput alone.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_manager_stress_cases(config, supported_features):
    ...

def run_bounded_manager_case(case, manager, oracle, budgets):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check authoritative-value preservation, no premature reuse, budget conservation, reservation cleanup, bounded telemetry, and required numerical results. For exact training extensions compare gradients and updates; for approximate storage compare predeclared quality tolerances. Report peak host and CUDA use, throughput, stalls, retries, and rejected work. Include a case with no eligible victim and one with unavoidable streaming. Do not score an unsafe forced completion as better than a correct infeasibility report.

Part 7 - Engineering Interpretation and Philosophy

The stress suite defines where the manager's guarantees hold. Explain which invariants survived interaction and which features require narrower support. Keep minimal counterexamples to universal policy claims and convert confirmed bugs into focused invariant checks. A trustworthy runtime can remain useful when it refuses unsupported migration, preserves required derivatives, and reports that the workload exceeds its controlled resources.

19.50.20 Exercise 19

Exercise Title: Build and Benchmark a Complete PyTorch Dynamic Memory Manager That Controls Tensor Residency, Prefetch, Eviction, Precision, Recomputation, and Recovery Across VRAM and RAM

Part 1 - Exercise Contract and Why It Matters

Integrate a complete manager within an explicitly supported application domain, combining registry, accounting, admission, residency, transfer scheduling, eviction, prefetch, optional precision, recomputation, recovery, and telemetry. Deliver a reviewable architecture and benchmark report. Complete means the supported components obey shared contracts; it does not mean transparent control of every tensor or a finished production allocator hidden inside a high-level trainer.

Part 2 - System and Memory Mental Model

The transition engine enforces correctness, the ledger enforces controlled commitments, and policy plugins optimize eligible choices. Managed handles preserve logical identity across physical replicas, while derivatives, precision, mutation, and side effects restrict permissible actions. External allocations and backend workspace remain scoped uncertainty. Optional NVMe persistence requires its own file protocol. No component may silently bypass reservations, release in-use storage, or change required mathematical work to satisfy a capacity target.

Part 3 - Quantitative Prediction Before Execution

Predict full workload peaks, transferred bytes, demand stalls, and runtime for an unmanaged baseline, a simple valid policy, and the integrated manager. Include initialization, calibration, planning, telemetry, and recovery costs in clearly declared scopes. Define success using correct values and derivatives, resource admission, and measured useful throughput. Avoid claiming optimality from one heuristic or treating a successful small workload as proof of universal OOM prevention.

Part 4 - Experimental Design and Instrumentation

Integrate one feature at a time behind common schemas and invariant checks. Use known cases for development and held-out traces for evaluation. Benchmark matched inputs, precision contracts, derivatives, seeds, budgets, and output retention. Keep clean and diagnostic replays separate. Bound speculative work, retry attempts, report size, and optional file storage. Export CPU-only evidence with run IDs and coverage. Verify shutdown drains or safely retains all pending work before releasing owned resources.

The final report needs workload and derivative contracts, resource scopes, registry coverage, budget versions, raw counters, policy decisions, transition outcomes, numerical checks, timing boundaries, and unresolved assumptions. Show exact lossless results separately from precision-degraded outcomes. Compare matched initial states and output-retention policies, including cold and warmed behavior. Report rejected actions and infeasible requests instead of removing them from throughput denominators without explanation. State whether setup, transfers, calibration, recovery, and telemetry are included. Claim only the best validated configuration within the tested range, and identify the smallest remaining experiment needed to resolve a material uncertainty.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class ManagerReport:
    contracts: object
    decisions: tuple
    invariant_checks: tuple
    numerical_checks: tuple
    resource_measurements: tuple
    limitations: tuple

def execute_managed_workload(workload, manager, contracts):
    ...

def benchmark_manager(config, policies, reference):
    ...

def E19(config):
    # Integrate policies only through admission and safe transitions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require an evidence chain from every claimed saving to a policy decision, eligibility proof, actual transition, and validated result. Report exact and approximate outcomes separately. Compare current and peak allocated bytes, reserved capacity, managed commitments, host footprint, transfers, latency, throughput, and recovery outcomes. Keep not-supported, not-measured, rejected, and infeasible cases visible. A low ledger total is not successful memory management when live aliases, lost values, or incorrect gradients remain.

Part 7 - Engineering Interpretation and Philosophy

The final manager should make memory behavior explicit enough to reason about and flexible enough to optimize within known limits. Explain remaining uncertainty about unmanaged state, allocator eligibility, future reuse, and unsupported side effects. The strongest result is a validated runtime with bounded overhead, conserved commitments, safe asynchronous lifetimes, and honest failure modes. Correct refusal is part of its functionality, not a defect to conceal behind an aggressive policy.

DMM49 ==========

19.51 DMM49

Chapter Title: Custom Offload Engine and Final Runtime
Specialization: Dynamic Memory Management and CUDA Systems

19.51.1 Exercise 00

Exercise Title: Design the Architecture of a Complete PyTorch Offload Engine Across VRAM, RAM, and NVMe with Explicit Runtime States and Memory Budgets

Part 1 - Exercise Contract and Why It Matters

Design the final runtime as an application-level execution engine spanning CUDA storage, host memory, and optional NVMe-backed records. Deliver component contracts, state transitions, resource ledgers, supported workloads, and failure boundaries. Complete means coherent integration within that declared domain; it does not mean automatic interception of every PyTorch allocation or transparent migration of arbitrary raw tensors held by external code.

Part 2 - System and Memory Mental Model

Separate logical values, physical replicas, value versions, allocation generations, and reader or writer leases. Parameters, activations, KV blocks, and optimizer state have different mutation and derivative obligations. CPU I/O completion, CUDA copy completion, and compute completion are distinct events. A valid replica can exist on several tiers simultaneously, but a pending destination must not be published as ready or counted as released source capacity.

Part 3 - Quantitative Prediction Before Execution

Predict occupancy across one layer's read, staging, promotion, compute, and retirement. Include source-destination overlap, pinned buffers, activations, KV growth, workspace allowances, and pending reservations. Define budgets per tier and a headroom assumption for unmanaged state. Construct a trace where parameter payload fits but the full layer execution cannot be admitted. Explain why storage capacity alone does not predict feasible throughput when sustained transfer demand exceeds link service capacity.

Part 4 - Experimental Design and Instrumentation

Begin with immutable inference weights and deterministic stage execution. Specify registry, tier stores, planner, admission engine, transfer pipeline, policy modules, telemetry, and recovery interfaces. Add training only through explicit derivative-aware adapters. Use a deterministic event simulator for invariants, then bounded hardware replays. Give every action prepare, submit, complete, commit, and abort semantics. Keep exact lossless execution separate from optional approximate precision or context-retention policies.

Define the initial support matrix explicitly: immutable dense inference state, managed access leases, known stage boundaries, and private versioned storage. Record extensions for training, dynamic graphs, compiled execution, capture, distributed collectives, and direct storage as separate capabilities. A Python registry cannot rewrite every raw alias when a value moves. Choose whether consumers borrow tensors only within leases or invoke managed operations. State who owns teardown and how pending I/O and CUDA work are drained. Preserve an exact baseline contract so optional approximation cannot become an invisible fallback when resource pressure increases.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RuntimeContract:
    workload_scope: object
    derivative_targets: tuple
    precision_contract: object
```

```
    tier_budgets: object
    side_effect_rules: object

def design_offload_runtime(contract):
    ...

def E00(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require counterexamples to immediate copy completion, automatic parameter reference repair, and guaranteed success after admission. Preserve hardware, versions, allocator backend, shapes, seeds, precision, optimizer, and initial state identifiers. Keep prediction, observation, and interpretation separate. Record byte budgets, timing scopes, outcomes, and failure phases. A missing GPU or NVMe path produces explicit not-measured or unsupported fields, never invented end-to-end benchmark numbers.

Part 7 - Engineering Interpretation and Philosophy

The runtime should make every residency decision traceable to a correctness contract and a resource commitment. Explain which limits are enforced and which uncertainty belongs to unmanaged allocations, future reuse, or backend behavior. Autonomous scheduling is valuable only when it preserves required values and derivatives, refuses unsupported operations, and reports infeasibility instead of concealing it through changed mathematics.

19.51.2 Exercise 01

Exercise Title: Build a Unified Model-State Registry for Parameters, Buffers, Activations, KV Cache Blocks, Gradients, and Optimizer State

Part 1 - Exercise Contract and Why It Matters

Build one registry schema for parameters, buffers, activations, KV blocks, gradients, and optimizer state while preserving their different semantics. Deliver role-specific ownership, mutation, version, lifetime, and access rules. Unified means a shared identity and resource framework, not one interchangeable policy for every state category. The registry must preserve tied parameters and shared storage without accidentally duplicating logical ownership or losing required update relationships.

Part 2 - System and Memory Mental Model

A module state_dict is not a complete runtime inventory: activations, some buffers, caches, gradients, and live optimizer internals require explicit adapters. Optimizers hold parameter references, and tied module names can refer to the same parameter. Graph saves or raw aliases can retain backing storage beyond a registry's apparent owner count. State role determines whether a replica is immutable, dirty, recomputable, shared, or required by a future derivative.

Part 3 - Quantitative Prediction Before Execution

Predict registry records for tied embeddings, a mutable running buffer, a saved activation view, a shared prefix block, a gradient, and Adam moments. Count unique backing capacity separately from named entries. Include a parameter update that invalidates older replicas and

a KV copy-on-write transition that separates shared ownership. Explain which state can be recreated from a recipe and which requires preserved current values.

Part 4 - Experimental Design and Instrumentation

Register supported roles through explicit adapters with logical IDs, generations, value versions, derivative contracts, and lease rules. Keep strong owning references separate from descriptive CPU metadata. Test duplicate names, shared storage, stale handles, and optimizer reference consistency. Preserve nonpersistent buffers even when absent from a saved state dictionary if they are managed at runtime. Reject unsupported escaped aliases or mutation paths rather than claiming comprehensive process-wide discovery.

Map tied names to one intended parameter identity and preserve optimizer state relationships separately from serialized key names. Include a nonpersistent buffer, a view sharing a parameter's backing, and an optimizer moment created only after its first update. Record logical role and physical storage links independently. A detached activation can still share storage with a saved value, so absence of history is not proof of independent ownership. If the registry holds strong references, identify that deliberate ownership and retire it explicitly. Export descriptive metadata without keeping another live copy of every managed value in telemetry.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ModelStateRecord:
    logical_id: object
    role: str
    aliases: tuple
    value_version: int
    replicas: tuple
    ownership_rules: object
    derivative_rules: object

def register_model_state(model, optimizer, runtime_adapters):
    ...

def E01(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate shared parameters retain one intended update relationship and that optimizer targets still match the active model. Test live gradients and moments after a supported update, checking replica invalidation. Do not infer all owners from sys.getrefcount or assume a weak wrapper's death means CUDA reads completed. Compare registry-enabled and clean runs for diagnostic self-retention. Report unsupported state categories and missing coverage rather than assigning them zero capacity.

Part 7 - Engineering Interpretation and Philosophy

Role-aware identity allows one scheduler to coordinate many memory consumers without erasing their obligations. Explain why the same transfer mechanism can serve several roles while eviction eligibility differs. The registry should preserve both sharing and semantic boundaries so later policy choices cannot discard a gradient, stale a parameter replica, or free a prefix still referenced by another sequence.

19.51.3 Exercise 02

Exercise Title: Calculate the Complete Memory Footprint of Every Managed Object and Construct a Global VRAM-RAM-NVMe Residency Map

Part 1 - Exercise Contract and Why It Matters

Construct a complete residency map for every object inside the registered supported domain. Deliver logical payload, unique backing capacity, representation metadata, per-tier replicas, pending commitments, and host staging charges. Complete is scoped to observed managed objects; it does not imply that shapes alone determine all CUDA use, resident host pages, filesystem allocation, allocator cache, or opaque workspace.

Part 2 - System and Memory Mental Model

Several logical objects can share backing storage, while one value can occupy multiple tiers and precision representations. Pinned memory may be a subset of total host RAM, so overlapping categories must not be added twice. File bytes, memory mapping size, resident pages, and page cache differ. PyTorch allocated and reserved CUDA bytes have broader or different boundaries than registry totals and require timestamped reconciliation rather than forced equality.

Part 3 - Quantitative Prediction Before Execution

Predict unique per-tier capacity for tied weights, overlapping views, a CPU-GPU pair, and a compressed replica with scales and padding. Add temporary coexistence during conversion. Build a peak envelope from simultaneously live backing allocations instead of summing independent object peaks. Identify the unmanaged allowance and unsupported fields. Explain why total checkpoint size need not equal currently resident RAM or the parameter-only CUDA payload.

Part 4 - Experimental Design and Instrumentation

Validate a synthetic residency catalog before collecting live measurements. Scope identity by tier and allocation generation, preserving value versions separately. Record shape, stride, dtype, offset, supported backing capacity, file representation, and confidence. Compare manager deltas with completed CUDA samples and named host metrics. Keep pending reservations distinct from already materialized allocations. Narrow unsupported sparse, quantized, or external layouts instead of applying a dense formula blindly.

Use one definition of total managed host occupancy and treat pinned staging as a subset where appropriate. Avoid counting the same destination in both pending reservations and materialized capacity after allocation. File-backed mappings require separate virtual, resident, and storage-size fields. A small view can retain or serialize a large backing extent depending on its representation; measure the actual supported format. Preserve zero-element and unknown-capacity cases in synthetic tests. Compare current and peak counters at matched boundaries,

and state which unmanaged allowance covers workspace, context, or external library use without claiming exact whole-process visibility.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_residency_map(registry, pending_operations, accounting_scope):
    ...

def reconcile_resource_views(residency_map, allocator_samples, coverage):
    ...

def E02(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact totals for supported synthetic cases, including zero-element views with retained backing and repeated references to one parameter. Propagate unknown capacity rather than substituting zero. Reconcile differences as hypotheses about scope, rounding, timestamps, or unmanaged state before assigning a cause. Export raw counters beside derived totals. Report file and host accounting separately so an apparently small mmap process footprint cannot be misrepresented as zero system RAM use.

Part 7 - Engineering Interpretation and Philosophy

The map should support decisions rather than collapse every memory layer into one number. Explain which totals enforce admission and which provide context about the complete process. Scoped exact bookkeeping can coexist with uncertain external usage. Its strength is exposing overlap, sharing, and missing coverage so the scheduler avoids double counting or spending capacity that has already been promised.

19.51.4 Exercise 03

Exercise Title: Implement a Three-Tier Storage Interface That Moves PyTorch Tensors Transparently Between CUDA, CPU Memory, and NVMe

Part 1 - Exercise Contract and Why It Matters

Implement one logical storage interface for CUDA replicas, CPU replicas, and versioned NVMe records. Deliver controlled access, transfer, serialization, readiness, and failure contracts. Transparency applies at managed-handle boundaries: a caller requests a value and receives a valid supported replica. It does not mean Tensor.to accepts an NVMe device or that arbitrary existing tensor references automatically change location when a registry entry changes.

Part 2 - System and Memory Mental Model

The ordinary NVMe path is explicit file I/O through host storage and staging. File-read futures and CUDA events have different completion semantics. A readable pathname is insufficient evidence of a complete valid value; metadata, length, encoding, version, and integrity must

agree. Dirty authoritative state must remain recoverable until a new replica commits. Lossless file representations should preserve required values and sharing according to their declared format.

Part 3 - Quantitative Prediction Before Execution

Predict resource and event stages for NVMe-to-RAM-to-CUDA and its reverse. Include file buffers, pageable-to-pinned copies, GPU destinations, and source retention. Estimate actual stored bytes rather than assuming a tensor slice serializes only its logical elements. Construct short-read, stale-version, and incomplete-write cases, then identify the last valid source and which reservations remain charged during cleanup.

Part 4 - Experimental Design and Instrumentation

Begin with a documented dense format or supported checkpoint-backed source, restricting inputs to trusted generated artifacts. Define manifests and temporary versus committed records. Use explicit I/O workers or futures without labeling blocking reads intrinsically asynchronous. Publish readiness only after validated I/O and required CUDA completion. Restrict direct-storage extensions to separately verified capabilities. Preserve caller access through leases and reject unsupported raw alias mutation.

Document byte order, dtype, layout, shape, offsets, and representation version for raw records, or use the actual supported checkpoint interface without assuming its archive layout matches a plain tensor file. Validate read length and identity before publishing a replica. Keep temporary writes separate from committed manifests and retain the previous valid source until commit. If durable recovery is promised, implement the necessary persistence protocol and test interruption; otherwise state process-local guarantees. A canceled I/O future can leave work or buffers in use, so cleanup follows actual completion rather than the caller's interest in the result.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TierAccess:
    handle: object
    expected_version: int
    requested_tier: str
    completion_token: object

def request_tier_access(store, request, reservations):
    ...

def commit_file_replica(store, operation, integrity_evidence):
    ...

def E03(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate byte-preserving round trips and supported tensor metadata. Test missing files, truncated data, corrupted metadata, stale records, and cancellation while I/O is pending. No failed write should invalidate the last authoritative source. Report whether file commit provides process-local recovery or durable persistence, implementing the corresponding protocol. Measure host footprint and complete path latency rather than reporting only the CUDA copy after unbounded file loading.

Part 7 - Engineering Interpretation and Philosophy

A common interface is valuable when it hides mechanical differences while preserving readiness and failure obligations. Explain which guarantees callers receive and which representation or storage limitations remain visible. The interface should make unsupported paths explicit and keep state versioning intact across tiers. Convenience cannot replace a correct file lifecycle or authorize stale data publication.

19.51.5 Exercise 04

Exercise Title: Build a Layer Execution Planner That Determines Parameter Load, Activation Residency, Compute, and Eviction Order Before Each Forward Pass

Part 1 - Exercise Contract and Why It Matters

Build a layer execution plan that orders weight readiness, activation production, compute, and retirement under resource budgets. Deliver an executable dependency schedule for a supported fixed graph and guarded plans for dynamic paths. Planning before forward does not mean all future lifetimes are known exactly; unknown shapes or branches require conservative admission, runtime guards, or replanning without violating already submitted work.

Part 2 - System and Memory Mental Model

Execution order differs from module registration order, especially with residuals, shared modules, and tied weights. Forward last use does not imply backward last use. A training plan needs the selected derivative schedule and parameter versions. Parameters, activations, KV state, and transfer buffers compete at each schedule cut. A valid plan specifies completion dependencies and peak overlap, not merely a sorted list of layer names.

Part 3 - Quantitative Prediction Before Execution

Draw a two-branch model and predict required weight versions, activation consumers, and per-tier occupancy across its schedule. Compare equal layer counts with unequal layer payloads. Identify a stage that cannot fit together with its required input, output, and workspace allowance even after all eligible eviction. Predict whether changing prefetch distance can solve the problem or whether the computation must be subdivided under another explicit contract.

Part 4 - Experimental Design and Instrumentation

Use a deterministic staged model with known shapes and named boundaries. Build a dependency DAG from application contracts or validated tracing, preserving unsupported dynamic behavior. Reserve materialization and workspace allowances before stage submission. Add residual and shared-layer controls. Validate plans in simulation with delayed completions, then compare actual execution against the same serial function. Replan only at supported boundaries with safe state and budget versions.

Separate graph dependencies from resource scheduling. A topologically valid layer order can still exceed memory because prefetch or retained activations overlap. Include a shared layer called twice and a residual value read after several later layers. For training, include forward production and backward last use in the planned lifetime rather than retiring state at forward return. If tracing misses dynamic control flow, mark that coverage and guard execution. An invalid plan must be rejected before it overwrites shared buffers or spends unreserved resources. Compare planned and actual resource envelopes with uncertainty about opaque workspace made explicit.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def plan_layer_execution(graph_contract, state_registry, cost_model):
    ...

def admit_stage(plan, stage_id, runtime_state, budgets):
    ...

def E04(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check every consumer waits for the correct ready version and every release follows all required readers. Compare values and requested derivatives with a serial reference. Report plan prediction error separately from invalid execution. Test a changing input shape and reject an obsolete capacity estimate. A planner that cannot admit a stage must report the limiting resource; it must not force an allocation or silently move part of the mathematical work outside measurement.

Part 7 - Engineering Interpretation and Philosophy

Planning converts future execution into explicit resource commitments and dependencies. Explain what is statically known, what is guarded, and what must remain a runtime decision. The strongest plan exposes infeasible stages early and preserves dynamic correctness when predictions fail. Better ordering can reduce overlap, but it cannot make every indivisible operation fit an arbitrarily small device budget.

19.51.6 Exercise 05

Exercise Title: Implement On-Demand Parameter Loading That Materializes Only the Weights Required by the Current Execution Stage

Part 1 - Exercise Contract and Why It Matters

Load only the weight groups required by the admitted stage and preserve module semantics, ties, value versions, and ownership. Deliver lazy metadata, materialization, execution, and retirement contracts. Establish a correct inference path before training extensions. Do not

equate successful tensor copying with safe replacement of live Parameters whose references may already belong to an optimizer or a backward graph.

Part 2 - System and Memory Mental Model

Meta construction stores metadata without initialized values. to_empty allocates uninitialized storage, so checkpoint loading or initialization must complete before use. assign-style loading can replace parameter references and needs version-checked optimizer handling. A controlled stage can use explicit functional parameter mappings or stable supported execution buffers, but tied weights, mutable buffers, and gradient accumulation require deliberate treatment. Training cannot overwrite a weight slot still needed by backward.

Part 3 - Quantitative Prediction Before Execution

Predict memory for metadata, one current weight group, optional lookahead, input/output activations, and workspace. Include temporary checkpoint and staging storage rather than assuming direct materialization has no overlap. Compare tied weight groups with duplicated copies. Identify when a stage cannot fit and why on-demand loading does not solve an oversized indivisible matrix operation by itself. State which training consumers extend each weight version's lifetime.

Part 4 - Experimental Design and Instrumentation

Use a tiny staged module with known checkpoint values and a tied-parameter control. Choose one supported execution adapter and document its reference semantics. Validate keys, shapes, dtypes, and value versions before publication. Avoid .data replacement and untracked parameter reassignment. If using assign, create the optimizer after final assignment unless a verified reference-preserving mechanism is explicitly enabled. Keep training support separate until its backward ownership protocol is validated.

For functional execution, validate mapping keys, tied-weight behavior, parametrizations, and mutable buffers against the installed interface. For stable execution slots, enforce leases so copies cannot overwrite values required by unfinished backward or another stream. Do not present repeated load_state_dict assignment as a universal streaming training mechanism. Parameter replacement can leave old optimizer targets alive, and a slot reused for another layer can invalidate saved values. Include an inference-only implementation scope first and label training support unsupported until its reference and gradient ownership tests pass. Count any retained CPU master and mapped checkpoint source in resource reports.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def materialize_stage_weights(stage, source, adapter, reservation):
    ...

def execute_with_weight_version(stage, inputs, weight_lease):
    ...

def retire_stage_weight_version(stage, completion_evidence):
    ...
```

```
def E05(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare stage outputs and tied relationships with the original model. Check no meta or uninitialized value reaches computation. Test missing keys, wrong shapes, stale sources, and optimizer-reference mismatches. For supported training, compare gradients and updates across several steps. A copied buffer must not be reused merely because forward submitted; its final required reader must complete. Report actual peak, including temporary loading overhead, and preserve unsupported adapters honestly.

Part 7 - Engineering Interpretation and Philosophy

On-demand weights reduce residency by shortening supported storage lifetimes, not by erasing model state obligations. Explain how the adapter preserves the model's identity and required values while physical copies change. A small correct inference implementation is a sound foundation; adding training requires proving backward and optimizer relationships rather than assuming forward equivalence covers them.

19.51.7 Exercise 06

Exercise Title: Build a Lookahead Prefetch Planner That Loads Future Layers from NVMe to RAM and RAM to VRAM Before Their Execution Deadline

Part 1 - Exercise Contract and Why It Matters

Build a two-hop lookahead planner from NVMe to RAM and RAM to VRAM with separate deadlines, reservations, and completion evidence. Deliver demand fallback, speculative cancellation, and useful-prefetch measurements. The planner should reduce waiting when resources permit, while respecting host staging and device budgets. It must not spend the same future capacity for multiple pending layers or assume every predicted branch will execute.

Part 2 - System and Memory Mental Model

An I/O future completing only makes a host representation ready under its format contract. A later CUDA copy still needs destination admission, source lifetime, and an event. Earlier prefetch increases residency and can evict useful state. NVMe service, page cache, CPU copying, pinning, and PCIe may be bottlenecks at different stages. More lookahead cannot hide a sustained rate deficit or remove mandatory dependency waits.

Part 3 - Quantitative Prediction Before Execution

Predict latest start times for both hops from consumer deadlines and measured service costs with uncertainty margins. Include queueing and competing transfers. Construct a case where weights arrive in RAM early but miss the GPU deadline, and another where speculative reading consumes the host budget needed by demand. Estimate useful ready bytes, late bytes, unused speculation, and peak commitments for each lookahead horizon.

Part 4 - Experimental Design and Instrumentation

Begin with a fixed trace and measured size-dependent costs. Reserve host, pinned, and CUDA capacity through one ledger before submission. Tag operations with expected value

versions and consumer stages. Bound queue depth and prioritize mandatory demand over speculation. Add a conditional path and compare predictions with actual demand. Collect cold and warm file-access results separately; a warm page-cache read is not equivalent to a physical NVMe read.

Use independent queues and timestamps for file preparation and CUDA promotion. Host data readiness must include any required decoding, packing, or pinning before an H2D event can represent completion. Measure size-specific costs, including small-read overhead and cache state, rather than applying one peak bandwidth to all layers. Prevent speculative reads from consuming every host slot needed by mandatory demand or writeback. If predictions become stale, stop future submission and settle already started work safely. Count useful, late, stale, and unused prefetch separately; only the correct ready version before demand is a successful hit.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def plan_two_hop_prefetch(stage_trace, costs, registry, budgets):
    ...

def dispatch_prefetch_plan(plan, io_workers, cuda_streams, ledger):
    ...

def E06(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Count a hit only when the correct version is ready at the required tier before demand. Distinguish late prefetch, unused work, canceled submission, and in-flight work that still needs cleanup. Compare end-to-end stalls, traffic, host peak, CUDA peak, and runtime with demand-only loading. Preserve cases where shorter lookahead wins. Do not infer a successful pipeline from low host submission latency while the eventual consumer waits for unfinished I/O.

Part 7 - Engineering Interpretation and Philosophy

Lookahead trades capacity and speculation for less demand waiting. Explain which hop limits the tested workload and which horizon remains useful after contention and budgets are included. A robust planner can reduce or disable prefetch when pressure rises, preserving safe demand loading. Its benefit must survive the complete storage-to-consumer path rather than only one isolated transfer benchmark.

19.51.8 Exercise 07

Exercise Title: Implement Asynchronous Eviction That Demotes Completed Layers and Tensors Without Blocking Active GPU Computation

Part 1 - Exercise Contract and Why It Matters

Demote eligible completed values without blocking unrelated active computation. Deliver an asynchronous eviction state machine with read completion, dirty writeback, publication, and cleanup rules. Distinguish dropping a redundant clean device replica from copying authoritative modified state to another tier. The target is safe overlap, not a promise that every eviction has zero host cost or no effect on bandwidth available to compute.

Part 2 - System and Memory Mental Model

A layer's forward completion does not necessarily end its parameter or activation lifetime in training. A last-use lease must reflect all required backward and asynchronous readers. Clean immutable weights already valid on CPU or NVMe can often drop their GPU replica without D2H writeback. Dirty state requires preserving the latest version before release. Pending copies retain both source and destination obligations even if a caller cancels the requested eviction.

Part 3 - Quantitative Prediction Before Execution

Predict occupancy and dependencies for clean weight retirement, dirty optimizer state demotion, and an activation with a late reader. Estimate actual recoverable unique GPU capacity after aliases and pending uses. Include host admission and writeback cost. Construct a case where an apparently completed layer cannot yet evict its weights, and another where needless D2H of immutable weights wastes bandwidth without improving recoverability.

Part 4 - Experimental Design and Instrumentation

Use explicit eviction proposals revalidated by the transition engine. Check expected version, active leases, valid alternate replicas, and all required events. Reserve destination and staging before copying dirty data. Submit on supported side streams, then commit only when completion makes the target valid. Keep locks independent of device waits and test cancellation, stale proposals, and late completion using deterministic simulation before CUDA replays.

Classify each candidate as redundant clean copy, dirty recoverable state, recomputable state, or ineligible required state. Evicting immutable weights with a valid source should not automatically trigger D2H. Dirty buffers or optimizer state require versioned writeback and future-use protection. Include a shared allocation whose logical handle retires while another handle still uses it. Track final reader completion across every relevant stream, using allocator lifetime handling separately from readiness dependencies. A successful copy does not authorize source release if another consumer still needs the same generation. Report promised relief and actually released capacity in different fields.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def classify_eviction_path(handle, replica_state, required_consumers):
    ...

def submit_safe_eviction(proposal, ledger, streams, io_workers):
    ...

def commit_eviction(operation, completion_evidence):
    ...
```

```
def E07(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare values and required derivatives with serial execution. Test two reader streams, shared backing, dirty invalid replicas, and failure before publication. Confirm canceled in-flight work retains safe cleanup ownership. Measure recoverable bytes, writeback volume, demand stalls, and overlap. No premature source release is acceptable even if ordinary tests happen to produce correct values. A policy with no eligible victim must wait or reject admission rather than force eviction.

Part 7 - Engineering Interpretation and Philosophy

Eviction is a correctness-preserving replica lifecycle, not merely deletion of a Python name. Explain which state can be dropped, which must be written, and which remains needed. Good scheduling avoids needless writeback and overlaps legal transfers while preserving all future consumers. Honest eligibility limits are essential when a device budget is smaller than the unavoidable live working set.

19.51.9 Exercise 08

Exercise Title: Build a Multi-Stage Pipeline That Overlaps NVMe Reads, CPU Staging, H2D Transfers, GPU Compute, D2H Evictions, and Buffer Reuse

Part 1 - Exercise Contract and Why It Matters

Integrate file reads, host preparation, H2D, compute, D2H, and buffer reuse into one bounded multi-stage pipeline. Deliver a causal schedule, resource leases, backpressure, and completed throughput measurements. Concurrency must be visible in actual completion evidence rather than inferred from multiple threads or streams. Blocking I/O can run in a worker, but that does not make it a CUDA operation or guarantee independent storage service.

Part 2 - System and Memory Mental Model

Each stage has a queue, service capacity, readiness condition, and storage lifetime. File-read completion, pinning, copy completion, compute completion, and writeback commit are different boundaries. Shared PCIe, host memory, or storage bandwidth can couple nominally independent stages. Backpressure prevents upstream production from filling all RAM while a slower stage drains. Ready data must retain its correct version and slot generation until the consumer's final read completes.

Part 3 - Quantitative Prediction Before Execution

Draw the critical path for a small repeated-layer trace. Estimate steady throughput from stage service demands and shared-resource constraints rather than adding all isolated rates. Predict queue growth when file production outpaces GPU consumption and when evictions contend with promotions. Include buffer capacities and transition overlap. State which stages can overlap under the actual hardware and which dependencies necessarily serialize.

Part 4 - Experimental Design and Instrumentation

Implement bounded queues and completion tokens in a simulator first. Map CPU I/O to workers or futures and GPU copies to explicit streams and events. Reserve downstream capacity before launching work that would otherwise become unbounded. Use consistent lock ordering and avoid completion handlers waiting on locks held by blocked submitters. Compare the complete pipeline with a serial reference using identical traces and output-retention policy.

Specify maximum queue depth and buffer capacity for each stage, not only a thread count. A worker can be blocked on storage or on downstream capacity, and these waits have different causes. Keep host I/O completion tokens distinct from CUDA events. Use backpressure that does not deadlock by holding a lock needed by the draining stage. Test pipeline fill, steady state, final drain, and cancellation during all three. Include source and destination overlap in the ledger. If direct GPU storage is unavailable, retain the explicit host-staged path and avoid implying ordinary file reads bypass CPU memory.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_pipeline_dependencies(plan, resource_pools):
    ...

def advance_pipeline(runtime, io_completions, cuda_completions):
    ...

def E08(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate values at every handoff and after repeated buffer reuse. Test delayed I/O, delayed compute, empty queues, full queues, and shutdown with pending work. Record queue waits, service times, resource peaks, and end-to-end throughput. A short H2D submission call is not evidence that its latency was hidden. Check telemetry does not synchronize every stage. Preserve cases where concurrency increases contention and slows the whole pipeline.

Part 7 - Engineering Interpretation and Philosophy

A pipeline is effective when it moves waiting off the critical path without turning capacity into unbounded queues. Explain the actual bottleneck and how backpressure preserves progress. Overlap is a property of completed execution under specific dependencies and hardware, not a feature implied by an asynchronous API name. The manager should expose both useful concurrency and its resource cost.

19.51.10 Exercise 09

Exercise Title: Add Double and Triple Buffering and Determine the Minimum Buffer Depth Required to Hide Storage and PCIe Latency

Part 1 - Exercise Contract and Why It Matters

Compare single, double, and triple buffering and determine the smallest tested depth meeting a declared stall target. Deliver capacity, latency, throughput, and slot-lifetime evidence for the same pipeline. The minimum is conditional on workload, service variation, resources, and target; no fixed depth can guarantee hiding every storage or PCIe delay, and buffering cannot fix sustained insufficient bandwidth.

Part 2 - System and Memory Mental Model

Additional slots let one stage prepare future data while another consumes current data, but increase early residency and pending commitments. Variable sizes, tail I/O latency, and shared links can make average service time a poor predictor. Slots may belong to pageable, pinned, or GPU pools with different constraints. Reuse is legal only after transfer and final consumer completion, not after the producer enqueues its next request.

Part 3 - Quantitative Prediction Before Execution

For a regular schedule, estimate the required lookahead from preparation latency and consumer spacing, stating overlap assumptions. Then add variability and a slower sustained upstream stage to show where that estimate fails. Predict memory for each depth using actual capacities, including larger variable-shape slots. Define a quantitative stall target before sweeping and allow the result that no admitted tested depth meets it.

Part 4 - Experimental Design and Instrumentation

Hold model, trace, precision, budgets, and consumer work constant while sweeping buffer depth. Preallocate or grow slots through admission with versioned leases. Separate cold fill and final drain from steady-state timing, while also reporting the complete run. Use repeatable synthetic delay traces and bounded real I/O. Test depths beyond three only when admitted and needed to establish the tested range, rather than claiming triple buffering is universally sufficient.

Give each slot a pool identity, generation, capacity, valid extent, and current lease set. Triple buffering at one tier does not require identical depth at every other tier; measure the limiting stages and shared budgets. Use a regular deterministic schedule to validate the initial latency estimate, then add recorded tail delays. A sustained slower storage stage cannot be hidden indefinitely by finite buffers. Define minimum as the smallest admitted tested depth meeting the stated target on the tested trace. Include fill and drain costs in complete runtime even when steady-state throughput is reported separately.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def evaluate_buffer_depth(depth, pipeline_contract, budgets, trace):
    ...

def select_tested_depth(results, stall_target, resource_limits):
    ...

def E09(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate no slot is overwritten before all readers finish. Report peak host and CUDA commitments, useful overlap, tail stalls, and throughput. Compare average and worst observed delays without presenting a finite run as a hard latency guarantee. State whether a depth was rejected by capacity or failed the performance target. Include a case where extra buffering lowers throughput by provoking eviction or link contention.

Part 7 - Engineering Interpretation and Philosophy

Buffering spends memory to tolerate latency and variation. Explain the smallest validated depth for the tested target and why further slots stop helping. A robust runtime should shrink speculative depth under pressure without invalidating active slots. The useful conclusion is a bounded policy supported by measured resource and timing behavior, not an unconditional rule that more buffers mean more overlap.

19.51.11 Exercise 10

Exercise Title: Integrate Activation Checkpointing and CPU Activation Offloading and Dynamically Choose Recompute, Keep, or Offload per Activation

Part 1 - Exercise Contract and Why It Matters

Integrate keep, checkpoint recompute, and CPU activation offload into the final scheduler. Deliver derivative-aware eligibility, versioned region inputs, budgeted restoration, and matched training comparisons. These actions preserve different representations of the same required information. They must be connected to supported autograd mechanisms rather than implemented by replacing arbitrary saved tensors or detaching required history behind the registry.

Part 2 - System and Memory Mental Model

Checkpointing saves a recipe and required inputs; offloading preserves values elsewhere; keeping retains device state. Recompute must use the correct parameter versions, RNG behavior, and mutable state. Offload needs source lifetime, host capacity, and restoration dependencies. Supported saved-tensor hooks and non-reentrant checkpointing have version-sensitive composition rules. A scalar metadata record is not a valid replacement for a tensor that backward needs to read.

Part 3 - Quantitative Prediction Before Execution

Predict unique peak reduction, checkpoint-input residency, host payload, transfer volume, and recomputation cost for each eligible region. Account for shared backing and another owner that prevents actual release. Compare whole-step overlap rather than summing independent savings. Include a region whose recomputation causes a backward workspace peak and a region whose offload cannot fit the available host budget.

Part 4 - Experimental Design and Instrumentation

Use deterministic pure regions and explicit use_reentrant=False for the primary checkpoint path. Integrate validated save_on_cpu or pack/unpack adapters with required value, dtype, and device restoration. Collect diagnostics in separate replays when hook composition is not proven. Hold model state, precision, optimizer, gradient clearing, and data fixed. Add stochastic, stateful, and higher-order extensions only through separate tests and support contracts.

Store the parameter and state version required by every recompute recipe. If an optimizer update occurs before the recipe's final backward use, the plan must preserve the old version

or reject that schedule. Do not assume RNG preservation covers all custom randomness or mutable side effects. Offloaded saved values need valid restoration for each retrieval, including repeated backward where supported. Keep hook inputs immutable and avoid payload reference cycles. Logging hooks and checkpoint policies may override or bypass one another depending on version and feature; verify active behavior or separate diagnostic collection from the actual policy benchmark.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.checkpoint import checkpoint

def classify_activation_actions(region, derivative_contract, versions):
    ...

def dispatch_activation_action(region, action, runtime, reservations):
    ...

def E10(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare outputs, required gradients, and several updates with ordinary backpropagation. Check active hooks actually perform the intended offload. Report host peak, CUDA peak, latency, restored bytes, and observer overhead. A lower forward endpoint does not establish a lower training peak. Reject stale parameter recipes, unsupported mutable effects, or hidden detach. Preserve cases where only keeping is eligible or no eligible policy meets the workload budget.

Part 7 - Engineering Interpretation and Philosophy

Activation strategy should follow correctness eligibility before cost optimization. Explain which information survives, where it lives, and when it must be available again. Dynamic pressure can change the preferred strategy only at supported boundaries. The runtime should expose the trade between recomputation, transport, and residency while preserving the original derivative task and its actual whole-step measurement scope.

19.51.12 Exercise 11

Exercise Title: Integrate Paged KV Cache Management with Keep, Quantize, CPU-Offload, and Evict Decisions for Long-Context Inference

Part 1 - Exercise Contract and Why It Matters

Integrate paged KV storage with keep, quantize, CPU offload, and eviction choices for long-context inference. Deliver block versions, reference counts, copy-on-write rules, precision contracts, and attention validation. Distinguish lossless removal of a redundant device replica from permanently deleting logical context. The latter changes full-attention semantics unless

a separately declared retention algorithm permits it; quantization likewise needs an explicit approximation contract.

Part 2 - System and Memory Mental Model

Logical token blocks map to physical key/value storage, possibly shared across sequences. Active references prevent releasing shared backing prematurely. A CPU-offloaded block remains part of the logical cache and must be restored for its required attention use. Unreferenced prefix-cache entries can be reclaimed under their cache contract. Prefix identity depends on more than raw token text, including model version and relevant positional or adapter configuration.

Part 3 - Quantitative Prediction Before Execution

Predict bytes per physical block from declared layer scope, KV heads, head dimension, token capacity, dtype, and metadata. Count shared blocks once and unused tail capacity separately. Compare lossless offload with quantization and logical deletion, specifying value and task-error requirements. Include a partially filled shared tail that requires copy-on-write when one sequence extends, and predict transient capacity before publication.

Part 4 - Experimental Design and Instrumentation

Use a small explicit attention implementation and a contiguous full-cache reference. Preserve original positions, masks, token ordering, and model configuration through paged retrieval. Start with lossless keep/offload, then evaluate approximate actions separately. Reserve copy-on-write destination and transfer capacity before mutation. Test shared-prefix release, stale block versions, active-reader protection, and whole-context restoration under an admitted budget.

Record a prefix-sharing identity that includes the model and relevant execution configuration, original positions, token prefix, and adapter context. Hashing a token block without its prefix context is insufficient because its KV values can depend on earlier tokens. Shared-tail writes require copy-on-write and transient destination admission. A block's physical release must respect all references and readers. Distinguish deleting an unreferenced cached prefix from dropping active logical context. If quantized blocks are shared, include representation metadata in compatibility checks. Report exact lossless and approximate attention outcomes separately, with positions and masks preserved for the retained context algorithm.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def classify_kv_actions(block, sequence_contracts, references, budgets):
    ...

def schedule_kv_action(proposal, block_table, runtime):
    ...

def E11(config):
    # Logical context deletion is distinct from lossless replica eviction.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check attention outputs and logits against the lossless reference at declared tolerances, and evaluate approximate policies against separate quality targets. Report physical bytes, tail waste, metadata, transfers, and decode stalls. A lower attention score alone does not prove a block is unused by full attention. Include refcount and copy-on-write invariants. Preserve failures to fit an indivisible working set rather than claiming paging or eviction guarantees arbitrary context capacity.

Part 7 - Engineering Interpretation and Philosophy

The KV policy manages both residency and, when authorized, representation or retained information. Explain which decisions preserve the same context and which alter it. A unified runtime must keep those semantics visible so a capacity gain cannot be mistaken for exact inference. The strongest policy preserves shared-block safety and reports measured quality and performance for every optional approximation.

19.51.13 Exercise 12

Exercise Title: Build a Cost Model That Estimates Compute Time, H2D Time, D2H Time, NVMe I/O, Recomputation Cost, and Expected Reuse Before Every Memory Decision

Part 1 - Exercise Contract and Why It Matters

Build a measured cost model for compute, directional copies, file I/O, recomputation, reuse, and queueing before policy decisions. Deliver calibration, uncertainty, held-out prediction error, and safe fallback. The model ranks eligible actions; it cannot authorize an unsafe transition because an estimate looks cheap. Before every decision means using valid cached or updated estimates, not necessarily running an expensive benchmark inside every scheduling step.

Part 2 - System and Memory Mental Model

Costs vary with size, dtype, layout, kernel choice, cache state, device, queue depth, and concurrent traffic. Isolated NVMe, PCIe, and compute timings are not independent under contention. Reuse distance is a forecast, not a promise. Host launch latency differs from completed device service. A file read served from page cache should not be treated as a measurement of sustained physical storage throughput.

Part 3 - Quantitative Prediction Before Execution

Fit a simple transfer estimate with fixed overhead and size-dependent service, stating the range where it is useful:

$$\widehat{t}(x) = \widehat{\alpha} + x/\widehat{\beta}.$$

Compare the estimate with piecewise measurements and contention corrections. Predict keep, offload, and recompute costs including future reloads and capacity overlap. Construct a case where uncertain reuse reverses the preferred action and require the scheduler to preserve that uncertainty.

Part 4 - Experimental Design and Instrumentation

Calibrate bounded representative sizes with warmup, repeated trials, completed events, and explicit timing scopes. Record cold and warm file access separately. Keep some traces out of calibration and evaluate prediction error on them. Invalidate cached estimates after relevant backend, shape, or contention changes. Bound calibration time and metadata. Use conservative

resource admission independently of performance estimates so prediction error causes slower execution rather than incorrect memory commitments.

Attach calibration provenance to every estimate: device, software, backend, shape range, dtype, layout, cache state, and contention scenario. Maintain separate directional transfer models and include fixed per-request overhead. A nominal storage rate does not capture page-cache service or decoding work. Reuse forecasts need confidence and an invalidation rule when execution branches change. For overlapping actions, predict critical-path effects instead of subtracting their isolated times twice. Evaluate held-out traces and bound calibration cost. If estimates are stale or unsupported, choose an eligible conservative fallback rather than treating absent data as zero cost.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CostEstimate:
    seconds: object
    uncertainty: object
    resource_overlap: object
    calibration_scope: object

def estimate_action_cost(action, workload_state, calibrated_models):
    ...

def E12(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report predicted and measured times, bias, tail error, sample count, and coverage. Do not claim transfer bandwidth from host enqueue duration. Compare serial and overlapped complete paths to reveal contention or double-counted savings. Preserve unsupported estimates and extrapolation warnings in the report. Validate that an inaccurate cost forecast cannot bypass generations, leases, reservations, or derivative requirements. Separate diagnostic usefulness from predictive accuracy.

Part 7 - Engineering Interpretation and Philosophy

A cost model should make trade-offs explicit and falsifiable. Explain where its assumptions hold and how uncertainty affects decisions. Simple measured models can be useful when they are cheap, scoped, and checked against actual outcomes. The strongest scheduler can revise a poor estimate while preserving correctness, rather than pretending every action's future cost is known precisely.

19.51.14 Exercise 13

Exercise Title: Implement a Unified Runtime Scheduler That Jointly Chooses Placement, Prefetch Distance, Eviction Victims, Precision, and Activation Strategy

Part 1 - Exercise Contract and Why It Matters

Implement a scheduler that jointly considers placement, prefetch distance, eviction, precision, and activation strategy under common resource and semantic constraints. Deliver eligible action sets, joint reservations, decisions, and independent validation. Autonomous means executing supported choices within declared contracts; it does not authorize silent loss of gradients, quality, context, or update consistency when a cheaper schedule is unavailable.

Part 2 - System and Memory Mental Model

Policies interact: longer prefetch consumes capacity needed for activations, compression adds conversion workspace, offload consumes host staging, and recompute needs preserved inputs and parameter versions. Local greedy choices can conflict or oscillate. The transition engine and ledger enforce legality while cost models rank alternatives. Some budgets admit no feasible schedule, especially when one indivisible stage exceeds unavoidable working capacity.

Part 3 - Quantitative Prediction Before Execution

Predict a joint decision for a small graph under three budgets and two accuracy contracts. Include competing host and CUDA demands and a candidate that appears cheap in isolation but blocks the next required stage. Define an objective such as completed latency under hard correctness and capacity constraints. State the heuristic's search scope and avoid implying a globally optimal solution from a limited candidate set.

Part 4 - Experimental Design and Instrumentation

Use one state snapshot with expected generations and budget versions. Generate only eligible actions, estimate joint overlap, reserve resources atomically, and dispatch through safe transition interfaces. Revalidate stale plans before commit. Begin with a deterministic fixed trace, then conditional demands. Separate policy proposal, admission, submission, and observed completion in telemetry. Keep exact mode as the baseline and require opt-in contracts for approximation or altered context retention.

Define precedence among semantic eligibility, hard admission, performance objectives, and heuristic tie-breaking. Precision or context changes require explicit opt-in quality budgets before they enter the action set. Use one coordinated ledger so two individually attractive proposals cannot spend the same future capacity. Plans carry expected state and budget versions; stale ones must be revalidated. Test a case where local largest-first eviction conflicts with near-term reuse and another where long lookahead blocks a required activation. Record candidate rejection reasons and search bounds, without claiming a finite heuristic discovers a global optimum.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def generate_eligible_runtime_actions(state, contracts):
```

```
    ...

def choose_joint_plan(actions, costs, ledger, objective):
    ...

def dispatch_joint_plan(plan, runtime, expected_versions):
    ...

def E13(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate numerical results and all invariant checks after each supported plan. Compare against simple valid policies and a manually reviewed small oracle, not just a favorable unmanaged baseline. Report decision overhead, search budget, rejected plans, and prediction error. Test stale state and concurrent admissions. A lower planned cost without a completed valid execution is not a successful optimization. Preserve infeasible workloads as explicit outcomes.

Part 7 - Engineering Interpretation and Philosophy

Joint scheduling is useful because memory techniques compete for the same resources. Explain which interactions the heuristic captures and which remain outside support. Correctness and admission should remain stable as policy ranking evolves. The runtime should provide a reasoned decision or refusal with enough evidence to review it, rather than hide assumptions behind an automatic mode label.

19.51.15 Exercise 14

Exercise Title: Detect Thrashing, Pipeline Bubbles, Bandwidth Saturation, Fragmentation, and Over-Prefetching and Automatically Reconfigure the Runtime

Part 1 - Exercise Contract and Why It Matters

Diagnose thrashing, pipeline bubbles, link saturation, candidate fragmentation, and over-prefetching, then test bounded reconfiguration. Deliver separate signals, counterexamples, and intervention outcomes. Do not collapse all performance or allocation failures into one memory-pressure score. Fragmentation requires request-aware allocator evidence; a large gap between reserved and allocated bytes alone is not a causal diagnosis.

Part 2 - System and Memory Mental Model

Similar symptoms can have different causes: late demand can reflect slow I/O, wrong-path speculation, queueing, or insufficient lead time. Repeated migration can be necessary for a working set larger than capacity. Native inactive split metrics describe one allocator phenomenon and may be unsupported under another backend. A small cached candidate does not guarantee failure because the allocator can grow, while hidden eligibility restrictions can invalidate apparent fit.

Part 3 - Quantitative Prediction Before Execution

Predict diagnostic signals for paired traces with equal traffic but different stalls and equal reserved-minus-allocated gaps but different request outcomes. Define windows, thresholds, and

supported allocator scope. Forecast which reconfiguration should improve each trace and what observation would falsify that interpretation. Preserve uncertainty when several causes fit the same data, rather than automatically changing every policy at once.

Part 4 - Experimental Design and Instrumentation

Use controlled traces for demand-only streaming, speculative churn, compute imbalance, and bounded allocator patterns. Collect detailed diagnostics in separate replays because probing changes state. Apply one reversible eligible control at a time, such as shorter lookahead or queue depth. Use hysteresis and cooldown with hard admission limits unchanged. Recheck actual outcomes under the original workload contract and keep all unsupported backend fields explicit.

Include a high inactive-share cache with healthy reuse and a small cached block followed by successful allocator growth. These counterexamples prevent simple reserved gaps or block scores from becoming universal failure predictors. Scope native split-block statistics to supported allocator backends. Distinguish observed request outcomes from candidate eligibility guesses. Reconfiguration experiments require fresh or carefully matched states because probing itself changes allocation and queue history. Preserve a stable working policy as a control. If no causal distinction is available, report competing explanations and the next discriminating measurement rather than automatically calling the symptom fragmentation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def diagnose_runtime_bottlenecks(telemetry, allocator_evidence, coverage):
    ...

def propose_bounded_reconfiguration(findings, contracts, cooldown_state):
    ...

def E14(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Evaluate alert accuracy, causal localization, and successful intervention separately. Include high reserved cache with healthy reuse, unavoidable streaming, and a prefetch policy that already performs well. Report false positives, missed cases, runtime, and migration changes. A positive correlation between a counter and stalls is not proof of fragmentation or policy causality. Do not promise that tuning can make every budget or interconnect configuration feasible.

Part 7 - Engineering Interpretation and Philosophy

Reconfiguration should follow a discriminating experiment, not a convenient label. Explain which evidence supports each diagnosis and which alternatives remain. A conservative runtime can preserve a stable policy when evidence is weak, or report that the bottleneck is structural. The useful result is a validated improvement with its causal limits and resource costs visible.

19.51.16 Exercise 15

Exercise Title: Add OOM Recovery That Rolls Back an Unsafe Execution Step, Tightens Memory Policy, and Retries Without Restarting the Model

Part 1 - Exercise Contract and Why It Matters

Add bounded same-process recovery for retryable execution regions, with rollback, policy tightening, and exact-state validation. Deliver failure injection, cleanup, retry limits, and explicit nonrecoverable cases. The engine cannot generally undo arbitrary optimizer updates, external side effects, or a poisoned CUDA context. Recovery must be scoped to a transaction whose state can actually be preserved or restored.

Part 2 - System and Memory Mental Model

Allocation can fail after partial materialization, RNG consumption, or buffer mutation. Failed-frame tracebacks can retain tensors, so retry outside the exception scope and avoid keeping traceback objects in logs. Source replicas and pending transfer buffers remain charged until safe cleanup. empty_cache releases unused cache rather than restoring model state. Distributed collectives and partially applied updates require coordinated protocols beyond a local exception handler.

Part 3 - Quantitative Prediction Before Execution

Predict transaction state before failure, after abort, and before retry, including reservations and retained rollback data. Set a finite retry budget and a measurable progress condition, such as reduced optional lookahead. Compare an exact policy retry with an explicitly authorized approximate fallback. Construct a stateful operation that must be refused and a pure inference stage that can be retried safely without duplicating externally visible work.

Part 4 - Experimental Design and Instrumentation

Start with deterministic stage-local inference and injected allocation failures at known preparation points. Catch the supported CUDA OOM type specifically, record scalar metadata, exit the exception scope, clean failed temporaries, and re-admit the modified plan. Include RNG and mutable buffers in the transaction when relevant, charging snapshot cost. Do not retry fatal CUDA errors or uncoordinated rank-local collective failures. Test a bounded real OOM separately when hardware allows.

Write a rollback table for every supported stage: original state, possible mutations, live partial allocations, pending operations, and restoration action. Charge any snapshot storage to the correct budget. Do not retry while failed exception frames or diagnostic containers still retain temporaries. Inject failure before allocation, after preparation, and before publication to validate cleanup. Include a partially updated optimizer or external side-effect case that is rejected. On multiple ranks, do not perform unilateral retry around collective operations. A policy change that alters batch semantics, precision, or context must use its own declared workload contract instead of masquerading as an exact unchanged retry.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
```

```
def prepare_retry_transaction(stage, runtime, side_effect_contract):
    ...

def abort_stage_attempt(transaction, failure_metadata, runtime):
    ...

def choose_retry_plan(transaction, policies, attempts_remaining):
    ...

def E15(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare successful results with a failure-free oracle, including update count, RNG, buffers, values, and required gradients for supported training. Verify ledger conservation and no premature reuse of in-flight storage. Distinguish injected failure, admission rejection, actual OOM, and fatal errors. Report all retries and recovery time in the chosen end-to-end scope. Preserve failed recovery rather than declaring that every OOM is solvable without restarting.

Part 7 - Engineering Interpretation and Philosophy

Recovery is a supported transaction protocol with a clear stopping rule. Explain why the selected retry preserves the workload and what policy actually changed. A trustworthy engine can recover eligible failures and stop when state integrity or progress is uncertain. Avoiding a process restart is useful only when the completed result has the same declared mathematical and side-effect contract.

19.51.17 Exercise 16

Exercise Title: Extend the Offload Engine to Multiple GPUs and Dynamically Balance Resident Model State Across Unequal VRAM Capacities

Part 1 - Exercise Contract and Why It Matters

Extend supported residency and stage placement to multiple GPUs with unequal available budgets. Deliver device-local ledgers, topology-aware transfer plans, safe migration boundaries, and per-device measurements. More devices add capacity but also movement and synchronization costs. The extension must not assume arbitrary live parameters can move while their optimizer references, backward consumers, process ownership, or distributed layout remain unchanged.

Part 2 - System and Memory Mental Model

Each device has its own allocator, streams, events, workspace, and competing allocations. Peer capability and actual topology constrain direct copies; CPU-staged paths require additional host capacity. Event synchronization and timing have device-specific rules, so do not combine cross-device elapsed measurements as one clock without support. Migration can temporarily occupy both devices and must preserve logical value versions, aliases, and required consumers.

Part 3 - Quantitative Prediction Before Execution

Predict normalized pressure using each GPU's effective budget and compare it with raw used bytes. Include source-destination overlap, activation boundary traffic, and unequal compute speeds. Construct a migration that relieves the busiest device but increases critical-path transfer time. State which safe-boundary moves are eligible and which require another supported parallelism strategy rather than a placement change.

Part 4 - Experimental Design and Instrumentation

Start with single-process stage inference across two devices and explicit activation transfers. Measure topology and supported peer paths rather than assuming direct movement. Reserve destination and any host staging before migration, then retire source replicas only after final readers. Compare static and adaptive placements with identical workload traces. Add training or distributed execution only with validated optimizer, gradient, and collective ownership adapters.

Record process and device ownership, peer capability, actual transfer route, and transient reservations. Single-process tensor movement does not reconfigure FSDP or DTensor layouts. Test safe migration and an unsupported gradient-dependent move. Normalize pressure by effective budgets and include later communication costs when judging capacity relief.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def plan_multi_gpu_placement(stages, device_ledgers, topology, costs):
    ...

def migrate_at_safe_boundary(proposal, runtime, reservations):
    ...

def E16(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate outputs and supported derivatives against a matched serial reference. Record current and peak allocated/reserved bytes per device, normalized pressure, migration volume, and complete latency. Test destination admission failure and stale migration proposals. Include a topology where host staging is required or mark it untested. Do not claim correctness from balanced memory alone, and do not treat extra GPUs as a guarantee that every indivisible stage or communication buffer fits.

Part 7 - Engineering Interpretation and Philosophy

Balancing should optimize useful execution under heterogeneous constraints, not merely make counters equal. Explain when migration's capacity relief justifies its transient overlap and communication cost. The runtime should retain a stable placement when moving data would worsen the objective, and report unsupported distributed semantics explicitly rather than presenting single-process movement as a universal parallel training engine.

19.51.18 Exercise 17

Exercise Title: Run a Transformer-Style Model Whose Parameter Footprint Is Several Times Larger Than Available VRAM and Verify Exact Output Equivalence Against a Fully Resident Reference

Part 1 - Exercise Contract and Why It Matters

Execute a Transformer-style model whose parameter payload exceeds the engine's admitted GPU budget by a declared multiple, and validate lossless output behavior against a legitimate fully resident reference. Separate artificial budget and physical-capacity experiments. The exact-equivalence title is a validation target under controlled arithmetic, not permission to invent a resident reference that cannot fit or to label cross-device tolerance agreement as guaranteed bitwise identity.

Part 2 - System and Memory Mental Model

Lossless transfers preserve stored values, but compute results can differ with backend, precision, operation order, shape, or nondeterministic algorithms. A same-device resident reference can be run separately when the model fits physical VRAM but exceeds a smaller engine quota. A model exceeding physical VRAM needs a larger reference device or another explicitly identified oracle. CPU execution can support tolerance-based numerical checks, but does not automatically establish exact CUDA equality.

Part 3 - Quantitative Prediction Before Execution

Predict unique parameter payload, the ratio to the declared managed budget, largest stage working set, activations, cache, workspace, and staging. Choose a quota permitting at least one valid stage and a payload several times that quota. State actual physical capacity separately. Predict full resident and streamed peaks, and verify the reference can fit its own declared hardware before planning either measurement.

Part 4 - Experimental Design and Instrumentation

Use a deterministic small Transformer-style model first, disabling approximation and logical context deletion. Preserve weight values, tied relationships, masks, positions, dtype, shapes, arithmetic settings, and output retention. Run resident and streamed same-device replays separately for the artificial- quota primary test. Compare exact transferred representations, intermediate values, and final outputs. Scale physical oversize only when a feasible reference path and adequate host or file capacity are available.

Record reference hardware, arithmetic settings, checkpoint identity, and feasibility. Label the artificial-quota ratio separately from physical capacity. A physically oversized model needs a feasible larger-device resident reference for that claim; otherwise mark it unavailable. CPU and layerwise checks retain their actual numerical criteria. Preserve exact mismatches and localize them with intermediate comparisons.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def plan_reference_feasibility(model_metadata, hardware, engine_quota):
```

```
    ...

def compare_resident_and_streamed(config, reference_plan, contracts):
    ...

def E17(config):
    # Label artificial quota, physical capacity, and equality criteria.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report bitwise equality and tolerance-based error as separate outcomes using predeclared criteria. Preserve any exact mismatch and investigate arithmetic settings before making an equivalence claim. A CPU oracle or unavailable larger GPU must be labeled honestly. Export the full configuration, payload- to-budget ratio, peak bytes, throughput, and reference provenance. A layerwise oracle is useful but is not itself a fully resident reference; do not rename it to satisfy the title.

Part 7 - Engineering Interpretation and Philosophy

The strongest demonstration proves the actual claim being made. Explain whether the result establishes lossless transport, same-device exact output, or broader numerical agreement. Distinguishing quota oversize from physical oversize makes the experiment reproducible and auditable. The runtime's capacity gain remains valuable when its hardware and numerical limits are reported accurately, without overstating what one available machine can verify.

19.51.19 Exercise 18

Exercise Title: Stress-Test the Complete Runtime with Long Contexts, Variable Batch Sizes, Artificial VRAM Limits, RAM Pressure, Slow NVMe, Concurrent Streams, and Injected OOM Failures

Part 1 - Exercise Contract and Why It Matters

Stress-test the integrated engine with changing contexts and batches, constrained VRAM and RAM, delayed I/O, concurrent streams, and injected failures. Deliver correctness, invariant, resource, performance, and recovery matrices. Use bounded artificial budgets and fault injection before optional physical pressure. A stress test should reveal unsupported interactions and infeasible workloads, not force a misleading successful result or exhaust the host to obtain a dramatic trace.

Part 2 - System and Memory Mental Model

Interactions couple resources and semantics: larger batches increase activation and transfer footprints, long contexts increase KV state, slow I/O expands queues, and retries retain rollback state. A pinned pool can become the limiting resource even with spare CUDA bytes. Context-retention or precision changes are not lossless fallback unless their separate contracts permit them. Mutable state and distributed operations constrain where recovery or replanning is safe.

Part 3 - Quantitative Prediction Before Execution

Predict expected outcomes for each case: admitted completion, bounded wait, policy rejection, unsupported feature, retryable failure, or irreducible capacity deficit. Include equal

logical payload with different backing sharing, and equal migration traffic with different consumer stalls. Estimate worst supported transient overlap, file space, and log size. Define success using correct values and valid outcomes rather than completion rate alone.

Part 4 - Experimental Design and Instrumentation

Build deterministic event traces for stale generations, short reads, delayed copies, duplicate callbacks, cancellation, dirty state, and admission races. Add small real CUDA and private-file tests one feature at a time, then selected interactions. Keep fresh initial state, fixed traces, deadlines, retry limits, and bounded telemetry. Separate injected I/O delay from measured hardware I/O behavior. Evaluate held-out cases not used for tuning policy thresholds.

Test short reads, stale manifests, delayed events, reservation races, and duplicate completions before hardware-dependent faults. Injected I/O delay is not measured NVMe behavior. Include independent host and GPU admission limits and invalid approximate fallback rejection. Score correctness, safe refusal, recovery, and performance separately, preserving minimal invariant reproducers.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_integrated_stress_cases(config, feature_support):
    ...

def execute_bounded_stress_case(case, runtime, oracle, resource_limits):
    ...

def E18(config):
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check authoritative-value preservation, no premature reuse, reservation conservation, reference correctness, bounded queues, safe cleanup, and numerical contracts. Report exact and approximate cases separately. Include false diagnostic alerts, failed savings, recovery attempts, and actual stopping reasons. A correct refusal under insufficient capacity is not a runtime bug, while a fast result with missing gradients or deleted context under an exact contract is a failure. Preserve unavailable hardware tests as not measured.

Part 7 - Engineering Interpretation and Philosophy

The suite defines the evidence-supported operating envelope. Explain which features remain valid together and which need narrower contracts. Minimal counterexamples should improve eligibility or invariants instead of being removed from the report. The goal is a runtime that remains understandable under pressure, preserves required work, and fails safely when its supported resources or semantics are exceeded.

19.51.20 Exercise 19

Exercise Title: Build and Benchmark a Production-Style PyTorch Dynamic Memory Runtime That Executes Models Larger Than VRAM Through Autonomous VRAM-RAM-NVMe Placement, Prefetching, Eviction, Compression, Recomputation, Scheduling, and Recovery

Part 1 - Exercise Contract and Why It Matters

Integrate a production-style educational runtime spanning registry, tier storage, planning, scheduling, admission, prefetch, eviction, optional compression, activation strategy, recovery, and telemetry. Deliver an auditable implementation plan and benchmark protocol for models beyond an admitted GPU budget. The scaffold remains learner work. Production-style describes disciplined interfaces, invariants, observability, and failure handling; it is not a claim of production certification or universal support for arbitrary PyTorch applications.

Part 2 - System and Memory Mental Model

The engine controls supported handles and execution boundaries, not all external allocations. State identity, validity, derivatives, precision, and side effects constrain policy choices. Resource ledgers include pending commitments and transient replicas. CPU and file workers coordinate with CUDA through explicit readiness and lifetime dependencies. Approximate compression or logical KV deletion must stay visibly separate from exact residency and recomputation policies. Multi-GPU and training support require their own validated adapters.

Part 3 - Quantitative Prediction Before Execution

Predict total throughput, latency, resource peaks, transferred bytes, stalls, and policy overhead for resident feasible, serial offload, simple valid, and adaptive configurations. State reference feasibility and separate artificial quota from physical-capacity claims. Include calibration, planning, conversion, recovery, and telemetry in declared timing scopes. Define success as preserved workload semantics within admitted resource constraints, with honest rejection or infeasibility where no supported plan exists.

Part 4 - Experimental Design and Instrumentation

Integrate components through one transition engine and reservation ledger. Develop on known cases and evaluate held-out traces. Match weights, shapes, precision contracts, derivative targets, output retention, seeds, and initial state. Separate clean performance replays from diagnostic collection. Bound queue depth, retries, speculative traffic, file capacity, and host report size. Validate startup, normal execution, cancellation, and shutdown with pending work, preserving valid authoritative sources throughout cleanup.

Report contracts, adapters, reference provenance, budgets, raw measurements, decisions, transitions, and numerical checks. Separate prediction, observation, and interpretation. State cold and warmed timing inclusions, quality contracts, and output retention. Preserve rejected work in throughput denominators and claim only the best validated configuration within the tested range.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RuntimeReport:
    supported_contracts: object
    reference_provenance: object
    policy_decisions: tuple
    invariant_results: tuple
    numerical_results: tuple
    measurements: tuple
    limitations: tuple

def run_offload_engine(workload, engine, contracts, evidence_sink):
    ...

def benchmark_final_runtime(config, variants, reference_plan):
    ...

def E19(config):
    # Every autonomous action must pass semantic and resource admission.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a traceable chain from each claimed improvement to eligibility, a decision, a committed transition, and a validated outcome. Report lossless and approximate results separately, including quality, gradients, updates, and context semantics when applicable. Export raw memory scopes beside derived pressure, and completed timing beside throughput. Keep rejected, unsupported, not-measured, and failed cases visible. A small internal ledger is not success if external aliases retain CUDA storage or required values were lost.

Part 7 - Engineering Interpretation and Philosophy

The final runtime should make complex memory behavior explicit enough to review and flexible enough to optimize within demonstrated limits. Explain remaining uncertainty about future reuse, opaque allocations, backend eligibility, and unsupported side effects. The strongest result combines correct execution, conserved resource commitments, safe asynchronous lifetimes, measured useful overlap, and bounded recovery. Autonomous operation is justified by those contracts and evidence, not by an unqualified promise to run every model on any amount of VRAM.

20

Conclusion of the Volume of Books

20.1 What next

The real goal is to delve deeper into artificial intelligence, machine learning, deep learning, and perhaps even self-programming in the future. Explore the philosophy of building mathematical models and move away from the notion that artificial intelligence will become uncontrollable. Research seeks solutions and development, not media attention. Focus on your research in artificial intelligence and create value in this world. What you've learned in these books is just a drop in the ocean. Artificial intelligence is like a black hole; once you get close to it, you'll be fascinated. And the strange thing is, you won't know if it has an end. Build your future with your own hands. Place yourself among the researchers. You are responsible for developing artificial intelligence. Be a role model for others.

20.2 Does this volume of books have an end

Yes, it has an end, and that's when the author dies. What I do is compile what I've learned throughout my life. Emirati society is my responsibility; I try to build a bright future for it, placing it among the ranks of the developed world. I believe we must expand our knowledge and compete with the rest of the world. The future must be bright, and bright, for the modern United Arab Emirates.

20.3 There are those who are smarter than you in artificial intelligence.

There are people who are smarter or more skilled than you, not because they learned more or started earlier, but because they learned something in a specific angle that you have not explored yet. There are also those who have studied artificial intelligence for many more years than you, and there is no shame in being late; the real problem begins when you say, "I know everything." The moment you feel that you have learned everything in AI, that is dangerous, because there is no such thing as learning everything in artificial intelligence. It is a vast world where learning never stops. Even when you specialize in one area, you will not say, "I know it all," but instead you will say, "There is a problem with no solution yet, so I must find one,"

and that is when you begin writing scientific papers and research. That is science: solving problems.
