        "bias_difference": bias_difference.item(),
        "decision_disagreement": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.4.13 Exercise 12 - Measure the Effect of Feature Scaling on Update Magnitude

Part 1 - Why this matters

Each perceptron correction is proportional to the input vector. Features with large numeric scales can dominate the update even when their semantic importance is not greater, bending the training path toward units rather than information.

Measuring update magnitudes before and after standardization demonstrates why preprocessing affects convergence. The experiment should preserve labels and learning rate so the observed difference can be attributed to feature scale.

Part 2 - Mathematical form

$$\|\Delta \mathbf{w}_i\|_2 = \eta \|\mathbf{x}_i\|_2, \qquad x'_{ij} = \frac{x_{ij} - \mu_j}{\sigma_j}.$$

Part 3 - Hints and Helper

Compute per-feature standard deviations with a small-value guard. Compare the distribution of correction norms and the number of mistakes under raw and scaled inputs.

Part 4 - Python code skeleton

```
import torch

def E12(features, labels, learning_rate, epsilon=1e-8):
    mean = features.mean(dim=0)
    scale = features.std(dim=0, unbiased=False).clamp_min(epsilon)
    scaled = (features - mean) / scale
    raw_update_norms = []
    scaled_update_norms = []
```

```
    for raw_i, scaled_i, label_i in zip(features, scaled, labels):
        raw_update_norms.append(...)
        scaled_update_norms.append(...)
    return {
        "raw": torch.stack(raw_update_norms),
        "scaled": torch.stack(scaled_update_norms),
    }

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.4.14 Exercise 13 - Analyze Sensitivity of Updates to Noisy Labels

Part 1 - Why this matters

A mislabeled sample pushes the perceptron in the direction demanded by the incorrect target. Because the update is discrete and mistake-driven, a few contradictory labels can create repeated corrections and destroy the possibility of zero training error.

Sensitivity analysis should measure more than accuracy. Comparing clean and corrupted runs reveals changes in update count, parameter direction, convergence status, and predictions on a clean evaluation set.

Part 2 - Mathematical form

$$\tilde{y}_i = \begin{cases} -y_i, & i \in \mathcal{N}, \\ y_i, & i \notin \mathcal{N}, \end{cases} \qquad \Delta \mathbf{w}_i = \eta \tilde{y}_i \mathbf{x}_i.$$

Part 3 - Hints and Helper

Flip a controlled fraction of labels using saved indices. Train from identical initialization and compare the cosine similarity between the resulting weight vectors.

Part 4 - Python code skeleton

```
import torch

def E13(features, labels, noise_rate, seed):
    generator = torch.Generator().manual_seed(seed)
    noisy_labels = labels.clone()
    count = int(len(labels) * noise_rate)
    noisy_indices = torch.randperm(len(labels), generator=generator)[:count]
    noisy_labels[noisy_indices] *= ...
    clean_state = ...
    noisy_state = ...
```

```
    cosine = torch.nn.functional.cosine_similarity(
        clean_state[0], noisy_state[0], dim=0
    )
    return noisy_indices, cosine, clean_state, noisy_state

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.4.15 Exercise 14 - Implement Early Stopping Criterion Based on Zero Classification Errors

Part 1 - Why this matters

For a separable training set, an epoch with zero classification errors means every sample is currently on the correct side of the boundary. Continuing to process identical data would waste computation because the perceptron performs no update on correct samples.

The stopping condition must be evaluated over a complete epoch. Stopping after one correct sample or after a short error-free interval can terminate training before the model has been tested against the remaining observations.

Part 2 - Mathematical form

$$M_e = \sum_{i=1}^{n} \mathbb{I}[y_i z_i \leq 0], \qquad e_{\text{stop}} = \min\{e : M_e = 0\}.$$

Part 3 - Hints and Helper

Reset mistakes at the start of each epoch and check it only after all samples have been processed. Retain `max_epochs` as protection for non-separable data.

Part 4 - Python code skeleton

```
import torch

def E14(features, labels, learning_rate, max_epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    history = []
    converged = False
    for epoch in range(max_epochs):
        mistakes = 0
        for features_i, label_i in zip(features, labels):
            if label_i * (weight @ features_i + bias) <= 0:
                weight = ...
                bias = ...
```

```
                mistakes += 1
        history.append(mistakes)
        if mistakes == ...:
            converged = True
            break
    return weight, bias, converged, epoch + 1, history

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.4.16 Exercise 15 - Log and Visualize Weight Trajectories During Training

Part 1 - Why this matters

A visual trajectory turns a sequence of parameter updates into an interpretable learning path. In two-weight models, points and arrows can reveal direct movement, repeated loops, large jumps, and stabilization near a separating solution.

The log remains essential even when a plot is produced. Epoch numbers, triggering samples, mistake flags, and bias values provide the context needed to explain why each segment of the trajectory exists.

Part 2 - Mathematical form

$$\mathcal{T} = \{(w_1^{(t)}, w_2^{(t)}, b^{(t)}, i_t, e_t)\}_{t=0}^{T}, \qquad \Delta\mathbf{w}^{(t)} = \mathbf{w}^{(t+1)} - \mathbf{w}^{(t)}.$$

Part 3 - Hints and Helper

Detach and move logged tensors to CPU before plotting. Use a scatter plot for states and arrows or connected lines for update order.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E15(weight_history):
    trajectory = torch.stack(weight_history).detach().cpu()
    if trajectory.shape[1] != 2:
        raise ValueError(...)
    figure, axis = plt.subplots()
    axis.plot(trajectory[:, 0], trajectory[:, 1], marker="o")
    for index in range(len(trajectory) - 1):
        delta = trajectory[index + 1] - trajectory[index]
        axis.arrow(
```

```
            trajectory[index, 0], trajectory[index, 1],
            delta[0], delta[1], ...
        )
    return figure

def main():
    E15(...)
    plt.show()

if __name__ == "__main__":
    main()
```

12.4.17 Exercise 16 - Demonstrate Catastrophic Update with Large Learning Rate

Part 1 - Why this matters

A very large learning rate can produce parameter jumps that are enormous relative to the data scale. The perceptron may still classify separable training data eventually, but the intermediate scores, parameter norms, and numerical stability can become difficult to control.

This experiment defines catastrophe through measurable symptoms rather than a large number alone. Non-finite values, explosive norm growth, severe boundary jumps, or unstable decisions near the margin are stronger evidence than the learning rate by itself.

Part 2 - Mathematical form

$$\|\mathbf{w}^{(t+1)} - \mathbf{w}^{(t)}\|_2 = \eta\|\mathbf{x}_{i_t}\|_2, \qquad \rho_t = \frac{\|\Delta\mathbf{w}^{(t)}\|_2}{\|\mathbf{w}^{(t)}\|_2 + \varepsilon}.$$

Part 3 - Hints and Helper

Compare a baseline and an extreme learning rate under identical data order. Monitor finiteness, update ratio, maximum score magnitude, and mistake history.

Part 4 - Python code skeleton

```
import torch

def E16(features, labels, weight, bias, learning_rate, threshold):
    events = []
    for features_i, label_i in zip(features, labels):
        score = weight @ features_i + bias
        if label_i * score <= 0:
            update = learning_rate * label_i * features_i
            ratio = torch.linalg.vector_norm(update) / (
                torch.linalg.vector_norm(weight) + 1e-12
            )
            weight = weight + update
```

```
            bias = bias + learning_rate * label_i
            events.append({"ratio": ratio.item(), "catastrophic": ...})
    return weight, bias, events, torch.isfinite(weight).all()

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.4.18 Exercise 17 - Validate Correctness of Update Rule Using Manual Calculations

Part 1 - Why this matters

A small hand-calculated example is one of the strongest tests of a learning-rule implementation. It verifies the score, margin, mistake decision, weight correction, and bias correction without relying on another training library as the reference.

The validation should include both a mistaken sample and a correct sample. This proves not only that the code updates in the right direction, but also that it leaves parameters unchanged when no correction is required.

Part 2 - Mathematical form

For $\mathbf{x} = (2, -1)$, $y = -1$, $\mathbf{w} = (1, 1)$, $b = 0$, and $\eta = 0.5$,

$$z = 1, \qquad \mathbf{w}' = (1, 1) + 0.5(-1)(2, -1) = (0, 1.5), \qquad b' = -0.5.$$

Part 3 - Hints and Helper

Write the expected values explicitly before running the function. Compare tensors with `torch.testing.assert_close()` and verify the mistake flag.

Part 4 - Python code skeleton

```
import torch

def E17(features, label, weight, bias, learning_rate):
    score = torch.dot(weight, features) + bias
    mistake = label * score <= 0
    if mistake:
        weight = weight + ...
        bias = bias + ...
    return score, mistake, weight, bias

def main():
    actual = E17(...)
    expected_weight = torch.tensor([0.0, 1.5])
    expected_bias = torch.tensor(-0.5)
```

```
    torch.testing.assert_close(actual[2], expected_weight)
    torch.testing.assert_close(actual[3], expected_bias)
    print(actual)

if __name__ == "__main__":
    main()
```

12.4.19 Exercise 18 - Stress Test Update Rule with High-Dimensional Feature Space

Part 1 - Why this matters

High-dimensional inputs test whether the implementation is genuinely vectorized and shape-safe. They also reveal the memory and transfer costs hidden by tiny demonstrations, especially when histories accidentally store a full weight copy after every sample.

A meaningful stress test separates correctness from performance. It verifies finite parameters and valid predictions while reporting elapsed time, update count, memory use, and throughput for a controlled workload.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \quad \mathbf{w} \in \mathbb{R}^{d}, \qquad \text{work per epoch} = \mathcal{O}(nd), \qquad \text{parameter memory} = \mathcal{O}(d).$$

Part 3 - Hints and Helper

Generate data from a known separating weight vector. Synchronize CUDA around timing and store aggregate statistics instead of every high-dimensional state.

Part 4 - Python code skeleton

```
import time

import torch

def E18(samples, dimensions, epochs, device):
    features = torch.randn(samples, dimensions, device=device)
    teacher = torch.randn(dimensions, device=device)
    labels = torch.where(features @ teacher >= 0, 1.0, -1.0)
    weight = torch.zeros(dimensions, device=device)
    bias = torch.zeros((), device=device)
    if device.type == "cuda":
        torch.cuda.synchronize()
    start = time.perf_counter()
    update_count = ...
    for _ in range(epochs):
        ...
    if device.type == "cuda":
```

```
        torch.cuda.synchronize()
    elapsed = time.perf_counter() - start
    return {"elapsed": elapsed, "updates": update_count, "finite": ...}

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.4.20 Exercise 19 - Produce a Detailed Failure Analysis of the Learning Rule

Part 1 - Why this matters

When perceptron training fails, the cause may lie in the data, representation, numerical environment, update implementation, or stopping logic. A structured failure analysis prevents repeated parameter tuning when the real problem is non-separability, label noise, shape corruption, or device inconsistency.

The report should connect evidence to conclusions. Mistake histories, cycle detections, parameter norms, scaling statistics, manual checks, and CPU–GPU comparisons together provide a reproducible explanation rather than a vague statement that the model did not learn.

Part 2 - Mathematical form

$$R = \{M_e, \|\mathbf{w}^{(e)}\|_2, \|\Delta\mathbf{w}\|_2, \text{cycles}, \text{label noise}, \text{scaling}, \text{numerics}, \text{separability}\}.$$

Part 3 - Hints and Helper

Require evidence for each diagnosis and distinguish observations from proven causes. Include the label convention, device, dtype, seed, sample order, and stopping criterion.

Part 4 - Python code skeleton

```
import torch

def E19(evidence):
    required = {
        "mistake_history", "weight_norms", "update_norms",
        "label_check", "scaling_check", "separability_check",
        "device", "dtype", "seed", "stopping_rule",
    }
    missing = sorted(required - evidence.keys())
    diagnoses = []
    if evidence.get("cycle_detected"):
        diagnoses.append(...)
    if evidence.get("non_finite_parameters"):
        diagnoses.append(...)
```

```
    if evidence.get("separability_check") is False:
        diagnoses.append(...)
    return {
        "complete": not missing,
        "missing": missing,
        "diagnoses": diagnoses,
        "evidence": evidence,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.5 PC03 - Training Dynamics and Convergence Theory

Models and Training

12.5.1 Exercise 00 - Define Formal Convergence Criteria for the Perceptron Algorithm

Part 1 - Why this matters

A training loop needs a precise definition of convergence. For the perceptron, convergence means that a complete pass over the training set produces no classification errors and therefore no parameter updates.

This criterion must be separated from a maximum epoch limit, a small parameter change, or high accuracy. Those conditions may stop computation, but they do not prove that the current hyperplane separates every training sample.

Part 2 - Mathematical form

$$M_e = \sum_{i=1}^{n} \mathbb{I}[y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) \le 0], \qquad \text{converged} \iff M_e = 0.$$

Part 3 - Hints and Helper

Evaluate the criterion only after a complete epoch. Return separate flags for proven training convergence and termination caused by the safety limit.

Part 4 - Python code skeleton

```
import torch

def E00(features, labels, weight, bias):
```

```
    margins = labels * (features @ weight + bias)
    mistakes = ...
    minimum_margin = ...
    converged = mistakes == 0
    return converged, mistakes, minimum_margin

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.5.2 Exercise 01 - Experimentally Verify the Perceptron Convergence Theorem

Part 1 - Why this matters

The convergence theorem predicts that the perceptron makes finitely many mistakes when the data are linearly separable and have bounded norm. An experiment can connect this abstract statement to an observable training history.

Empirical convergence does not prove the theorem by itself. The experiment must verify its assumptions, record the number of updates, and compare the observation with the theoretical mistake bound.

Part 2 - Mathematical form

$$K \leq \left(\frac{R}{\gamma}\right)^2, \qquad R = \max_i \|\mathbf{x}_i\|_2, \quad \gamma = \min_i y_i \mathbf{u}^{\mathsf{T}} \mathbf{x}_i.$$

Part 3 - Hints and Helper

Generate data with a known unit separator. Compute its margin and radius before training, then check whether the observed update count respects the bound.

Part 4 - Python code skeleton

```
import torch

def E01(features, labels, separator, max_epochs):
    radius = torch.linalg.vector_norm(features, dim=1).max()
    margin = (labels * (features @ separator)).min()
    theoretical_bound = ...
    state, updates, converged = ...
    return {
        "converged": converged,
        "updates": updates,
        "bound": theoretical_bound.item(),
        "within_bound": ...,
```

```
    }

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.5.3 Exercise 02 - Analyze the Effect of Margin Size on Training Stability

Part 1 - Why this matters

The geometric margin measures how far the closest labeled sample lies from the separating boundary. A larger margin leaves more room for perturbations before a prediction changes and usually produces a smaller theoretical mistake bound.

Margin experiments must normalize the separating weight vector. Otherwise multiplying the parameters changes the numeric score while leaving the same boundary, creating a false impression that the geometric margin improved.

Part 2 - Mathematical form

$$\gamma = \min_i \frac{y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b)}{\|\mathbf{w}\|_2}, \qquad |\delta_i| < \gamma \Rightarrow \text{label stability along the normal direction.}$$

Part 3 - Hints and Helper

Create datasets with controlled separation while keeping radius and sample count comparable. Measure update counts and prediction changes after equal perturbations.

Part 4 - Python code skeleton

```
import torch

def E02(datasets, perturbation):
    results = {}
    for name, (features, labels) in datasets.items():
        weight, bias, history = ...
        norm = torch.linalg.vector_norm(weight)
        margin = (labels * (features @ weight + bias) / norm).min()
        shifted = features + perturbation
        disagreement = ...
        results[name] = {"margin": margin.item(), "disagreement": ...}
    return results

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.5.4 Exercise 03 - Measure Number of Updates Until Convergence

Part 1 - Why this matters

The number of updates is the perceptron's natural measure of learning effort because correct samples do not modify the parameters. Counting epochs alone can be misleading when dataset sizes or sample orderings differ.

A correct measurement distinguishes processed samples, mistakes, updates, and epochs. These counts answer different questions and together describe how efficiently the algorithm found a separator.

Part 2 - Mathematical form

$$U_T = \sum_{t=1}^{T} \mathbb{I}[y_{i_t} z_{i_t} \leq 0], \qquad e_* = \min\{e : M_e = 0\}.$$

Part 3 - Hints and Helper

Increment the update counter exactly where the parameters change. Keep a per-epoch history and verify that the final epoch contributes zero updates.

Part 4 - Python code skeleton

```
import torch

def E03(features, labels, learning_rate, max_epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    total_updates = 0
    history = []
    for epoch in range(max_epochs):
        updates = ...
        for features_i, label_i in zip(features, labels):
            if label_i * (weight @ features_i + bias) <= 0:
                weight, bias = ...
                updates += 1
        total_updates += updates
        history.append(updates)
        if updates == 0:
            break
    return total_updates, epoch + 1, history

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.5.5 Exercise 04 - Study the Impact of Data Ordering on Convergence Speed

Part 1 - Why this matters

Online updates make the optimization path dependent on sample order. Different permutations of the same separable dataset can produce different intermediate boundaries and different numbers of mistakes before convergence.

One ordering is not sufficient evidence. Repeated seeded permutations allow convergence speed to be summarized as a distribution and reveal unusually easy or difficult presentations of the data.

Part 2 - Mathematical form

$$U(\pi) = \sum_{t} \mathbb{I}[y_{\pi(t)} z_{\pi(t)} \leq 0], \qquad \bar{U} = \frac{1}{q} \sum_{r=1}^{q} U(\pi_r).$$

Part 3 - Hints and Helper

Reset the parameters for every trial and use a separate seeded generator. Report minimum, mean, maximum, and standard deviation of update counts.

Part 4 - Python code skeleton

```
import torch

def E04(features, labels, seeds, max_epochs):
    update_counts = []
    for seed in seeds:
        generator = torch.Generator().manual_seed(seed)
        weight = torch.zeros(features.shape[1])
        bias = torch.tensor(0.0)
        updates = 0
        for _ in range(max_epochs):
            order = torch.randperm(len(features), generator=generator)
            epoch_updates = ...
            updates += epoch_updates
            if epoch_updates == 0:
                break
        update_counts.append(updates)
    values = torch.tensor(update_counts, dtype=torch.float64)
    return {"minimum": ..., "mean": ..., "maximum": ..., "std": ...}

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.5.6 Exercise 05 - Investigate Training Behavior on Nearly Separable Data

Part 1 - Why this matters

Nearly separable data contain samples with extremely small margins or a few points that conflict with an otherwise clear boundary. Such datasets can cause many corrections and make convergence fragile under tiny perturbations.

The analysis should not assume that a low error rate implies convergence. It must inspect the minimum margin, persistent mistake identities, trajectory length, and sensitivity to noise.

Part 2 - Mathematical form

$$\gamma_{\min} = \min_i \frac{y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b)}{\|\mathbf{w}\|_2}, \qquad \gamma_{\min} \approx 0.$$

Part 3 - Hints and Helper

Move selected points progressively toward the boundary. For each distance, record convergence, update count, and the indices that are repeatedly misclassified.

Part 4 - Python code skeleton

```
import torch

def E05(dataset_versions, max_epochs):
    report = {}
    for distance, (features, labels) in dataset_versions.items():
        weight, bias, history, mistake_ids = ...
        norm = torch.linalg.vector_norm(weight).clamp_min(1e-12)
        minimum_margin = (labels * (features @ weight + bias) / norm).min()
        report[distance] = {
            "converged": history[-1] == 0,
            "updates": sum(history),
            "minimum_margin": minimum_margin.item(),
            "persistent_samples": ...,
        }
    return report

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.5.7 Exercise 06 - Demonstrate Divergence on Non-Separable Datasets

Part 1 - Why this matters

When no separating hyperplane exists, the convergence theorem does not apply. The perceptron continues correcting contradictory samples, and the mistake count never reaches zero under ordinary training.

Divergence here does not necessarily mean that parameter magnitudes approach infinity. It can appear as endless updates, cycles, or irregular movement, so the report must define and measure the observed behavior precisely.

Part 2 - Mathematical form

$$\nexists(\mathbf{w}, b) \text{ such that } y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) > 0 \ \forall i \quad \Longrightarrow \quad M_e \neq 0 \text{ may persist.}$$

Part 3 - Hints and Helper

Use a known non-separable dataset and a separable control. Track positive mistake counts, repeated states, and failure to meet the formal convergence criterion.

Part 4 - Python code skeleton

```
import torch

def E06(features, labels, epochs):
    states = []
    mistake_history = []
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    for _ in range(epochs):
        mistakes = ...
        state = torch.cat((weight, bias.reshape(1))).clone()
        states.append(state)
        mistake_history.append(mistakes)
    cycle = ...
    return {
        "converged": 0 in mistake_history,
        "cycle": cycle,
        "mistakes": mistake_history,
    }

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.5.8 Exercise 07 - Compare Deterministic vs Randomized Sample Ordering

Part 1 - Why this matters

A fixed order produces a reproducible trajectory but can repeatedly expose the model to an unfavorable pattern. Randomized ordering changes the correction sequence and may reduce or increase the number of updates in a particular run.

The comparison should evaluate both efficiency and variability. Deterministic training provides one path, while randomized training requires several seeded trials and a distribution of outcomes.

Part 2 - Mathematical form

$$U_{\text{fixed}} = U(\pi_0), \qquad \{U_r\}_{r=1}^{q} = \{U(\pi_r)\}_{r=1}^{q}.$$

Part 3 - Hints and Helper

Use identical initialization and stopping rules. Report convergence rate, update statistics, and the reproducibility of each seeded randomized trial.

Part 4 - Python code skeleton

```
import torch

def E07(features, labels, seeds, max_epochs):
    fixed_result = ...
    randomized_results = []
    for seed in seeds:
        randomized_results.append(...)
    updates = torch.tensor([item["updates"] for item in randomized_results])
    return {
        "fixed": fixed_result,
        "random_mean": updates.float().mean().item(),
        "random_range": (..., ...),
        "convergence_rate": ...,
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.5.9 Exercise 08 - Observe Weight Norm Growth During Training

Part 1 - Why this matters

The perceptron adds a scaled training vector after every mistake, so the weight norm evolves with the correction history. Growth can reflect progress toward a separator, repeated conflict, large feature scales, or an excessive learning rate.

Norm growth alone is not convergence. It should be interpreted beside the signed margins, mistake counts, and normalized boundary because multiplying all parameters can increase scores without changing classifications.

Part 2 - Mathematical form

$$\|\mathbf{w}^{(t+1)}\|_2^2 = \|\mathbf{w}^{(t)}\|_2^2 + 2\eta y_{i_t} {\mathbf{w}^{(t)}}^{\mathsf{T}} \mathbf{x}_{i_t} + \eta^2 \|\mathbf{x}_{i_t}\|_2^2.$$

Part 3 - Hints and Helper

Record the norm before and after each update. Plot it with mistake counts and inspect whether growth stabilizes, repeats, or becomes non-finite.

Part 4 - Python code skeleton

```
import torch

def E08(features, labels, learning_rate, epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    norms = [torch.linalg.vector_norm(weight).item()]
    margins = []
    for _ in range(epochs):
        for features_i, label_i in zip(features, labels):
            margin = label_i * (weight @ features_i + bias)
            if margin <= 0:
                weight = weight + ...
                bias = bias + ...
                norms.append(...)
                margins.append(margin.item())
    return norms, margins

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.5.10 Exercise 09 - Analyze the Relationship Between Margin and Generalization

Part 1 - Why this matters

A separator that classifies training samples correctly can still behave poorly on unseen data. Among valid separators, a larger normalized margin often indicates greater robustness to small perturbations and can support better generalization.

This is a relationship to investigate, not a guarantee that margin alone determines test performance. Data distribution, sample size, noise, and model mismatch must remain controlled when comparing runs.

Part 2 - Mathematical form

$$\hat{\gamma} = \min_{i \in \text{train}} \frac{y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b)}{\|\mathbf{w}\|_2}, \qquad E_{\text{test}} = \frac{1}{m}\sum_{j=1}^{m} \mathbb{I}[\hat{y}_j \neq y_j].$$

Part 3 - Hints and Helper

Train many seeded models, then pair each training margin with test error. Plot the pairs and compute correlation without claiming causation from one experiment.

Part 4 - Python code skeleton

```
import torch

def E09(train_runs, test_features, test_labels):
    rows = []
    for weight, bias in train_runs:
        norm = torch.linalg.vector_norm(weight).clamp_min(1e-12)
        train_margin = ...
        test_scores = test_features @ weight + bias
        test_predictions = torch.where(test_scores >= 0, 1, -1)
        test_error = ...
        rows.append((train_margin.item(), test_error.item()))
    values = torch.tensor(rows)
    correlation = torch.corrcoef(values.T)[0, 1]
    return rows, correlation.item()

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.5.11 Exercise 10 - Run Long-Horizon Training on CUDA for Stability Observation

Part 1 - Why this matters

Long GPU runs reveal problems that short demonstrations may hide, including gradual norm growth, non-finite values, memory accumulation, and unnecessary updates after the best state has already appeared.

A stability run should use periodic summaries rather than storing every tensor state. It must synchronize around timing, monitor device memory, and preserve enough checkpoints to identify when instability began.

Part 2 - Mathematical form

$$S_t = \{M_t, \|\mathbf{w}^{(t)}\|_2, \max_i |z_i^{(t)}|, \text{finite}(\mathbf{w}^{(t)}, b^{(t)})\}.$$

Part 3 - Hints and Helper

Check CUDA availability and log at fixed intervals. Stop safely on non-finite parameters while keeping the last valid checkpoint and diagnostic record.

Part 4 - Python code skeleton

```
import torch

def E10(features, labels, epochs, log_interval):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    device = torch.device("cuda")
    features, labels = features.to(device), labels.to(device)
    weight = torch.zeros(features.shape[1], device=device)
    bias = torch.zeros((), device=device)
    summaries = []
    for epoch in range(epochs):
        mistakes = ...
        if epoch % log_interval == 0:
            summaries.append({
                "epoch": epoch,
                "norm": ...,
                "mistakes": mistakes,
            })
        if not torch.isfinite(weight).all():
            break
    return weight.cpu(), bias.cpu(), summaries

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.5.12 Exercise 11 - Compare Float Precision Effects on Convergence

Part 1 - Why this matters

Floating-point precision affects dot products, margins, and the exact moment a hard decision changes sign. Differences are most visible when samples lie close to the boundary or training continues for many updates.

The comparison must use the same original data values, initialization, and order. Converting separately generated datasets would mix precision effects with different random samples.

Part 2 - Mathematical form

$$\delta_t = \|\mathbf{w}_{32}^{(t)} - \mathbf{w}_{64}^{(t)}\|_2, \qquad D_t = \sum_i \mathbb{I}[\text{sign}(z_{i,32}^{(t)}) \neq \text{sign}(z_{i,64}^{(t)})].$$

Part 3 - Hints and Helper

Generate the reference data once in float64 and cast a copy to float32. Compare update histories, convergence epoch, parameters, and prediction disagreement.

Part 4 - Python code skeleton

```
import torch

def E11(features64, labels, epochs):
    results = {}
    for dtype in (torch.float32, torch.float64):
        features = features64.to(dtype)
        weight, bias, history = ...
        results[str(dtype)] = (
            weight.to(torch.float64),
            bias.to(torch.float64),
            history,
        )
    difference = (
        results["torch.float32"][0]
        - results["torch.float64"][0]
    )
    weight_difference = torch.linalg.vector_norm(difference)
    return results, weight_difference.item()

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.5.13 Exercise 12 - Detect Numerical Drift in Extended Training Runs

Part 1 - Why this matters

Numerical drift is the gradual separation of states that began from equivalent conditions but used different precision, devices, or operation order. Small early differences can alter later mistake decisions near a hard threshold.

Detection requires aligned checkpoints. Comparing only final weights cannot show when the trajectories separated or whether the drift remained harmless until a decision disagreement occurred.

Part 2 - Mathematical form

$$d_t = \frac{\|\mathbf{w}_A^{(t)} - \mathbf{w}_B^{(t)}\|_2}{\|\mathbf{w}_B^{(t)}\|_2 + \varepsilon}, \qquad t_* = \min\{t : d_t > \tau\}.$$

Part 3 - Hints and Helper

Save states at identical update counts. Compute absolute and relative deviations, then locate the first tolerance breach and first prediction disagreement.

Part 4 - Python code skeleton

```
import torch

def E12(checkpoints_a, checkpoints_b, tolerance):
    drift = []
    first_breach = None
    paired_states = zip(checkpoints_a, checkpoints_b)
    for step, (state_a, state_b) in enumerate(paired_states):
        absolute = torch.linalg.vector_norm(state_a - state_b)
        relative = absolute / (torch.linalg.vector_norm(state_b) + 1e-12)
        drift.append(relative.item())
        if first_breach is None and relative > tolerance:
            first_breach = step
    return drift, first_breach

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.5.14 Exercise 13 - Visualize Convergence Trajectories in Parameter Space

Part 1 - Why this matters

A parameter-space trajectory shows how mistake-driven updates move the model from initialization toward a separating solution. Direct paths, zigzags, repeated cycles, and large jumps become visible in a way that final parameters cannot provide.

Visualization is exact only for low-dimensional parameter vectors. Higher-dimensional states require a declared projection, and the plot must report how much variation the chosen axes preserve.

Part 2 - Mathematical form

$$\mathbf{s}^{(t)} = (\mathbf{w}^{(t)}, b^{(t)}), \qquad \mathbf{q}^{(t)} = P^{\mathsf{T}}(\mathbf{s}^{(t)} - \bar{\mathbf{s}}) \in \mathbb{R}^2.$$

Part 3 - Hints and Helper

Stack detached states, use direct coordinates for two dimensions or PCA for larger states, and color points by epoch or mistake count.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E13(states):
    matrix = torch.stack(states).detach().cpu()
    centered = matrix - matrix.mean(dim=0)
    _, singular_values, vectors = torch.linalg.svd(
        centered, full_matrices=False
    )
    coordinates = centered @ vectors[:2].T
    visible_variance = singular_values[:2].square().sum()
    total_variance = singular_values.square().sum()
    explained = visible_variance / total_variance
    figure, axis = plt.subplots()
    axis.plot(coordinates[:, 0], coordinates[:, 1], marker="o")
    return figure, explained.item()

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.5.15 Exercise 14 - Investigate Overfitting Behavior in Linearly Separable Data

Part 1 - Why this matters

A perceptron can reach zero training error while relying on a boundary that is sensitive to sampling noise or unrepresentative examples. Perfect separation of the observed data therefore does not establish reliable performance on new samples.

The experiment should track train and validation behavior across epochs. It must also recognize that the standard perceptron stops updating after zero training mistakes, so overfitting is studied through data selection, noisy labels, ordering, or alternative retained states.

Part 2 - Mathematical form

$$E_{\text{train}}^{(e)} = 0, \qquad E_{\text{val}}^{(e)} > 0, \qquad G^{(e)} = E_{\text{val}}^{(e)} - E_{\text{train}}^{(e)}.$$

Part 3 - Hints and Helper

Evaluate both sets after every epoch and retain the state with minimum validation error. Compare it with the first zero-training-error state.

Part 4 - Python code skeleton

```
import torch

def E14(train_data, validation_data, epochs):
    train_features, train_labels = train_data
    validation_features, validation_labels = validation_data
    history = []
    best_state = None
    best_validation_error = float("inf")
    for epoch in range(epochs):
        weight, bias = ...
        train_error = ...
        validation_error = ...
        history.append((train_error, validation_error))
        if validation_error < best_validation_error:
            best_validation_error = validation_error
            best_state = (weight.clone(), bias.clone())
    return history, best_state

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.5.16 Exercise 15 - Analyze Training Failure Modes and Their Root Causes

Part 1 - Why this matters

Perceptron failure can originate from non-separable data, label noise, incorrect label encoding, feature-scale imbalance, numerical overflow, device mismatch, or faulty stopping logic. These causes require different remedies.

A root-cause analysis must connect symptoms to evidence. Persistent mistakes alone are insufficient because the same symptom may arise from a mathematical limitation or an implementation defect.

Part 2 - Mathematical form

$$F = \{\text{assumptions}, \text{data}, \text{updates}, \text{numerics}, \text{devices}, \text{termination}\}.$$

Part 3 - Hints and Helper

Build diagnostic checks in a fixed order: shapes and labels, finiteness, separability evidence, update correctness, trajectory behavior, and stopping conditions.

Part 4 - Python code skeleton

```
import torch

def E15(features, labels, training_log):
    diagnostics = {}
    diagnostics["shape_valid"] = ...
    allowed_labels = torch.tensor([-1, 1], device=labels.device)
    diagnostics["labels_valid"] = torch.isin(
        labels, allowed_labels
    ).all().item()
    diagnostics["finite"] = torch.isfinite(features).all().item()
    diagnostics["persistent_errors"] = ...
    diagnostics["cycle_detected"] = ...
    causes = []
    if not diagnostics["labels_valid"]:
        causes.append(...)
    if diagnostics["cycle_detected"]:
        causes.append(...)
    return diagnostics, causes

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.5.17 Exercise 16 - Compare Convergence Between CPU and GPU Implementations

Part 1 - Why this matters

CPU and GPU versions should implement the same mistake condition and update rule. Their trajectories may still differ slightly because floating-point reductions and threshold decisions can respond to rounding near zero.

A strong comparison aligns sample order and checkpoints, then measures both numerical distance and behavioral agreement. Final accuracy alone can hide diverging parameter paths.

Part 2 - Mathematical form

$$\delta_w = \|\mathbf{w}_C - \mathbf{w}_G\|_2, \qquad \delta_U = |U_C - U_G|, \qquad D = \sum_i \mathbb{I}[\hat{y}_i^C \neq \hat{y}_i^G].$$

Part 3 - Hints and Helper

Use identical dtype, initialization, and permutations. Move GPU checkpoints to CPU before comparison and report tolerances explicitly.

Part 4 - Python code skeleton

```
import torch

def E16(cpu_result, gpu_result, probe_features, atol, rtol):
    cpu_weight, cpu_bias, cpu_history = cpu_result
    gpu_weight, gpu_bias, gpu_history = gpu_result
    gpu_weight, gpu_bias = gpu_weight.cpu(), gpu_bias.cpu()
    parameter_close = torch.allclose(
        cpu_weight, gpu_weight, atol=atol, rtol=rtol
    )
    cpu_predictions = probe_features @ cpu_weight + cpu_bias >= 0
    gpu_predictions = probe_features @ gpu_weight + gpu_bias >= 0
    return {
        "parameter_close": parameter_close,
        "history_equal": cpu_history == gpu_history,
        "disagreement": ...,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.5.18 Exercise 17 - Stress Test Convergence with Large-Scale Synthetic Data

Part 1 - Why this matters

Large synthetic datasets test whether convergence measurements remain correct under realistic memory, throughput, and dimensionality pressure. They also expose accidental history growth and inefficient device transfers.

The generator should provide a known separator and controllable margin so the convergence assumptions are not ambiguous. Performance statistics must be reported beside correctness and stability checks.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \quad y_i = \operatorname{sign}(\mathbf{u}^{\mathsf{T}} \mathbf{x}_i), \quad \text{work per epoch} = \mathcal{O}(nd).$$

Part 3 - Hints and Helper

Generate data in chunks if memory is limited. Synchronize CUDA around timing and store aggregate histories rather than every full parameter vector.

Part 4 - Python code skeleton

```
import time
```

```
import torch

def E17(samples, dimensions, epochs, device):
    features = torch.randn(samples, dimensions, device=device)
    teacher = torch.randn(dimensions, device=device)
    labels = torch.where(features @ teacher >= 0, 1.0, -1.0)
    weight = torch.zeros(dimensions, device=device)
    bias = torch.zeros((), device=device)
    if device.type == "cuda":
        torch.cuda.synchronize()
    start = time.perf_counter()
    updates = ...
    if device.type == "cuda":
        torch.cuda.synchronize()
    elapsed = time.perf_counter() - start
    return {"updates": updates, "elapsed": elapsed, "finite": ...}

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.5.19 Exercise 18 - Validate Theoretical Claims Using Empirical Results

Part 1 - Why this matters

Theory states conclusions under explicit assumptions, while experiments observe finite datasets and finite-precision implementations. Validation connects the two by translating each claim into measurable quantities and checking its assumptions first.

An empirical match supports the implementation and illustrates the theorem, but it does not constitute a universal proof. A mismatch should trigger investigation of assumptions, measurements, and code before the theory is rejected.

Part 2 - Mathematical form

$$C_j = (A_j, P_j, O_j), \qquad V_j = \mathbb{I}[A_j \text{ verified and } O_j \text{ is consistent with } P_j].$$

Part 3 - Hints and Helper

Create a table containing the assumption, prediction, observation, tolerance, and verdict for each claim. Include convergence, mistake bound, margin stability, and non-separable failure.

Part 4 - Python code skeleton

```
import torch
```

```
def E18(claims):
    results = []
    for claim in claims:
        assumptions_hold = all(check() for check in claim["assumptions"])
        observed = claim["measure"]()
        consistent = claim["compare"](observed) if assumptions_hold else None
        results.append({
            "name": claim["name"],
            "assumptions_hold": assumptions_hold,
            "observed": observed,
            "consistent": consistent,
        })
    return results

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.5.20 Exercise 19 - Write a Formal Convergence and Stability Report

Part 1 - Why this matters

A formal report combines mathematical assumptions, experimental design, convergence evidence, numerical diagnostics, and limitations into one reproducible account. It prevents isolated plots or final accuracies from being mistaken for complete analysis.

The conclusion must distinguish theorem-supported statements, empirical observations, and unresolved failure causes. Seeds, data order, dtype, device, tolerance, and stopping rules are part of the result and must be recorded.

Part 2 - Mathematical form

$$R = \{\text{assumptions}, R, \gamma, U, K, \text{ordering}, \text{precision}, \text{drift}, \text{generalization}, \text{limitations}\}.$$

Part 3 - Hints and Helper

Require every section before marking the report complete. Cross-reference each conclusion to a formula, measurement, or diagnostic artifact.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
```

```
        "assumptions", "radius", "margin", "update_count",
        "mistake_bound", "ordering", "precision", "drift",
        "generalization", "failure_modes", "limitations",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if sections.get("margin", 0.0) <= 0:
        warnings.append(...)
    if not sections.get("assumptions", {}).get("linearly_separable", False):
        warnings.append(...)
    return {
        "complete": not missing,
        "missing": missing,
        "warnings": warnings,
        "sections": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.6 PC04 - Perceptron Loss Perspective and Errors

Models and Training

12.6.1 Exercise 00 - Interpret Perceptron Learning as Error-Driven Optimization

Part 1 - Why this matters

Perceptron learning reacts only to samples whose signed scores are non-positive. Each mistake creates a corrective movement that increases the sample's signed score, while correctly classified samples leave the parameters unchanged.

This view connects the historical update rule to optimization language without pretending that the hard step prediction is differentiable. The update can be interpreted as a subgradient step on a piecewise-linear perceptron criterion.

Part 2 - Mathematical form

$$m_i = y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b), \qquad (\mathbf{w}, b) \leftarrow (\mathbf{w}, b) + \eta y_i(\mathbf{x}_i, 1) \text{ when } m_i \leq 0.$$

Part 3 - Hints and Helper

Compute the signed margin before the prediction. Return the mistake mask and parameter correction so that the optimization signal remains observable.

Part 4 - Python code skeleton

```
import torch

def E00(features, labels, weight, bias, learning_rate):
    margins = labels * (features @ weight + bias)
    mistakes = margins <= 0
    correction_w = learning_rate * ...
    correction_b = learning_rate * ...
    return mistakes, correction_w, correction_b

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.6.2 Exercise 01 - Define Implicit Loss Function Used by the Perceptron

Part 1 - Why this matters

The perceptron criterion assigns zero loss to positive signed margins and a linear penalty to non-positive margins. It therefore measures both whether a sample is mistaken and how far its score lies on the wrong side of the boundary.

The boundary convention must be stated because a zero margin is normally treated as a violation during training. Reduction by sum or mean also changes the scale of a batch loss and its resulting update.

Part 2 - Mathematical form

$$\ell_P(m) = \max(0, -m), \qquad m = y(\mathbf{w}^\mathsf{T}\mathbf{x} + b), \qquad L_P = \sum_{i=1}^{n} \ell_P(m_i).$$

Part 3 - Hints and Helper

Use torch.clamp with a minimum of zero. Return unreduced losses first, then apply the requested reduction explicitly.

Part 4 - Python code skeleton

```
import torch

def E01(scores, labels, reduction="mean"):
    margins = labels * scores
    losses = torch.clamp(-margins, min=0)
    if reduction == "none":
        return losses
```

```
    if reduction == "sum":
        return ...
    if reduction == "mean":
        return ...
    raise ValueError(...)

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.6.3 Exercise 02 - Compare Perceptron Loss with Hinge Loss

Part 1 - Why this matters

Perceptron and hinge losses are both piecewise linear, but they define different violation regions. Perceptron loss stops penalizing as soon as the signed margin is positive, whereas hinge loss continues until the margin reaches one.

This distinction makes hinge loss encourage a safety margin rather than mere correct classification. Comparing both curves and subgradients explains why two models can have identical accuracy but different loss values.

Part 2 - Mathematical form

$$\ell_P(m) = \max(0, -m), \qquad \ell_H(m) = \max(0, 1 - m).$$

Part 3 - Hints and Helper

Evaluate both losses on the same margin grid, especially below zero, between zero and one, and above one. Compare active masks and slopes.

Part 4 - Python code skeleton

```
import torch

def E02(margins):
    perceptron_loss = torch.clamp(-margins, min=0)
    hinge_loss = torch.clamp(1 - margins, min=0)
    return {
        "perceptron": perceptron_loss,
        "hinge": hinge_loss,
        "different": ...,
    }

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.6.4 Exercise 03 - Analyze Zero-One Loss Limitations in Optimization

Part 1 - Why this matters

Zero-one loss directly counts incorrect predictions, making it natural for evaluation. As an optimization objective, however, it is constant across broad parameter regions and discontinuous when a score crosses the decision boundary.

Its derivative is zero almost everywhere and undefined at the boundary, so ordinary gradient methods receive no useful direction. Surrogate losses replace this flat signal with magnitude-sensitive penalties.

Part 2 - Mathematical form

$$\ell_{0\text{–}1}(m) = \mathbb{I}[m \leq 0], \qquad \frac{d\ell_{0\text{–}1}}{dm} = 0 \text{ a.e.}$$

Part 3 - Hints and Helper

Perturb one score across zero and compare zero-one loss with perceptron and hinge losses. Observe information lost when every mistake has the same cost.

Part 4 - Python code skeleton

```
import torch

def E03(margins):
    zero_one = (margins <= 0).to(margins.dtype)
    perceptron = torch.clamp(-margins, min=0)
    hinge = torch.clamp(1 - margins, min=0)
    return zero_one, perceptron, hinge

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.6.5 Exercise 04 - Visualize Loss Landscape for Simple Perceptron Models

Part 1 - Why this matters

A loss landscape shows how candidate weights and biases change the total perceptron criterion. Even a two-parameter slice reveals flat zero-loss regions, linear faces, ridges, and non-smooth boundaries created by different active samples.

The visualization is a slice of parameter space rather than the entire high-dimensional objective. Fixed parameters, axis ranges, reduction choice, and dataset must be recorded so the picture can be interpreted correctly.

Part 2 - Mathematical form

$$L(w, b) = \sum_{i=1}^{n} \max\{0, -y_i(wx_i + b)\}.$$

Part 3 - Hints and Helper

Create a mesh with torch.meshgrid, evaluate every parameter pair without Python loops when possible, and label the plotted reduction.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E04(features, labels, weight_values, bias_values):
    weight_grid, bias_grid = torch.meshgrid(
        weight_values, bias_values, indexing="ij"
    )
    scores = ...
    margins = labels * scores
    landscape = torch.clamp(-margins, min=0).sum(dim=-1)
    figure, axis = plt.subplots()
    contour = axis.contourf(...)
    figure.colorbar(contour, ax=axis)
    return figure, landscape

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.6.6 Exercise 05 - Implement Perceptron Loss Manually in PyTorch

Part 1 - Why this matters

A manual PyTorch implementation exposes every assumption hidden inside a packaged objective: label encoding, score shape, margin sign, boundary treatment, dtype, and reduction. These details determine whether the returned value matches the learning rule.

The function should remain vectorized and preserve gradient tracking when its inputs require gradients. Shape validation is necessary because accidental broadcasting can produce a plausible but incorrect loss tensor.

Part 2 - Mathematical form

$$L_P(X, y; \mathbf{w}, b) = \frac{1}{n} \sum_{i=1}^{n} \max\{0, -y_i(\mathbf{x}_i^\top \mathbf{w} + b)\}.$$

Part 3 - Hints and Helper

Require a two-dimensional feature matrix and one-dimensional labels. Check batch sizes before computing scores and make reduction an explicit argument.

Part 4 - Python code skeleton

```
import torch

def E05(features, labels, weight, bias, reduction="mean"):
    if features.ndim != 2 or labels.ndim != 1:
        raise ValueError(...)
    if features.shape[0] != labels.shape[0]:
        raise ValueError(...)
    scores = features @ weight + bias
    losses = torch.clamp(-(labels * scores), min=0)
    return ...

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.6.7 Exercise 06 - Compare Gradient-Free Updates vs Gradient-Based Losses

Part 1 - Why this matters

The classical perceptron applies an explicit mistake-driven update without calling automatic differentiation. The same correction direction can also emerge as a subgradient of the perceptron criterion away from its non-smooth boundary.

This comparison separates implementation mechanism from mathematical objective. Autograd, manual subgradients, and optimizer state can change how updates are produced even when their first-step directions agree.

Part 2 - Mathematical form

$$\partial_{\mathbf{w}} \ell_P = \begin{cases} -y\mathbf{x}, & m < 0, \\ \mathbf{0}, & m > 0, \end{cases} \qquad \mathbf{w} \leftarrow \mathbf{w} - \eta \mathbf{g}.$$

Part 3 - Hints and Helper

Use one violated sample away from zero. Compare the explicit perceptron correction with an autograd step and state how the boundary subgradient is chosen.

Part 4 - Python code skeleton

```
import torch

def E06(features, label, weight, bias, learning_rate):
    manual_weight = weight.detach().clone()
    if label * (manual_weight @ features + bias.detach()) <= 0:
        manual_weight = manual_weight + learning_rate * label * features
    differentiable_weight = weight.detach().clone().requires_grad_(True)
    loss = torch.clamp(
        -label * (differentiable_weight @ features + bias), min=0
    )
    loss.backward()
    gradient_weight = differentiable_weight - learning_rate * ...
    return manual_weight, gradient_weight.detach()

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.6.8 Exercise 07 - Observe Non-Smooth Loss Behavior at Decision Boundary

Part 1 - Why this matters

At zero signed margin, the perceptron loss changes from a linear penalty to a flat region. The function is continuous there, but its slope changes abruptly, so the ordinary derivative is not uniquely defined.

Finite differences from the left and right reveal the two slopes. An automatic differentiation system selects one valid convention for the boundary, which should not be mistaken for a unique mathematical derivative.

Part 2 - Mathematical form

$$\ell_P(m) = \max(0, -m), \qquad \ell'_P(0^-) = -1, \qquad \ell'_P(0^+) = 0.$$

Part 3 - Hints and Helper

Evaluate symmetric points around zero and compute one-sided finite differences. Inspect the autograd gradient at exactly zero separately.

Part 4 - Python code skeleton

```
import torch

def E07(epsilon):
    margins = torch.tensor(
        [-epsilon, 0.0, epsilon], requires_grad=True
    )
    losses = torch.clamp(-margins, min=0)
    left_slope = ...
    right_slope = ...
    losses.sum().backward()
    return losses.detach(), left_slope, right_slope, margins.grad

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.6.9 Exercise 08 - Analyze Sensitivity of Loss to Margin Violations

Part 1 - Why this matters

Perceptron loss distinguishes shallow and deep violations because the penalty grows linearly with negative signed margin. Two mistaken samples therefore contribute differently even though zero-one loss counts both as one error.

Sensitivity should be studied under controlled scaling. Changing feature units or parameter magnitude changes score margins and loss values without necessarily changing predicted classes.

Part 2 - Mathematical form

$$m < 0 \Rightarrow \ell_P(m) = -m, \qquad \frac{\partial \ell_P}{\partial m} = -1.$$

Part 3 - Hints and Helper

Create margins of increasing negative magnitude. Compare per-sample loss, zero-one error, and the effect of multiplying all scores by a positive constant.

Part 4 - Python code skeleton

```
import torch

def E08(margins, scales):
    results = {}
    for scale in scales:
        scaled = scale * margins
        results[scale] = {
            "loss": torch.clamp(-scaled, min=0),
            "errors": (scaled <= 0).to(torch.int64),
```

```
        }
    return results

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.6.10 Exercise 09 - Study Error Accumulation Across Epochs

Part 1 - Why this matters

Summing losses and mistakes across epochs describes the total correction pressure experienced during training. It also reveals whether errors disappear, oscillate, or remain concentrated in a small set of difficult samples.

Cumulative quantities must not replace per-epoch values because they never decrease. Both views are needed to distinguish continuing failure from historical errors that were already corrected.

Part 2 - Mathematical form

$$C_E = \sum_{e=1}^{E} M_e, \qquad Q_E = \sum_{e=1}^{E} L_e, \qquad M_e = \sum_{i} \mathbb{I}[m_i^{(e)} \leq 0].$$

Part 3 - Hints and Helper

Log epoch loss and mistake count before or after updates consistently. Then compute cumulative sums with torch.cumsum and retain sample-level counts if possible.

Part 4 - Python code skeleton

```
import torch

def E09(epoch_losses, epoch_errors):
    losses = torch.as_tensor(epoch_losses, dtype=torch.float64)
    errors = torch.as_tensor(epoch_errors, dtype=torch.int64)
    return {
        "cumulative_loss": torch.cumsum(losses, dim=0),
        "cumulative_errors": torch.cumsum(errors, dim=0),
        "final_epoch_loss": ...,
        "final_epoch_errors": ...,
    }

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.6.11 Exercise 10 - Implement Loss Computation on CUDA

Part 1 - Why this matters

CUDA loss computation requires every participating tensor to share a compatible device and dtype. Hidden CPU scalars, labels, or parameters can interrupt an otherwise vectorized operation.

The exercise also distinguishes device correctness from performance. Small workloads may be slower on a GPU, so timing should synchronize CUDA and should not be used as proof that the formula is correct.

Part 2 - Mathematical form

$$L_P^{\mathrm{GPU}} = \mathrm{reduce}(\max\{0, -y \odot (X\mathbf{w} + b)\}) .$$

Part 3 - Hints and Helper

Check CUDA availability, transfer tensors once, and compute scores, margins, and reduction on the device. Move only the final reporting values back to CPU.

Part 4 - Python code skeleton

```
import torch

def E10(features, labels, weight, bias):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    device = torch.device("cuda")
    features = features.to(device)
    labels = labels.to(device)
    weight = weight.to(device)
    bias = bias.to(device)
    scores = features @ weight + bias
    losses = torch.clamp(-(labels * scores), min=0)
    return losses.mean(), losses

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.6.12 Exercise 11 - Compare CPU vs GPU Loss Evaluation Consistency

Part 1 - Why this matters

Equivalent CPU and GPU formulas should produce close loss values when they receive the same data and dtype. Exact equality is not always expected because floating-point operation

order can differ across hardware.

A useful parity test compares unreduced losses, reduced loss, active violation masks, and tolerances. Agreement of only the mean can hide compensating per-sample differences.

Part 2 - Mathematical form

$$\delta = |L_C - L_G|, \qquad D = \sum_i \mathbb{I}[(m_i^C \le 0) \neq (m_i^G \le 0)].$$

Part 3 - Hints and Helper

Move GPU results to CPU, call `torch.testing.assert_close()` with documented tolerances, and separately count violation-mask disagreement.

Part 4 - Python code skeleton

```
import torch

def E11(cpu_losses, gpu_losses, atol, rtol):
    gpu_losses = gpu_losses.detach().cpu()
    close = torch.allclose(cpu_losses, gpu_losses, atol=atol, rtol=rtol)
    absolute_difference = torch.abs(cpu_losses - gpu_losses)
    return {
        "close": close,
        "maximum_difference": absolute_difference.max().item(),
        "mean_difference": absolute_difference.mean().item(),
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.6.13 Exercise 12 - Examine Numerical Stability of Loss Under Extreme Values

Part 1 - Why this matters

Very large features or weights can create scores that overflow finite floating-point ranges. The perceptron loss has no logarithm or exponential, but its dot products and reductions can still become infinite or lose precision.

Stability analysis should inspect intermediate scores and unreduced losses before trusting a finite-looking reduction. Float32 and float64 comparisons help locate whether the failure is caused by representation limits.

Part 2 - Mathematical form

$$z = \mathbf{w}^\top \mathbf{x} + b, \qquad |z| > F_{\max} \Rightarrow z = \pm\infty \text{ in finite precision.}$$

Part 3 - Hints and Helper

Sweep input magnitudes across dtypes. Report finiteness, maximum absolute score, maximum loss, and whether the reduction overflowed.

Part 4 - Python code skeleton

```
import torch

def E12(features, labels, weight, bias, dtypes):
    report = {}
    for dtype in dtypes:
        scores = features.to(dtype) @ weight.to(dtype) + bias.to(dtype)
        losses = torch.clamp(-(labels.to(dtype) * scores), min=0)
        report[str(dtype)] = {
            "scores_finite": torch.isfinite(scores).all().item(),
            "losses_finite": torch.isfinite(losses).all().item(),
            "maximum_loss": losses.max().item(),
        }
    return report

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.6.14 Exercise 13 - Relate Loss Behavior to Classification Performance

Part 1 - Why this matters

Loss and classification error answer different questions. Error counts wrong labels, while perceptron loss also measures how far violated scores lie beyond the boundary; neither alone fully describes confidence or generalization.

A model can reduce loss without changing accuracy, or maintain zero perceptron loss while positive margins remain extremely small. Training and validation curves should therefore be interpreted together with normalized margins.

Part 2 - Mathematical form

$$E = \frac{1}{n}\sum_i \mathbb{I}[m_i \le 0], \qquad L_P = \frac{1}{n}\sum_i \max(0, -m_i), \qquad \gamma_{\min} = \min_i \frac{m_i}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

For every checkpoint, compute loss, error rate, and normalized minimum margin. Identify epochs where loss changes but error remains constant.

Part 4 - Python code skeleton

```
import torch

def E13(checkpoints, features, labels):
    rows = []
    for weight, bias in checkpoints:
        margins = labels * (features @ weight + bias)
        loss = torch.clamp(-margins, min=0).mean()
        error = (margins <= 0).float().mean()
        normalized_margin = margins.min() / (
            torch.linalg.vector_norm(weight) + 1e-12
        )
        rows.append((loss.item(), error.item(), normalized_margin.item()))
    return rows

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.6.15 Exercise 14 - Debug Unexpected Loss Values During Training

Part 1 - Why this matters

Unexpected losses often originate from incorrect label encoding, reversed margin signs, accidental broadcasting, wrong reduction, stale parameters, or non-finite input values. The scalar loss alone cannot identify which defect occurred.

A disciplined debugger inspects shapes, devices, dtypes, label values, scores, signed margins, active masks, and per-sample losses in that order. Small hand-computed cases provide an independent reference.

Part 2 - Mathematical form

$$\ell_i = \max\{0, -y_i z_i\}, \qquad y_i \in \{-1, +1\}, \qquad z \in \mathbb{R}^n.$$

Part 3 - Hints and Helper

Reject invalid shapes and labels before reduction. Return a diagnostic dictionary containing intermediate tensors rather than printing only the final mean.

Part 4 - Python code skeleton

```
import torch

def E14(features, labels, weight, bias):
    diagnostics = {}
    diagnostics["shape_valid"] = ...
    allowed = torch.tensor([-1, 1], device=labels.device)
    diagnostics["labels_valid"] = torch.isin(labels, allowed).all().item()
    scores = features @ weight + bias
    margins = labels * scores
    losses = torch.clamp(-margins, min=0)
    diagnostics.update({
        "scores": scores,
        "margins": margins,
        "losses": losses,
        "finite": torch.isfinite(losses).all().item(),
    })
    return diagnostics

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.6.16 Exercise 15 - Visualize Loss Evolution Over Training Iterations

Part 1 - Why this matters

A loss curve exposes rapid corrections, plateaus, oscillations, and unstable jumps during training. Placing mistake counts beside loss shows whether magnitude improvements translate into changed classifications.

The curve must state whether values were recorded before or after each epoch's updates and whether the reduction was a sum or mean. Otherwise comparisons across batch sizes or datasets become misleading.

Part 2 - Mathematical form

$$\mathcal{C} = \{(t, L_t, M_t)\}_{t=0}^{T}.$$

Part 3 - Hints and Helper

Store plain numeric values rather than graph-connected tensors. Plot loss and errors on labeled axes, using separate scales when their ranges differ.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E15(loss_history, error_history):
    if len(loss_history) != len(error_history):
        raise ValueError(...)
    steps = range(len(loss_history))
    figure, loss_axis = plt.subplots()
    error_axis = loss_axis.twinx()
    loss_axis.plot(steps, loss_history, label="loss")
    error_axis.plot(steps, error_history, color="tab:red", label="errors")
    return figure

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.6.17 Exercise 16 - Contrast Loss-Based Training with Backprop-Based Models

Part 1 - Why this matters

Classical perceptron training uses an explicit local correction after a mistake. Backpropagation instead differentiates a scalar objective through a computational graph, allowing credit assignment across many layers and parameters.

The contrast is not simply loss versus no loss: perceptron updates can be viewed as subgradient steps on a loss. The central differences are differentiability, graph depth, update aggregation, and the machinery used to obtain parameter derivatives.

Part 2 - Mathematical form

$$\text{perceptron: } \Delta \mathbf{w} = \eta y \mathbf{x} \mathbb{I}[m \leq 0], \qquad \text{backprop: } \theta \leftarrow \theta - \eta \nabla_\theta L.$$

Part 3 - Hints and Helper

Apply both mechanisms to a one-layer example. Compare update direction, batch reduction, gradient storage, and behavior at the non-smooth boundary.

Part 4 - Python code skeleton

```
import torch

def E16(features, labels, manual_state, model, learning_rate):
    manual_weight, manual_bias = manual_state
    manual_weight, manual_bias = ...
    optimizer = torch.optim.SGD(model.parameters(), lr=learning_rate)
```

```
    optimizer.zero_grad()
    scores = model(features).squeeze(-1)
    loss = torch.clamp(-(labels * scores), min=0).mean()
    loss.backward()
    optimizer.step()
    return (manual_weight, manual_bias), model.state_dict(), loss.item()

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.6.18 Exercise 17 - Evaluate Robustness of Loss to Label Noise

Part 1 - Why this matters

A flipped label converts a previously correct margin into a violation and can create a large loss when the model was confidently correct under the clean target. Repeated noisy corrections may dominate training and prevent convergence.

Robustness should be measured across controlled noise rates and repeated seeds. Clean evaluation performance, total loss, update count, and parameter drift provide a fuller picture than noisy training accuracy.

Part 2 - Mathematical form

$$\tilde{y}_i = -y_i \text{ for } i \in \mathcal{N}, \qquad \ell_P(\tilde{y}_i z_i) = \max(0, y_i z_i).$$

Part 3 - Hints and Helper

Save the flipped indices and train clean and noisy variants from the same initialization. Compare weight direction and performance on untouched labels.

Part 4 - Python code skeleton

```
import torch

def E17(features, labels, noise_rates, seed):
    generator = torch.Generator().manual_seed(seed)
    report = {}
    for rate in noise_rates:
        noisy = labels.clone()
        count = int(rate * len(labels))
        indices = torch.randperm(len(labels), generator=generator)[:count]
        noisy[indices] *= -1
        state, loss_history = ...
        clean_error = ...
        report[rate] = {
```

```
            "flipped": indices,
            "final_loss": loss_history[-1],
            "clean_error": clean_error,
        }
    return report

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.6.19 Exercise 18 - Identify Scenarios Where Loss Minimization Fails

Part 1 - Why this matters

A decreasing training loss does not guarantee a useful model. Failure can arise from non-separable data, corrupted labels, poor feature representation, distribution shift, numerical overflow, or optimizing a surrogate that is misaligned with the real evaluation cost.

The diagnosis must distinguish optimization failure from objective failure and generalization failure. Each category produces different evidence and requires a different remedy.

Part 2 - Mathematical form

$$\begin{aligned} \text{success requires} \quad & \text{an optimizable objective} \\ & + \text{ a suitable representation} \\ & + \text{ representative data} \\ & + \text{ an aligned metric.} \end{aligned}$$

Part 3 - Hints and Helper

Construct at least one controlled example for each failure category. Record loss, train error, validation error, finiteness, and convergence status.

Part 4 - Python code skeleton

```
import torch

def E18(experiments):
    results = []
    for experiment in experiments:
        training = experiment["run"]()
        category = ...
        results.append({
            "name": experiment["name"],
            "category": category,
            "train_loss": training["train_loss"],
```

```
            "train_error": training["train_error"],
            "validation_error": training["validation_error"],
            "finite": training["finite"],
        })
    return results

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.6.20 Exercise 19 - Produce a Critical Analysis of Perceptron Loss Limitations

Part 1 - Why this matters

A critical analysis should explain what the perceptron criterion captures and what it ignores. It provides a simple correction signal for violated margins but does not reward positive margin size, handle label noise robustly, or supply probabilistic outputs.

The report must support each limitation with equations or experiments and distinguish the loss from the broader limitations of a single linear classifier. Alternatives should be proposed according to the identified failure rather than presented as universal replacements.

Part 2 - Mathematical form

$$R = \{\text{definition}, \text{subgradient}, \text{boundary}, \text{margin}, \text{noise}, \text{numerics}, \text{generalization}, \text{alternatives}\}.$$

Part 3 - Hints and Helper

Require the label convention, reduction, device, dtype, and evidence for every conclusion. Compare zero-one, perceptron, and hinge loss explicitly.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
        "definition", "zero_one_comparison", "hinge_comparison",
        "subgradient", "boundary", "margin", "label_noise",
        "numerical_stability", "generalization", "alternatives",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        name for name, value in sections.items()
        if isinstance(value, dict) and not value.get("evidence")
```

```
    ]
    return {
        "complete": not missing and not unsupported,
        "missing": missing,
        "unsupported": unsupported,
        "sections": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.7 PC05 - Multi-Class Perceptron Extensions

Models and Training

12.7.1 Exercise 00 - Extend Binary Perceptron to One-vs-Rest Multi-Class Setting

Part 1 - Why this matters

One-vs-rest converts a problem with many classes into one binary perceptron per class. Each classifier learns whether a sample belongs to its assigned class or to the combined set of all remaining classes.

The strategy is simple and reuses binary training, but the negative class can be much larger and classifier scores may not be calibrated. A prediction rule is still required to resolve simultaneous positive outputs or complete rejection.

Part 2 - Mathematical form

$$y_i^{(k)} = \begin{cases} +1, & y_i = k, \\ -1, & y_i \neq k, \end{cases} \qquad f_k(\mathbf{x}) = \mathbf{w}_k^{\mathsf{T}}\mathbf{x} + b_k.$$

Part 3 - Hints and Helper

Construct a binary target vector for every class and train classifiers independently. Preserve the mapping between row index and original class label.

Part 4 - Python code skeleton

```
import torch

def E00(features, labels, classes, train_binary):
    models = {}
    for class_id in classes:
```

```
        binary_labels = torch.where(labels == class_id, 1, -1)
        models[int(class_id)] = train_binary(features, binary_labels, ...)
    return models

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.7.2 Exercise 01 - Implement Class-Specific Weight Vectors for Multi-Class Output

Part 1 - Why this matters

A direct multi-class perceptron assigns one weight vector and one bias to every class. Stacking them creates a parameter matrix that scores all candidate classes in one matrix multiplication.

Shape reasoning is essential because rows represent classes and columns represent features. A transposed matrix may still multiply after other accidental transpositions while attaching scores to the wrong classes.

Part 2 - Mathematical form

$$W = [\mathbf{w}_1^\mathsf{T}; \ldots; \mathbf{w}_K^\mathsf{T}] \in \mathbb{R}^{K \times d}, \quad \mathbf{b} \in \mathbb{R}^K, \quad S = XW^\mathsf{T} + \mathbf{b}.$$

Part 3 - Hints and Helper

Validate the feature count and class count. Return a score matrix of shape batch size by number of classes.

Part 4 - Python code skeleton

```
import torch

def E01(features, class_count):
    feature_count = features.shape[1]
    weight = torch.zeros(class_count, feature_count)
    bias = torch.zeros(class_count)
    scores = features @ weight.T + bias
    if scores.shape != (len(features), class_count):
        raise RuntimeError(...)
    return weight, bias, scores

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.7.3 Exercise 02 - Define Prediction Rule for Multi-Class Perceptron

Part 1 - Why this matters

The direct multi-class perceptron predicts the class with the largest linear score. Unlike softmax, these scores are not probabilities and their absolute scale has no probabilistic interpretation.

Ties require an explicit deterministic or randomized policy. The default argmax rule selects the first maximum, which can create systematic preference for lower class indices.

Part 2 - Mathematical form

$$\hat{y} = \underset{k \in \{1,\ldots,K\}}{\arg\max} (\mathbf{w}_k^\top \mathbf{x} + b_k).$$

Part 3 - Hints and Helper

Compute all scores together and retain both the selected index and winning score. Detect ties before applying the chosen policy.

Part 4 - Python code skeleton

```
import torch

def E02(features, weight, bias):
    scores = features @ weight.T + bias
    predictions = torch.argmax(scores, dim=1)
    maximum = scores.max(dim=1, keepdim=True).values
    tie_counts = (scores == maximum).sum(dim=1)
    return predictions, scores, tie_counts

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.7.4 Exercise 03 - Implement Multi-Class Training Loop with Error Updates

Part 1 - Why this matters

On a mistake, the multi-class perceptron increases the score of the true class and decreases the score of the incorrectly predicted class. This paired update changes only two class-specific parameter rows.

The symmetry matters: updating only the correct row may leave the competing wrong score high. Training logs should identify both affected classes and verify that unrelated rows remain unchanged.

Part 2 - Mathematical form

$$W_{y_i} \leftarrow W_{y_i} + \eta \mathbf{x}_i, \quad W_{\hat{y}_i} \leftarrow W_{\hat{y}_i} - \eta \mathbf{x}_i, \quad \text{if } \hat{y}_i \neq y_i.$$

Part 3 - Hints and Helper

Clone rows when logging them and update biases with the same positive and negative pattern. Stop only after a complete error-free epoch.

Part 4 - Python code skeleton

```
import torch

def E03(features, labels, weight, bias, learning_rate, epochs):
    history = []
    for _ in range(epochs):
        mistakes = 0
        for features_i, label_i in zip(features, labels):
            prediction = torch.argmax(weight @ features_i + bias)
            if prediction != label_i:
                weight[label_i] += ...
                weight[prediction] -= ...
                bias[label_i] += learning_rate
                bias[prediction] -= learning_rate
                mistakes += 1
        history.append(mistakes)
        if mistakes == 0:
            break
    return weight, bias, history

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.7.5 Exercise 04 - Analyze Decision Regions in Multi-Class Feature Space

Part 1 - Why this matters

Every class owns the points where its score exceeds all competing scores. These regions are intersections of linear half-spaces and can form polyhedral areas rather than one isolated binary split.

Pairwise equality lines explain the borders, but only portions that dominate every other class appear in the final decision map. Plotting all pairwise lines without checking dominance can therefore be misleading.

Part 2 - Mathematical form

$$\mathcal{R}_k = \bigcap_{j \neq k} \{\mathbf{x} : (\mathbf{w}_k - \mathbf{w}_j)^\mathsf{T}\mathbf{x} + (b_k - b_j) \geq 0\}.$$

Part 3 - Hints and Helper

Evaluate a dense two-dimensional grid, assign each point by argmax, and compare visible regions with pairwise score-equality boundaries.

Part 4 - Python code skeleton

```
import torch

def E04(weight, bias, x_values, y_values):
    grid_x, grid_y = torch.meshgrid(x_values, y_values, indexing="xy")
    points = torch.stack((grid_x.reshape(-1), grid_y.reshape(-1)), dim=1)
    scores = points @ weight.T + bias
    regions = torch.argmax(scores, dim=1).reshape(grid_x.shape)
    return grid_x, grid_y, regions

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.7.6 Exercise 05 - Compare One-vs-Rest and One-vs-One Strategies

Part 1 - Why this matters

One-vs-rest trains one classifier per class, whereas one-vs-one trains a classifier for every pair of classes. The second approach uses smaller pairwise datasets but increases the number of models quadratically.

Their outputs are combined differently: one-vs-rest compares class scores, while one-vs-one usually uses votes. Accuracy, training cost, memory, tie frequency, and imbalance should all be compared.

Part 2 - Mathematical form

$$N_{\mathrm{OvR}} = K, \qquad N_{\mathrm{OvO}} = \binom{K}{2} = \frac{K(K-1)}{2}.$$

Part 3 - Hints and Helper

Generate every unordered class pair without duplication. Report model count and define deterministic tie-breaking for both score and vote aggregation.

Part 4 - Python code skeleton

```
import torch

def E05(classes):
    one_vs_rest = [(class_id, "rest") for class_id in classes]
    one_vs_one = []
    for left in range(len(classes)):
        for right in range(left + 1, len(classes)):
            one_vs_one.append((classes[left], classes[right]))
    return {
        "ovr_models": one_vs_rest,
        "ovo_models": one_vs_one,
        "counts": (..., ...),
    }

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.7.7 Exercise 06 - Handle Class Imbalance in Multi-Class Perceptron Training

Part 1 - Why this matters

Rare classes may receive too few corrective opportunities, while majority classes dominate the update history and global accuracy. Multi-class training must therefore inspect error rates separately for every class.

Class weighting or balanced sampling can amplify minority corrections, but they also change update magnitudes and training dynamics. The chosen method and its effect on each class must be measured explicitly.

Part 2 - Mathematical form

$$\alpha_k = \frac{n}{Kn_k}, \qquad W_{y_i} \leftarrow W_{y_i} + \eta\alpha_{y_i}\mathbf{x}_i, \quad W_{\hat{y}_i} \leftarrow W_{\hat{y}_i} - \eta\alpha_{y_i}\mathbf{x}_i.$$

Part 3 - Hints and Helper

Compute weights only from the training split and guard against absent classes. Compare macro recall and per-class updates before and after balancing.

Part 4 - Python code skeleton

```
import torch

def E06(labels, class_count):
    counts = torch.bincount(labels, minlength=class_count)
    if (counts == 0).any():
        raise ValueError(...)
    class_weights = len(labels) / (class_count * counts.float())
    sample_weights = class_weights[labels]
    return counts, class_weights, sample_weights

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.7.8 Exercise 07 - Evaluate Multi-Class Accuracy and Confusion Matrix

Part 1 - Why this matters

Overall accuracy summarizes correct decisions but hides which classes are confused. A confusion matrix records true classes by predicted classes and exposes asymmetric errors and minority-class failure.

Metric conventions must be fixed before interpretation. Class order, row normalization, ignored labels, and macro versus weighted averaging can materially change the reported conclusion.

Part 2 - Mathematical form

$$C_{ab} = \sum_{i=1}^{n} \mathbb{I}[y_i = a \wedge \hat{y}_i = b], \qquad \text{Accuracy} = \frac{\operatorname{tr}(C)}{\sum_{a,b} C_{ab}}.$$

Part 3 - Hints and Helper

Build the matrix vectorially with flattened class-pair indices. Verify that its total equals the number of evaluated samples.

Part 4 - Python code skeleton

```
import torch

def E07(labels, predictions, class_count):
    indices = labels * class_count + predictions
    matrix = torch.bincount(
        indices, minlength=class_count * class_count
    ).reshape(class_count, class_count)
    accuracy = matrix.diag().sum() / matrix.sum()
```

```
    per_class_recall = matrix.diag() / matrix.sum(dim=1).clamp_min(1)
    return accuracy, matrix, per_class_recall

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.7.9 Exercise 08 - Observe Training Instability with Increasing Number of Classes

Part 1 - Why this matters

Adding classes creates more competing scores and more opportunities for a sample to be overtaken by an incorrect class. The update path can become longer, more variable, and more sensitive to initialization or sample order.

Instability should be measured rather than assumed. Update counts, convergence rate, score margins, seed variance, and class-specific errors reveal whether complexity actually damaged a given experiment.

Part 2 - Mathematical form

$$\Delta_i = s_{y_i}(\mathbf{x}_i) - \max_{k \neq y_i} s_k(\mathbf{x}_i), \qquad \hat{y}_i = y_i \iff \Delta_i \geq 0.$$

Part 3 - Hints and Helper

Train nested class subsets under repeated seeds. Keep samples per class and feature scale comparable so class count is the main changing factor.

Part 4 - Python code skeleton

```
import torch

def E08(experiments, seeds):
    report = {}
    for class_count, dataset in experiments.items():
        trials = [train_trial(dataset, seed, ...) for seed in seeds]
        report[class_count] = {
            "mean_updates": ...,
            "convergence_rate": ...,
            "margin_variability": ...,
        }
    return report

def main():
    print(E08(...))
```

```
if __name__ == "__main__":
    main()
```

12.7.10 Exercise 09 - Visualize Multi-Class Decision Boundaries

Part 1 - Why this matters

A colored decision map reveals how class-specific linear scores partition a two-dimensional feature space. It can expose missing regions, narrow unstable areas, and boundaries shaped by unexpected competitors.

The picture is exact only for two input features. Higher-dimensional data require a declared slice or projection, and predictions must be recomputed in that same representation.

Part 2 - Mathematical form

$$\hat{y}(x_1, x_2) = \arg\max_k (w_{k1}x_1 + w_{k2}x_2 + b_k).$$

Part 3 - Hints and Helper

Evaluate a grid in batches if necessary. Overlay labeled samples and use a discrete color map with a documented class-to-color mapping.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E09(features, labels, weight, bias, resolution=200):
    x_values = torch.linspace(
        features[:, 0].min(), features[:, 0].max(), resolution
    )
    y_values = torch.linspace(
        features[:, 1].min(), features[:, 1].max(), resolution
    )
    grid_x, grid_y = torch.meshgrid(x_values, y_values, indexing="xy")
    points = torch.stack((grid_x.flatten(), grid_y.flatten()), dim=1)
    predictions = torch.argmax(points @ weight.T + bias, dim=1)
    figure, axis = plt.subplots()
    axis.contourf(grid_x, grid_y, predictions.reshape(grid_x.shape), ...)
    axis.scatter(features[:, 0], features[:, 1], c=labels)
    return figure

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.7.11 Exercise 10 - Execute Multi-Class Perceptron Training on CUDA

Part 1 - Why this matters

CUDA can accelerate score computation when batches, feature counts, or class counts are large. Correct device placement must include features, labels, the full weight matrix, biases, and temporary indices.

A sample-by-sample Python loop may still dominate runtime even when tensors live on the GPU. The exercise separates device correctness from true parallel efficiency and reports both.

Part 2 - Mathematical form

$$S = XW^{\mathsf{T}} + \mathbf{b}, \qquad \hat{\mathbf{y}} = \operatorname{argmax}_k S_{:k}.$$

Part 3 - Hints and Helper

Check CUDA availability and avoid repeated transfers inside epochs. Synchronize before and after timing and return CPU copies only for reporting.

Part 4 - Python code skeleton

```
import torch

def E10(features, labels, class_count, epochs):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    device = torch.device("cuda")
    features, labels = features.to(device), labels.to(device)
    weight = torch.zeros(class_count, features.shape[1], device=device)
    bias = torch.zeros(class_count, device=device)
    history = ...
    return weight.cpu(), bias.cpu(), history

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.7.12 Exercise 11 - Compare CPU vs GPU Scaling with Number of Classes

Part 1 - Why this matters

The score matrix grows with class count, increasing arithmetic on both CPU and GPU. GPU parallelism may become advantageous only after the workload is large enough to outweigh launch and synchronization overhead.

Benchmarking must include warm-up, repeated trials, identical dtypes, and synchronization. A single unsynchronized GPU time measures command submission rather than completed computation.

Part 2 - Mathematical form

$$\text{score work} = \mathcal{O}(nKd), \qquad \text{score memory} = \mathcal{O}(nK).$$

Part 3 - Hints and Helper

Sweep class count while holding batch size and feature count fixed. Report median latency, throughput, and CPU–GPU output parity.

Part 4 - Python code skeleton

```
import torch

def E11(features, class_counts, repeats):
    results = []
    for class_count in class_counts:
        cpu_weight = torch.randn(class_count, features.shape[1])
        cpu_time = benchmark(features, cpu_weight, repeats, ...)
        gpu_time = benchmark(
            features.cuda(), cpu_weight.cuda(), repeats, ...
        )
        results.append({
            "classes": class_count,
            "cpu": cpu_time,
            "gpu": gpu_time,
            "speedup": cpu_time / gpu_time,
        })
    return results

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.7.13 Exercise 12 - Measure Memory Growth with Class Count

Part 1 - Why this matters

Every additional class adds one feature-length weight vector and one bias. Batched score tensors and optimizer or history state can consume even more memory than the parameters themselves.

Theoretical byte counts should be compared with measured allocations. This reveals hidden copies, dtype effects, and temporary tensors that a parameter-only estimate ignores.

Part 2 - Mathematical form

$$M_{\text{parameters}} = K(d+1)q \text{ bytes}, \qquad M_{\text{scores}} = nKq \text{ bytes},$$

Part 3 - Hints and Helper

Use tensor element size rather than assuming four bytes. On CUDA, reset and read peak memory statistics around a controlled forward or training step.

Part 4 - Python code skeleton

```
import torch

def E12(batch_size, feature_count, class_counts, dtype):
    element_size = torch.empty((), dtype=dtype).element_size()
    rows = []
    for class_count in class_counts:
        parameter_bytes = class_count * (feature_count + 1) * element_size
        score_bytes = batch_size * class_count * element_size
        rows.append({
            "classes": class_count,
            "parameter_bytes": parameter_bytes,
            "score_bytes": score_bytes,
            "measured_peak": ...,
        })
    return rows

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.7.14 Exercise 13 - Investigate Error Propagation Across Classes

Part 1 - Why this matters

A multi-class mistake modifies both the true class and the winning incorrect class. Future scores for these two classes change for every sample, so one correction can repair some decisions while disrupting others.

This interaction is absent from independent binary intuition. Measuring the confusion matrix before and after one update reveals which classes and samples inherit the consequences.

Part 2 - Mathematical form

$$\Delta s_k(\mathbf{x}_j) = \Delta \mathbf{w}_k^{\mathsf{T}} \mathbf{x}_j + \Delta b_k, \qquad k \in \{y_i, \hat{y}_i\}.$$

Part 3 - Hints and Helper

Save the entire score matrix before a selected update. Recompute it afterward and verify that parameter rows outside the two involved classes remain unchanged.

Part 4 - Python code skeleton

```
import torch

def E13(probe_features, weight, bias, sample, true_class, learning_rate):
    scores_before = probe_features @ weight.T + bias
    predicted_class = torch.argmax(weight @ sample + bias)
    weight_after = weight.clone()
    bias_after = bias.clone()
    if predicted_class != true_class:
        weight_after[true_class] += learning_rate * sample
        weight_after[predicted_class] -= learning_rate * sample
        bias_after[true_class] += learning_rate
        bias_after[predicted_class] -= learning_rate
    scores_after = probe_features @ weight_after.T + bias_after
    return scores_after - scores_before, predicted_class

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.7.15 Exercise 14 - Analyze Misclassification Patterns in Multi-Class Setting

Part 1 - Why this matters

Multi-class errors often form patterns: two visually similar classes may be confused in both directions, while a dominant class may absorb examples from several minorities. Aggregate accuracy cannot expose these structures.

Analysis should combine confusion counts, normalized rates, score gaps, and representative failed samples. Small winning-score gaps indicate ambiguity, whereas large gaps may reveal systematic feature or label problems.

Part 2 - Mathematical form

$$g_i = s_{\hat{y}_i}(\mathbf{x}_i) - s_{y_i}(\mathbf{x}_i), \qquad \mathcal{E}_{ab} = \{i : y_i = a, \hat{y}_i = b\}.$$

Part 3 - Hints and Helper

Rank off-diagonal confusion pairs and then inspect samples with the largest and smallest error gaps for each pair.

Part 4 - Python code skeleton

```
import torch

def E14(scores, labels):
    predictions = torch.argmax(scores, dim=1)
    true_scores = scores.gather(1, labels[:, None]).squeeze(1)
    winning_scores = scores.max(dim=1).values
    gaps = winning_scores - true_scores
    errors = predictions != labels
    pairs = torch.stack((labels[errors], predictions[errors]), dim=1)
    return pairs, gaps[errors], ...

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.7.16 Exercise 15 - Implement Weight Regularization for Multi-Class Stability

Part 1 - Why this matters

Regularization discourages large class-specific weights and can reduce sensitivity to noisy features. In a manual perceptron loop, weight decay must be inserted explicitly because no optimizer applies it automatically.

Decay changes the classical algorithm and its convergence properties, so it should be treated as an experimental extension. Bias regularization and decay timing must also be stated.

Part 2 - Mathematical form

$$W \leftarrow (1 - \eta\lambda)W + \eta(\mathbf{e}_y - \mathbf{e}_{\hat{y}})\mathbf{x}^\mathsf{T}.$$

Part 3 - Hints and Helper

Apply decay consistently before or after each sample or epoch and document the choice. Compare norms, accuracy, and margins across regularization strengths.

Part 4 - Python code skeleton

```
import torch

def E15(weight, bias, features, label, learning_rate, decay):
    weight = (1 - learning_rate * decay) * weight
    prediction = torch.argmax(weight @ features + bias)
    if prediction != label:
        weight[label] += learning_rate * features
        weight[prediction] -= learning_rate * features
        bias[label] += learning_rate
```

```
        bias[prediction] -= learning_rate
    return weight, bias, prediction

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.7.17 Exercise 16 - Compare Multi-Class Perceptron with Softmax Regression

Part 1 - Why this matters

Both models use linear class scores and argmax prediction. The perceptron applies mistake-driven paired updates, while softmax regression converts logits to probabilities and minimizes cross-entropy through gradients.

Their decision boundaries can be similar, but their training signals differ. Softmax uses every sample and score, whereas the classical perceptron ignores correctly classified samples regardless of margin size.

Part 2 - Mathematical form

$$p_k = \frac{e^{s_k}}{\sum_j e^{s_j}}, \quad L_{CE} = -\log p_y, \qquad \Delta W_P = \eta(\mathbf{e}_y - \mathbf{e}_{\hat{y}})\mathbf{x}^\mathsf{T}.$$

Part 3 - Hints and Helper

Train both from matched initial scores. Compare accuracy, negative log-likelihood, calibration, margins, update count, and runtime.

Part 4 - Python code skeleton

```
import torch

def E16(features, labels, perceptron_state, softmax_model):
    perceptron_scores = ...
    perceptron_predictions = torch.argmax(perceptron_scores, dim=1)
    softmax_logits = softmax_model(features)
    softmax_probabilities = torch.softmax(softmax_logits, dim=1)
    softmax_loss = torch.nn.functional.cross_entropy(
        softmax_logits, labels
    )
    return {
        "perceptron_accuracy": ...,
        "softmax_accuracy": ...,
        "softmax_loss": softmax_loss.item(),
        "probabilities": softmax_probabilities,
```

```
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.7.18 Exercise 17 - Stress Test Multi-Class Model with High-Dimensional Inputs

Part 1 - Why this matters

High-dimensional multi-class data expands both the weight matrix and score computation. The stress test reveals memory pressure, throughput limits, non-finite states, and whether shape assumptions survive realistic scale.

Synthetic labels should come from a known teacher matrix so the task remains controlled. Aggregate statistics are safer than saving every large parameter state.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \quad W \in \mathbb{R}^{K \times d}, \quad S = XW^{\mathsf{T}} \in \mathbb{R}^{n \times K}.$$

Part 3 - Hints and Helper

Generate tensors directly on the target device and synchronize CUDA around timing. Report peak memory, examples per second, updates, and finiteness.

Part 4 - Python code skeleton

```
import torch

def E17(samples, dimensions, classes, device):
    features = torch.randn(samples, dimensions, device=device)
    teacher = torch.randn(classes, dimensions, device=device)
    labels = torch.argmax(features @ teacher.T, dim=1)
    weight = torch.zeros_like(teacher)
    bias = torch.zeros(classes, device=device)
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats()
    history = ...
    return {
        "history": history,
        "finite": torch.isfinite(weight).all().item(),
        "peak_memory": ...,
    }

def main():
```

```
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.7.19 Exercise 18 - Debug Class-Specific Training Failures

Part 1 - Why this matters

A model may perform well overall while one class never learns. Common causes include a missing training class, incorrect class-index mapping, imbalance, frozen parameter rows, invalid labels, or an update applied to the wrong rows.

Debugging must inspect state per class. Counts, update frequency, row norms, recall, and score distributions show whether the class lacks data, lacks corrections, or loses every competition.

Part 2 - Mathematical form

$$D_k = \{n_k, U_k, \|\mathbf{w}_k\|_2, \mathrm{Recall}_k, \bar{s}_k\}.$$

Part 3 - Hints and Helper

Validate contiguous class indices or maintain an explicit mapping. Flag classes with zero samples, zero updates, non-finite rows, or persistently zero recall.

Part 4 - Python code skeleton

```
import torch

def E18(labels, updates_per_class, weight, recalls):
    class_count = weight.shape[0]
    counts = torch.bincount(labels, minlength=class_count)
    norms = torch.linalg.vector_norm(weight, dim=1)
    failures = []
    for class_id in range(class_count):
        reasons = []
        if counts[class_id] == 0:
            reasons.append(...)
        if updates_per_class[class_id] == 0:
            reasons.append(...)
        if recalls[class_id] == 0:
            reasons.append(...)
        if reasons:
            failures.append({"class": class_id, "reasons": reasons})
    return counts, norms, failures

def main():
    print(E18(...))
```

```
if __name__ == "__main__":
    main()
```

12.7.20 Exercise 19 - Produce a Comprehensive Multi-Class Analysis Report

Part 1 - Why this matters

A complete report connects formulation, training dynamics, class-specific metrics, resource scaling, and failure analysis. It prevents a single accuracy value from hiding unstable classes, memory costs, or unresolved tie behavior.

Conclusions should distinguish one-vs-rest, one-vs-one, and direct multi-class results. Class mapping, data balance, device, dtype, seeds, update convention, and evaluation averaging are required for reproducibility.

Part 2 - Mathematical form

$$R = \{\text{strategy}, W, \text{updates}, C, \text{per-class metrics}, \text{regions}, \text{scaling}, \text{failures}, \text{limitations}\}.$$

Part 3 - Hints and Helper

Require evidence for every class and every compared strategy. Include confusion matrices, resource measurements, and unresolved limitations.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
        "strategy", "class_mapping", "training", "confusion_matrix",
        "per_class_metrics", "decision_regions", "imbalance",
        "cpu_gpu_scaling", "memory", "failure_analysis", "limitations",
    }
    missing = sorted(required - sections.keys())
    failed_classes = sections.get("failure_analysis", {}).get(
        "failed_classes", []
    )
    return {
        "complete": not missing and not failed_classes,
        "missing": missing,
        "failed_classes": failed_classes,
        "sections": sections,
    }

def main():
```

```
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.8 PC06 - Computational Performance and CUDA Effects

Models and Training

12.8.1 Exercise 00 - Benchmark Perceptron Forward Pass on CPU vs GPU

Part 1 - Why this matters

A fair forward-pass benchmark determines whether matrix and vector operations are large enough to benefit from GPU parallelism. Tiny perceptron workloads can run faster on a CPU because GPU launch and transfer costs dominate the arithmetic.

CPU wall-clock timing and asynchronous CUDA execution cannot be compared naively. Both paths need warm-up and repeated measurements, while CUDA timing must use events or explicit synchronization.

Part 2 - Mathematical form

$$T_C = \text{median}(t_C), \qquad T_G = \text{median}(t_G), \qquad S = \frac{T_C}{T_G}.$$

Part 3 - Hints and Helper

Preallocate inputs and parameters on each device. Exclude host-to-device transfer unless end-to-end latency is the metric being studied.

Part 4 - Python code skeleton

```
import time

import torch

def E00(features, weight, bias, repeats):
    cpu_times = benchmark_cpu(features, weight, bias, repeats, ...)
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    gpu_features = features.cuda()
    gpu_weight = weight.cuda()
    gpu_bias = bias.cuda()
    gpu_times = benchmark_cuda(
        gpu_features, gpu_weight, gpu_bias, repeats, ...
```

```
    )
    return summarize(cpu_times, gpu_times, ...)

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.8.2 Exercise 01 - Benchmark Training Throughput on CUDA

Part 1 - Why this matters

Training throughput measures how many samples or updates are processed per second under a specified workload. It combines score computation, mistake detection, corrections, and loop overhead rather than timing only one matrix multiplication.

The result depends on update strategy because sequential online updates expose little parallelism, while a batch perceptron can aggregate corrections. The algorithmic variant must be reported beside throughput.

Part 2 - Mathematical form

$$\text{throughput} = \frac{En}{T_{\text{train}}} \text{ samples/s.}$$

Part 3 - Hints and Helper

Warm up the complete training step, synchronize around the measured region, and report batch size, feature count, class count, dtype, and update policy.

Part 4 - Python code skeleton

```
import time

import torch

def E01(features, labels, weight, bias, epochs):
    for _ in range(...):
        weight, bias = training_epoch(features, labels, weight, bias, ...)
    torch.cuda.synchronize()
    start = time.perf_counter()
    for _ in range(epochs):
        weight, bias = training_epoch(features, labels, weight, bias, ...)
    torch.cuda.synchronize()
    elapsed = time.perf_counter() - start
    return {"elapsed": elapsed, "samples_per_second": ...}

def main():
    print(E01(...))
```

```
if __name__ == "__main__":
    main()
```

12.8.3 Exercise 02 - Measure Memory Usage During Training on GPU

Part 1 - Why this matters

GPU memory usage includes persistent parameters, input batches, intermediate scores, temporary masks, allocator reservations, and optional histories. Peak memory can therefore be much larger than the mathematical parameter size.

Allocated and reserved memory describe different quantities. Resetting peak statistics around a controlled step makes before-and-after experiments comparable and helps identify hidden retained tensors.

Part 2 - Mathematical form

$$M_{\text{peak}} = \max_t M_{\text{allocated}}(t), \qquad M_{\text{reserved}} \geq M_{\text{allocated}}.$$

Part 3 - Hints and Helper

Synchronize before reading final statistics and avoid storing graph-connected tensors. Report bytes and convert units only when presenting results.

Part 4 - Python code skeleton

```
import time

import torch

def E02(training_step):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    torch.cuda.empty_cache()
    torch.cuda.reset_peak_memory_stats()
    before = torch.cuda.memory_allocated()
    output = training_step()
    torch.cuda.synchronize()
    return {
        "before": before,
        "after": torch.cuda.memory_allocated(),
        "peak_allocated": torch.cuda.max_memory_allocated(),
        "peak_reserved": torch.cuda.max_memory_reserved(),
        "output": output,
    }

def main():
```

```
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.8.4 Exercise 03 - Analyze Kernel Launch Overhead for Small Batches

Part 1 - Why this matters

Every CUDA operation launches work through the GPU runtime. For a small batch, launch latency and Python dispatch can exceed the time spent performing the perceptron's dot products.

The experiment should compare many batch sizes and separate a fused or vectorized operation from a sequence of tiny operations. This reveals the workload size at which useful parallel work begins to dominate overhead.

Part 2 - Mathematical form

$$T_G(n) = T_{\text{launch}} + T_{\text{compute}}(n), \qquad n \to 0 \Rightarrow T_{\text{launch}}/T_G \to 1.$$

Part 3 - Hints and Helper

Use CUDA events over many repetitions and divide by the repetition count. Do not call synchronize or item inside the measured inner loop.

Part 4 - Python code skeleton

```
import time

import torch

def E03(batch_sizes, dimensions, repeats):
    rows = []
    for batch_size in batch_sizes:
        features = torch.randn(batch_size, dimensions, device="cuda")
        weight = torch.randn(dimensions, device="cuda")
        elapsed = cuda_event_benchmark(
            lambda: features @ weight, repeats, ...
        )
        rows.append({"batch_size": batch_size, "microseconds": ...})
    return rows

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.8.5 Exercise 04 - Evaluate Scaling Behavior with Increasing Batch Size

Part 1 - Why this matters

Batch-size scaling shows how fixed overhead is amortized and how device utilization improves before memory bandwidth or capacity becomes limiting. Latency usually rises while throughput may improve and later plateau.

A benchmark must report both latency and samples per second. Failed allocations and the last complete batch are part of the scaling result rather than values to silently discard.

Part 2 - Mathematical form

$$Q(B) = \frac{B}{T(B)}, \qquad E(B) = \frac{Q(B)}{Q(B_0)}.$$

Part 3 - Hints and Helper

Sweep powers of two, reuse the same feature count, and record peak memory. Catch out-of-memory conditions without continuing from a corrupted measurement state.

Part 4 - Python code skeleton

```
import time

import torch

def E04(batch_sizes, feature_count, repeats):
    results = []
    for batch_size in batch_sizes:
        try:
            features = torch.randn(
                batch_size, feature_count, device="cuda"
            )
            latency = benchmark(...)
            results.append({
                "batch_size": batch_size,
                "latency": latency,
                "throughput": batch_size / latency,
                "peak_memory": ...,
            })
        except torch.OutOfMemoryError:
            results.append({"batch_size": batch_size, "status": "oom"})
            break
    return results

def main():
    print(E04(...))
```

```
if __name__ == "__main__":
    main()
```

12.8.6 Exercise 05 - Compare Float32 vs Mixed Precision Performance

Part 1 - Why this matters

Mixed precision can increase throughput and reduce memory when hardware supports fast lower-precision operations. A perceptron's hard boundary makes it especially important to verify that reduced precision does not change too many decisions near zero.

Performance and correctness must be evaluated together. Speedup without score, prediction, and update comparisons may hide a different training trajectory rather than an equivalent faster computation.

Part 2 - Mathematical form

$$S = \frac{T_{32}}{T_{\mathrm{MP}}}, \qquad D = \sum_i \mathbb{I}[\hat{y}_i^{32} \neq \hat{y}_i^{\mathrm{MP}}].$$

Part 3 - Hints and Helper

Use autocast for the measured operations and keep a float32 reference. Report latency, peak memory, maximum score error, and decision disagreement.

Part 4 - Python code skeleton

```
import time

import torch

def E05(features, weight, bias, repeats):
    float32_result = benchmark_mode(
        features, weight, bias, repeats, autocast_enabled=False
    )
    mixed_result = benchmark_mode(
        features, weight, bias, repeats, autocast_enabled=True
    )
    disagreement = (
        float32_result["predictions"]
        != mixed_result["predictions"]
    ).sum()
    return float32_result, mixed_result, disagreement.item()

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.8.7 Exercise 06 - Identify Performance Bottlenecks in Training Loop

Part 1 - Why this matters

A slow training loop may be limited by Python control flow, host-to-device copies, synchronization, memory allocation, score computation, or update scattering. Optimizing the wrong component produces complexity without meaningful speedup.

Bottleneck analysis decomposes time and validates the finding with controlled changes. Percentages should be based on synchronized measurements and add up to the measured iteration time within expected overhead.

Part 2 - Mathematical form

$$T_{\text{iter}} = T_{\text{input}} + T_{\text{forward}} + T_{\text{decision}} + T_{\text{update}} + T_{\text{sync}} + T_{\text{other}}.$$

Part 3 - Hints and Helper

Instrument named regions and compare online and vectorized variants. Check GPU utilization and kernel counts before rewriting the algorithm.

Part 4 - Python code skeleton

```
import time

import torch

def E06(batch):
    timings = {}
    with timed_region("transfer", timings, ...):
        device_batch = move_to_device(batch, ...)
    with timed_region("forward", timings, ...):
        scores = ...
    with timed_region("decision", timings, ...):
        mistakes = ...
    with timed_region("update", timings, ...):
        state = ...
    total = sum(timings.values())
    shares = {name: value / total for name, value in timings.items()}
    return timings, shares

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.8.8 Exercise 07 - Profile CUDA Execution Using PyTorch Tools

Part 1 - Why this matters

A profiler exposes CPU operators, CUDA kernels, memory activity, shapes, and call stacks. It turns a broad statement such as GPU training is slow into evidence about the exact operations consuming time.

Profiling adds overhead and should cover a short representative schedule rather than the entire training run. The profiled workload, warm-up steps, and exported trace must be reproducible.

Part 2 - Mathematical form

$$P = \{\text{operator}, \text{CPU time}, \text{CUDA time}, \text{calls}, \text{shapes}, \text{memory}\}.$$

Part 3 - Hints and Helper

Use torch.profiler with CPU and CUDA activities, record shapes, and a wait–warmup–active schedule. Avoid reading only aggregate wall time.

Part 4 - Python code skeleton

```
import time

import torch

def E07(training_step, steps):
    schedule = torch.profiler.schedule(wait=1, warmup=1, active=3)
    with torch.profiler.profile(
        activities=[
            torch.profiler.ProfilerActivity.CPU,
            torch.profiler.ProfilerActivity.CUDA,
        ],
        schedule=schedule,
        record_shapes=True,
        profile_memory=True,
    ) as profiler:
        for _ in range(steps):
            training_step()
            profiler.step()
    return profiler.key_averages().table(...)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.8.9 Exercise 08 - Optimize Data Transfer Between Host and Device

Part 1 - Why this matters

Repeated blocking transfers can starve the GPU and serialize the pipeline. Pinned host memory and non-blocking copies allow transfer to overlap with computation when the hardware and execution stream support it.

Optimization must compare identical end-to-end workloads. Moving data once before training may outperform elaborate overlap when the dataset fits in device memory.

Part 2 - Mathematical form

$$T_{\text{pipeline}} \approx \max(T_{\text{copy}}, T_{\text{compute}}) \text{ with effective overlap.}$$

Part 3 - Hints and Helper

Use a DataLoader with pinned memory and transfer batches with non-blocking enabled. Synchronize only at measurement boundaries and verify output parity.

Part 4 - Python code skeleton

```
import time

import torch

def E08(data_loader, model_step, device):
    processed = 0
    torch.cuda.synchronize()
    start = time.perf_counter()
    for features, labels in data_loader:
        features = features.to(device, non_blocking=True)
        labels = labels.to(device, non_blocking=True)
        model_step(features, labels)
        processed += len(features)
    torch.cuda.synchronize()
    elapsed = time.perf_counter() - start
    return processed / elapsed

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.8.10 Exercise 09 - Investigate Synchronization Overhead

Part 1 - Why this matters

CUDA launches are asynchronous with respect to the CPU. Calling synchronize, item, or transferring results to the host forces the CPU to wait and can destroy overlap when done inside a tight loop.

Removing synchronization blindly is also wrong because timing and dependencies may require it. The goal is to place necessary synchronization at clear boundaries and measure its cost.

Part 2 - Mathematical form

$$T_{\text{loop}}^{\text{sync}} - T_{\text{loop}}^{\text{async}} \approx NT_{\text{wait}}.$$

Part 3 - Hints and Helper

Compare a loop with per-step scalar extraction against one that accumulates device tensors and synchronizes once. Ensure both perform equivalent work.

Part 4 - Python code skeleton

```
import time

import torch

def E09(step, iterations):
    synchronized_values = []
    start_sync = time.perf_counter()
    for _ in range(iterations):
        synchronized_values.append(step().item())
    sync_elapsed = time.perf_counter() - start_sync
    start_async = time.perf_counter()
    device_values = [step() for _ in range(iterations)]
    torch.cuda.synchronize()
    async_elapsed = time.perf_counter() - start_async
    return sync_elapsed, async_elapsed, device_values

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.8.11 Exercise 10 - Stress Test GPU with Large-Scale Synthetic Data

Part 1 - Why this matters

A stress test explores throughput, peak memory, numerical finiteness, and failure behavior near device limits. Synthetic generation allows sample count, dimensions, classes, and margin

to be controlled.

The test should increase load gradually and stop safely on out-of-memory or non-finite states. A crash is not a useful benchmark result unless the last successful configuration is preserved.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \qquad \text{forward work} = \mathcal{O}(nd), \qquad \text{input memory} = ndq \text{ bytes}.$$

Part 3 - Hints and Helper

Generate data directly on the GPU or in chunks to avoid measuring transfer unintentionally. Record temperature or throttling context for long runs.

Part 4 - Python code skeleton

```
import time

import torch

def E10(configurations):
    results = []
    for samples, dimensions in configurations:
        try:
            features = torch.randn(samples, dimensions, device="cuda")
            weight = torch.randn(dimensions, device="cuda")
            result = benchmark_and_validate(features, weight, ...)
            results.append(result)
        except torch.OutOfMemoryError:
            results.append({
                "samples": samples,
                "dimensions": dimensions,
                "status": "oom",
            })
            break
    return results

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.8.12 Exercise 11 - Compare Multi-GPU vs Single-GPU Perceptron Execution

Part 1 - Why this matters

Multiple GPUs can split large batches or datasets, but the perceptron has very few parameters and limited computation per sample. Communication and process coordination can easily cost more than the saved compute time.

The comparison must use the same global batch and algorithmic update. Data-parallel local corrections require an explicit reduction rule so that multi-GPU training remains mathematically comparable.

Part 2 - Mathematical form

$$T_p \approx \frac{T_{\text{compute}}}{p} + T_{\text{communication}} + T_{\text{imbalance}}, \qquad S_p = \frac{T_1}{T_p}.$$

Part 3 - Hints and Helper

Use one process per GPU and aggregate corrections with a collective reduction. Report world size, interconnect, scaling efficiency, and output agreement.

Part 4 - Python code skeleton

```
import time

import torch

def E11(local_features, local_labels, weight, bias):
    if not torch.distributed.is_initialized():
        raise RuntimeError(...)
    local_weight_update, local_bias_update = batch_update(
        local_features, local_labels, weight, bias, ...
    )
    torch.distributed.all_reduce(local_weight_update)
    torch.distributed.all_reduce(local_bias_update)
    world_size = torch.distributed.get_world_size()
    weight = weight + local_weight_update / world_size
    bias = bias + local_bias_update / world_size
    return weight, bias

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.8.13 Exercise 12 - Measure Determinism Across GPU Runs

Part 1 - Why this matters

Repeated GPU runs may differ when random order, nondeterministic kernels, or uncontrolled initialization changes the training path. Hard threshold decisions can amplify a tiny

numerical difference into a different update sequence.

Determinism must be tested at multiple levels: final parameters, mistake histories, predictions, and bitwise or tolerance-based equality. Performance cost should also be measured when deterministic algorithms are enabled.

Part 2 - Mathematical form

$$D_r = \|\mathbf{w}^{(r)} - \mathbf{w}^{(1)}\|_2, \qquad H_r = \mathbb{I}[\text{history}_r = \text{history}_1].$$

Part 3 - Hints and Helper

Seed Python and PyTorch, enable deterministic algorithms, and run from fresh state. Record environment and library versions with the result.

Part 4 - Python code skeleton

```
import time

import torch

def E12(run_training, seed, repeats):
    outputs = []
    torch.use_deterministic_algorithms(True)
    for _ in range(repeats):
        torch.manual_seed(seed)
        torch.cuda.manual_seed_all(seed)
        outputs.append(run_training())
    reference = outputs[0]
    comparisons = [compare_runs(reference, output, ...) for output in outputs]
    return outputs, comparisons

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.8.14 Exercise 13 - Analyze Precision-Induced Performance Variations

Part 1 - Why this matters

Dtype changes arithmetic throughput, tensor-core eligibility, memory traffic, and capacity. The fastest dtype depends on hardware, shapes, operator support, and whether casts introduce extra kernels.

A precision benchmark is incomplete without numerical analysis. Score error, boundary disagreement, convergence changes, and non-finite values determine whether a speedup is usable.

Part 2 - Mathematical form

$$R_q = (T_q, M_q, \epsilon_q, D_q), \qquad q \in \{16, \text{bf16}, 32, 64\}.$$

Part 3 - Hints and Helper

Run supported dtypes over the same base data and warm-up each mode independently. Report unsupported modes instead of silently substituting another dtype.

Part 4 - Python code skeleton

```
import time

import torch

def E13(features, weight, dtypes, repeats):
    reference = features.float() @ weight.float()
    results = {}
    for dtype in dtypes:
        try:
            output, latency, memory = benchmark_dtype(
                features, weight, dtype, repeats, ...
            )
            results[str(dtype)] = {
                "latency": latency,
                "memory": memory,
                "maximum_error": (
                    output.float() - reference
                ).abs().max().item(),
                "finite": torch.isfinite(output).all().item(),
            }
        except RuntimeError as error:
            results[str(dtype)] = {
                "status": "unsupported",
                "error": str(error),
            }
    return results

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.8.15 Exercise 14 - Benchmark Perceptron vs Logistic Regression Performance

Part 1 - Why this matters

Both models compute a linear score, but logistic regression adds a differentiable loss, backward pass, gradient storage, and optimizer step. The perceptron's explicit correction may be cheaper while providing different statistical behavior.

The comparison must define the same data, batch size, device, dtype, and stopping budget. Accuracy and convergence quality belong beside runtime because unequal work can produce a misleading speed claim.

Part 2 - Mathematical form

$$C_P \approx C_{\text{forward}} + C_{\text{update}}, \qquad C_L \approx C_{\text{forward}} + C_{\text{loss}} + C_{\text{backward}} + C_{\text{optimizer}}.$$

Part 3 - Hints and Helper

Benchmark forward-only and full-training paths separately. Report throughput, peak memory, accuracy, and total time to the chosen target metric.

Part 4 - Python code skeleton

```
import time

import torch

def E14(perceptron_step, logistic_step, evaluation, epochs):
    perceptron_result = benchmark_training(
        perceptron_step, evaluation, epochs, ...
    )
    logistic_result = benchmark_training(
        logistic_step, evaluation, epochs, ...
    )
    return {
        "perceptron": perceptron_result,
        "logistic_regression": logistic_result,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.8.16 Exercise 15 - Identify When GPU Usage Is Counterproductive

Part 1 - Why this matters

A GPU is counterproductive when launch, transfer, synchronization, or setup costs exceed the parallel compute benefit. This often occurs for tiny batches, few features, sequential online

updates, or infrequent inference.

The break-even point is workload- and machine-specific. It should be measured across shapes and include both compute-only and end-to-end latency rather than declared from one example.

Part 2 - Mathematical form

$$\text{GPU counterproductive} \iff T_G^{\text{end-to-end}} > T_C^{\text{end-to-end}}.$$

Part 3 - Hints and Helper

Sweep batch and feature sizes, include transfer time, and find the smallest workload where the GPU wins consistently across repeated trials.

Part 4 - Python code skeleton

```
import time

import torch

def E15(workloads, repeats):
    rows = []
    for workload in workloads:
        cpu_latency = benchmark_cpu(workload, repeats, ...)
        gpu_compute = benchmark_gpu(workload, repeats, include_transfer=False)
        gpu_end_to_end = benchmark_gpu(
            workload, repeats, include_transfer=True
        )
        rows.append({
            "workload": workload,
            "cpu": cpu_latency,
            "gpu_compute": gpu_compute,
            "gpu_end_to_end": gpu_end_to_end,
            "gpu_counterproductive": gpu_end_to_end > cpu_latency,
        })
    return rows

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.8.17 Exercise 16 - Evaluate Energy Efficiency of GPU Execution

Part 1 - Why this matters

Energy efficiency considers work completed per joule rather than speed alone. A faster GPU run can consume less total energy if it finishes quickly, or more energy if utilization is poor and

power remains high.

Reliable energy measurement requires sampled device power or an external energy counter over the same synchronized workload. Idle baseline, sampling interval, and measurement uncertainty must be recorded.

Part 2 - Mathematical form

$$E \approx \sum_{j=1}^{m} P_j \Delta t_j, \qquad \eta_E = \frac{N_{\text{samples}}}{E} \text{ samples/J}.$$

Part 3 - Hints and Helper

Sample power from Python while the workload runs, subtract idle power only if the chosen methodology requires it, and align timestamps with synchronized start and end boundaries.

Part 4 - Python code skeleton

```
import time

import torch

def E16(run_workload, power_sampler, interval):
    samples = []
    start = time.perf_counter()
    while workload_is_running(...):
        samples.append((time.perf_counter(), power_sampler()))
        time.sleep(interval)
    processed = run_workload.result(...)
    energy_joules = integrate_power(samples, start, ...)
    return {
        "energy_joules": energy_joules,
        "samples_per_joule": processed / energy_joules,
        "power_samples": samples,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.8.18 Exercise 17 - Optimize Training Loop for Throughput

Part 1 - Why this matters

Throughput optimization removes Python work, repeated allocation, unnecessary transfers, and frequent synchronization from the critical path. Vectorized batch corrections can expose more parallelism than online sample-by-sample updates.

Changing the update schedule can change the algorithm, so every optimization must preserve a declared reference or report the behavioral difference. Correctness gates should precede speed comparisons.

Part 2 - Mathematical form

$$\Delta \mathbf{w} = \eta \sum_{i \in \mathcal{M}} y_i \mathbf{x}_i, \qquad \Delta b = \eta \sum_{i \in \mathcal{M}} y_i.$$

Part 3 - Hints and Helper

Profile first, vectorize active-sample aggregation, reuse buffers, and consider compilation only after shape stability is established. Compare predictions and update counts with the reference.

Part 4 - Python code skeleton

```
import time

import torch

def E17(features, labels, weight, bias, learning_rate):
    scores = features @ weight + bias
    margins = labels * scores
    active = margins <= 0
    active_features = features[active]
    active_labels = labels[active]
    weight_update = learning_rate * (
        active_labels[:, None] * active_features
    ).sum(dim=0)
    bias_update = learning_rate * active_labels.sum()
    return weight + weight_update, bias + bias_update, active.sum()

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.8.19 Exercise 18 - Detect Performance Regression After Code Changes

Part 1 - Why this matters

A performance regression occurs when a code change makes a stable workload slower, more memory-intensive, or less efficient beyond expected measurement noise. Automated benchmarks can catch these changes before they accumulate.

A single timing comparison is unreliable. Baselines need repeated samples, controlled environments, robust statistics, and thresholds that distinguish meaningful degradation from ordinary variance.

Part 2 - Mathematical form

$$r = \frac{\tilde{T}_{\text{new}} - \tilde{T}_{\text{base}}}{\tilde{T}_{\text{base}}}, \qquad \text{regression} \iff r > \tau.$$

Part 3 - Hints and Helper

Store workload metadata with the baseline and compare medians or confidence intervals. Check correctness before accepting a faster result.

Part 4 - Python code skeleton

```
import time

import torch

def E18(baseline_times, candidate_times, threshold):
    baseline = torch.tensor(baseline_times, dtype=torch.float64)
    candidate = torch.tensor(candidate_times, dtype=torch.float64)
    baseline_median = baseline.median()
    candidate_median = candidate.median()
    relative_change = (
        candidate_median - baseline_median
    ) / baseline_median
    return {
        "baseline_median": baseline_median.item(),
        "candidate_median": candidate_median.item(),
        "relative_change": relative_change.item(),
        "regression": relative_change > threshold,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.8.20 Exercise 19 - Produce a Performance Optimization Report

Part 1 - Why this matters

A performance report converts measurements into an optimization decision. It connects workload shapes, methodology, profiler evidence, latency, throughput, memory, precision, scaling, energy, and correctness.

The report must distinguish observed facts from recommendations and preserve raw measurements. An optimization is accepted only when it improves the target metric without violating numerical or model-quality tolerances.

Part 2 - Mathematical form

$$R = \{\text{method}, \text{hardware}, T, Q, M, P, E, \text{precision}, \text{parity}, \text{bottlenecks}, \text{actions}\}.$$

Part 3 - Hints and Helper

Require hardware and software context, synchronization policy, warm-up, repetitions, and statistical summary. Rank recommendations by measured impact and implementation risk.

Part 4 - Python code skeleton

```
import time

import torch

def E19(sections):
    required = {
        "methodology", "hardware", "software", "latency",
        "throughput", "memory", "precision", "cpu_gpu_parity",
        "profiling", "scaling", "energy", "regressions",
        "recommendations",
    }
    missing = sorted(required - sections.keys())
    failed_checks = sections.get("cpu_gpu_parity", {}).get(
        "failed_checks", []
    )
    return {
        "complete": not missing and not failed_checks,
        "missing": missing,
        "failed_checks": failed_checks,
        "sections": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.9 PC07 - Generalization and Theoretical Limits

Models and Training

12.9.1 Exercise 00 - Analyze Generalization Capability of the Perceptron Model

Part 1 - Why this matters

Generalization is the ability to classify unseen samples drawn from the target population, not merely to separate the training set. A perceptron can achieve zero training error while selecting a boundary that performs poorly outside the observed examples.

Capacity and sample size provide theoretical context. Affine linear separators in a fixed feature space have limited capacity, but high dimension, weak margin, biased sampling, and distribution mismatch can still produce a large generalization gap.

Part 2 - Mathematical form

$$d_{\mathrm{VC}} = d + 1, \qquad G = E_{\mathrm{test}} - E_{\mathrm{train}}.$$

Part 3 - Hints and Helper

Use an untouched test split and report feature dimension, sample count, normalized margin, train error, test error, and their gap.

Part 4 - Python code skeleton

```
import torch

def E00(model, train_data, test_data):
    train_features, train_labels = train_data
    test_features, test_labels = test_data
    train_error = classification_error(model, train_features, train_labels)
    test_error = classification_error(model, test_features, test_labels)
    return {
        "train_error": train_error,
        "test_error": test_error,
        "generalization_gap": test_error - train_error,
        "feature_dimension": train_features.shape[1],
    }

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.9.2 Exercise 01 - Study the Impact of Margin on Generalization Performance

Part 1 - Why this matters

The normalized margin measures the distance of the closest labeled training sample from the decision boundary. A larger margin often supports robustness and tighter capacity bounds than a separator that barely classifies every sample correctly.

Raw scores are not geometric margins because multiplying weights and bias changes their magnitude without moving the boundary. Every comparison must normalize by the weight norm and control data radius.

Part 2 - Mathematical form

$$\gamma = \min_i \frac{y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b)}{\|\mathbf{w}\|_2}, \qquad \text{complexity depends on } R^2/\gamma^2.$$

Part 3 - Hints and Helper

Train multiple separators or orderings, pair each normalized margin with test error, and report correlation without claiming that the experiment proves causation.

Part 4 - Python code skeleton

```
import torch

def E01(models, train_data, test_data):
    rows = []
    train_features, train_labels = train_data
    for weight, bias in models:
        norm = torch.linalg.vector_norm(weight).clamp_min(1e-12)
        margins = train_labels * (train_features @ weight + bias) / norm
        test_error = classification_error(
            (weight, bias), test_data[0], test_data[1]
        )
        rows.append((margins.min().item(), test_error))
    return rows, ...

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.9.3 Exercise 02 - Compare Training Accuracy vs Test Accuracy

Part 1 - Why this matters

Training accuracy measures fit to observed examples, while test accuracy estimates performance on unseen data. Their difference reveals possible overfitting, underfitting, leakage, or distribution mismatch.

A valid comparison requires identical preprocessing learned only from training data and a test set that was not used for model selection. Confidence intervals or repeated splits make the estimate more informative.

Part 2 - Mathematical form

$$A_{\text{train}} = \frac{1}{n}\sum_{i} \mathbb{I}[\hat{y}_i = y_i], \qquad A_{\text{test}} = \frac{1}{m}\sum_{j} \mathbb{I}[\hat{y}_j = y_j].$$

Part 3 - Hints and Helper

Evaluate in one function with no parameter updates. Check class balance and report both accuracy and class-specific metrics when the distribution is imbalanced.

Part 4 - Python code skeleton

```
import torch

def E02(weight, bias, train_data, test_data):
    metrics = {}
    for name, (features, labels) in {
        "train": train_data, "test": test_data
    }.items():
        predictions = torch.where(features @ weight + bias >= 0, 1, -1)
        metrics[name] = {
            "accuracy": (predictions == labels).float().mean().item(),
            "sample_count": len(labels),
        }
    metrics["gap"] = (
        metrics["train"]["accuracy"]
        - metrics["test"]["accuracy"]
    )
    return metrics

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.9.4 Exercise 03 - Investigate Overfitting in Linearly Separable Data

Part 1 - Why this matters

Linear separability guarantees that some boundary fits the training labels, but it does not guarantee that the selected boundary reflects the population. Sparse samples, outliers, and mislabeled points can steer the perceptron toward a fragile separator.

Because the standard perceptron stops changing after zero training errors, overfitting is investigated across datasets, orderings, or retained states rather than by assuming that endless zero-loss epochs continue to fit the data.

Part 2 - Mathematical form

$$E_{\text{train}} = 0 \not\Rightarrow E_{\text{population}} = 0.$$

Part 3 - Hints and Helper

Vary training size and outlier placement while using a fixed population test set. Compare margins, test gaps, and boundary variability.

Part 4 - Python code skeleton

```
import torch

def E03(training_sets, fixed_test):
    report = []
    for name, train_data in training_sets.items():
        weight, bias, history = train_perceptron(train_data, ...)
        report.append({
            "name": name,
            "train_error": ...,
            "test_error": ...,
            "margin": ...,
            "updates": sum(history),
        })
    return report

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.9.5 Exercise 04 - Evaluate Robustness to Input Noise

Part 1 - Why this matters

Input noise perturbs a sample's score by the projection of the disturbance onto the weight vector. Samples with small normalized margin can change class under much weaker noise than samples far from the boundary.

Robustness curves should use multiple noise magnitudes and random trials. Average accuracy alone can hide a vulnerable subgroup, so flip rates should also be reported by original margin range.

Part 2 - Mathematical form

$$f(\mathbf{x}+\boldsymbol{\delta}) = f(\mathbf{x}) + \mathbf{w}^{\mathsf{T}}\boldsymbol{\delta}, \qquad |\mathbf{w}^{\mathsf{T}}\boldsymbol{\delta}| < |f(\mathbf{x})| \Rightarrow \text{stable}.$$

Part 3 - Hints and Helper

Generate noise with controlled norm and keep one clean prediction reference. Report prediction flips, label accuracy, and results grouped by clean margin.

Part 4 - Python code skeleton

```
import torch

def E04(features, labels, weight, bias, noise_levels, trials):
    clean_predictions = torch.where(features @ weight + bias >= 0, 1, -1)
    rows = []
    for level in noise_levels:
        flip_rates = []
        accuracies = []
        for _ in range(trials):
            noisy = features + level * torch.randn_like(features)
            predictions = torch.where(noisy @ weight + bias >= 0, 1, -1)
            flip_rates.append(
                (predictions != clean_predictions).float().mean()
            )
            accuracies.append((predictions == labels).float().mean())
        rows.append({"level": level, "flip_rate": ..., "accuracy": ...})
    return rows

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.9.6 Exercise 05 - Analyze Sensitivity to Label Noise

Part 1 - Why this matters

Incorrect labels create contradictory corrections and can destroy linear separability. A single confidently mislabeled point may repeatedly pull the boundary away from a solution that generalizes well on clean data.

Sensitivity should be measured across controlled noise rates and seeds. Clean test performance, update count, convergence status, and parameter drift reveal damage hidden by noisy training accuracy.

Part 2 - Mathematical form

$$\tilde{y}_i = \begin{cases} -y_i, & i \in \mathcal{N}, \\ y_i, & i \notin \mathcal{N}, \end{cases} \qquad |\mathcal{N}|/n = \rho.$$

Part 3 - Hints and Helper

Save flipped indices and begin every run from identical parameters. Evaluate on untouched labels and compare weight direction with the clean reference.

Part 4 - Python code skeleton

```
import torch

def E05(features, labels, noise_rates, seed):
    generator = torch.Generator().manual_seed(seed)
    report = {}
    for rate in noise_rates:
        noisy_labels = labels.clone()
        count = int(rate * len(labels))
        indices = torch.randperm(len(labels), generator=generator)[:count]
        noisy_labels[indices] *= -1
        state, history = train_perceptron(
            (features, noisy_labels), ...
        )
        report[rate] = {
            "state": state,
            "updates": sum(history),
            "clean_error": ...,
        }
    return report

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.9.7 Exercise 06 - Explore the Effect of Regularization on Generalization

Part 1 - Why this matters

Weight regularization discourages large parameter norms and may reduce sensitivity to noisy or weak features. In a perceptron, decay is an extension to the classical update rather than an automatic property of the algorithm.

Smaller norms alone do not guarantee a larger geometric margin because scores and fit also change. Regularization strength must be selected on validation data and evaluated on an untouched test set.

Part 2 - Mathematical form

$$W \leftarrow (1 - \eta\lambda)W + \Delta W_P, \qquad J = L_P + \frac{\lambda}{2}\|W\|_2^2.$$

Part 3 - Hints and Helper

Sweep regularization values with fixed seeds. Report train error, validation error, test error, norm, and normalized margin.

Part 4 - Python code skeleton

```
import torch

def E06(train_data, validation_data, strengths):
    rows = []
    for strength in strengths:
        weight, bias = train_regularized_perceptron(
            train_data, strength, ...
        )
        rows.append({
            "strength": strength,
            "weight_norm": torch.linalg.vector_norm(weight).item(),
            "validation_error": classification_error(
                (weight, bias), *validation_data
            ),
            "test_error": ...,
        })
    return rows

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.9.8 Exercise 07 - Compare Perceptron Generalization to Logistic Regression

Part 1 - Why this matters

Both classifiers use a linear score, but logistic regression optimizes probabilistic log loss while the perceptron updates only on mistakes. Their boundaries, calibration, noise response, and regularization behavior can therefore differ.

A fair comparison uses identical splits, preprocessing, feature representation, and tuning budget. Accuracy should be accompanied by log loss or calibration only for the probabilistic model and by margin or update statistics for the perceptron.

Part 2 - Mathematical form

$$\hat{y}_P = \operatorname{sign}(\mathbf{w}_P^\top \mathbf{x} + b_P), \qquad p_L(y = 1 \mid \mathbf{x}) = \sigma(\mathbf{w}_L^\top \mathbf{x} + b_L).$$

Part 3 - Hints and Helper

Train both across repeated seeds and report mean and variance of test metrics. Do not interpret perceptron scores as probabilities.

Part 4 - Python code skeleton

```
import torch

def E07(perceptron, logistic, test_data):
    features, labels = test_data
    perceptron_predictions = perceptron.predict(features)
    logistic_logits = logistic(features).squeeze(-1)
    logistic_predictions = torch.where(logistic_logits >= 0, 1, -1)
    return {
        "perceptron_accuracy": ...,
        "logistic_accuracy": ...,
        "logistic_log_loss": ...,
        "perceptron_margin": ...,
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.9.9 Exercise 08 - Study Bias-Variance Tradeoff in Simple Models

Part 1 - Why this matters

Bias describes systematic error from an overly restricted hypothesis class, while variance describes sensitivity to the sampled training data. A linear perceptron has high bias on non-linear structure but can still show substantial variance in sparse high-dimensional settings.

Classification bias and variance do not have one universal decomposition like squared regression error. This exercise uses repeated datasets and prediction disagreement as empirical proxies and states that limitation.

Part 2 - Mathematical form

$$\mathrm{Var}_{\mathcal{D}}[\hat{y}(\mathbf{x})] \approx 1 - \max_{c} \Pr_{\mathcal{D}}(\hat{y}(\mathbf{x}) = c).$$

Part 3 - Hints and Helper

Train on many resampled datasets and predict one fixed evaluation grid. Measure consensus, disagreement, and systematic error against known target labels.

Part 4 - Python code skeleton

```
import torch

def E08(training_sets, evaluation_features, evaluation_labels):
    predictions = []
    for training_set in training_sets:
        model = train_perceptron(training_set, ...)
        predictions.append(model.predict(evaluation_features))
    matrix = torch.stack(predictions)
    positive_rate = (matrix == 1).float().mean(dim=0)
    consensus = torch.where(positive_rate >= 0.5, 1, -1)
    disagreement = 1 - torch.maximum(positive_rate, 1 - positive_rate)
    systematic_error = (consensus != evaluation_labels).float().mean()
    return systematic_error, disagreement

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.9.10 Exercise 09 - Identify Scenarios Where Perceptron Generalization Fails

Part 1 - Why this matters

Generalization can fail when classes are nonlinear, labels are noisy, features omit causal information, dimension is large relative to sample count, classes are imbalanced, or deployment data differ from training data.

These failures belong to different layers: representation, data, objective, optimization, or deployment. A useful diagnosis maps evidence to the correct layer instead of treating every low test score as the same problem.

Part 2 - Mathematical form

$$F = \{\text{nonlinearity}, \text{noise}, \text{sampling}, \text{dimension}, \text{imbalance}, \text{shift}\}.$$

Part 3 - Hints and Helper

Construct controlled datasets where only one assumption changes. Record train fit, test gap, margin, and the evidence supporting each failure label.

Part 4 - Python code skeleton

```
import torch

def E09(scenarios):
    results = []
    for scenario in scenarios:
```

```
        model = train_perceptron(scenario["train"], ...)
        metrics = evaluate(model, scenario["train"], scenario["test"])
        results.append({
            "name": scenario["name"],
            "expected_failure": scenario["failure_type"],
            "metrics": metrics,
            "evidence": ...,
        })
    return results

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.9.11 Exercise 10 - Evaluate Generalization on High-Dimensional Sparse Data

Part 1 - Why this matters

Sparse data can contain far more features than samples, allowing a linear classifier to fit training labels with weak evidence for unseen cases. Efficient storage helps computation but does not remove statistical overfitting risk.

Evaluation should vary dimension, density, sample count, and regularization. Dense conversion may erase the computational advantage and exceed memory, so representation costs belong in the result.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \qquad \text{density} = \frac{\text{nnz}(X)}{nd}, \qquad d \gg n.$$

Part 3 - Hints and Helper

Generate sparse tensors with controlled informative features. Report train and test error, nonzero count, memory, update time, and weight sparsity.

Part 4 - Python code skeleton

```
import torch

def E10(sparse_features, labels, weight, bias):
    if sparse_features.layout != torch.sparse_coo:
        raise ValueError(...)
    scores = torch.sparse.mm(
        sparse_features, weight[:, None]
    ).squeeze(1) + bias
```

```
    predictions = torch.where(scores >= 0, 1, -1)
    return {
        "accuracy": (predictions == labels).float().mean().item(),
        "nonzero_values": sparse_features._nnz(),
        "density": sparse_features._nnz() / sparse_features.numel(),
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.9.12 Exercise 11 - Measure Stability Across Different Random Seeds

Part 1 - Why this matters

Random initialization, sample order, split generation, and noise can produce different perceptron boundaries. Stable generalization requires conclusions that survive these sources of randomness rather than one favorable seed.

Seed analysis should preserve both aggregate metrics and individual runs. Mean performance can hide a catastrophic tail, while parameter variation can be large even when predictions remain similar.

Part 2 - Mathematical form

$$\bar{A} = \frac{1}{q}\sum_{r=1}^{q} A_r, \qquad s_A^2 = \frac{1}{q-1}\sum_{r}(A_r - \bar{A})^2.$$

Part 3 - Hints and Helper

Run the full pipeline for each seed, including splitting if that randomness is part of the study. Report mean, standard deviation, range, and worst run.

Part 4 - Python code skeleton

```
import torch

def E11(run_experiment, seeds):
    rows = [run_experiment(seed) for seed in seeds]
    accuracies = torch.tensor(
        [row["test_accuracy"] for row in rows], dtype=torch.float64
    )
    return {
        "runs": rows,
        "mean": accuracies.mean().item(),
        "std": accuracies.std(unbiased=True).item(),
```

```
        "minimum": accuracies.min().item(),
        "maximum": accuracies.max().item(),
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.9.13 Exercise 12 - Compare Deterministic vs Stochastic Training Outcomes

Part 1 - Why this matters

A deterministic order produces one reproducible trajectory, while stochastic shuffling explores different mistake sequences. Both can converge on separable data but may select different valid separators with different margins and test behavior.

The comparison concerns outcomes as well as speed. Update count, parameter similarity, prediction disagreement, margin, and test error reveal whether randomness changes only the path or also the deployed behavior.

Part 2 - Mathematical form

$$\pi_e = \pi_0 \text{ deterministic}, \qquad \pi_e \sim \text{Uniform}(S_n) \text{ stochastic}.$$

Part 3 - Hints and Helper

Keep initialization and stopping rules fixed. Repeat stochastic runs and compare their distribution with the single deterministic reference.

Part 4 - Python code skeleton

```
import torch

def E12(train_data, deterministic_order, seeds):
    deterministic = train_with_order(
        train_data, deterministic_order, ...
    )
    stochastic = []
    for seed in seeds:
        generator = torch.Generator().manual_seed(seed)
        stochastic.append(train_with_shuffle(train_data, generator, ...))
    return compare_outcomes(deterministic, stochastic, ...)

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.9.14 Exercise 13 - Analyze Generalization Under Distribution Shift

Part 1 - Why this matters

Distribution shift occurs when deployment inputs, label frequencies, or relationships differ from training conditions. A boundary that generalized well in-distribution may fail even though its code and training metrics remain unchanged.

Shift analysis must define what changed. Covariate shift, label shift, and concept shift require different evidence and cannot be summarized by one accuracy drop alone.

Part 2 - Mathematical form

$$P_{\text{train}}(X, Y) \neq P_{\text{test}}(X, Y), \qquad \Delta A = A_{\text{ID}} - A_{\text{shift}}.$$

Part 3 - Hints and Helper

Create controlled shifted sets and evaluate them separately. Compare feature statistics, class priors, error rates, margins, and calibration only where applicable.

Part 4 - Python code skeleton

```
import torch

def E13(model, in_distribution, shifted_sets):
    baseline = evaluate(model, in_distribution)
    report = {"in_distribution": baseline}
    for shift_name, dataset in shifted_sets.items():
        metrics = evaluate(model, dataset)
        report[shift_name] = {
            "metrics": metrics,
            "accuracy_drop": baseline["accuracy"] - metrics["accuracy"],
            "feature_shift": ...,
            "class_prior_shift": ...,
        }
    return report

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.9.15 Exercise 14 - Investigate Adversarial-Like Perturbations

Part 1 - Why this matters

For a linear classifier, the shortest direction toward the boundary is aligned with the weight vector. This makes a minimal boundary-crossing perturbation analytically understandable

rather than dependent on a complex attack algorithm.

The experiment should distinguish a perturbation that reaches the boundary from one that crosses it by a chosen safety amount. Feature constraints and semantic validity still matter in real data.

Part 2 - Mathematical form

$$\boldsymbol{\delta}^* = -\frac{\mathbf{w}^\mathsf{T}\mathbf{x} + b}{\|\mathbf{w}\|_2^2}\mathbf{w}, \qquad \|\boldsymbol{\delta}^*\|_2 = \frac{|f(\mathbf{x})|}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Compute the analytic perturbation, verify the new score is near zero, then add a small step across the boundary and check the prediction flip.

Part 4 - Python code skeleton

```
import torch

def E14(features, weight, bias, crossing_epsilon):
    scores = features @ weight + bias
    norm_squared = torch.dot(weight, weight).clamp_min(1e-12)
    boundary_delta = -(scores / norm_squared)[:, None] * weight
    direction = -torch.sign(scores)[:, None] * weight
    direction = direction / torch.linalg.vector_norm(weight)
    adversarial = features + boundary_delta + crossing_epsilon * direction
    new_scores = adversarial @ weight + bias
    return boundary_delta, adversarial, new_scores

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.9.16 Exercise 15 - Produce Empirical Evidence Supporting Theoretical Claims

Part 1 - Why this matters

Empirical evidence translates a theoretical statement into verified assumptions, measurable predictions, and observed results. It can illustrate a theorem and test an implementation, but finite experiments do not replace a proof.

Every claim should include a negative control where an assumption is violated. This shows whether the experiment can distinguish theorem-supported behavior from cases outside its scope.

Part 2 - Mathematical form

$$V_j = (A_j, P_j, O_j, \tau_j), \qquad \text{supported}_j = \mathbb{I}[A_j \wedge d(P_j, O_j) \leq \tau_j].$$

Part 3 - Hints and Helper

Build a structured table for margin robustness, convergence, capacity, noise, and shift. Preserve raw measurements and tolerances.

Part 4 - Python code skeleton

```
import torch

def E15(claims):
    results = []
    for claim in claims:
        assumptions_hold = all(check() for check in claim["assumptions"])
        observation = claim["experiment"]()
        supported = (
            claim["compare"](observation, claim["tolerance"])
            if assumptions_hold else None
        )
        results.append({
            "claim": claim["name"],
            "assumptions_hold": assumptions_hold,
            "observation": observation,
            "supported": supported,
        })
    return results

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.9.17 Exercise 16 - Document Limitations of Perceptron in Real-World Data

Part 1 - Why this matters

Real-world data can contain nonlinear structure, missing values, changing distributions, noisy labels, unequal costs, correlated groups, and ambiguous classes. A single hard linear boundary cannot represent or communicate all of these conditions.

Limitations must be tied to consequences and evidence. The report should separate the perceptron's representational limits from failures caused by poor preprocessing, evaluation, monitoring, or data governance.

Part 2 - Mathematical form

$$L = \{\text{linearity}, \text{hard output}, \text{noise}, \text{imbalance}, \text{missingness}, \text{shift}, \text{uncertainty}\}.$$

Part 3 - Hints and Helper

Create a limitation registry with a detection test, observed impact, mitigation, residual risk, and responsible monitoring metric.

Part 4 - Python code skeleton

```
import torch

def E16(observations):
    limitations = []
    for name, evidence in observations.items():
        limitations.append({
            "name": name,
            "evidence": evidence,
            "impact": ...,
            "mitigation": ...,
            "residual_risk": ...,
        })
    return limitations

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.9.18 Exercise 17 - Compare Perceptron to Modern Linear Classifiers

Part 1 - Why this matters

Modern linear classifiers retain efficient linear prediction while using objectives and regularization designed for margins, probabilities, noisy data, or large-scale stochastic optimization. The perceptron remains a valuable baseline and conceptual model.

A useful comparison includes logistic regression, linear support vector machines, and averaged or regularized perceptron variants. Each should receive a fair tuning budget and identical data processing.

Part 2 - Mathematical form

$$\text{objectives: } L_P = \max(0, -m), \quad L_H = \max(0, 1 - m), \quad L_L = \log(1 + e^{-m}).$$

Part 3 - Hints and Helper

Compare predictive quality, calibration where defined, margin, runtime, memory, robustness, and interpretability. Do not rank models by accuracy alone.

Part 4 - Python code skeleton

```
import torch

def E17(models, datasets):
    report = {}
    for name, model in models.items():
        trained = model.fit(datasets["train"], ...)
        report[name] = {
            "validation": evaluate(trained, datasets["validation"]),
            "test": evaluate(trained, datasets["test"]),
            "runtime": ...,
            "memory": ...,
            "supports_probability": ...,
        }
    return report

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.9.19 Exercise 18 - Evaluate Suitability of Perceptron for Production Use

Part 1 - Why this matters

Production suitability depends on more than test accuracy. Latency, throughput, memory, stability, explainability, calibration needs, class costs, drift monitoring, update safety, and rollback behavior all influence the decision.

A perceptron may be appropriate for a simple low-latency linearly separable task or as a baseline. It is unsuitable when probabilistic confidence, nonlinear structure, robust noise handling, or complex class interactions are required.

Part 2 - Mathematical form

$$S = \sum_j \omega_j q_j, \qquad \text{deploy only if every critical gate } g_j = 1.$$

Part 3 - Hints and Helper

Define critical gates separately from weighted preferences. Include shadow evaluation, drift thresholds, failure fallback, and model-version reproducibility.

Part 4 - Python code skeleton

```
import torch

def E18(evidence, requirements):
    gates = {
        name: check(evidence, rule)
        for name, rule in requirements["critical_gates"].items()
    }
    scores = {
        name: score(evidence, rule)
        for name, rule in requirements["weighted_criteria"].items()
    }
    weighted_score = sum(
        requirements["weights"][name] * value
        for name, value in scores.items()
    )
    return {
        "deploy": all(gates.values()),
        "gates": gates,
        "score": weighted_score,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.9.20 Exercise 19 - Write a Critical Theoretical Review of the Perceptron

Part 1 - Why this matters

A critical review should explain why the perceptron is historically and mathematically important while evaluating its assumptions, guarantees, capacity, generalization behavior, and failure modes without exaggeration.

The review must distinguish proven statements from empirical findings and practical judgments. It should state when later linear methods solve a limitation and when only a richer representation or nonlinear model can do so.

Part 2 - Mathematical form

$$R = \{\text{model}, \text{algorithm}, \text{convergence}, \text{capacity}, \text{margin}, \text{robustness}, \text{shift}, \text{comparisons}, \text{limits}\}.$$

Part 3 - Hints and Helper

Require sources or internal experimental evidence for every major claim. Include assumptions, counterexamples, unresolved questions, and a balanced conclusion.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
        "model", "learning_rule", "convergence", "capacity",
        "margin", "generalization", "noise", "distribution_shift",
        "adversarial_robustness", "modern_comparisons",
        "production_suitability", "limitations", "conclusion",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        name for name, value in sections.items()
        if isinstance(value, dict) and not value.get("evidence")
    ]
    return {
        "complete": not missing and not unsupported,
        "missing": missing,
        "unsupported": unsupported,
        "sections": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.10 PC08 - Transition to Multi-Layer Networks

Models and Training

12.10.1 Exercise 00 - Demonstrate the Inability of Single Perceptron to Model XOR

Part 1 - Why this matters

XOR assigns the same class to opposite corners of a square, so no single line can place both positive corners on one side and both negative corners on the other. This is a representational failure rather than a training failure.

Changing the learning rate, initialization, epoch count, or hardware cannot create a missing linear separator. The contradiction should be demonstrated mathematically and confirmed through persistent training errors.

Part 2 - Mathematical form

$$w_1 + b < 0, \quad w_2 + b > 0, \quad w_1 + b > 0, \quad w_1 + w_2 + b < 0 \quad \text{cannot all hold for XOR.}$$

Part 3 - Hints and Helper

Use all four binary inputs and try several data orders. Record the best achievable error and explain why non-convergence is expected.

Part 4 - Python code skeleton

```
import torch

def E00(features, labels, learning_rate, epochs):
    best_errors = len(labels)
    history = []
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    for _ in range(epochs):
        mistakes = ...
        best_errors = min(best_errors, mistakes)
        history.append(mistakes)
    return {
        "converged": best_errors == 0,
        "best_errors": best_errors,
        "history": history,
    }

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.10.2 Exercise 01 - Manually Combine Two Perceptrons to Solve XOR

Part 1 - Why this matters

A hidden layer can transform the four XOR points into features that become linearly separable. One construction computes OR and NAND with two perceptrons, then applies AND to their outputs.

This network solves XOR by composition, not because any individual unit becomes nonlinear in its boundary geometry. The intermediate binary representation is the crucial new capability.

Part 2 - Mathematical form

$$h_1 = H(x_1 + x_2 - 0.5), \quad h_2 = H(-x_1 - x_2 + 1.5), \quad y = H(h_1 + h_2 - 1.5).$$

Part 3 - Hints and Helper

Implement the step function once and print every hidden pair. Verify the truth table manually rather than training these known parameters.

Part 4 - Python code skeleton

```
import torch

def step(value):
    return (value >= 0).to(value.dtype)

def E01(features):
    hidden_or = step(features[:, 0] + features[:, 1] - 0.5)
    hidden_nand = step(-features[:, 0] - features[:, 1] + 1.5)
    hidden = torch.stack((hidden_or, hidden_nand), dim=1)
    output = step(hidden[:, 0] + hidden[:, 1] - 1.5)
    return hidden, output

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.10.3 Exercise 02 - Interpret Hidden Units as Feature Transformers

Part 1 - Why this matters

Hidden units do more than produce intermediate predictions. They create a new coordinate system in which combinations such as OR, NAND, thresholds, or learned directions become features for the next layer.

The output layer sees hidden activations rather than the original inputs. A problem that is inseparable in input space can therefore become separable after a suitable nonlinear transformation.

Part 2 - Mathematical form

$$\mathbf{h} = \phi(W_1\mathbf{x} + \mathbf{b}_1), \qquad \hat{y} = H(\mathbf{w}_2^{\mathsf{T}}\mathbf{h} + b_2).$$

Part 3 - Hints and Helper

Compare pairwise distances and class separability before and after the hidden transformation. Inspect each unit's activation pattern.

Part 4 - Python code skeleton

```
import torch

def E02(features, first_weight, first_bias):
    pre_activation = features @ first_weight.T + first_bias
    hidden_features = (pre_activation >= 0).to(features.dtype)
    input_distances = torch.cdist(features, features)
    hidden_distances = torch.cdist(hidden_features, hidden_features)
    return pre_activation, hidden_features, input_distances, hidden_distances

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.10.4 Exercise 03 - Build a Two-Layer Perceptron Network Manually

Part 1 - Why this matters

A manual two-layer network exposes the sequence of affine transformation, hidden activation, second affine transformation, and output decision. Shape discipline becomes more important because matrices connect groups of units.

Hard step activations are suitable for a logical construction but do not provide useful ordinary gradients. This manual model therefore demonstrates expressiveness before gradient-based learning is introduced.

Part 2 - Mathematical form

$$\mathbf{h} = H(XW_1^{\mathsf{T}} + \mathbf{b}_1), \qquad \hat{\mathbf{y}} = H(\mathbf{h}W_2^{\mathsf{T}} + \mathbf{b}_2).$$

Part 3 - Hints and Helper

Validate every matrix dimension and return pre-activations as well as hard outputs. Keep the batch dimension first.

Part 4 - Python code skeleton

```
import torch

def E03(features, weight_1, bias_1, weight_2, bias_2):
    hidden_scores = features @ weight_1.T + bias_1
    hidden = (hidden_scores >= 0).to(features.dtype)
    output_scores = hidden @ weight_2.T + bias_2
    output = (output_scores >= 0).to(features.dtype)
    return {
        "hidden_scores": hidden_scores,
        "hidden": hidden,
```

```
        "output_scores": output_scores,
        "output": output,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.10.5 Exercise 04 - Compare Single-Layer vs Multi-Layer Expressiveness

Part 1 - Why this matters

A single perceptron represents one linear half-space. Multiple hidden units can create several half-spaces whose activation patterns are combined into unions, intersections, and piecewise-defined regions.

Greater expressiveness does not guarantee successful training or generalization. Width, activation, parameter values, and optimization determine which of the available functions the model actually learns.

Part 2 - Mathematical form

$$\mathcal{H}_1 = \{H(\mathbf{w}^\mathsf{T}\mathbf{x} + b)\}, \qquad \mathcal{H}_2 = \{H(W_2 H(W_1\mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2)\}.$$

Part 3 - Hints and Helper

Evaluate both models on linearly separable and XOR datasets. Compare best error, parameter count, decision-region count, and training method.

Part 4 - Python code skeleton

```
import torch

def E04(datasets, single_layer, multi_layer):
    report = {}
    for name, (features, labels) in datasets.items():
        single_predictions = single_layer(features)
        multi_predictions = multi_layer(features)
        report[name] = {
            "single_error": ...,
            "multi_error": ...,
            "single_parameters": ...,
            "multi_parameters": ...,
        }
    return report
```

```
def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.10.6 Exercise 05 - Analyze Decision Boundaries Formed by Two-Layer Models

Part 1 - Why this matters

Each hidden unit introduces a linear boundary in input space, dividing it into activation regions. The output unit assigns classes to combinations of these regions, producing a piecewise-linear or piecewise-constant decision map.

Not every theoretical activation pattern occurs for a given set of weights. Region analysis should sample the space and identify observed patterns instead of assuming all combinations are reachable.

Part 2 - Mathematical form

$$\mathcal{R}_{\mathbf{a}} = \{\mathbf{x} : H(W_1\mathbf{x} + \mathbf{b}_1) = \mathbf{a}\}, \qquad \mathbf{a} \in \{0,1\}^h.$$

Part 3 - Hints and Helper

Evaluate a two-dimensional grid, encode each hidden pattern as an integer, and compare pattern borders with final class borders.

Part 4 - Python code skeleton

```
import torch

def E05(points, weight_1, bias_1, weight_2, bias_2):
    hidden = (points @ weight_1.T + bias_1 >= 0).to(torch.int64)
    powers = 2 ** torch.arange(hidden.shape[1])
    region_ids = (hidden * powers).sum(dim=1)
    outputs = (
        hidden.to(weight_2.dtype) @ weight_2.T + bias_2 >= 0
    ).to(torch.int64)
    return region_ids, outputs

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.10.7 Exercise 06 - Observe Emergent Non-Linearity in Hidden Representations

Part 1 - Why this matters

The affine transformations in a network remain linear, but applying a nonlinear activation between them prevents the layers from collapsing into one matrix. The hidden representation can bend, fold, or gate the original geometry.

Without a nonlinear activation, two affine layers are equivalent to one affine layer and still cannot solve XOR. This comparison isolates the source of the expressive gain.

Part 2 - Mathematical form

$$W_2(W_1\mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2 = (W_2W_1)\mathbf{x} + (W_2\mathbf{b}_1 + \mathbf{b}_2).$$

Part 3 - Hints and Helper

Run the same weights with identity and nonlinear activations. Compare XOR error and verify the collapsed affine parameters reproduce the identity case.

Part 4 - Python code skeleton

```
import torch

def E06(features, weight_1, bias_1, weight_2, bias_2):
    linear_hidden = features @ weight_1.T + bias_1
    linear_output = linear_hidden @ weight_2.T + bias_2
    collapsed_weight = weight_2 @ weight_1
    collapsed_bias = weight_2 @ bias_1 + bias_2
    collapsed_output = features @ collapsed_weight.T + collapsed_bias
    nonlinear_hidden = torch.relu(linear_hidden)
    nonlinear_output = nonlinear_hidden @ weight_2.T + bias_2
    return linear_output, collapsed_output, nonlinear_output

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.10.8 Exercise 07 - Implement Simple Two-Layer Network in PyTorch

Part 1 - Why this matters

PyTorch modules register parameters, manage devices, and build an automatic differentiation graph. A two-layer network combines two linear transformations with a nonlinear hidden activation.

The final layer should usually return logits during training. Applying sigmoid inside the model is unnecessary when a numerically stable logits-based binary loss is used.

Part 2 - Mathematical form

$$\mathbf{h} = \mathrm{ReLU}(W_1\mathbf{x} + \mathbf{b}_1), \qquad z = W_2\mathbf{h} + b_2.$$

Part 3 - Hints and Helper

Subclass torch.nn.Module, define layers in the constructor, and keep forward free of device transfers or parameter creation.

Part 4 - Python code skeleton

```
import torch

class TwoLayerNetwork(torch.nn.Module):
    def __init__(self, input_size, hidden_size):
        super().__init__()
        self.hidden = torch.nn.Linear(input_size, hidden_size)
        self.output = torch.nn.Linear(hidden_size, 1)

    def forward(self, features):
        hidden = torch.relu(self.hidden(features))
        return self.output(hidden).squeeze(-1)

def E07(input_size, hidden_size):
    model = TwoLayerNetwork(input_size, hidden_size)
    return model, sum(parameter.numel() for parameter in model.parameters())

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.10.9 Exercise 08 - Compare Manual Network vs nn.Module Implementation

Part 1 - Why this matters

A manual tensor implementation and an nn.Module implementation should agree when they use identical parameters, activation, shapes, and dtype. This parity test verifies that abstraction has not changed the mathematics.

Parameters must be copied with the correct orientation and without creating a tracked assignment operation. Comparing intermediate hidden activations locates discrepancies more precisely than final outputs alone.

Part 2 - Mathematical form

$$Z_{\text{manual}} = \phi(XW_1^\top + \mathbf{b}_1)W_2^\top + \mathbf{b}_2 = Z_{\text{module}}.$$

Part 3 - Hints and Helper

Copy weights inside `torch.no_grad()`, switch the module to evaluation mode, and compare hidden pre-activations, activations, and logits.

Part 4 - Python code skeleton

```
import torch

def E08(features, parameters, model):
    weight_1, bias_1, weight_2, bias_2 = parameters
    with torch.no_grad():
        model.hidden.weight.copy_(weight_1)
        model.hidden.bias.copy_(bias_1)
        model.output.weight.copy_(weight_2)
        model.output.bias.copy_(bias_2)
    manual_hidden = torch.relu(features @ weight_1.T + bias_1)
    manual_logits = (manual_hidden @ weight_2.T + bias_2).squeeze(-1)
    module_logits = model(features)
    outputs_close = torch.allclose(manual_logits, module_logits)
    return manual_logits, module_logits, outputs_close

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.10.10 Exercise 09 - Train Two-Layer Network Using Gradient-Based Optimization

Part 1 - Why this matters

Learning hidden features requires credit assignment from the final error back through the output and hidden layers. A differentiable activation and loss allow backpropagation to compute these parameter gradients.

The hard step used by the classical perceptron has zero derivative almost everywhere, so it is replaced by a trainable activation such as ReLU or tanh while logits feed a stable loss function.

Part 2 - Mathematical form

$$L = \text{BCEWithLogits}(z, y), \qquad \theta \leftarrow \theta - \eta \nabla_\theta L.$$

Part 3 - Hints and Helper

Use the standard order: clear gradients, forward, loss, backward, optimizer step. Record both loss and XOR accuracy.

Part 4 - Python code skeleton

```
import torch

def E09(model, features, targets, optimizer, epochs):
    criterion = torch.nn.BCEWithLogitsLoss()
    history = []
    for _ in range(epochs):
        optimizer.zero_grad()
        logits = model(features)
        loss = criterion(logits, targets.float())
        loss.backward()
        optimizer.step()
        predictions = (logits.detach() >= 0).to(targets.dtype)
        history.append({"loss": loss.item(), "accuracy": ...})
    return model, history

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.10.11 Exercise 10 - Execute Two-Layer Training on CUDA

Part 1 - Why this matters

CUDA training requires model parameters, inputs, targets, loss computation, and optimizer state to use the same device. Moving only the input leaves hidden device mismatches that interrupt the forward or update step.

A tiny XOR dataset will not demonstrate GPU speedup because launch overhead dominates. The goal is device-correct end-to-end training and CPU–GPU result comparison under controlled seeds.

Part 2 - Mathematical form

$$\theta_G^{(t+1)} = \theta_G^{(t)} - \eta \nabla_{\theta_G} L_G.$$

Part 3 - Hints and Helper

Check CUDA availability, move the model before constructing or restoring optimizer state, and synchronize around timing only.

Part 4 - Python code skeleton

```
import torch

def E10(model, features, targets, epochs):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    device = torch.device("cuda")
    model = model.to(device)
    features = features.to(device)
    targets = targets.to(device)
    optimizer = torch.optim.Adam(model.parameters(), lr=...)
    trained_model, history = E09(
        model, features, targets, optimizer, epochs
    )
    return trained_model.cpu(), history

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.10.12 Exercise 11 - Visualize Hidden Layer Activations

Part 1 - Why this matters

Hidden activation plots reveal which units respond to each input region and whether different classes receive distinct internal representations. Dead, saturated, or redundant units become visible.

For more than two hidden units, a heatmap preserves the full activation matrix better than forcing it into two axes. Any dimensionality reduction must report that it is a projection.

Part 2 - Mathematical form

$$H_{ij} = \phi(\mathbf{w}_j^{\mathsf{T}}\mathbf{x}_i + b_j).$$

Part 3 - Hints and Helper

Capture activations directly in a modified forward pass or with a temporary hook. Detach them before plotting and label samples and units.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E11(model, features):
    captured = {}
```

```
    def save_hidden(module, inputs, output):
        captured["hidden_pre_activation"] = output.detach().cpu()

    handle = model.hidden.register_forward_hook(save_hidden)
    try:
        logits = model(features)
    finally:
        handle.remove()
    hidden = torch.relu(captured["hidden_pre_activation"])
    figure, axis = plt.subplots()
    axis.imshow(hidden, aspect="auto", ...)
    return logits, hidden, figure

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.10.13 Exercise 12 - Study Gradient Flow Through Multiple Layers

Part 1 - Why this matters

Backpropagation multiplies local derivatives along paths from the loss to earlier parameters. Small derivatives can weaken gradients, while large products can amplify them and destabilize training.

Layer-wise gradient norms provide a practical view of this chain rule. Missing gradients can also indicate a detached tensor, frozen parameter, in-place graph damage, or inactive units.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial W_1} = \frac{\partial L}{\partial z_2}\frac{\partial z_2}{\partial \mathbf{h}}\frac{\partial \mathbf{h}}{\partial z_1}\frac{\partial z_1}{\partial W_1}.$$

Part 3 - Hints and Helper

Run one backward pass and record parameter and gradient norms by layer. Treat None gradients separately from zero gradients.

Part 4 - Python code skeleton

```
import torch

def E12(model, features, targets):
    model.zero_grad(set_to_none=True)
    logits = model(features)
    loss = torch.nn.functional.binary_cross_entropy_with_logits(
```

```
        logits, targets.float()
    )
    loss.backward()
    report = {}
    for name, parameter in model.named_parameters():
        report[name] = {
            "parameter_norm": parameter.detach().norm().item(),
            "gradient_norm": (
                None
                if parameter.grad is None
                else parameter.grad.norm().item()
            ),
        }
    return loss.item(), report

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.10.14 Exercise 13 - Analyze Training Stability in Multi-Layer Networks

Part 1 - Why this matters

Multi-layer optimization can oscillate, diverge, plateau, or become highly seed-dependent. Learning rate, initialization, activation choice, feature scale, batch order, and optimizer interact more strongly than in a single perceptron.

Stability analysis combines loss, accuracy, gradient norms, parameter norms, activation statistics, and finiteness. One decreasing loss curve is insufficient evidence of a reliable configuration.

Part 2 - Mathematical form

$$S_t = \{L_t, A_t, \|\nabla\theta_t\|_2, \|\theta_t\|_2, \text{finite}(\theta_t)\}.$$

Part 3 - Hints and Helper

Repeat training over seeds and learning rates. Stop safely on non-finite values and retain the last valid checkpoint for diagnosis.

Part 4 - Python code skeleton

```
import torch

def E13(run_training, seeds, learning_rates):
    results = []
```

```
    for seed in seeds:
        for learning_rate in learning_rates:
            torch.manual_seed(seed)
            history = run_training(learning_rate, ...)
            results.append({
                "seed": seed,
                "learning_rate": learning_rate,
                "history": history,
                "finite": ...,
                "converged": ...,
            })
    return results

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.10.15 Exercise 14 - Compare Perceptron Training to Backpropagation

Part 1 - Why this matters

Classical perceptron training applies a local correction to one linear unit after a mistake. Backpropagation propagates a differentiable loss through a graph and assigns gradients to every parameter that influenced the output.

The comparison should preserve the distinction between architecture and learning algorithm. A network may contain perceptron-like affine units while being trained by backpropagation rather than the classical rule.

Part 2 - Mathematical form

$$\Delta \mathbf{w}_P = \eta y \mathbf{x} \mathbb{I}[yz \leq 0], \qquad \Delta \theta_{BP} = -\eta \nabla_\theta L.$$

Part 3 - Hints and Helper

Compare required derivatives, affected parameters, batch behavior, hidden credit assignment, memory, and ability to train an XOR solution.

Part 4 - Python code skeleton

```
import torch

def E14(perceptron_step, network_step, batch):
    perceptron_before, perceptron_after = perceptron_step(batch, ...)
    network_before, network_after, gradients = network_step(batch, ...)
    return {
```

```
        "perceptron_changed": changed_parameters(
            perceptron_before, perceptron_after
        ),
        "network_changed": changed_parameters(network_before, network_after),
        "network_gradient_paths": ...,
        "xor_result": ...,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.10.16 Exercise 15 - Identify Failure Modes in Shallow Neural Networks

Part 1 - Why this matters

A shallow network can fail through insufficient hidden width, unsuitable activation, dead ReLU units, saturated sigmoids, poor initialization, unstable gradients, bad scaling, overfitting, or an inappropriate loss.

These failures can share the same symptom of low accuracy. Diagnosis must inspect activations, gradients, train–validation behavior, parameter changes, and data assumptions before selecting a remedy.

Part 2 - Mathematical form

$$F = \{\text{capacity}, \text{activation}, \text{initialization}, \text{gradient}, \text{optimization}, \text{data}, \text{generalization}\}.$$

Part 3 - Hints and Helper

Run diagnostic checks in a fixed order and connect every proposed cause to measured evidence. Avoid declaring dead units from one zero activation alone.

Part 4 - Python code skeleton

```
import torch

def E15(model, activations, gradients, history):
    diagnostics = {
        "dead_unit_rates": (activations == 0).float().mean(dim=0),
        "gradient_norms": gradients,
        "loss_plateau": ...,
        "train_validation_gap": ...,
        "finite_parameters": all(
            torch.isfinite(parameter).all()
```

```
            for parameter in model.parameters()
        ),
    }
    causes = infer_failure_causes(diagnostics, ...)
    return diagnostics, causes

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.10.17 Exercise 16 - Evaluate Expressive Power Gain with Additional Layers

Part 1 - Why this matters

Additional layers compose learned transformations and can represent complex decision regions with reusable intermediate features. Depth may express some functions more compactly than a much wider shallow network.

More layers do not automatically improve results. Optimization difficulty, data volume, regularization, and architecture choice determine whether theoretical capacity becomes useful performance.

Part 2 - Mathematical form

$$f_L(\mathbf{x}) = W_L\phi(W_{L-1}\phi(\cdots\phi(W_1\mathbf{x}+\mathbf{b}_1)\cdots)+\mathbf{b}_{L-1})+\mathbf{b}_L.$$

Part 3 - Hints and Helper

Compare architectures under matched parameter budgets where possible. Report train fit, test behavior, region complexity, runtime, and gradient stability.

Part 4 - Python code skeleton

```
import torch

def E16(architectures, train_data, test_data, seeds):
    report = []
    for name, build_model in architectures.items():
        for seed in seeds:
            torch.manual_seed(seed)
            model = build_model()
            history = train_model(model, train_data, ...)
            report.append({
                "architecture": name,
                "parameters": sum(p.numel() for p in model.parameters()),
                "train_metrics": ...,
```

```
                "test_metrics": ...,
                "history": history,
            })
    return report

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.10.18 Exercise 17 - Bridge Conceptual Gap Between Perceptron and MLP

Part 1 - Why this matters

An MLP preserves the perceptron's affine score as a basic building block, then repeats it across many units and layers with nonlinear activations. The key transition is from one fixed representation to learned hidden representations.

The learning rule also changes. Hard local corrections give way to a scalar loss, differentiable computation graph, chain rule, and optimizer that coordinate all parameters.

Part 2 - Mathematical form

$$\begin{aligned} \text{perceptron} \subset\ & \text{affine unit}, \\ \text{MLP} = & \text{ stacked affine units} \\ & + \text{nonlinear activations} + \text{backpropagation}. \end{aligned}$$

Part 3 - Hints and Helper

Create an explicit mapping between perceptron concepts and MLP concepts: score, activation, parameters, error signal, update, representation, and evaluation.

Part 4 - Python code skeleton

```
import torch

def E17():
    return {
        "linear_score": ("w^T x + b", "W x + b per layer"),
        "activation": ("hard step", "differentiable non-linearity"),
        "representation": ("input features", "learned hidden features"),
        "error_signal": ("misclassification", "scalar differentiable loss"),
        "update": ("local perceptron rule", "backpropagation + optimizer"),
        "capacity": ("one half-space", "composed decision regions"),
    }

def main():
```

```
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.10.19 Exercise 18 - Stress Test Multi-Layer Perceptron with Complex Data

Part 1 - Why this matters

Complex nonlinear data tests whether hidden layers learn useful representations beyond XOR. Increasing samples, dimensions, class overlap, noise, and hidden width reveals capacity and computational limits.

A stress test must preserve evaluation quality while measuring throughput and memory. Success on training data alone may indicate memorization rather than a meaningful representation.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{n \times d}, \qquad h \text{ hidden units}, \qquad \text{parameter scale} = \mathcal{O}(dh + h).$$

Part 3 - Hints and Helper

Generate controlled train and test sets, sweep hidden width, and monitor loss, accuracy, gradient norms, peak memory, and runtime on the target device.

Part 4 - Python code skeleton

```
import torch

def E18(configurations, dataset_factory, device):
    results = []
    for configuration in configurations:
        train_data, test_data = dataset_factory(configuration, ...)
        model = build_network(configuration).to(device)
        history, performance = train_and_profile(
            model, train_data, device, ...
        )
        results.append({
            "configuration": configuration,
            "history": history,
            "test_metrics": evaluate(model, test_data, device),
            "performance": performance,
        })
    return results

def main():
    print(E18(...))
```

```
if __name__ == "__main__":
    main()
```

12.10.20 Exercise 19 - Produce a Final Transition Report Toward Neural Networks

Part 1 - Why this matters

The final report should explain how the perceptron's limitation motivates hidden units, how nonlinear representations solve XOR, and why differentiable activations and backpropagation are needed to learn those representations.

It must distinguish manually constructed logical networks from trainable MLPs and connect expressiveness to optimization, stability, generalization, and computational cost. The report becomes the bridge to the next neural-network book.

Part 2 - Mathematical form

$$R = \{\text{XOR proof}, \text{hidden features}, \text{depth}, \text{activation},\\ \text{loss}, \text{backpropagation}, \text{stability},\\ \text{limits}, \text{next steps}\}.$$

Part 3 - Hints and Helper

Require equations, code evidence, activation views, gradient diagnostics, and train–test results. Mark unsupported conclusions and unresolved failure modes.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
        "xor_limit", "manual_xor", "hidden_representation",
        "two_layer_architecture", "nonlinearity", "pytorch_module",
        "gradient_training", "gradient_flow", "stability",
        "expressiveness", "failure_modes", "generalization",
        "computational_cost", "next_steps",
    }
    missing = sorted(required - sections.keys())
    unresolved = sections.get("failure_modes", {}).get("unresolved", [])
    return {
        "complete": not missing and not unresolved,
        "missing": missing,
        "unresolved": unresolved,
        "sections": sections,
    }
```

```
def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

Book 13

MLP (Feed-Forward Network)

13.1 Introduction

13.1.1 What will the book teach you

This book marks the transition from studying individual linear models to engineering complete neural networks. In the previous books, the reader learned how tensors, gradients, loss functions, optimizers, training loops, linear regression, logistic regression, and the perceptron work as separate ideas. The Multi-Layer Perceptron brings these ideas together inside one trainable system. Instead of using a single decision boundary, an MLP composes multiple affine transformations with non-linear activation functions, allowing the model to learn intermediate representations and approximate relationships that cannot be captured by one linear transformation.

The reader will begin by understanding why stacking linear layers without an activation function does not create a more expressive model. Two consecutive linear transformations can always be reduced to one linear transformation. Non-linearity is therefore not an optional decoration between layers; it is the mechanism that prevents the network from collapsing into a single linear model. The exercises will require the reader to inspect hidden activations, follow the dimensions through every layer, and explain what information each transformation creates, preserves, suppresses, or loses.

The book then moves from mathematical composition to architecture design. The reader will build configurable networks with different depths and widths, register parameters correctly with `nn.Module`, count trainable parameters, capture intermediate outputs with hooks, and compare shallow and deep architectures under controlled conditions. The purpose is not to build the largest possible network, but to learn how architectural decisions affect capacity, computation, memory, optimization difficulty, and generalization. A network should never be described only by the number of layers; its input and output dimensions, hidden widths, activation functions, parameter count, and data requirements must all be understood together.

Activation functions receive dedicated attention because they determine how signals and gradients move through the network. The reader will implement and compare ReLU, LeakyReLU, sigmoid, tanh, GELU, and other useful transformations, then observe saturation, dying units, activation distributions, and numerical behavior under different precisions. These experiments will show that choosing an activation is not merely selecting a familiar function. The choice

interacts with initialization, depth, input scale, gradient flow, hardware performance, and the type of representation the model can learn.

Backpropagation will be studied as the central learning mechanism of the MLP. The reader will trace gradients through several layers, verify the chain rule manually, inspect parameter gradients, use hooks to locate broken paths, and diagnose vanishing or exploding gradients. Automatic differentiation will be used as a tool, but it will not be treated as an invisible process. The reader must understand which tensors belong to the computational graph, how the final loss influences early layers, why gradients accumulate, and how an apparently small coding decision can prevent an entire section of the network from learning.

Weight initialization connects architecture to training stability. The book will demonstrate why setting all hidden weights to zero creates a symmetry failure, why arbitrary scales can destroy activation and gradient statistics, and how Xavier and He initialization are derived from signal-preservation requirements. The reader will measure activation variance and gradient variance across depth instead of accepting an initializer only because it is commonly used. Initialization will also be tested with different activation functions, floating-point formats, random seeds, and very deep architectures.

Optimization is approached as a dynamic process rather than a function call. The reader will implement and compare SGD, momentum, Adam, and AdamW, investigate learning-rate schedules, gradient clipping, weight decay, batch-size effects, and gradient accumulation, and identify silent failures such as forgetting to clear gradients or applying operations in the wrong order. Every optimizer experiment will connect parameter changes to loss behavior, gradient norms, convergence speed, memory cost, and stability. Faster initial loss reduction will not automatically be interpreted as a better final model.

The complete training pipeline will then be assembled. The reader will build correct classification and regression loops, separate training and evaluation modes, calculate metrics over complete datasets, create validation loops, add early stopping, save checkpoints, resume optimizer and scheduler state, and record structured experiment logs. The exercises will also include deliberate failure cases: good loss with bad accuracy, NaN loss, incorrect label encoding, wrong output shapes, data-device mismatch, silent overflow, and checkpoints that resume with unexpected drift. Debugging these failures is a core learning goal, not an optional appendix.

Generalization will be studied through the gap between fitting the training data and performing reliably on unseen data. The reader will experiment with weight decay, explicit L2 penalties, dropout, early stopping, data augmentation, feature normalization, model capacity, label noise, cross-validation, and model ensembling. Train and validation behavior will be interpreted together so that underfitting, overfitting, optimization failure, and distribution shift are not confused with one another. Regularization will be evaluated as a trade-off with measurable effects rather than as a collection of settings that should always be enabled.

Finally, the book moves from a correct experiment to an engineering-ready system. The reader will profile training, study the DataLoader pipeline, use pinned memory, gradient accumulation, mixed precision, and CUDA carefully, measure latency and throughput, detect memory growth, rotate checkpoints, test failure recovery, and validate exported or compiled

models against a trusted reference. Production readiness will include input validation, deterministic controls, experiment tracking, regression tests, monitoring expectations, and a clear record of remaining sources of non-determinism. The goal is not merely to train an MLP once, but to build one that can be explained, reproduced, debugged, scaled, evaluated, saved, restored, and trusted within defined limits.

13.1.2 Why this book comes after the Perceptron

The perceptron introduced the essential idea of a trainable decision unit: an input is multiplied by weights, combined with a bias, and converted into a decision. It also exposed a fundamental limitation. A single perceptron can represent only one linear separation and therefore cannot solve problems such as XOR. Combining units into layers creates new feature spaces in which these problems may become separable, but architecture alone is not enough. The hard step function used by the classical perceptron does not provide the useful derivatives required to coordinate the learning of many hidden units.

An MLP resolves this limitation by combining differentiable non-linear activations with backpropagation. The output error is transformed into gradients for the final layer and then propagated backward through every earlier layer. This turns hidden units from manually configured logical components into learned feature transformers. The transition from perceptron to MLP is therefore not simply an increase in layer count. It is a change in representation, optimization, credit assignment, computational cost, and the types of failure that must be diagnosed.

13.1.3 How to study this book

Each exercise should be treated as an experiment with a claim that must be verified. Before writing code, identify the tensor shapes, mathematical operation, expected output, and failure condition. After writing the code, inspect intermediate activations, gradients, parameter changes, devices, dtypes, and memory behavior rather than checking only the final prediction. When an exercise compares two configurations, keep the dataset, random seed, evaluation procedure, and computational budget controlled so that the comparison has a clear meaning.

The reader should resist the temptation to hide the training process behind large abstractions too early. PyTorch modules and optimizers will be used, but manual calculations and explicit tensor operations remain necessary for verification. A successful result should be reproducible and explainable: the reader must know why the shapes are valid, why gradients reach every intended parameter, why the chosen loss matches the task, why the model generalizes, and which limitations remain after training.

13.1.4 The Chapters (MLP00 - MLP08) included in this book

- MLP00 - Conceptual Foundation of MLP
- MLP01 - Architecture Design and Layer Composition
- MLP02 - Activation Functions and Non-Linearity
- MLP03 - Backpropagation Mechanics in MLP

- MLP04 - Weight Initialization and Training Stability
- MLP05 - Optimizers and Learning Rate Dynamics
- MLP06 - Loss Functions, Training Loop, and Logging
- MLP07 - Regularization, Dropout, and Generalization
- MLP08 - Scaling, Profiling, and Production Readiness

13.2 MLP00 - Conceptual Foundation of MLP

Models and Training

13.2.1 Exercise 00 - Understand Why Single Perceptron Is Insufficient for Complex Functions

Part 1 - Why this matters

A single perceptron creates one affine score and one linear decision boundary. It can separate two classes only when one half-space is sufficient, so patterns such as XOR and curved class regions remain outside its representational capacity.

This is a limitation of the hypothesis class rather than insufficient training. More epochs, a different optimizer, or a GPU cannot make one linear boundary represent a fundamentally non-linear relationship.

Part 2 - Mathematical form

$$\hat{y} = H(\mathbf{w}^\mathsf{T}\mathbf{x} + b), \qquad \mathcal{B} = \{\mathbf{x} : \mathbf{w}^\mathsf{T}\mathbf{x} + b = 0\}.$$

Part 3 - Hints and Helper

Compare a linearly separable dataset with XOR. Record the best error and identify whether failure comes from representation or optimization.

Part 4 - Python code skeleton

```
import torch

def E00(datasets, train_perceptron):
    report = {}
    for name, (features, labels) in datasets.items():
        model, history = train_perceptron(features, labels, ...)
        predictions = model(features)
        report[name] = {
            "best_errors": ...,
            "final_accuracy": ...,
            "converged": ...,
            "history": history,
```

```
        }
    return report

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

13.2.2 Exercise 01 - Define Feed-Forward Network as Layered Function Composition

Part 1 - Why this matters

A feed-forward network applies an ordered sequence of functions in which information moves from the input toward the output without recurrent feedback. Each layer receives the representation produced by the previous layer.

Writing the model as a composition makes depth explicit and prepares the reader for backpropagation, where the chain rule follows the same sequence in reverse.

Part 2 - Mathematical form

$$f(\mathbf{x}) = f_L \circ f_{L-1} \circ \cdots \circ f_1(\mathbf{x}), \qquad f_l(\mathbf{h}_{l-1}) = \phi_l(W_l \mathbf{h}_{l-1} + \mathbf{b}_l).$$

Part 3 - Hints and Helper

Store activations in order and verify that every layer consumes the previous output. Keep the batch dimension unchanged.

Part 4 - Python code skeleton

```
import torch

def E01(features, layers, activations):
    hidden = features
    trace = [hidden]
    for index, (weight, bias) in enumerate(layers):
        hidden = hidden @ weight.T + bias
        hidden = activations[index](hidden)
        trace.append(hidden)
    return hidden, trace

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

13.2.3 Exercise 02 - Interpret Hidden Layers as Learned Feature Transformers

Part 1 - Why this matters

Hidden layers convert raw inputs into intermediate representations that can make the final task easier. Their units are not fixed semantic concepts; their meaning arises from parameters learned jointly for the objective.

A useful representation can separate classes, suppress irrelevant variation, or combine simple patterns into higher-level features. Interpretation requires inspecting activation behavior rather than assigning names from weight values alone.

Part 2 - Mathematical form

$$\mathbf{h}_l = \phi_l(W_l \mathbf{h}_{l-1} + \mathbf{b}_l), \qquad \mathbf{h}_0 = \mathbf{x}.$$

Part 3 - Hints and Helper

Compare distances and class separation in input and hidden spaces. Inspect unit activation distributions over meaningful sample groups.

Part 4 - Python code skeleton

```
import torch

def E02(model, features, labels):
    representations = model.forward_with_activations(features)
    analysis = []
    for layer_index, hidden in enumerate(representations):
        analysis.append({
            "layer": layer_index,
            "shape": tuple(hidden.shape),
            "mean": hidden.mean(dim=0),
            "standard_deviation": hidden.std(dim=0),
            "class_separation": ...,
        })
    return analysis

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

13.2.4 Exercise 03 - Compare Linear Model Output vs Multi-Layer Non-Linear Output

Part 1 - Why this matters

A linear model maps inputs through one affine transformation, while an MLP inserts non-linear transformations between affine layers. This prevents the complete mapping from collapsing into one matrix.

The comparison must hold the dataset and output convention fixed. A larger parameter count alone is not the source of non-linearity; removing every activation makes the deep model affine again.

Part 2 - Mathematical form

$$f_{\text{linear}}(X) = XW^{\mathsf{T}} + \mathbf{b}, \qquad f_{\text{MLP}}(X) = W_2\phi(W_1X + \mathbf{b}_1) + \mathbf{b}_2.$$

Part 3 - Hints and Helper

Evaluate both models on linear and non-linear targets. Also replace the hidden activation with identity and verify the network collapses to a linear mapping.

Part 4 - Python code skeleton

```
import torch

def E03(features, linear_model, mlp_model, identity_mlp):
    linear_output = linear_model(features)
    nonlinear_output = mlp_model(features)
    identity_output = identity_mlp(features)
    return {
        "linear": linear_output,
        "nonlinear": nonlinear_output,
        "identity_mlp": identity_output,
        "nonlinear_difference": ...,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

13.2.5 Exercise 04 - Visualize Information Flow Through Multiple Layers

Part 1 - Why this matters

Information flow can be represented as a sequence of tensor shapes, affine scores, activations, and output logits. This trace reveals where dimensionality changes and where information is compressed or expanded.

A diagram should reflect the actual forward pass rather than a generic architecture sketch. Batch size, feature width, activation, and device should be captured from real tensors.

Part 2 - Mathematical form

$$X^{(B\times d_0)} \to H_1^{(B\times d_1)} \to \cdots \to H_L^{(B\times d_L)}.$$

Part 3 - Hints and Helper

Collect one summary per layer and draw nodes connected in execution order. Avoid storing gradient-connected tensors solely for visualization.

Part 4 - Python code skeleton

```
import torch

def E04(model, features):
    trace = []
    hidden = features
    trace.append({"name": "input", "shape": tuple(hidden.shape)})
    for name, layer in model.named_children():
        hidden = layer(hidden)
        trace.append({
            "name": name,
            "shape": tuple(hidden.shape),
            "minimum": hidden.detach().min().item(),
            "maximum": hidden.detach().max().item(),
        })
    return trace, build_flow_visualization(trace, ...)

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

13.2.6 Exercise 05 - Implement a Two-Layer Network Using Pure Tensor Operations

Part 1 - Why this matters

A pure tensor implementation exposes the exact operations behind a two-layer MLP: first affine transformation, hidden activation, and output affine transformation. No module abstraction hides parameter orientation or broadcasting.

This implementation becomes a reference for later nn.Module code. It should validate dimensions and return intermediate tensors so each operation can be tested independently.

Part 2 - Mathematical form

$$H = \phi(XW_1^\mathsf{T} + \mathbf{b}_1), \qquad Z = HW_2^\mathsf{T} + \mathbf{b}_2.$$

Part 3 - Hints and Helper

Use matrix multiplication rather than loops. Keep output as logits and apply task-specific probabilities outside this function.

Part 4 - Python code skeleton

```
import torch

def E05(features, weight_1, bias_1, weight_2, bias_2):
    if features.shape[1] != weight_1.shape[1]:
        raise ValueError(...)
    hidden_scores = features @ weight_1.T + bias_1
    hidden = torch.relu(hidden_scores)
    logits = hidden @ weight_2.T + bias_2
    return hidden_scores, hidden, logits

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

13.2.7 Exercise 06 - Translate Mathematical MLP Formulation into PyTorch Code

Part 1 - Why this matters

Translating equations into PyTorch requires a consistent convention for batches, layer widths, and matrix orientation. Mathematical column-vector notation often becomes batch-first matrix multiplication in code.

A correct translation preserves both values and dimensions. The reader should be able to connect every code statement to one equation term and explain each broadcasted bias.

Part 2 - Mathematical form

$$Z_l = H_{l-1} W_l^{\mathsf{T}} + \mathbf{b}_l, \qquad H_l = \phi_l(Z_l).$$

Part 3 - Hints and Helper

Write the tensor shape beside every variable before coding. Compare a manual result with nn.Linear initialized from the same parameters.

Part 4 - Python code skeleton

```
import torch

def E06(features, weights, biases, activations):
    hidden = features
```

```
    states = []
    for weight, bias, activation in zip(weights, biases, activations):
        pre_activation = torch.matmul(hidden, weight.T) + bias
        hidden = activation(pre_activation)
        states.append((pre_activation, hidden))
    return hidden, states

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

13.2.8 Exercise 07 - Analyze the Role of Non-Linearity Between Linear Layers

Part 1 - Why this matters

Without a non-linear activation, several affine layers are algebraically equivalent to one affine transformation. Depth alone therefore cannot produce curved or disconnected decision regions.

Non-linearity changes which input-dependent patterns survive into the next layer. Different activation functions also alter gradient flow, sparsity, smoothness, and numerical behavior.

Part 2 - Mathematical form

$$W_2(W_1\mathbf{x} + \mathbf{b}_1) + \mathbf{b}_2 = (W_2W_1)\mathbf{x} + (W_2\mathbf{b}_1 + \mathbf{b}_2).$$

Part 3 - Hints and Helper

Verify equality between stacked affine layers and collapsed parameters. Insert ReLU and show that one global affine map no longer reproduces the result.

Part 4 - Python code skeleton

```
import torch

def E07(features, weight_1, bias_1, weight_2, bias_2):
    stacked_linear = (features @ weight_1.T + bias_1) @ weight_2.T + bias_2
    collapsed_weight = weight_2 @ weight_1
    collapsed_bias = bias_1 @ weight_2.T + bias_2
    collapsed = features @ collapsed_weight.T + collapsed_bias
    hidden = torch.relu(features @ weight_1.T + bias_1)
    nonlinear = hidden @ weight_2.T + bias_2
    outputs_close = torch.allclose(stacked_linear, collapsed)
    return stacked_linear, collapsed, nonlinear, outputs_close

def main():
```

```
    print(E07(...))

if __name__ == "__main__":
    main()
```

13.2.9 Exercise 08 - Verify Dimensional Consistency Across All Layers

Part 1 - Why this matters

Every layer requires its input width to match the previous layer's output width. Dimensional consistency is a structural condition that can be checked before parameters are initialized or data are processed.

Batch size is not part of the layer configuration and should remain flexible. Confusing batch width with feature width creates designs that work for one test tensor and fail on real data.

Part 2 - Mathematical form

$$W_l \in \mathbb{R}^{d_l \times d_{l-1}}, \quad \mathbf{b}_l \in \mathbb{R}^{d_l}, \quad H_l \in \mathbb{R}^{B \times d_l}.$$

Part 3 - Hints and Helper

Validate every adjacent pair and report the exact layer index on failure. Test several batch sizes after the architecture passes static checks.

Part 4 - Python code skeleton

```
import torch

def E08(layer_sizes, weights, biases):
    if len(weights) != len(layer_sizes) - 1:
        raise ValueError(...)
    checks = []
    paired_parameters = zip(weights, biases)
    for layer_index, (weight, bias) in enumerate(
        paired_parameters, start=1
    ):
        expected = (layer_sizes[layer_index], layer_sizes[layer_index - 1])
        checks.append({
            "layer": layer_index,
            "expected_weight": expected,
            "actual_weight": tuple(weight.shape),
            "bias_valid": tuple(bias.shape) == (layer_sizes[layer_index],),
            "valid": ...,
        })
    return checks

def main():
```

```
    print(E08(...))

if __name__ == "__main__":
    main()
```

13.2.10 Exercise 09 - Identify Common Conceptual Misunderstandings About Hidden Layers

Part 1 - Why this matters

Hidden units are neither automatically interpretable concepts nor independent miniature models. They are jointly optimized coordinates whose usefulness depends on downstream layers, activation functions, data, and loss.

More hidden units or layers do not guarantee better learning. Capacity, optimization, regularization, signal propagation, and dataset size interact, so architecture claims require controlled evidence.

Part 2 - Mathematical form

$$\text{hidden representation} \neq \text{guaranteed semantic feature},$$
$$\text{greater capacity} \neq \text{better generalization}.$$

Part 3 - Hints and Helper

Turn each misconception into a falsifiable experiment. Record the claim, counterexample, measurement, and corrected interpretation.

Part 4 - Python code skeleton

```
import torch

def E09(experiments):
    corrections = []
    for experiment in experiments:
        evidence = experiment["run"]()
        corrections.append({
            "misconception": experiment["claim"],
            "evidence": evidence,
            "supported": experiment["test"](evidence),
            "corrected_interpretation": ...,
        })
    return corrections

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

13.2.11 Exercise 10 - Execute Forward Pass of MLP on CUDA Device

Part 1 - Why this matters

A CUDA forward pass requires inputs, parameters, buffers, and temporary operations to use the same device. A model copied to CUDA does not automatically move a CPU input batch.

Device correctness should be verified independently from speed. Small MLPs may run slower on a GPU because transfer and launch overhead exceed the computation.

Part 2 - Mathematical form

$$H_l^G = \phi_l(H_{l-1}^G {W_l^G}^{\mathsf{T}} + \mathbf{b}_l^G).$$

Part 3 - Hints and Helper

Check availability, move the model and input once, disable gradient tracking for inference, and return only required reporting tensors to CPU.

Part 4 - Python code skeleton

```
import torch

def E10(model, features):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    device = torch.device("cuda")
    model = model.to(device)
    features = features.to(device)
    model.eval()
    with torch.inference_mode():
        output = model(features)
    return output.cpu(), next(model.parameters()).device

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

13.2.12 Exercise 11 - Compare CPU vs GPU Forward Execution Outputs

Part 1 - Why this matters

Equivalent CPU and GPU forward passes should produce numerically close outputs when model state, input values, dtype, and evaluation mode match. Exact bitwise equality is not always expected.

Comparing only predicted classes can hide score drift. Layer-wise activations and final logits reveal where numerical differences first appear.

Part 2 - Mathematical form

$$\delta_l = \|H_l^C - H_l^G\|_\infty, \qquad \text{close}_l = \mathbb{I}[\delta_l \le \text{atol} + \text{rtol}|H_l^C|].$$

Part 3 - Hints and Helper

Deep-copy one model state to both devices and use identical inputs. Compare outputs with documented tolerances and count prediction disagreement separately.

Part 4 - Python code skeleton

```
import torch

def E11(cpu_model, gpu_model, features, atol, rtol):
    cpu_model.eval()
    gpu_model.load_state_dict(cpu_model.state_dict())
    gpu_model = gpu_model.cuda().eval()
    with torch.inference_mode():
        cpu_output = cpu_model(features)
        gpu_output = gpu_model(features.cuda()).cpu()
    return {
        "close": torch.allclose(cpu_output, gpu_output, atol=atol, rtol=rtol),
        "maximum_difference": (cpu_output - gpu_output).abs().max().item(),
        "cpu_output": cpu_output,
        "gpu_output": gpu_output,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

13.2.13 Exercise 12 - Inspect Intermediate Activations at Each Hidden Layer

Part 1 - Why this matters

Intermediate activations show how the representation evolves through depth. Their ranges, means, variances, sparsity, and finiteness can expose saturation, dead units, scale explosion, or information collapse.

Inspection should not retain computational graphs across many batches. Detached summaries are usually safer than saving every complete activation tensor.

Part 2 - Mathematical form

$$A_l = \{\mu(H_l), \sigma(H_l), \min(H_l), \max(H_l), \Pr(H_l = 0), \text{finite}(H_l)\}.$$

Part 3 - Hints and Helper

Use temporary forward hooks and remove them after the pass. Label summaries by module name and execution order.

Part 4 - Python code skeleton

```
import torch

def E12(model, features):
    summaries = {}
    handles = []

    def capture(name):
        def hook(module, inputs, output):
            value = output.detach()
            summaries[name] = {
                "shape": tuple(value.shape),
                "mean": value.mean().item(),
                "std": value.std().item(),
                "zero_rate": (value == 0).float().mean().item(),
                "finite": torch.isfinite(value).all().item(),
            }
        return hook

    for name, module in model.named_modules():
        if should_capture(module):
            handles.append(module.register_forward_hook(capture(name)))
    try:
        output = model(features)
    finally:
        for handle in handles:
            handle.remove()
    return output, summaries

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

13.2.14 Exercise 13 - Analyze the Effect of Depth on Representational Power

Part 1 - Why this matters

Depth composes transformations so later layers can reuse features created earlier. Some complex functions can be represented more efficiently by deep compositions than by one extremely wide layer.

Representational possibility is not the same as trainability. Deeper networks can suffer unstable signals, difficult optimization, higher latency, and overfitting if architecture and data are not matched.

Part 2 - Mathematical form

$$f_L = f_L \circ f_{L-1} \circ \cdots \circ f_1, \qquad \text{capacity generally grows with depth and width.}$$

Part 3 - Hints and Helper

Compare architectures under similar parameter budgets. Measure train fit, validation behavior, activation health, gradient flow, runtime, and memory.

Part 4 - Python code skeleton

```
import torch

def E13(architectures, dataset, seeds):
    results = []
    for name, build_model in architectures.items():
        for seed in seeds:
            torch.manual_seed(seed)
            model = build_model()
            history = train_model(model, dataset, ...)
            results.append({
                "architecture": name,
                "depth": count_linear_layers(model),
                "parameters": sum(p.numel() for p in model.parameters()),
                "history": history,
                "validation_metric": ...,
            })
    return results

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

13.2.15 Exercise 14 - Implement Forward Pass Without Using nn.Module

Part 1 - Why this matters

A function-based forward pass separates the mathematics of inference from PyTorch's module system. It demonstrates that an MLP is fundamentally a sequence of tensor operations over parameter collections.

Without nn.Module, parameters are not registered automatically, device movement is manual, and state serialization requires an explicit structure. These limitations explain the value of the abstraction.

Part 2 - Mathematical form

$$H_0 = X, \qquad H_l = \phi_l(H_{l-1}W_l^{\mathsf{T}} + \mathbf{b}_l), \quad l = 1, \ldots, L.$$

Part 3 - Hints and Helper

Store weights, biases, and activations in aligned lists. Validate their lengths and avoid creating parameters inside the forward function.

Part 4 - Python code skeleton

```
import torch

def E14(features, parameters, activations):
    weights = parameters["weights"]
    biases = parameters["biases"]
    if not (len(weights) == len(biases) == len(activations)):
        raise ValueError(...)
    hidden = features
    for weight, bias, activation in zip(weights, biases, activations):
        hidden = activation(hidden @ weight.T + bias)
    return hidden

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

13.2.16 Exercise 15 - Debug Shape Errors in Multi-Layer Tensor Computations

Part 1 - Why this matters

Shape errors can originate several layers before the operation that finally fails. A wrong width, transposed matrix, lost batch dimension, or unintended broadcast may propagate until a later matrix multiplication.

A useful debugger reports expected and actual shapes at every boundary. It should detect semantically wrong broadcasting even when PyTorch accepts the operation.

Part 2 - Mathematical form

$$H_{l-1}^{(B\times d_{l-1})} W_l^{\mathsf{T}^{(d_{l-1}\times d_l)}} = Z_l^{(B\times d_l)}.$$

Part 3 - Hints and Helper

Trace shapes before each operation and raise an error containing the layer index. Test one sample with an explicit batch dimension rather than squeezing it away.

Part 4 - Python code skeleton

```
import torch

def E15(features, weights, biases):
    hidden = features
    trace = []
    for layer_index, (weight, bias) in enumerate(zip(weights, biases)):
        expected_width = weight.shape[1]
        trace.append({
            "layer": layer_index,
            "input": tuple(hidden.shape),
            "weight": tuple(weight.shape),
            "bias": tuple(bias.shape),
        })
        if hidden.ndim != 2 or hidden.shape[1] != expected_width:
            raise ValueError(...)
        if bias.shape != (weight.shape[0],):
            raise ValueError(...)
        hidden = torch.relu(hidden @ weight.T + bias)
    return hidden, trace

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

13.2.17 Exercise 16 - Stress Test Forward Pass with Large Batch Sizes

Part 1 - Why this matters

Large batches test throughput, peak memory, numerical finiteness, and the ability of the architecture to process realistic workloads. Activation memory can exceed parameter memory by a large factor.

A stress test should increase load gradually and retain the last successful configuration. Out-of-memory behavior is part of the result and must be handled safely.

Part 2 - Mathematical form

$$M_{\text{activations}} \approx qB \sum_{l=1}^{L} d_l \text{ bytes.}$$

Part 3 - Hints and Helper

Use inference mode when testing forward-only memory, synchronize CUDA around timing, and report batch size, latency, throughput, and peak memory.

Part 4 - Python code skeleton

```
import torch

def E16(model, batch_sizes, input_size, device):
    results = []
    model = model.to(device).eval()
    for batch_size in batch_sizes:
        try:
            features = torch.randn(batch_size, input_size, device=device)
            output, latency, peak_memory = benchmark_forward(
                model, features, ...
            )
            results.append({
                "batch_size": batch_size,
                "latency": latency,
                "throughput": batch_size / latency,
                "peak_memory": peak_memory,
                "finite": torch.isfinite(output).all().item(),
            })
        except torch.OutOfMemoryError:
            results.append({"batch_size": batch_size, "status": "oom"})
            break
    return results

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

13.2.18 Exercise 17 - Validate Determinism of Forward Pass Under Fixed Seeds

Part 1 - Why this matters

A fixed model state and identical input should normally produce repeatable deterministic forward outputs when the selected operations are deterministic. Random initialization and

stochastic layers must be controlled separately.

Dropout behaves randomly in training mode even under a fixed initial seed if repeated calls advance the random state. Evaluation mode disables it and changes the meaning of the determinism test.

Part 2 - Mathematical form

$$f_{\theta,s}(X) = f_{\theta,s}(X) \text{ for repeated deterministic evaluation under fixed state.}$$

Part 3 - Hints and Helper

Seed all relevant generators, enable deterministic algorithms, fix model mode, and compare repeated outputs both bitwise and within tolerance.

Part 4 - Python code skeleton

```
import torch

def E17(build_model, features, seed, repeats):
    torch.manual_seed(seed)
    model = build_model().eval()
    torch.use_deterministic_algorithms(True)
    outputs = []
    with torch.inference_mode():
        for _ in range(repeats):
            outputs.append(model(features).clone())
    reference = outputs[0]
    return {
        "exact": [torch.equal(reference, output) for output in outputs],
        "close": [torch.allclose(reference, output) for output in outputs],
        "outputs": outputs,
    }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

13.2.19 Exercise 18 - Examine Numerical Stability of Deep Forward Computation

Part 1 - Why this matters

Repeated affine transformations can cause activation magnitudes to shrink, grow, saturate, or overflow with depth. Initialization, activation choice, normalization, dtype, and input scale determine how signals propagate.

The final output may be finite even after useful variation has collapsed. Layer-wise statistics are necessary to detect loss of signal before visible failure.

Part 2 - Mathematical form

$$v_l = \mathrm{Var}(H_l), \qquad r_l = \frac{v_l}{v_{l-1} + \varepsilon}, \qquad \mathrm{finite}(H_l)\ \forall l.$$

Part 3 - Hints and Helper

Sweep depth, dtype, and initialization scale. Record mean, variance, extrema, saturation rate, and finiteness at every layer.

Part 4 - Python code skeleton

```
import torch

def E18(layer_outputs):
    report = []
    previous_variance = None
    for layer_index, hidden in enumerate(layer_outputs):
        variance = hidden.var(unbiased=False)
        report.append({
            "layer": layer_index,
            "mean": hidden.mean().item(),
            "variance": variance.item(),
            "variance_ratio": None if previous_variance is None else ...,
            "maximum_absolute": hidden.abs().max().item(),
            "finite": torch.isfinite(hidden).all().item(),
        })
        previous_variance = variance
    return report

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

13.2.20 Exercise 19 - Write a Conceptual Summary Explaining Why MLP Enables Universal Approximation

Part 1 - Why this matters

Universal approximation results show that, under suitable conditions, a feed-forward network with a non-linear activation and enough hidden units can approximate continuous functions on compact domains as closely as desired. This explains the broad representational potential of MLPs.

The theorem does not guarantee that a finite network is small, that training will find the required parameters, that data are sufficient, or that the learned function will generalize. Approximation capacity, optimization, computation, and statistical learning remain separate problems.

Part 2 - Mathematical form

$$\forall f \in C(K),\ \forall \varepsilon > 0,\ \exists N :\ \sup_{\mathbf{x} \in K} |f(\mathbf{x}) - N(\mathbf{x})| < \varepsilon.$$

Part 3 - Hints and Helper

State the domain, target function class, activation assumptions, and approximation norm. Separate theorem claims from practical training claims.

Part 4 - Python code skeleton

```
import torch

def E19(sections):
    required = {
        "single_perceptron_limit", "layered_composition",
        "hidden_representations", "nonlinearity", "dimensions",
        "depth", "universal_approximation_statement",
        "activation_assumptions", "compact_domain",
        "optimization_limitations", "generalization_limitations",
        "computational_limitations",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if sections.get("claims_training_always_succeeds"):
        warnings.append(...)
    if sections.get("claims_finite_data_is_sufficient"):
        warnings.append(...)
    return {
        "complete": not missing and not warnings,
        "missing": missing,
        "warnings": warnings,
        "sections": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

13.3 MLP01 - Architecture Design and Layer Composition

Models and Training

13.3.1 Exercise 00 - Design a Configurable MLP Architecture with Variable Depth

Part 1 - Why this matters

A configurable architecture separates the definition of a network from one fixed implementation. Instead of rewriting the model whenever the number or width of hidden layers changes, the reader represents the architecture as data and lets the program construct the corresponding transformations.

This design makes controlled experiments possible because depth, width, and output size can change while the surrounding training pipeline remains stable. It also introduces an important engineering principle: every valid configuration must preserve a continuous dimension flow from the input features to the final output.

Part 2 - Mathematical form

$$\mathbf{d} = (d_0, d_1, \ldots, d_L), \qquad f(\mathbf{x}) = f_L \circ f_{L-1} \circ \cdots \circ f_1(\mathbf{x}), \quad f_l : \mathbb{R}^{d_{l-1}} \to \mathbb{R}^{d_l}.$$

Part 3 - Hints and Helper

Accept the layer widths as a sequence. Validate that it contains at least an input and an output width, and do not hard-code the number of hidden layers.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E00(layer_sizes, activation_factory):
    if len(layer_sizes) < 2:
        raise ValueError(...)
    layers = []
    for index in range(len(layer_sizes) - 1):
        layers.append(nn.Linear(..., ...))
        if index < len(layer_sizes) - 2:
            layers.append(activation_factory())
    return nn.Sequential(...)

def main():
    model = E00([8, 16, 12, 4], nn.ReLU)
    print(model)

if __name__ == "__main__":
    main()
```

13.3.2 Exercise 01 - Implement MLP Using nn.Module and nn.Linear Layers

Part 1 - Why this matters

Subclassing nn.Module gives an MLP a clear computational interface while allowing PyTorch to discover its trainable state. Each nn.Linear layer owns a weight matrix and bias vector, and the forward method specifies how data pass through those registered transformations.

The exercise connects mathematical composition to the module system used in real training projects. A correct implementation must define layers during initialization, call them in the intended order, and apply non-linearity between linear transformations rather than accidentally omitting it.

Part 2 - Mathematical form

$$\mathbf{h}_1 = \phi(\mathbf{x}W_1^\mathsf{T} + \mathbf{b}_1), \qquad \hat{\mathbf{y}} = \mathbf{h}_1 W_2^\mathsf{T} + \mathbf{b}_2.$$

Part 3 - Hints and Helper

Create the submodules in the initializer and use them inside the forward method. Inspect the model parameters to confirm that both linear layers are registered.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class MLP(nn.Module):
    def __init__(self, input_size, hidden_size, output_size):
        super().__init__()
        self.hidden = nn.Linear(..., ...)
        self.activation = nn.ReLU()
        self.output = nn.Linear(..., ...)

    def forward(self, features):
        hidden = self.activation(...)
        return ...

def E01(features):
    model = MLP(features.shape[-1], ..., ...)
    return model(...)

def main():
    print(E01(torch.randn(5, 8)))

if __name__ == "__main__":
    main()
```

13.3.3 Exercise 02 - Dynamically Build Network from Layer Configuration List

Part 1 - Why this matters

A layer configuration list turns architecture construction into a systematic transformation. This is useful for experiments, configuration files, and automated searches where the network layout is selected at runtime rather than written directly into the source code.

Dynamic construction must still preserve architectural intent. The reader must distinguish hidden transformations from the output transformation, place activation functions only where intended, and reject invalid widths before a malformed network reaches training.

Part 2 - Mathematical form

$$(d_0, d_1, \ldots, d_L) \longmapsto \{(W_l, \mathbf{b}_l)\}_{l=1}^{L}, \qquad W_l \in \mathbb{R}^{d_l \times d_{l-1}}.$$

Part 3 - Hints and Helper

Iterate over adjacent pairs from the configuration list. Decide explicitly whether the output layer receives an activation.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E02(layer_sizes, activation_factory):
    modules = []
    pairs = zip(layer_sizes[:-1], layer_sizes[1:])
    for index, (in_size, out_size) in enumerate(pairs):
        modules.append(nn.Linear(..., ...))
        is_hidden = index < ...
        if is_hidden:
            modules.append(...)
    return nn.Sequential(*modules)

def main():
    model = E02([10, 32, 16, 2], nn.GELU)
    print(model(torch.randn(4, 10)))

if __name__ == "__main__":
    main()
```

13.3.4 Exercise 03 - Register Parameters Correctly for Arbitrary Network Depth

Part 1 - Why this matters

PyTorch optimizers can update only parameters that are registered under a module. Storing layers in an ordinary Python list may produce a forward pass that appears correct while silently hiding the weights from model.parameters(), state dictionaries, and device transfers.

Networks with arbitrary depth therefore require containers that register their modules. This exercise exposes a subtle failure mode in which computation succeeds but learning, saving, or CUDA placement is incomplete because the framework cannot see part of the model.

Part 2 - Mathematical form

$$\Theta = \bigcup_{l=1}^{L} \{W_l, \mathbf{b}_l\}, \qquad \Theta_{\text{registered}} = \Theta.$$

Part 3 - Hints and Helper

Build one correct model with a registered module container and one broken model with a plain list. Compare the named parameters and explain the missing entries.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class DeepMLP(nn.Module):
    def __init__(self, layer_sizes):
        super().__init__()
        self.layers = nn.ModuleList([
            nn.Linear(in_size, out_size)
            for in_size, out_size in zip(..., ...)
        ])

    def forward(self, features):
        hidden = features
        for index, layer in enumerate(self.layers):
            hidden = layer(hidden)
            if index < len(self.layers) - 1:
                hidden = torch.relu(...)
        return hidden

def E03(layer_sizes):
    model = DeepMLP(layer_sizes)
    return model, dict(model.named_parameters())

def main():
    print(E03([6, 12, 8, 1]))

if __name__ == "__main__":
    main()
```

13.3.5 Exercise 04 - Verify Parameter Count for Custom Architectures

Part 1 - Why this matters

Parameter counting connects architectural choices to storage cost, optimization difficulty, and model capacity. A seemingly small increase in adjacent layer widths can create a large weight matrix and dominate the total number of trainable values.

Manual counting also provides a direct correctness test for dynamically constructed networks. If the theoretical count differs from the registered count, the architecture may contain an unintended layer, a missing bias, or parameters that were not registered correctly.

Part 2 - Mathematical form

$$P = \sum_{l=1}^{L} \left(d_l d_{l-1} + d_l \right), \qquad P_{\text{trainable}} = \sum_{\theta \in \Theta,\, \theta \text{ trainable}} \text{numel}(\theta).$$

Part 3 - Hints and Helper

Compute the formula from the width list, then compare it with the sum of `numel()` over parameters whose `requires_grad` flag is true.

Part 4 - Python code skeleton

```
import torch

def E04(model, layer_sizes):
    expected = 0
    for in_size, out_size in zip(..., ...):
        weights = ...
        biases = ...
        expected += weights + biases
    registered = sum(
        parameter.numel()
        for parameter in model.parameters()
        if parameter.requires_grad
    )
    return expected, registered, ...

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

13.3.6 Exercise 05 - Inspect Weight and Bias Shapes for Each Layer

Part 1 - Why this matters

Every linear layer defines a contract between its incoming and outgoing feature dimensions. Inspecting parameter shapes makes this contract visible and helps the reader relate PyTorch storage conventions to batch-first matrix multiplication.

Shape inspection is especially important in deep configurable models because an early width mistake propagates into later layers. A structured report can reveal the first incompatible transition before the error becomes buried inside a long forward trace.

Part 2 - Mathematical form

$$W_l \in \mathbb{R}^{d_l \times d_{l-1}}, \qquad \mathbf{b}_l \in \mathbb{R}^{d_l}, \qquad H_l \in \mathbb{R}^{B \times d_l}.$$

Part 3 - Hints and Helper

Iterate through `named_modules()`, select `nn.Linear` instances, and record the input width, output width, weight shape, and bias shape.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E05(model):
    report = []
    for name, module in model.named_modules():
        if isinstance(module, nn.Linear):
            report.append({
                "name": name,
                "weight_shape": tuple(...),
                "bias_shape": tuple(...) if module.bias is not None else None,
                "transition": (..., ...),
            })
    return report

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

13.3.7 Exercise 06 - Implement Forward Hook to Capture Intermediate Outputs

Part 1 - Why this matters

Forward hooks allow intermediate activations to be observed without rewriting a model's forward method. They are valuable for debugging, representation analysis, and verifying that signals retain sensible shapes and values across deep architectures.

Hooks must be managed carefully because they remain attached until removed and may retain tensors longer than expected. The exercise therefore treats observation as a temporary resource: attach hooks, execute one pass, save only the required information, and remove every handle.

Part 2 - Mathematical form

$$H_l = \phi_l(H_{l-1}W_l^{\mathsf{T}} + \mathbf{b}_l), \qquad \mathcal{R}_l = (\text{shape}(H_l), \min H_l, \max H_l).$$

Part 3 - Hints and Helper

Create one closure per layer name. Detach captured tensors when gradients are unnecessary, and store the removable handles returned by `register_forward_hook()`.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E06(model, features):
    captured = {}
    handles = []

    def make_hook(name):
        def hook(module, inputs, output):
            captured[name] = ...
        return hook

    for name, module in model.named_modules():
        if isinstance(module, nn.Linear):
            handles.append(module.register_forward_hook(...))
    output = model(features)
    for handle in handles:
        handle.remove()
    return output, captured

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

13.3.8 Exercise 07 - Compare Shallow vs Deep Architectures on Same Task

Part 1 - Why this matters

A fair architecture comparison changes depth while controlling the dataset, evaluation protocol, optimizer budget, and preferably parameter count. Without these controls, an apparent benefit may come from greater capacity or additional training rather than depth itself.

Shallow and deep networks can express different functions efficiently, but depth also changes optimization behavior and computational cost. The reader should compare training loss, validation performance, runtime, and parameter count instead of reducing the experiment to one final accuracy value.

Part 2 - Mathematical form

$$\Delta_m = m(f_{\text{deep}}) - m(f_{\text{shallow}}), \qquad \Delta_P = P_{\text{deep}} - P_{\text{shallow}}, \qquad \Delta_t = t_{\text{deep}} - t_{\text{shallow}}.$$

Part 3 - Hints and Helper

Use identical data splits and random-seed policy. Record capacity and compute alongside predictive metrics, and repeat the comparison across several seeds.

Part 4 - Python code skeleton

```
import torch

def E07(build_model, train_and_evaluate, configurations, seeds):
    results = []
    for seed in seeds:
        torch.manual_seed(...)
        for name, layer_sizes in configurations.items():
            model = build_model(...)
            metrics = train_and_evaluate(model, ...)
            results.append({
                "seed": seed,
                "architecture": name,
                "parameters": sum(p.numel() for p in model.parameters()),
                "metrics": ...,
            })
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

13.3.9 Exercise 08 - Analyze Trade-Off Between Width and Depth

Part 1 - Why this matters

Width determines how many features a layer can represent simultaneously, whereas depth determines how many stages of transformation can be composed. Both can increase expressiveness, but they create different parameter, memory, latency, and optimization profiles.

A meaningful trade-off analysis compares architectures under a declared constraint such as equal parameter count, equal latency, or equal validation performance. This prevents the conclusion from being predetermined by giving one model substantially more resources than another.

Part 2 - Mathematical form

$$P = \sum_{l=1}^{L}(d_{l-1}+1)d_l, \qquad A = \sum_{l=1}^{L} Bd_l, \qquad C \propto \sum_{l=1}^{L} Bd_{l-1}d_l.$$

Part 3 - Hints and Helper

Generate several width-depth configurations, calculate theoretical parameters and activation elements, and compare them with measured validation and timing results.

Part 4 - Python code skeleton

```
import torch

def E08(configurations, build_model, benchmark):
    analysis = []
    for layer_sizes in configurations:
        model = build_model(layer_sizes)
        parameter_count = sum(...)
        activation_elements = sum(...)
        measurements = benchmark(model, ...)
        analysis.append({
            "layers": layer_sizes,
            "parameters": parameter_count,
            "activation_elements": activation_elements,
            "measurements": measurements,
        })
    return analysis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

13.3.10 Exercise 09 - Detect Architecture-Induced Bottlenecks

Part 1 - Why this matters

A narrow hidden layer forces information through a lower-dimensional representation. This may be useful when compression is intentional, but an accidental bottleneck can discard task-relevant variation and restrict every later layer regardless of its width.

Bottlenecks can be detected structurally and empirically. The reader should inspect abrupt width reductions, activation rank, saturation, and downstream performance, while remembering that a narrow layer is not automatically defective if the data truly lie on a low-dimensional manifold.

Part 2 - Mathematical form

$$\operatorname{rank}(H_l) \le \min(B, d_l), \qquad d_l \ll \min(d_{l-1}, d_{l+1}) \implies \text{candidate bottleneck.}$$

Part 3 - Hints and Helper

Flag sharp contractions in the width list, then use captured activations to estimate matrix rank and inactive-unit ratios for each hidden layer.

Part 4 - Python code skeleton

```
import torch

def E09(layer_sizes, activations, contraction_ratio=0.25):
    report = []
    for index, hidden in enumerate(activations):
        previous_width = layer_sizes[index]
        width = layer_sizes[index + 1]
        next_width = layer_sizes[index + 2]
        structural = width < contraction_ratio * min(..., ...)
        rank = torch.linalg.matrix_rank(hidden.float()).item()
        inactive = (...).float().mean().item()
        report.append({
            "layer": index,
            "structural": structural,
            "rank": rank,
            "inactive_ratio": inactive,
        })
    return report

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

13.3.11 Exercise 10 - Move Entire Architecture to CUDA and Validate Placement

Part 1 - Why this matters

Moving a model to CUDA must relocate every registered parameter and buffer, not merely the input tensor or one visible layer. A partially moved architecture fails during computation because PyTorch operations require participating tensors to share a compatible device.

Device validation is also a registration test. If model.to(device) leaves a layer on the CPU, that layer may have been stored outside the module hierarchy, revealing an architectural defect that would also affect optimization and serialization.

Part 2 - Mathematical form

$$\forall \theta \in \Theta,\ \text{device}(\theta) = D, \qquad \text{device}(X) = D \implies \text{device}(f_\Theta(X)) = D.$$

Part 3 - Hints and Helper

Select CUDA only when it is available. Check every named parameter and named buffer after moving the model, then run a sample forward pass on the same device.

Part 4 - Python code skeleton

```
import torch

def E10(model, features):
    device = torch.device(
        "cuda" if torch.cuda.is_available() else "cpu"
    )
    model = model.to(...)
    features = features.to(...)
    parameter_devices = {
        name: parameter.device
        for name, parameter in model.named_parameters()
    }
    all_placed = all(value == device for value in ...)
    output = model(...)
    return output, parameter_devices, all_placed

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

13.3.12 Exercise 11 - Debug Device Mismatch Errors in Multi-Layer Networks

Part 1 - Why this matters

Device mismatch errors often appear at the first operation that combines tensors, even when the real cause was an earlier unregistered layer, a newly created CPU tensor, or an input batch that was never transferred. Deep networks make the source harder to locate because many

modules may execute correctly before the failure.

A systematic debugger records the device of inputs, parameters, buffers, and intermediate outputs layer by layer. This turns a vague runtime exception into an exact report of the first transition whose tensors are not colocated.

Part 2 - Mathematical form

$$D(H_{l-1}) = D(W_l) = D(\mathbf{b}_l) \quad \text{for every } l.$$

Part 3 - Hints and Helper

Inspect devices before changing them. Avoid silently moving individual tensors inside forward because that can hide the architectural cause and add repeated transfer costs.

Part 4 - Python code skeleton

```
import torch

def E11(model, features):
    report = {"input": str(features.device), "parameters": {}}
    for name, parameter in model.named_parameters():
        report["parameters"][name] = str(...)
    unique_devices = set(report["parameters"].values())
    expected = str(features.device)
    mismatches = [
        name for name, device in report["parameters"].items()
        if device != ...
    ]
    return {
        "unique_devices": unique_devices,
        "mismatches": mismatches,
        "ready": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

13.3.13 Exercise 12 - Test Forward Compatibility with Different Input Shapes

Part 1 - Why this matters

An MLP generally treats the final tensor dimension as the feature dimension and preserves all leading dimensions. This allows the same linear layers to process a single sample, a batch,

or additional grouped dimensions when the final width matches the architecture input size.

Compatibility should be defined deliberately rather than inferred from one successful example. The reader must separate valid leading-dimension variation from invalid feature widths and verify the exact output-shape contract for every accepted input form.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{s_1 \times \cdots \times s_k \times d_0} \implies f(X) \in \mathbb{R}^{s_1 \times \cdots \times s_k \times d_L}.$$

Part 3 - Hints and Helper

Test scalar-free single samples, ordinary batches, and multi-leading-dimension inputs. Include one intentionally wrong final dimension and capture the expected failure.

Part 4 - Python code skeleton

```
import torch

def E12(model, input_size, output_size):
    shapes = [(input_size,), (4, input_size), (2, 3, input_size)]
    report = []
    for shape in shapes:
        features = torch.randn(*shape)
        output = model(...)
        expected = shape[:-1] + (...,)
        report.append((shape, tuple(output.shape), ...))
    try:
        model(torch.randn(4, input_size + 1))
        invalid_rejected = False
    except RuntimeError:
        invalid_rejected = ...
    return report, invalid_rejected

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

13.3.14 Exercise 13 - Clone Architecture and Compare Parameter Independence

Part 1 - Why this matters

Two models may have the same architecture while requiring completely independent parameter storage. Simple assignment creates another reference to the same object, so modifying one name modifies the same underlying model rather than an independent clone.

Parameter independence matters for ensemble members, experiment baselines, target networks, and checkpoint comparisons. The reader must distinguish equality of initial values from identity of storage and confirm that a later update to one clone does not alter the other.

Part 2 - Mathematical form

$$\theta_l^{(A)} = \theta_l^{(B)} \text{ initially}, \qquad \text{ptr}(\theta_l^{(A)}) \neq \text{ptr}(\theta_l^{(B)}).$$

Part 3 - Hints and Helper

Use `deepcopy` for a full independent clone. Compare `data_ptr()` values, then mutate one model under `torch.no_grad()` and test whether the other remains unchanged.

Part 4 - Python code skeleton

```
import copy
import torch

def E13(model):
    clone = copy.deepcopy(...)
    pairs = zip(model.parameters(), clone.parameters())
    value_equal = []
    storage_independent = []
    for original, copied in pairs:
        value_equal.append(torch.equal(..., ...))
        storage_independent.append(original.data_ptr() != ...)
    before = [parameter.detach().clone() for parameter in clone.parameters()]
    with torch.no_grad():
        next(model.parameters()).add_(...)
    unchanged = all(
        torch.equal(old, new)
        for old, new in zip(before, clone.parameters())
    )
    return clone, value_equal, storage_independent, unchanged

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

13.3.15 Exercise 14 - Save and Reload Architecture with State Dict

Part 1 - Why this matters

A state dictionary stores learned parameters and persistent buffers while leaving the architecture definition in code. Reloading therefore succeeds only when the destination model is constructed with a compatible arrangement of layer names and tensor shapes.

Serialization should be verified by behavior, not merely by the absence of an exception. After loading, the reader should compare keys, parameters, and predictions under evaluation mode using the same input tensor.

Part 2 - Mathematical form

$$S = \{k \mapsto T_k\}, \qquad S_A \cong S_B \implies f_A(X) = f_B(X) \text{ after loading.}$$

Part 3 - Hints and Helper

Save only the `state_dict` for this exercise. Rebuild the same architecture, load with `strict=True`, and compare outputs with `torch.allclose()`.

Part 4 - Python code skeleton

```
import io
import torch

def E14(model, model_factory, features):
    buffer = io.BytesIO()
    torch.save(..., buffer)
    buffer.seek(0)
    restored = model_factory()
    state = torch.load(buffer, map_location=features.device)
    load_result = restored.load_state_dict(..., strict=True)
    model.eval()
    restored.eval()
    with torch.no_grad():
        original_output = model(features)
        restored_output = restored(features)
    return restored, load_result, torch.allclose(..., ...)

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

13.3.16 Exercise 15 - Stress Test Architecture Creation with Large Layer Counts

Part 1 - Why this matters

Very deep architecture construction tests the scalability of configuration logic before expensive training begins. It can expose recursion assumptions, registration mistakes, initialization cost, and naming behavior that remain invisible in a small demonstration network.

Creation success alone is not enough: the resulting model must contain the expected number of layers and parameters, and a forward pass must preserve valid shapes. The stress test

should use explicit resource limits so it investigates construction without accidentally exhausting memory.

Part 2 - Mathematical form

$$L \gg 1, \qquad P = \sum_{l=1}^{L} (d_{l-1} + 1) d_l, \qquad \#\{\text{registered linear layers}\} = L.$$

Part 3 - Hints and Helper

Begin with narrow layers and increase depth gradually. Measure construction time, confirm module count, and run a small batch before attempting wider configurations.

Part 4 - Python code skeleton

```
import time
import torch
from torch import nn

def E15(build_model, depth, width, input_size, output_size):
    layer_sizes = [input_size] + [width] * depth + [output_size]
    start = time.perf_counter()
    model = build_model(...)
    creation_time = time.perf_counter() - start
    linear_count = sum(
        isinstance(module, nn.Linear) for module in model.modules()
    )
    with torch.no_grad():
        output = model(torch.randn(2, input_size))
    return {
        "model": model,
        "creation_time": creation_time,
        "linear_count": linear_count,
        "output_shape": tuple(...),
    }

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

13.3.17 Exercise 16 - Evaluate Memory Footprint of Deep Architectures

Part 1 - Why this matters

Model memory includes parameter values, gradients, optimizer state, and activations retained for backward computation. Counting parameter bytes alone can substantially underestimate training requirements, especially when batch size and hidden widths make activations

dominant.

A useful memory report distinguishes persistent architecture storage from the runtime memory required by a workload. This helps the reader predict whether a design fits the selected device and identify whether reducing width, depth, precision, or batch size will address the actual source of pressure.

Part 2 - Mathematical form

$$M_{\text{train}} \approx M_{\text{param}} + M_{\text{grad}} + M_{\text{optimizer}} + M_{\text{activation}},$$
$$M_{\text{param}} = \sum_{\theta \in \Theta} \text{numel}(\theta)\, \text{size}(\theta).$$

Part 3 - Hints and Helper

Compute exact parameter and buffer bytes first. On CUDA, reset peak memory statistics before the measured forward-backward step and synchronize before reading the result.

Part 4 - Python code skeleton

```
import torch

def E16(model, features, loss_function):
    parameter_bytes = sum(
        parameter.numel() * parameter.element_size()
        for parameter in model.parameters()
    )
    buffer_bytes = sum(
        buffer.numel() * buffer.element_size()
        for buffer in model.buffers()
    )
    peak_bytes = None
    if features.is_cuda:
        torch.cuda.reset_peak_memory_stats(features.device)
    output = model(features)
    loss = loss_function(output, ...)
    loss.backward()
    if features.is_cuda:
        torch.cuda.synchronize(features.device)
        peak_bytes = torch.cuda.max_memory_allocated(...)
    return parameter_bytes, buffer_bytes, peak_bytes

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

13.3.18 Exercise 17 - Compare Manual Tensor Implementation vs nn.Module

Part 1 - Why this matters

A manual tensor implementation makes every affine transformation and activation explicit, while nn.Module organizes the same computation into registered, reusable components. Comparing them reveals which responsibilities belong to the mathematics and which are supplied by the framework.

The comparison is valid only when both paths use identical parameter values, matrix orientation, activation placement, and bias broadcasting. Matching outputs then demonstrate computational equivalence, while differences in registration, serialization, and device management reveal the practical value of the module abstraction.

Part 2 - Mathematical form

$$H_l^{\text{manual}} = \phi_l(H_{l-1}W_l^{\mathsf{T}} + \mathbf{b}_l), \qquad H_l^{\text{module}} = \phi_l(\text{Linear}_l(H_{l-1})).$$

Part 3 - Hints and Helper

Copy each module weight and bias into the manual parameter lists. Run both paths in evaluation mode and report maximum absolute and relative differences.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E17(model, features, activation):
    manual = features
    linear_layers = [
        module for module in model.modules()
        if isinstance(module, nn.Linear)
    ]
    for index, layer in enumerate(linear_layers):
        manual = manual @ layer.weight.T + layer.bias
        if index < len(linear_layers) - 1:
            manual = activation(...)
    with torch.no_grad():
        modular = model(...)
    difference = (manual - modular).abs()
    return manual, modular, difference.max().item(), torch.allclose(..., ...)

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

13.3.19 Exercise 18 - Identify Architectural Failure Modes Early

Part 1 - Why this matters

Architectural defects are cheaper to detect before training consumes data and compute. Invalid widths, missing non-linearities, unregistered layers, incompatible output dimensions, and mixed devices can all make a model impossible to train or silently different from the intended design.

An architecture preflight check converts assumptions into executable conditions. It should inspect structure, registration, dimension flow, devices, data types, forward output, and gradient reachability using a small synthetic batch before the real training loop begins.

Part 2 - Mathematical form

$$\mathcal{V} = V_{\text{shape}} \wedge V_{\text{register}} \wedge V_{\text{device}} \wedge V_{\text{forward}} \wedge V_{\text{gradient}}.$$

Part 3 - Hints and Helper

Return a structured list of failures instead of stopping after the first one. Include both static checks and a safe synthetic forward-backward test.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E18(model, input_size, output_size, device):
    failures = []
    if not list(model.parameters()):
        failures.append(...)
    parameter_devices = {parameter.device for parameter in model.parameters()}
    if parameter_devices != {device}:
        failures.append(...)
    try:
        sample = torch.randn(3, input_size, device=device)
        output = model(sample)
        if output.shape != (3, output_size):
            failures.append(...)
        output.sum().backward()
        missing_gradients = [
            name for name, parameter in model.named_parameters()
            if parameter.requires_grad and parameter.grad is None
        ]
        if missing_gradients:
            failures.append(...)
    except (RuntimeError, ValueError) as error:
        failures.append(str(error))
    return {"ready": not failures, "failures": failures}
```

```
def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

13.3.20 Exercise 19 - Produce an Architecture Design Rationale Document

Part 1 - Why this matters

An architecture should be justified by the input structure, output objective, available data, compute budget, and risks discovered during validation. A rationale document makes these decisions reviewable instead of presenting layer widths and activation choices as unexplained guesses.

The document must separate evidence from assumptions and state what alternatives were considered. It should also define validation criteria and failure signals so future experiments can confirm, revise, or reject the proposed architecture rather than preserving it by habit.

Part 2 - Mathematical form

$$A^* = \arg\min_{A \in \mathcal{A}} \Big(\widehat{R}_{\text{val}}(A) + \lambda_C C(A) + \lambda_M M(A) + \lambda_L L(A) \Big),$$

Part 3 - Hints and Helper

Require sections for requirements, dimension flow, depth-width choice, activation choice, parameter budget, memory, alternatives, risks, tests, and revision conditions.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "problem_requirements", "input_output_contract",
        "layer_configuration", "depth_width_rationale",
        "activation_rationale", "parameter_budget",
        "memory_and_latency", "alternatives_considered",
        "failure_modes", "validation_plan",
        "revision_conditions",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        key for key, value in sections.items()
        if isinstance(value, dict)
        and value.get("claim")
        and not value.get("evidence")
    ]
    return {
        "complete": not missing and not unsupported,
```

```
        "missing": missing,
        "unsupported_claims": unsupported,
        "document": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

13.4 MLP02 - Activation Functions and Non-Linearity

Models and Training

13.4.1 Exercise 00 - Implement ReLU Activation and Observe Its Piecewise Behavior

Part 1 - Why this matters

The rectified linear unit keeps positive values unchanged and maps negative values to zero. Its piecewise-linear form is simple, inexpensive, and capable of introducing the non-linearity that prevents stacked affine layers from collapsing into one affine transformation.

The point at zero separates two behaviors and makes the derivative undefined in classical calculus, so software adopts a conventional subgradient there. Observing values and gradients on both sides of zero connects the mathematical definition to PyTorch's actual backward behavior.

Part 2 - Mathematical form

$$\mathrm{ReLU}(x) = \max(0, x) = \begin{cases} 0, & x \le 0, \\ x, & x > 0, \end{cases} \qquad \mathrm{ReLU}'(x) = \begin{cases} 0, & x \le 0, \\ 1, & x > 0. \end{cases}$$

Part 3 - Hints and Helper

Create inputs below, at, and above zero. Compare a manual maximum operation with the built-in function, then inspect the gradients produced by backward.

Part 4 - Python code skeleton

```
import torch

def E00(values):
    values = values.clone().requires_grad_(True)
    manual = torch.maximum(values, torch.zeros_like(values))
    built_in = torch.relu(...)
    built_in.sum().backward()
```

```
    return manual, built_in, values.grad, torch.equal(..., ...)

def main():
    values = torch.tensor([-2.0, -0.1, 0.0, 0.1, 2.0])
    print(E00(values))

if __name__ == "__main__":
    main()
```

13.4.2 Exercise 01 - Compare ReLU, Sigmoid, and Tanh in Forward Propagation

Part 1 - Why this matters

ReLU, sigmoid, and tanh transform the same pre-activation values into very different ranges. ReLU is unbounded above and sparse on negative inputs, sigmoid compresses values into probabilities between zero and one, and tanh produces zero-centered outputs between negative one and one.

These differences change the distributions delivered to later layers and therefore affect optimization. A controlled forward comparison should reuse the same inputs and parameters so the observed changes arise from the activation rather than from different network weights.

Part 2 - Mathematical form

$$r(z) = \max(0, z), \qquad \sigma(z) = \frac{1}{1 + e^{-z}}, \qquad \tanh(z) = \frac{e^{z} - e^{-z}}{e^{z} + e^{-z}}.$$

Part 3 - Hints and Helper

Calculate all three activations from one tensor. Report range, mean, standard deviation, and the proportion of exact zeros for each output.

Part 4 - Python code skeleton

```
import torch

def E01(pre_activation):
    functions = {
        "relu": torch.relu,
        "sigmoid": torch.sigmoid,
        "tanh": torch.tanh,
    }
    report = {}
    for name, function in functions.items():
        output = function(...)
        report[name] = {
            "output": output,
            "mean": output.mean().item(),
```

```
            "std": output.std().item(),
            "zero_ratio": (...).float().mean().item(),
        }
    return report

def main():
    print(E01(torch.linspace(-6, 6, 25)))

if __name__ == "__main__":
    main()
```

13.4.3 Exercise 02 - Visualize Activation Output Distributions Across Layers

Part 1 - Why this matters

Activation distributions reveal how signals evolve as they pass through a network. Means that drift, variances that collapse or explode, and large concentrations at activation limits can indicate that useful information is being lost before the output layer.

A layer-by-layer visualization is more informative than inspecting only the final prediction. Histograms should be collected from the same batch and paired with numerical summaries so that visual impressions can be verified quantitatively.

Part 2 - Mathematical form

$$H_l = \phi(Z_l), \qquad \mu_l = \mathbb{E}[H_l], \qquad s_l^2 = \mathrm{Var}(H_l).$$

Part 3 - Hints and Helper

Capture hidden outputs with hooks or an explicit forward trace. Detach the values, move them to the CPU, and plot comparable histogram ranges for all layers.

Part 4 - Python code skeleton

```
import torch
import matplotlib.pyplot as plt

def E02(activations, bins=40):
    figure, axes = plt.subplots(len(activations), 1, ...)
    summaries = []
    for index, (axis, values) in enumerate(zip(axes, activations)):
        flat = values.detach().float().cpu().flatten()
        axis.hist(..., bins=bins)
        axis.set_title(f"Layer {index}")
        summaries.append({
            "mean": flat.mean().item(),
            "std": flat.std().item(),
        })
```

```
    return figure, summaries

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

13.4.4 Exercise 03 - Analyze Gradient Flow for Different Activation Choices

Part 1 - Why this matters

Backpropagation multiplies local derivatives along computational paths. The activation derivative therefore controls how strongly an error signal reaches earlier layers, and repeated derivatives smaller than one can progressively weaken the gradient.

A fair experiment gives networks identical initial weights, inputs, targets, and loss functions while changing only the activation. Layer-wise gradient norms then show whether the signal remains balanced, vanishes, or becomes unstable across depth.

Part 2 - Mathematical form

$$\frac{\partial \mathcal{L}}{\partial H_{l-1}} = \frac{\partial \mathcal{L}}{\partial H_l} W_l \operatorname{diag}(\phi'(Z_{l-1})) .$$

Part 3 - Hints and Helper

Clone one initialized model for each activation. After one backward pass, record weight-gradient norms in forward layer order and compare their ratios.

Part 4 - Python code skeleton

```
import copy
import torch

def E03(base_model, activation_factories, features, targets, loss_fn):
    reports = {}
    for name, factory in activation_factories.items():
        model = copy.deepcopy(base_model)
        model.set_activation(...)
        model.zero_grad(set_to_none=True)
        loss = loss_fn(model(features), targets)
        loss.backward()
        reports[name] = [
            parameter.grad.norm().item()
            for parameter in model.weight_parameters()
        ]
    return reports
```

```
def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

13.4.5 Exercise 04 - Demonstrate Vanishing Gradient in Deep Sigmoid Networks

Part 1 - Why this matters

The sigmoid derivative never exceeds one quarter and becomes close to zero when its input is strongly positive or negative. Repeating this behavior through many layers can make gradients at early layers extremely small even though later layers still receive a measurable signal.

The experiment should demonstrate the mechanism rather than merely produce a failed training run. Recording pre-activation saturation and gradient norms across depth links the observed vanishing gradient to the local derivatives that caused it.

Part 2 - Mathematical form

$$\sigma'(z) = \sigma(z)(1 - \sigma(z)) \leq \frac{1}{4}, \qquad \left\| \prod_{l=1}^{L} \sigma'(z_l) \right\| \longrightarrow 0 \text{ as } L \text{ grows.}$$

Part 3 - Hints and Helper

Build a deep sigmoid MLP, perform one backward pass, and compare the first and last layer gradient norms. Repeat across several depths using the same seed.

Part 4 - Python code skeleton

```
import torch

def E04(build_sigmoid_model, depths, features, targets, loss_fn):
    report = []
    for depth in depths:
        torch.manual_seed(0)
        model = build_sigmoid_model(...)
        loss = loss_fn(model(features), targets)
        loss.backward()
        norms = [
            layer.weight.grad.norm().item()
            for layer in model.linear_layers()
        ]
        report.append({
            "depth": depth,
            "first_norm": norms[0],
            "last_norm": norms[-1],
```

```
            "ratio": norms[0] / (... + 1e-12),
        })
    return report

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

13.4.6 Exercise 05 - Demonstrate Dying ReLU Phenomenon Experimentally

Part 1 - Why this matters

A ReLU unit becomes inactive when its pre-activation remains non-positive for all relevant samples. Its output and local derivative are then zero, so ordinary gradient descent may be unable to move the unit back into an active region.

Dying ReLU is influenced by initialization, data distribution, bias, and update size. The experiment should track individual units over time and distinguish a temporarily inactive unit from one that remains inactive across many batches.

Part 2 - Mathematical form

$$z_j^{(i)} \leq 0 \ \forall i \quad \Longrightarrow \quad h_j^{(i)} = 0 \text{ and } \frac{\partial \mathcal{L}}{\partial z_j^{(i)}} = 0 \ \forall i.$$

Part 3 - Hints and Helper

Record the fraction of hidden units whose output is zero for every sample in a batch. Use an aggressive learning rate as one experimental condition, not as an unexplained default.

Part 4 - Python code skeleton

```
import torch

def E05(model, data_loader, optimizer, loss_fn, epochs):
    history = []
    for epoch in range(epochs):
        for features, targets in data_loader:
            optimizer.zero_grad(set_to_none=True)
            output, hidden = model.forward_with_hidden(features)
            loss = loss_fn(output, targets)
            loss.backward()
            optimizer.step()
        dead_units = (hidden == 0).all(dim=0)
        history.append({
            "epoch": epoch,
```

```
            "dead_ratio": dead_units.float().mean().item(),
            "loss": ...,
        })
    return history

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

13.4.7 Exercise 06 - Implement LeakyReLU and Compare Gradient Behavior

Part 1 - Why this matters

LeakyReLU replaces ReLU's zero negative branch with a small linear slope. Negative inputs therefore retain a gradient path, reducing the chance that a unit becomes permanently disconnected from learning.

The slope is a design choice rather than a universal solution. Comparing several negative slopes reveals the trade-off between preserving gradient flow and changing the activation's asymmetry and output distribution.

Part 2 - Mathematical form

$$\mathrm{LeakyReLU}_\alpha(x) = \begin{cases} x, & x \geq 0, \\ \alpha x, & x < 0, \end{cases} \qquad \phi'(x) = \begin{cases} 1, & x \geq 0, \\ \alpha, & x < 0. \end{cases}$$

Part 3 - Hints and Helper

Implement the piecewise rule with a tensor operation. Compare values and gradients against the built-in function for negative, zero, and positive inputs.

Part 4 - Python code skeleton

```
import torch
from torch.nn import functional as F

def E06(values, negative_slope=0.01):
    values = values.clone().requires_grad_(True)
    manual = torch.where(values >= 0, values, negative_slope * values)
    built_in = F.leaky_relu(values, negative_slope=...)
    built_in.sum().backward()
    return {
        "manual": manual,
        "built_in": built_in,
        "gradients": values.grad,
        "matches": torch.allclose(..., ...),
```

```
    }

def main():
    print(E06(torch.tensor([-2.0, 0.0, 2.0])))

if __name__ == "__main__":
    main()
```

13.4.8 Exercise 07 - Test GELU Activation in Deep Networks

Part 1 - Why this matters

GELU scales an input smoothly according to its magnitude instead of applying a hard gate at zero. Small negative values can pass with reduced influence, while sufficiently positive values remain close to the identity transformation.

Its smooth behavior may improve some deep-network optimization problems, but the benefit depends on the task, initialization, and compute environment. The reader should compare learning curves and gradient statistics rather than assuming that a more complex activation is always superior.

Part 2 - Mathematical form

$$\mathrm{GELU}(x) = x\Phi(x) \approx \frac{x}{2}\left(1 + \tanh\left[\sqrt{\frac{2}{\pi}}\left(x + 0.044715x^3\right)\right]\right).$$

Part 3 - Hints and Helper

Train matched ReLU and GELU networks across the same seeds. Record convergence, gradient norms, validation performance, and execution time.

Part 4 - Python code skeleton

```
import copy
import time
import torch
from torch import nn

def E07(base_model, train_model, seeds):
    results = []
    for seed in seeds:
        for name, activation in {
            "relu": nn.ReLU(), "gelu": nn.GELU()
        }.items():
            torch.manual_seed(...)
            model = copy.deepcopy(base_model)
            model.set_activation(activation)
            start = time.perf_counter()
            metrics = train_model(model, ...)
```

```
            elapsed = time.perf_counter() - start
            results.append((seed, name, metrics, elapsed))
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

13.4.9 Exercise 08 - Evaluate Activation Choice Impact on Training Stability

Part 1 - Why this matters

Training stability includes more than the final loss. A stable run avoids non-finite values, uncontrolled gradient growth, severe oscillation, prolonged plateaus, and large sensitivity to the random seed.

Activation functions influence all of these behaviors through their output ranges and derivatives. Evaluation should therefore aggregate multiple runs and report failure frequency and variability alongside average predictive performance.

Part 2 - Mathematical form

$$S(\phi) = \Big(p_{\text{finite}}, \operatorname{Var}_s(L_T), \max_t \|g_t\|, \operatorname{osc}(L_{1:T})\Big).$$

Part 3 - Hints and Helper

Use the same architecture and hyperparameters for each activation. Define instability criteria before running the experiment so conclusions are not chosen after seeing results.

Part 4 - Python code skeleton

```
import math
import torch

def E08(run_training, activations, seeds):
    report = {}
    for name, activation in activations.items():
        runs = [run_training(activation, seed, ...) for seed in seeds]
        finite = [math.isfinite(run["final_loss"]) for run in runs]
        report[name] = {
            "success_rate": sum(finite) / len(finite),
            "mean_final_loss": ...,
            "loss_variance": ...,
            "max_gradient_norm": max(...),
            "runs": runs,
        }
```

```
    return report

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

13.4.10 Exercise 09 - Debug Activation-Induced Training Failures

Part 1 - Why this matters

An activation-related failure may appear as dead units, saturated outputs, vanishing gradients, exploding activations, or a mismatch between the output activation and loss function. These symptoms can resemble data, initialization, or optimizer problems.

Debugging should connect each symptom to evidence at the layer where it begins. Logging pre-activation values, activation statistics, and gradients makes it possible to identify whether the activation is a cause, an amplifier, or merely the location where another defect becomes visible.

Part 2 - Mathematical form

$$D_l = (p_{\text{dead},l}, p_{\text{sat},l}, \|H_l\|, \|\nabla_{W_l}\mathcal{L}\|, p_{\text{finite},l}).$$

Part 3 - Hints and Helper

Collect diagnostics before changing the activation. Compare the failing model with one controlled alternative while keeping the weights, batch, and loss fixed.

Part 4 - Python code skeleton

```
import torch

def E09(layer_records, gradient_records, threshold=1e-6):
    failures = []
    for name, values in layer_records.items():
        finite = torch.isfinite(values).all().item()
        near_zero = (values.abs() < threshold).float().mean().item()
        gradient_norm = gradient_records[name].norm().item()
        if not finite:
            failures.append((name, "non_finite_activation"))
        if near_zero > ...:
            failures.append((name, "mostly_inactive"))
        if gradient_norm < ...:
            failures.append((name, "vanishing_gradient"))
    return failures

def main():
```

```
    print(E09(...))

if __name__ == "__main__":
    main()
```

13.4.11 Exercise 10 - Execute Activation Functions on CUDA and Compare Performance

Part 1 - Why this matters

CUDA can accelerate activation processing when tensors are large enough to amortize transfer and kernel-launch costs. Small isolated operations may be faster on the CPU, so device choice should be based on synchronized measurements rather than assumptions.

A correct benchmark separates one-time setup from repeated execution and keeps data on the measured device. CUDA work is asynchronous, which means timing without synchronization can measure dispatch rather than completed computation.

Part 2 - Mathematical form

$$T_D(\phi; N) = \frac{1}{R} \sum_{r=1}^{R} \left(t_{r,\text{end}} - t_{r,\text{start}} \right), \qquad D \in \{\text{CPU}, \text{CUDA}\}.$$

Part 3 - Hints and Helper

Warm up both paths, synchronize CUDA around timed regions, and test several tensor sizes. Do not include host-to-device transfer unless transfer is explicitly part of the scenario.

Part 4 - Python code skeleton

```
import time
import torch

def benchmark(function, values, repeats):
    for _ in range(10):
        function(values)
    if values.is_cuda:
        torch.cuda.synchronize(values.device)
    start = time.perf_counter()
    for _ in range(repeats):
        output = function(...)
    if values.is_cuda:
        torch.cuda.synchronize(values.device)
    return (time.perf_counter() - start) / repeats, output

def E10(function, shape, repeats=100):
    cpu_values = torch.randn(*shape)
    cpu_time, cpu_output = benchmark(function, cpu_values, repeats)
    if not torch.cuda.is_available():
```

```
        return {"cpu": cpu_time, "cuda": None}
    cuda_values = cpu_values.to("cuda")
    cuda_time, cuda_output = benchmark(function, cuda_values, repeats)
    return {"cpu": cpu_time, "cuda": cuda_time, "matches": ...}

def main():
    print(E10(torch.relu, (4096, 4096)))

if __name__ == "__main__":
    main()
```

13.4.12 Exercise 11 - Compare Float Precision Effects on Activation Output

Part 1 - Why this matters

Floating-point precision affects the range and resolution with which activation outputs are represented. Saturating functions may reach exact limits sooner in lower precision, while exponential terms can underflow or overflow for less extreme inputs.

Precision differences should be measured against a higher-precision reference and separated into ordinary rounding error, saturation changes, and non-finite results. The impact on gradients can be more important than the forward difference alone.

Part 2 - Mathematical form

$$e_p(x) = |\phi_p(x) - \phi_{64}(x)|, \qquad r_p(x) = \frac{e_p(x)}{|\phi_{64}(x)| + \varepsilon}.$$

Part 3 - Hints and Helper

Evaluate a wide input range in several supported data types. Convert outputs to double precision before calculating errors against the reference.

Part 4 - Python code skeleton

```
import torch

def E11(function, values, dtypes):
    reference = function(values.to(torch.float64))
    report = {}
    for dtype in dtypes:
        output = function(values.to(dtype)).to(torch.float64)
        absolute = (output - reference).abs()
        relative = absolute / (reference.abs() + 1e-12)
        report[str(dtype)] = {
            "max_absolute": absolute.max().item(),
            "max_relative": relative.max().item(),
            "finite": torch.isfinite(output).all().item(),
```

```
        }
    return report

def main():
    values = torch.linspace(-50, 50, 10001)
    print(E11(torch.sigmoid, values, [...]))

if __name__ == "__main__":
    main()
```

13.4.13 Exercise 12 - Track Activation Saturation Across Layers

Part 1 - Why this matters

Saturation occurs when an activation enters a region where its derivative is very small. In sigmoid and tanh networks, a high saturation ratio indicates that many units transmit little gradient even if their outputs appear numerically valid.

The appropriate saturation rule depends on the activation. A derivative-based definition is more general than checking output values alone and allows statistics from different functions to be compared on a shared gradient-flow interpretation.

Part 2 - Mathematical form

$$s_l(\tau) = \frac{1}{|Z_l|} \sum_i \mathbf{1}(|\phi'(z_{l,i})| < \tau) \, .$$

Part 3 - Hints and Helper

Capture pre-activations, calculate the analytical derivative for the selected function, and report the fraction below a declared threshold at every layer.

Part 4 - Python code skeleton

```
import torch

def E12(pre_activations, derivative_function, threshold=1e-3):
    report = []
    for index, values in enumerate(pre_activations):
        derivatives = derivative_function(...)
        saturated = derivatives.abs() < threshold
        report.append({
            "layer": index,
            "saturation_ratio": saturated.float().mean().item(),
            "minimum_derivative": derivatives.abs().min().item(),
        })
    return report

def main():
```

```
    print(E12(...))

if __name__ == "__main__":
    main()
```

13.4.14 Exercise 13 - Instrument Network to Log Activation Statistics

Part 1 - Why this matters

Instrumentation turns hidden activation behavior into time-series evidence during training. Layer means, standard deviations, extrema, sparsity, saturation, and non-finite counts can reveal degradation well before the final loss becomes unusable.

The logger must remain lightweight and avoid retaining computation graphs. Logging every tensor on every step can distort performance and memory, so the reader should detach summaries, choose a sampling interval, and remove hooks when monitoring ends.

Part 2 - Mathematical form

$$R_{l,t} = (\mu_{l,t}, s_{l,t}, \min H_{l,t}, \max H_{l,t}, p_{0,l,t}, p_{\neg\text{finite},l,t}).$$

Part 3 - Hints and Helper

Attach hooks only to activation modules. Store scalar summaries rather than full tensors, include the training step, and return a function that removes all hook handles.

Part 4 - Python code skeleton

```
import torch

def E13(model, current_step):
    records = []
    handles = []

    def make_hook(name):
        def hook(module, inputs, output):
            values = output.detach()
            records.append({
                "step": current_step(),
                "layer": name,
                "mean": values.float().mean().item(),
                "std": values.float().std().item(),
                "zero_ratio": (...).float().mean().item(),
                "finite": torch.isfinite(values).all().item(),
            })
        return hook

    for name, module in model.named_modules():
```

```
        if model.is_activation(module):
            handles.append(module.register_forward_hook(...))
    return records, handles

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

13.4.15 Exercise 14 - Replace Activation Mid-Training and Observe Effects

Part 1 - Why this matters

Changing an activation during training changes the function represented by the current parameters and the derivative landscape used for all future updates. Even without modifying weights, predictions and loss may jump immediately after replacement.

This intervention can reveal how strongly learned parameters depend on the original activation, but it is not a standard tuning shortcut. The experiment must checkpoint the pre-change state and compare a switched run with an unchanged control from the same point.

Part 2 - Mathematical form

$$f_{\theta,\phi_a}(X) \longrightarrow f_{\theta,\phi_b}(X), \qquad \Delta\mathcal{L} = \mathcal{L}(f_{\theta,\phi_b}(X), Y) - \mathcal{L}(f_{\theta,\phi_a}(X), Y).$$

Part 3 - Hints and Helper

Record predictions and loss immediately before and after replacement, then continue both a control and intervention run with identical data order and optimizer settings.

Part 4 - Python code skeleton

```
import copy

def E14(model, replace_activation, continue_training, batch, loss_fn):
    control = copy.deepcopy(model)
    switched = copy.deepcopy(model)
    features, targets = batch
    before = loss_fn(switched(features), targets).item()
    replace_activation(switched, ...)
    after = loss_fn(switched(features), targets).item()
    control_history = continue_training(control, ...)
    switched_history = continue_training(switched, ...)
    return {
        "immediate_loss_change": after - before,
        "control": control_history,
        "switched": switched_history,
```

```
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

13.4.16 Exercise 15 - Analyze Activation Interaction with Weight Initialization

Part 1 - Why this matters

Weight initialization controls the scale of pre-activations presented to an activation. An unsuitable scale can push sigmoid or tanh units into saturation, or cause ReLU networks to lose or amplify variance as depth increases.

Initialization and activation must therefore be studied as a pair. Comparing Xavier-style and He-style scaling across activations demonstrates that a method's assumptions about derivative and variance behavior determine where it is appropriate.

Part 2 - Mathematical form

$$\mathrm{Var}(W) \approx \frac{1}{n_{\text{in}}} \text{ for balanced activations,} \qquad \mathrm{Var}(W) \approx \frac{2}{n_{\text{in}}} \text{ for ReLU.}$$

Part 3 - Hints and Helper

Construct activation-initialization pairs under fixed seeds. Before training, record layer-wise pre-activation and output variances; then compare gradient norms after one backward pass.

Part 4 - Python code skeleton

```
import torch

def E15(build_model, combinations, features, targets, loss_fn):
    report = []
    for activation_name, initializer_name in combinations:
        torch.manual_seed(0)
        model = build_model(activation_name)
        model.apply_initialization(initializer_name)
        output, states = model.forward_with_states(features)
        loss = loss_fn(output, targets)
        loss.backward()
        report.append({
            "activation": activation_name,
            "initializer": initializer_name,
            "variances": [state.float().var().item() for state in states],
            "gradient_norms": model.gradient_norms(),
```

```
        })
    return report

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

13.4.17 Exercise 16 - Compare Custom Activation vs Built-In PyTorch Activation

Part 1 - Why this matters

A custom activation should match the intended forward values and gradients before it is used in a model. Forward agreement alone is insufficient because an incorrect derivative can silently train a different system.

Built-in PyTorch operations provide optimized kernels and tested autograd behavior. A manual implementation is valuable for understanding and specialized research, but equivalence testing should cover shapes, data types, devices, extreme inputs, and gradient calculations.

Part 2 - Mathematical form

$$\max_x |\phi_{\text{custom}}(x) - \phi_{\text{built-in}}(x)| < \varepsilon_f, \qquad \max_x |\phi'_{\text{custom}}(x) - \phi'_{\text{built-in}}(x)| < \varepsilon_g.$$

Part 3 - Hints and Helper

Use cloned inputs that require gradients, apply identical upstream gradients, and compare both outputs and input gradients with tolerances appropriate to the data type.

Part 4 - Python code skeleton

```
import torch

def E16(custom_function, built_in_function, values, tolerance):
    custom_input = values.clone().requires_grad_(True)
    built_in_input = values.clone().requires_grad_(True)
    custom_output = custom_function(custom_input)
    built_in_output = built_in_function(built_in_input)
    upstream = torch.randn_like(custom_output)
    custom_output.backward(upstream)
    built_in_output.backward(upstream)
    return {
        "forward_match": torch.allclose(
            custom_output, built_in_output, atol=tolerance, rtol=tolerance
        ),
        "gradient_match": torch.allclose(...),
        "maximum_output_error": (...).abs().max().item(),
```

```
        "maximum_gradient_error": (...).abs().max().item(),
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

13.4.18 Exercise 17 - Stress Test Activations Under Extreme Inputs

Part 1 - Why this matters

Extreme inputs expose overflow, underflow, saturation, and invalid-value behavior that ordinary samples may never reveal. This is particularly important for formulas containing exponentials or divisions, where a mathematically equivalent naive implementation may be numerically unsafe.

A stress test should include large finite values, signed zeros, infinities, and not-a-number inputs when supported. The objective is to document behavior and gradient safety, not to demand that every special input produce a finite output.

Part 2 - Mathematical form

$$X_{\text{stress}} = \{-\infty, -M, \ldots, -0, +0, \ldots, M, +\infty, \text{NaN}\}.$$

Part 3 - Hints and Helper

Compare custom and built-in functions, classify finite and non-finite results, and run backward only on a safe finite subset when a full reduction would contaminate every gradient.

Part 4 - Python code skeleton

```
import torch

def E17(function, dtype=torch.float32):
    limit = torch.finfo(dtype).max
    values = torch.tensor(
        [-float("inf"), -limit, -1e4, -0.0,
         0.0, 1e4, limit, float("inf"), float("nan")],
        dtype=dtype,
    )
    output = function(...)
    return {
        "input": values,
        "output": output,
        "finite_mask": torch.isfinite(output),
        "nan_mask": torch.isnan(output),
        "positive_infinity": torch.isposinf(output),
```

```
        "negative_infinity": torch.isneginf(output),
    }

def main():
    print(E17(torch.sigmoid))

if __name__ == "__main__":
    main()
```

13.4.19 Exercise 18 - Identify Scenarios Where Activation Choice Dominates Performance

Part 1 - Why this matters

Activation choice is most influential when depth, input scale, initialization, precision, or task geometry repeatedly places units in regions with very different outputs or derivatives. In other settings, data quality or model capacity may dominate and activation changes may have little effect.

Determining dominance requires a factorial experiment rather than one pairwise run. The reader should measure the variation explained by activation across several controlled contexts and compare it with seed variation and interactions with other design factors.

Part 2 - Mathematical form

$$Y = \mu + A_\phi + B_c + (AB)_{\phi,c} + \varepsilon, \qquad \eta_\phi^2 = \frac{SS_\phi}{SS_{\text{total}}}.$$

Part 3 - Hints and Helper

Vary activation, depth, initialization, and input scaling systematically. Repeat seeds, store every configuration, and identify contexts where activation effect exceeds run-to-run noise.

Part 4 - Python code skeleton

```
import itertools

def E18(run_experiment, factors, seeds):
    results = []
    keys = list(factors)
    combinations = itertools.product(*(factors[key] for key in keys))
    for values in combinations:
        configuration = dict(zip(keys, values))
        for seed in seeds:
            metrics = run_experiment(configuration, seed, ...)
            results.append({
                "configuration": configuration.copy(),
                "seed": seed,
                "metrics": metrics,
```

```
            })
    activation_effect = ...
    interaction_effects = ...
    return results, activation_effect, interaction_effects

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

13.4.20 Exercise 19 - Write an Activation Function Selection Guide Based on Experiments

Part 1 - Why this matters

An activation selection guide should translate experimental evidence into conditional recommendations. It must explain which properties matter for deep gradient flow, bounded outputs, sparse representations, numerical precision, hardware cost, and compatibility with initialization and loss design.

The guide should not declare one universal winner. It must record the tested conditions, uncertainty, failure cases, and situations where differences were too small to support a recommendation, allowing future readers to revise conclusions when architectures or workloads change.

Part 2 - Mathematical form

$$\phi^*(c) = \arg\min_{\phi \in \Phi} \left(\widehat{R}(\phi, c) + \lambda_s I_{\text{unstable}} + \lambda_t T(\phi, c) + \lambda_m M(\phi, c) \right).$$

Part 3 - Hints and Helper

Require evidence for every recommendation. Include a decision table, experimental scope, stability findings, precision and CUDA results, limitations, and retesting conditions.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "activation_properties", "decision_table",
        "forward_experiments", "gradient_experiments",
        "saturation_and_dead_units", "initialization_interactions",
        "precision_results", "cuda_results",
        "stability_results", "failure_diagnostics",
        "recommendations", "limitations", "retesting_conditions",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        recommendation
```

```
        for recommendation in sections.get("recommendations", [])
        if not recommendation.get("evidence")
    ]
    return {
        "complete": not missing and not unsupported,
        "missing": missing,
        "unsupported_recommendations": unsupported,
        "guide": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

13.5 MLP03 - Backpropagation Mechanics in MLP

Models and Training

13.5.1 Exercise 00 - Perform a Full Forward Pass and Confirm Autograd Graph Construction

Part 1 - Why this matters

A forward pass does more than produce predictions when trainable tensors require gradients. PyTorch records differentiable operations and connects their outputs to gradient functions, creating the graph that will later carry error information back to every contributing parameter.

Confirming graph construction prevents a model from appearing correct while being disconnected from learning. The reader should distinguish leaf parameters from intermediate tensors and verify that the loss remains connected to the expected chain of operations.

Part 2 - Mathematical form

$$H_1 = \phi(XW_1^\mathsf{T} + \mathbf{b}_1), \quad \widehat{Y} = H_1 W_2^\mathsf{T} + \mathbf{b}_2, \quad \widehat{Y}.\,\text{grad_fn} \neq \varnothing.$$

Part 3 - Hints and Helper

Inspect the gradient requirement and gradient function of the input, parameters, hidden state, prediction, and scalar loss. Do not call backward yet.

Part 4 - Python code skeleton

```
import torch

def E00(model, features, targets, loss_fn):
    prediction, hidden = model.forward_with_hidden(features)
```

```
    loss = loss_fn(prediction, targets)
    report = {
        "prediction_requires_grad": prediction.requires_grad,
        "prediction_grad_fn": type(prediction.grad_fn).__name__,
        "hidden_grad_fn": type(hidden.grad_fn).__name__,
        "loss_grad_fn": type(loss.grad_fn).__name__,
        "parameters": {
            name: (parameter.is_leaf, parameter.requires_grad)
            for name, parameter in model.named_parameters()
        },
    }
    return prediction, loss, report

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

13.5.2 Exercise 01 - Compute Loss and Trigger Backward Pass Through Multiple Layers

Part 1 - Why this matters

A scalar loss summarizes prediction error and becomes the starting point for reverse-mode automatic differentiation. Calling backward sends derivatives through the output layer, hidden activations, and earlier affine transformations in the reverse order of the forward computation.

The operation computes gradients but does not update parameters. Keeping loss computation, gradient creation, and optimization as separate steps helps the reader reason about which stage failed when a model does not learn.

Part 2 - Mathematical form

$$\mathcal{L} = \ell(f_\Theta(X), Y), \qquad \mathcal{L}.\,\text{backward}() \Longrightarrow \nabla_\theta \mathcal{L} \text{ for every } \theta \in \Theta.$$

Part 3 - Hints and Helper

Clear existing gradients, run one forward pass, confirm that the reduced loss is scalar, and call backward exactly once before inspecting parameters.

Part 4 - Python code skeleton

```
import torch

def E01(model, features, targets, loss_fn):
    model.zero_grad(set_to_none=True)
    predictions = model(...)
    loss = loss_fn(..., ...)
```

```
    if loss.ndim != 0:
        raise ValueError(...)
    loss.backward()
    gradients = {
        name: parameter.grad
        for name, parameter in model.named_parameters()
    }
    return loss.item(), gradients

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

13.5.3 Exercise 02 - Inspect Gradients of Each Layer and Verify Their Tensor Shapes

Part 1 - Why this matters

Every parameter gradient must have the same shape as the parameter it differentiates. A mismatch would make an element-wise optimizer update undefined, while a missing gradient indicates that the parameter did not contribute to the loss or was disconnected from the graph.

A layer-wise shape report provides an immediate structural check after backward. It also reinforces that a weight matrix receives one sensitivity value per weight and a bias vector receives one aggregated sensitivity per output feature.

Part 2 - Mathematical form

$$\nabla_{W_l}\mathcal{L} \in \mathbb{R}^{d_l \times d_{l-1}}, \qquad \nabla_{\mathbf{b}_l}\mathcal{L} \in \mathbb{R}^{d_l}.$$

Part 3 - Hints and Helper

Iterate through named parameters after backward. Record parameter shape, gradient shape, missing status, and whether the two shapes match exactly.

Part 4 - Python code skeleton

```
def E02(model):
    report = []
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        report.append({
            "name": name,
            "parameter_shape": tuple(parameter.shape),
            "gradient_shape": None if gradient is None else tuple(...),
            "missing": gradient is None,
            "shape_match": gradient is not None and gradient.shape == ...,
```

```
        })
    return report

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

13.5.4 Exercise 03 - Validate Gradient Flow by Checking Non-Zero Gradients in Hidden Layers

Part 1 - Why this matters

Hidden layers learn only when the loss has a differentiable path to their parameters and that path carries a meaningful signal. A tensor can possess a gradient object while every element is zero, so checking only for a non-missing gradient is not sufficient.

Non-zero gradients are evidence of flow for a specific batch, but they are not automatically healthy. The reader should record norms and non-zero ratios, then interpret exact zeros in relation to activations, frozen parameters, loss construction, and the data.

Part 2 - Mathematical form

$$g_l = \nabla_{W_l} \mathcal{L}, \qquad q_l = \frac{1}{|g_l|} \sum_i \mathbf{1}(g_{l,i} \neq 0), \qquad \|g_l\|_2 > 0.$$

Part 3 - Hints and Helper

Check only trainable hidden-layer parameters. Use a tolerance for near-zero norms and report each failing layer instead of returning one uninformative Boolean.

Part 4 - Python code skeleton

```
import torch

def E03(model, tolerance=1e-12):
    report = {}
    for name, parameter in model.hidden_named_parameters():
        gradient = parameter.grad
        if gradient is None:
            report[name] = {"flow": False, "reason": "missing"}
            continue
        norm = gradient.norm().item()
        nonzero_ratio = (gradient != 0).float().mean().item()
        report[name] = {
            "flow": norm > tolerance,
            "norm": norm,
            "nonzero_ratio": nonzero_ratio,
```

```
        }
    return report

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

13.5.5 Exercise 04 - Demonstrate Vanishing Gradients in Deep Networks Using Saturating Activations

Part 1 - Why this matters

Saturating activations such as sigmoid have derivatives close to zero for large-magnitude inputs. In a deep network, repeated multiplication by small local derivatives can make early-layer gradients orders of magnitude smaller than gradients near the output.

The experiment should connect gradient decay to activation saturation instead of treating small gradients as an unexplained observation. Recording both derivative statistics and layer gradient norms across several depths reveals how the problem develops.

Part 2 - Mathematical form

$$\frac{\partial \mathcal{L}}{\partial H_l} = \frac{\partial \mathcal{L}}{\partial H_L} \prod_{k=l+1}^{L} W_k \operatorname{diag}(\phi'(Z_{k-1})), \qquad |\phi'| \ll 1.$$

Part 3 - Hints and Helper

Use identical seeds for each tested depth. Compare first-to-last gradient ratios and the saturation ratio of every hidden layer after one backward pass.

Part 4 - Python code skeleton

```
import torch

def E04(build_model, depths, batch, loss_fn):
    features, targets = batch
    results = []
    for depth in depths:
        torch.manual_seed(0)
        model = build_model(depth=depth, activation="sigmoid")
        output, states = model.forward_with_states(features)
        loss = loss_fn(output, targets)
        loss.backward()
        norms = model.weight_gradient_norms()
        results.append({
            "depth": depth,
```

```
            "gradient_norms": norms,
            "first_to_last_ratio": norms[0] / (norms[-1] + 1e-12),
            "saturation": model.saturation_statistics(states),
        })
    return results

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

13.5.6 Exercise 05 - Demonstrate Exploding Gradients and Apply Gradient Clipping Correctly

Part 1 - Why this matters

Exploding gradients produce very large update directions that can destabilize parameters, overflow numerical ranges, and turn the loss into a non-finite value. Deep products, large weights, and recurrent amplification are common mechanisms behind the growth.

Gradient clipping limits an update after backward has computed gradients and before the optimizer changes parameters. It treats the immediate symptom rather than proving the underlying architecture or learning rate is correct, so norms must be recorded before and after clipping.

Part 2 - Mathematical form

$$g = \nabla_\Theta \mathcal{L}, \qquad \widetilde{g} = g \min\left(1, \frac{c}{\|g\|_2}\right), \qquad \|\widetilde{g}\|_2 \le c.$$

Part 3 - Hints and Helper

Use global norm clipping after backward and before the optimizer step. Save the norm returned by the clipping function and calculate the post-clipping norm separately.

Part 4 - Python code skeleton

```
import torch

def E05(model, loss, optimizer, max_norm):
    optimizer.zero_grad(set_to_none=True)
    loss.backward()
    before = torch.nn.utils.clip_grad_norm_(
        model.parameters(), max_norm=...
    )
    after = torch.sqrt(sum(
        parameter.grad.detach().pow(2).sum()
        for parameter in model.parameters()
```

```
        if parameter.grad is not None
    ))
    optimizer.step()
    return before.item(), after.item(), after.item() <= max_norm + 1e-6

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

13.5.7 Exercise 06 - Compare Manual Gradient Computation vs Autograd for a Small Network

Part 1 - Why this matters

Manual differentiation exposes the matrix operations hidden inside automatic differentiation. For a small two-layer network, the reader can propagate the loss derivative through the output weights, activation derivative, hidden weights, and bias reductions explicitly.

Agreement with autograd validates both mathematical reasoning and tensor orientation. The comparison must use the same forward values, reduction convention, and batch treatment because a missing transpose or averaging factor can create a plausible but incorrect result.

Part 2 - Mathematical form

$$\nabla_{W_2}\mathcal{L} = \Delta_2^{\mathsf{T}} H, \qquad \Delta_1 = (\Delta_2 W_2) \odot \phi'(Z_1), \qquad \nabla_{W_1}\mathcal{L} = \Delta_1^{\mathsf{T}} X.$$

Part 3 - Hints and Helper

Choose a simple activation with a known derivative and a scalar mean-squared loss. Retain every forward intermediate needed by the manual backward calculation.

Part 4 - Python code skeleton

```
import torch

def E06(features, targets, w1, b1, w2, b2):
    z1 = features @ w1.T + b1
    hidden = torch.tanh(z1)
    predictions = hidden @ w2.T + b2
    loss = ((predictions - targets) ** 2).mean()
    loss.backward()

    delta2 = 2 * (predictions.detach() - targets) / predictions.numel()
    manual_w2 = delta2.T @ hidden.detach()
    manual_b2 = delta2.sum(dim=0)
    delta1 = (delta2 @ w2.detach()) * (1 - hidden.detach() ** 2)
```

```
    manual_w1 = delta1.T @ features
    manual_b1 = delta1.sum(dim=0)
    return {
        "w1_match": torch.allclose(manual_w1, w1.grad, atol=...),
        "b1_match": torch.allclose(manual_b1, b1.grad, atol=...),
        "w2_match": torch.allclose(manual_w2, w2.grad, atol=...),
        "b2_match": torch.allclose(manual_b2, b2.grad, atol=...),
    }

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

13.5.8 Exercise 07 - Verify Backward Correctness Using Finite Difference Gradient Checking

Part 1 - Why this matters

Finite differences approximate a derivative by measuring how the loss changes after a small positive and negative perturbation. This provides an implementation-independent check of autograd for selected parameters in a small deterministic network.

The perturbation must balance truncation error against floating-point cancellation. Gradient checking is therefore usually performed in double precision with smooth functions, a small model, and no stochastic layers or state-changing operations.

Part 2 - Mathematical form

$$\frac{\partial \mathcal{L}}{\partial \theta_i} \approx \frac{\mathcal{L}(\theta_i + \varepsilon) - \mathcal{L}(\theta_i - \varepsilon)}{2\varepsilon}, \qquad e_i = \frac{|g_i - \widetilde{g}_i|}{|g_i| + |\widetilde{g}_i| + \delta}.$$

Part 3 - Hints and Helper

Use double precision, restore the original parameter after each perturbation, and compare a sampled set of entries rather than modifying all parameters at once.

Part 4 - Python code skeleton

```
import torch

def E07(model, loss_closure, parameter, indices, epsilon=1e-6):
    model.zero_grad(set_to_none=True)
    loss = loss_closure()
    loss.backward()
    analytical = parameter.grad.detach().clone()
    results = []
    with torch.no_grad():
```

```
        for index in indices:
            original = parameter[index].item()
            parameter[index] = original + epsilon
            plus = loss_closure().item()
            parameter[index] = original - epsilon
            minus = loss_closure().item()
            parameter[index] = original
            numerical = (plus - minus) / (2 * epsilon)
            relative_error = abs(analytical[index].item() - numerical) / (...)
            results.append({
                "index": index,
                "numerical": numerical,
                "analytical": analytical[index].item(),
                "relative_error": relative_error,
            })
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

13.5.9 Exercise 08 - Detect and Fix Common Backprop Bugs Caused by Detached Tensors

Part 1 - Why this matters

Detaching a tensor creates a value that shares no gradient history with the operations that produced it. If this happens inside a training path, later layers may receive gradients while every parameter before the detach point remains unchanged.

The bug is difficult to notice because the forward values and loss can remain valid. Diagnosis requires locating the first intermediate tensor whose gradient function disappears, then removing unintended conversion, detachment, or reconstruction without retaining unnecessary graphs.

Part 2 - Mathematical form

$$H_k^{\text{stop}} = \text{detach}(H_k), \qquad \frac{\partial H_k^{\text{stop}}}{\partial H_k} = 0, \qquad \nabla_{W_l}\mathcal{L} = 0 \text{ for } l \leq k.$$

Part 3 - Hints and Helper

Inspect gradient functions across intermediate states and parameter gradients after backward. Fix the path at its source rather than manually setting gradient requirements on the detached result.

Part 4 - Python code skeleton

```
def E08(model, features, targets, loss_fn):
    model.zero_grad(set_to_none=True)
    output, states = model.forward_with_states(features)
    loss = loss_fn(output, targets)
    loss.backward()
    report = []
    for index, state in enumerate(states):
        report.append({
            "layer": index,
            "requires_grad": state.requires_grad,
            "has_grad_fn": state.grad_fn is not None,
        })
    missing = [
        name for name, parameter in model.named_parameters()
        if parameter.requires_grad and parameter.grad is None
    ]
    first_break = next(
        (item["layer"] for item in report if not item["has_grad_fn"]),
        None,
    )
    return report, missing, first_break

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

13.5.10 Exercise 09 - Debug Gradient Mismatch Caused by Wrong Loss Reduction Mode

Part 1 - Why this matters

Loss reduction determines how per-sample errors become the scalar used by backward. Summing and averaging produce gradients with identical directions for a fixed batch but different magnitudes, usually by a factor related to the number of reduced elements.

A mismatch between a manual derivation and PyTorch may therefore come from reduction rather than calculus. The reader must state whether the loss is summed, averaged, or left unreduced and apply the same convention to every gradient comparison.

Part 2 - Mathematical form

$$\mathcal{L}_{\text{sum}} = \sum_{i=1}^{N} \ell_i, \qquad \mathcal{L}_{\text{mean}} = \frac{1}{N} \sum_{i=1}^{N} \ell_i, \qquad \nabla \mathcal{L}_{\text{sum}} = N \nabla \mathcal{L}_{\text{mean}}.$$

Part 3 - Hints and Helper

Compute gradients from identical predictions with sum and mean reductions. Compare their direction, norm ratio, and the exact number of elements included in the reduction.

Part 4 - Python code skeleton

```
import copy
import torch

def E09(model, features, targets, elementwise_loss):
    gradients = {}
    for reduction in ("sum", "mean"):
        current = copy.deepcopy(model)
        losses = elementwise_loss(current(features), targets)
        loss = losses.sum() if reduction == "sum" else losses.mean()
        loss.backward()
        gradients[reduction] = [
            parameter.grad.detach().clone()
            for parameter in current.parameters()
        ]
    ratios = [
        summed.norm() / (meaned.norm() + 1e-12)
        for summed, meaned in zip(gradients["sum"], gradients["mean"])
    ]
    return gradients, ratios, targets.numel()

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

13.5.11 Exercise 10 - Execute Backward Pass on CUDA and Validate Gradient Consistency

Part 1 - Why this matters

CUDA executes the same computational graph on GPU kernels and should produce gradients consistent with a CPU reference within numerical tolerances. Exact bitwise equality is not generally required because operation order and hardware arithmetic may differ.

A valid comparison starts both models from identical state, uses identical data and precision, and transfers the resulting gradients to one device before comparison. It must also verify that every CUDA parameter receives a gradient on the CUDA device.

Part 2 - Mathematical form

$$g_{\text{CPU}} \approx g_{\text{CUDA}}, \qquad \frac{\|g_{\text{CPU}} - g_{\text{CUDA}}\|}{\|g_{\text{CPU}}\| + \varepsilon} < \tau.$$

Part 3 - Hints and Helper

Skip the CUDA branch cleanly when unavailable. Load one state dictionary into both models, disable stochastic layers, and compare named gradients with declared tolerances.

Part 4 - Python code skeleton

```
import copy
import torch

def run_backward(model, features, targets, loss_fn):
    model.zero_grad(set_to_none=True)
    loss = loss_fn(model(features), targets)
    loss.backward()
    return {
        name: parameter.grad.detach().cpu()
        for name, parameter in model.named_parameters()
    }

def E10(model, features, targets, loss_fn):
    cpu_model = copy.deepcopy(model).cpu().eval()
    cpu_gradients = run_backward(
        cpu_model, features.cpu(), targets.cpu(), loss_fn
    )
    if not torch.cuda.is_available():
        return {"available": False, "cpu": cpu_gradients}
    cuda_model = copy.deepcopy(model).cuda().eval()
    cuda_gradients = run_backward(
        cuda_model, features.cuda(), targets.cuda(), loss_fn
    )
    matches = {
        name: torch.allclose(cpu_gradients[name], cuda_gradients[name], ...)
        for name in cpu_gradients
    }
    return {"available": True, "matches": matches}

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

13.5.12 Exercise 11 - Investigate CPU vs GPU Gradient Parity Under Different Random Seeds

Part 1 - Why this matters

One successful CPU-GPU comparison does not measure sensitivity to initialization and input sampling. Repeating the experiment across seeds reveals whether small numerical differences remain consistently bounded or become amplified by particular parameter states.

Seed control must cover model initialization and generated data, while nondeterministic operations should be documented. The result should report a distribution of absolute and relative errors instead of only a pass or fail conclusion.

Part 2 - Mathematical form

$$e_s = \max_{\theta} \|g_{\theta,s}^{\mathrm{CPU}} - g_{\theta,s}^{\mathrm{GPU}}\|_{\infty}, \qquad s \in \mathcal{S}.$$

Part 3 - Hints and Helper

Recreate the model and batch after setting each seed, then copy identical state to both devices. Aggregate maximum, mean, and worst-seed errors.

Part 4 - Python code skeleton

```
import torch

def E11(build_case, compare_devices, seeds):
    results = []
    for seed in seeds:
        torch.manual_seed(seed)
        model, features, targets = build_case(...)
        comparison = compare_devices(model, features, targets)
        results.append({"seed": seed, **comparison})
    worst = max(results, key=lambda item: item["max_relative_error"])
    mean_error = sum(
        item["max_relative_error"] for item in results
    ) / len(results)
    return {
        "runs": results,
        "mean_error": mean_error,
        "worst_seed": worst["seed"],
        "worst_error": worst["max_relative_error"],
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

13.5.13 Exercise 12 - Compare float32 vs float64 Gradients for Stability and Precision Insights

Part 1 - Why this matters

Double precision represents smaller changes and a wider range of magnitudes than single precision, making it a useful reference for sensitive gradient calculations. Differences become more visible in deep chains, ill-conditioned problems, and finite-difference verification.

Higher precision does not correct a broken graph or an unsuitable optimization problem, and it increases memory and compute cost. The comparison should measure gradient error and non-finite behavior while keeping model values and data logically identical.

Part 2 - Mathematical form

$$e_{32} = \frac{\|g_{32}^{(64)} - g_{64}\|_2}{\|g_{64}\|_2 + \varepsilon}, \qquad g_{32}^{(64)} = \mathrm{cast}_{64}(g_{32}).$$

Part 3 - Hints and Helper

Create both models from the same double-precision state, cast one copy to single precision, and compare gradients after moving both results to double precision on the CPU.

Part 4 - Python code skeleton

```
import copy
import torch

def E12(model, features, targets, loss_fn):
    reports = {}
    for dtype in (torch.float32, torch.float64):
        current = copy.deepcopy(model).to(dtype=dtype)
        current_features = features.to(dtype=dtype)
        current_targets = targets.to(dtype=dtype)
        loss = loss_fn(current(current_features), current_targets)
        loss.backward()
        reports[dtype] = {
            name: parameter.grad.detach().cpu().double()
            for name, parameter in current.named_parameters()
        }
    errors = {}
    for name in reports[torch.float64]:
        reference = reports[torch.float64][name]
        candidate = reports[torch.float32][name]
        errors[name] = (candidate - reference).norm() / (...)
    return reports, errors

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

13.5.14 Exercise 13 - Use Autograd Hooks to Log Gradient Norms Layer by Layer During Training

Part 1 - Why this matters

Gradient hooks observe tensors as backward computes their gradients, allowing layer-wise monitoring without rewriting autograd. A time series of norms can reveal the first layer where gradients vanish, explode, or become non-finite during training.

Hooks are persistent callbacks and must be removed when monitoring ends. The logger should store detached scalar summaries rather than full gradient tensors so the diagnostic system does not create unnecessary memory pressure.

Part 2 - Mathematical form

$$R_{l,t} = (\|g_{l,t}\|_2, \|g_{l,t}\|_\infty, p_{\neg\text{finite}}(g_{l,t})) \,.$$

Part 3 - Hints and Helper

Register one hook per trainable parameter and capture the current step through a closure. Keep every removable handle and test cleanup after logging.

Part 4 - Python code skeleton

```
import torch

def E13(model, current_step):
    records = []
    handles = []

    def make_hook(name):
        def hook(gradient):
            records.append({
                "step": current_step(),
                "parameter": name,
                "l2_norm": gradient.norm().item(),
                "max_abs": gradient.abs().max().item(),
                "finite": torch.isfinite(gradient).all().item(),
            })
            return gradient
        return hook

    for name, parameter in model.named_parameters():
        if parameter.requires_grad:
            handles.append(parameter.register_hook(...))
    return records, handles

def main():
    print(E13(...))
```

```
if __name__ == "__main__":
    main()
```

13.5.15 Exercise 14 - Prove the Need for zero_grad by Demonstrating Gradient Accumulation Errors

Part 1 - Why this matters

PyTorch accumulates new derivatives into an existing parameter gradient. This supports deliberate accumulation across micro-batches, but forgetting to clear gradients causes an optimizer step to use the sum of current and previous backward passes.

The effect should be demonstrated with repeated backward calls on the same controlled batch. Comparing uncleared, cleared, and intentionally accumulated cases proves that gradient clearing is part of training-loop semantics rather than optional housekeeping.

Part 2 - Mathematical form

$$g^{(t)} \leftarrow g^{(t-1)} + \nabla_\theta \mathcal{L}_t, \qquad \text{zero_grad} \Longrightarrow g^{(t-1)} = 0 \text{ or } \varnothing.$$

Part 3 - Hints and Helper

Run two identical backward passes without an optimizer update. Verify that the second uncleared gradient is twice the first, then repeat with gradients cleared between passes.

Part 4 - Python code skeleton

```
import torch

def E14(model, loss_closure):
    model.zero_grad(set_to_none=True)
    loss_closure(model).backward()
    first = {
        name: parameter.grad.detach().clone()
        for name, parameter in model.named_parameters()
    }
    loss_closure(model).backward()
    accumulated = {
        name: parameter.grad.detach().clone()
        for name, parameter in model.named_parameters()
    }
    model.zero_grad(set_to_none=True)
    loss_closure(model).backward()
    cleared = {
        name: parameter.grad.detach().clone()
        for name, parameter in model.named_parameters()
    }
```

```
    return {
        name: {
            "doubled": torch.allclose(accumulated[name], 2 * first[name]),
            "cleared_matches": torch.allclose(cleared[name], first[name]),
        }
        for name in first
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

13.5.16 Exercise 15 - Analyze the Effect of Batch Size on Gradient Variance and Update Stability

Part 1 - Why this matters

A mini-batch gradient estimates the full-dataset gradient from a sample. Smaller batches usually contain more sampling noise, while larger batches reduce variance but require more memory and may change the optimization behavior for a fixed learning rate.

The analysis must distinguish variance across independently sampled batches from the scale introduced by loss reduction. Comparing gradients with mean reduction and repeated batches allows update direction variability to be measured fairly.

Part 2 - Mathematical form

$$g_B = \frac{1}{B}\sum_{i=1}^{B} \nabla_\theta \ell_i, \qquad \mathrm{Var}(g_B) \approx \frac{\Sigma}{B}.$$

Part 3 - Hints and Helper

For each batch size, sample many batches without changing parameters. Flatten all parameter gradients, then report their mean norm, component variance, and cosine similarity to a large-batch reference.

Part 4 - Python code skeleton

```
import torch

def E15(model, sample_batch, batch_sizes, repeats, loss_fn):
    report = {}
    for batch_size in batch_sizes:
        vectors = []
        for _ in range(repeats):
            features, targets = sample_batch(batch_size)
            model.zero_grad(set_to_none=True)
```

```
            loss_fn(model(features), targets).backward()
            vector = torch.cat([
                parameter.grad.detach().flatten()
                for parameter in model.parameters()
            ])
            vectors.append(vector)
        stacked = torch.stack(vectors)
        report[batch_size] = {
            "mean_norm": stacked.norm(dim=1).mean().item(),
            "component_variance": stacked.var(dim=0).mean().item(),
            "vectors": stacked,
        }
    return report

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

13.5.17 Exercise 16 - Demonstrate Graph Retention Costs Using retain_graph and Memory Profiling

Part 1 - Why this matters

Autograd normally frees saved intermediate values after backward because they are no longer needed. Retaining the graph permits another backward traversal through the same forward computation but keeps those intermediates alive and increases memory lifetime.

Graph retention is justified only when the same graph must be differentiated again. Repeatedly retaining graphs in an ordinary training loop can create severe memory growth, so the reader should measure peak allocation and compare it with recomputing a fresh forward pass.

Part 2 - Mathematical form

$$M_{\text{retain}} \approx M_{\Theta} + M_g + M_{\text{saved states}}, \qquad M_{\text{fresh}} \text{ releases saved states after backward.}$$

Part 3 - Hints and Helper

On CUDA, reset peak memory statistics and synchronize measurements. Compare repeated backward with retention against repeated fresh forward-backward passes, then release references.

Part 4 - Python code skeleton

```
import torch

def E16(model, features, targets, loss_fn, repeats):
```

```
    if not features.is_cuda:
        raise ValueError(...)
    torch.cuda.reset_peak_memory_stats(features.device)
    output = model(features)
    loss = loss_fn(output, targets)
    for index in range(repeats):
        model.zero_grad(set_to_none=True)
        loss.backward(retain_graph=index < repeats - 1)
    torch.cuda.synchronize(features.device)
    retained_peak = torch.cuda.max_memory_allocated(features.device)
    fresh_peak = ...
    return {"retained_peak": retained_peak, "fresh_peak": fresh_peak}

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

13.5.18 Exercise 17 - Debug Device Mismatch Errors During Backward Computation on CUDA

Part 1 - Why this matters

A device mismatch may appear only during backward when a custom loss, target, mask, hook, or saved tensor resides on a different device from the graph. The forward prediction can therefore succeed while gradient computation fails later.

Debugging requires checking every tensor that participates in loss creation and every registered parameter or buffer. Moving tensors silently inside a backward hook can hide the source and introduce transfers, so placement should be corrected before graph construction.

Part 2 - Mathematical form

$$D(X) = D(Y) = D(\Theta) = D(\mathcal{L}) = \text{CUDA}, \qquad D(\nabla_\theta \mathcal{L}) = D(\theta).$$

Part 3 - Hints and Helper

Build a placement report before backward for inputs, targets, parameters, buffers, predictions, and loss. Identify mismatches relative to the model's first parameter device.

Part 4 - Python code skeleton

```
def E17(model, features, targets, loss_fn):
    expected = next(model.parameters()).device
    prediction = model(features)
    loss = loss_fn(prediction, targets)
    report = {
```

```
        "expected": str(expected),
        "features": str(features.device),
        "targets": str(targets.device),
        "prediction": str(prediction.device),
        "loss": str(loss.device),
        "parameters": {
            name: str(parameter.device)
            for name, parameter in model.named_parameters()
        },
        "buffers": {
            name: str(buffer.device)
            for name, buffer in model.named_buffers()
        },
    }
    mismatches = ...
    if not mismatches:
        loss.backward()
    return report, mismatches

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

13.5.19 Exercise 18 - Stress Test Backpropagation with Deep Architecture and Large Batch Inputs

Part 1 - Why this matters

A stress test explores whether backward remains numerically finite and computationally feasible as depth, width, and batch size increase. It can expose memory exhaustion, weak gradient flow, excessive runtime, and precision limits that small examples conceal.

The test must increase load gradually and record the last successful configuration. Resource failure is a result to document, but the experiment should avoid destabilizing the environment by defining maximum dimensions and cleaning references between trials.

Part 2 - Mathematical form

$$C_{\text{backward}} \propto \sum_{l=1}^{L} B d_{l-1} d_l, \qquad M_{\text{activation}} \propto \sum_{l=1}^{L} B d_l.$$

Part 3 - Hints and Helper

Sweep bounded configurations from small to large. Synchronize device timings, monitor peak memory, test gradient finiteness, and catch out-of-memory failures separately from mathematical failures.

Part 4 - Python code skeleton

```
import time
import torch

def E18(build_case, configurations):
    results = []
    for configuration in configurations:
        try:
            model, features, targets, loss_fn = build_case(configuration)
            if features.is_cuda:
                torch.cuda.reset_peak_memory_stats(features.device)
            start = time.perf_counter()
            loss = loss_fn(model(features), targets)
            loss.backward()
            if features.is_cuda:
                torch.cuda.synchronize(features.device)
            elapsed = time.perf_counter() - start
            finite = all(
                parameter.grad is not None
                and torch.isfinite(parameter.grad).all()
                for parameter in model.parameters()
            )
            results.append({
                "configuration": configuration,
                "success": True,
                "finite": finite,
                "elapsed": elapsed,
                "peak_memory": ...,
            })
        except RuntimeError as error:
            results.append({
                "configuration": configuration,
                "success": False,
                "error": str(error),
            })
    return results

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

13.5.20 Exercise 19 - Write a Full Backprop Debugging Playbook Based on Observed Failure Modes

Part 1 - Why this matters

A backpropagation playbook converts isolated debugging experiments into a repeatable di-

agnostic sequence. It should begin with graph connectivity and loss construction, then inspect gradient presence, shape, magnitude, finiteness, accumulation, device placement, and numerical parity.

The playbook must map each symptom to evidence, likely causes, controlled tests, and safe corrections. It should also state when clipping or graph retention only masks a deeper problem and preserve experiment records so a future failure can be compared with known patterns.

Part 2 - Mathematical form

$$\text{symptom} \longrightarrow \text{measurement} \longrightarrow \text{hypotheses} \longrightarrow \text{controlled test} \longrightarrow \text{verified correction}.$$

Part 3 - Hints and Helper

Require observed evidence for every failure entry. Include graph, loss, gradients, accumulation, precision, CUDA, memory, stress testing, and escalation criteria.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "graph_connectivity", "loss_and_reduction",
        "missing_gradients", "gradient_shapes",
        "vanishing_gradients", "exploding_gradients",
        "gradient_accumulation", "detached_tensors",
        "finite_difference_check", "precision_parity",
        "cuda_device_checks", "hooks_and_logging",
        "graph_retention_memory", "stress_test_protocol",
        "symptom_decision_tree", "verified_fixes",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        name for name, entry in sections.get("verified_fixes", {}).items()
        if not entry.get("evidence") or not entry.get("verification")
    ]
    return {
        "complete": not missing and not unsupported,
        "missing": missing,
        "unsupported_fixes": unsupported,
        "playbook": sections,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

13.6 MLP04 - Weight Initialization and Training Stability

Models and Training

13.6.1 Exercise 00 - Implement Zero Initialization and Observe Symmetry Failure in Hidden Units

Part 1 - Why this matters

When every hidden unit begins with identical zero weights and biases, the units produce identical outputs and receive identical gradients. Training cannot assign them different roles, so a wide hidden layer behaves like repeated copies of one unit.

Zero initialization is therefore not merely slow for hidden weights; it creates a symmetry that gradient-based learning cannot break. The experiment should compare unit outputs and weight gradients after one update to show that equality persists.

Part 2 - Mathematical form

$$W_l^{(0)} = 0,\ \mathbf{b}_l^{(0)} = 0 \quad \Longrightarrow \quad h_{l,1} = \cdots = h_{l,d_l},\ \nabla W_{l,1} = \cdots = \nabla W_{l,d_l}.$$

Part 3 - Hints and Helper

Initialize every linear parameter to zero, run one backward step, and compare hidden-unit activations and gradient rows before applying the update.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E00(model, features, targets, loss_fn):
    for module in model.modules():
        if isinstance(module, nn.Linear):
            nn.init.zeros_(...)
            nn.init.zeros_(...)
    output, hidden = model.forward_with_hidden(features)
    loss_fn(output, targets).backward()
    first = model.first_linear_layer()
    return {
        "identical_hidden_units": torch.allclose(hidden[:, 0], hidden[:, 1]),
        "identical_gradient_rows": torch.allclose(
            first.weight.grad[0], first.weight.grad[1]
        ),
    }
```

```
def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

13.6.2 Exercise 01 - Compare Random Uniform vs Random Normal Initialization in Early Training

Part 1 - Why this matters

Uniform and normal distributions can share the same variance while assigning different probabilities to extreme values. If their scales are not matched, an early-training comparison confounds distribution shape with parameter magnitude.

A controlled experiment should initialize identical architectures from both distributions with equal target variance and then compare initial loss, activation statistics, gradient norms, and the first training steps across several seeds.

Part 2 - Mathematical form

$$W_U \sim \mathcal{U}(-a, a),\ \mathrm{Var}(W_U) = a^2/3, \qquad W_N \sim \mathcal{N}(0, \sigma^2),\ \sigma^2 = a^2/3.$$

Part 3 - Hints and Helper

Match the theoretical variances and reset the seed policy for every run. Do not judge the methods from one initialization.

Part 4 - Python code skeleton

```
import torch

def E01(build_model, initialize, train_steps, seeds, variance):
    results = []
    for seed in seeds:
        for distribution in ("uniform", "normal"):
            torch.manual_seed(seed)
            model = build_model()
            initialize(model, distribution, variance)
            metrics = train_steps(model, ...)
            results.append({
                "seed": seed,
                "distribution": distribution,
                "metrics": metrics,
            })
    return results

def main():
    print(E01(...))
```

```
if __name__ == "__main__":
    main()
```

13.6.3 Exercise 02 - Implement Xavier Initialization and Validate Activation Variance Preservation

Part 1 - Why this matters

Xavier initialization selects a weight scale from both the incoming and outgoing widths. It is designed to keep forward and backward signal variance reasonably balanced for approximately symmetric activations such as tanh.

Validation requires more than calling an initializer. The reader should measure input, pre-activation, and activation variance layer by layer in a deep untrained network and compare observed behavior with a poorly scaled baseline.

Part 2 - Mathematical form

$$\mathrm{Var}(W) = \frac{2}{n_{\text{in}} + n_{\text{out}}}, \qquad W \sim \mathcal{U}\left(-\sqrt{\frac{6}{n_{\text{in}} + n_{\text{out}}}}, \sqrt{\frac{6}{n_{\text{in}} + n_{\text{out}}}}\right).$$

Part 3 - Hints and Helper

Implement the uniform formula manually, keep biases at zero, and estimate layer variances from a large random batch.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

def E02(model, features):
    with torch.no_grad():
        for module in model.modules():
            if isinstance(module, nn.Linear):
                fan_in, fan_out = module.in_features, module.out_features
                bound = math.sqrt(6.0 / (... + ...))
                module.weight.uniform_(-bound, bound)
                module.bias.zero_()
        output, states = model.forward_with_states(features)
    variances = [state.float().var().item() for state in states]
    return output, variances

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

13.6.4 Exercise 03 - Implement He Initialization and Validate ReLU-Compatible Gradient Flow

Part 1 - Why this matters

ReLU removes the negative portion of a roughly symmetric pre-activation distribution. He initialization compensates for this loss by using a variance near two divided by the incoming width, helping signals survive through deep ReLU networks.

The assumption is tied to the activation and network structure. The reader should verify activation variance and weight-gradient norms across depth rather than treating He initialization as universally optimal.

Part 2 - Mathematical form

$$W_{ij} \sim \mathcal{N}\left(0, \frac{2}{n_{\text{in}}}\right), \qquad \text{Std}(W) = \sqrt{\frac{2}{n_{\text{in}}}}.$$

Part 3 - Hints and Helper

Initialize ReLU layers manually, run a forward-backward pass, and report variance and gradient norms for every layer.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

def E03(model, features, targets, loss_fn):
    with torch.no_grad():
        for module in model.modules():
            if isinstance(module, nn.Linear):
                std = math.sqrt(2.0 / module.in_features)
                module.weight.normal_(0.0, ...)
                module.bias.zero_()
    output, states = model.forward_with_states(features)
    loss_fn(output, targets).backward()
    gradients = model.weight_gradient_norms()
    variances = [state.float().var().item() for state in states]
    return variances, gradients

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

13.6.5 Exercise 04 - Track Activation Statistics to Confirm Initialization Quality Across Layers

Part 1 - Why this matters

A useful initialization keeps activation scale informative across many layers. Collapsing variance, rapidly increasing magnitude, excessive sparsity, saturation, or non-finite values can reveal instability before the first optimizer step.

Layer-wise statistics turn initialization quality into measurable evidence. The same fixed batch should be used for all methods so differences reflect the initial parameters rather than sampling noise.

Part 2 - Mathematical form

$$R_l = (\mu_l, s_l^2, \min H_l, \max H_l, p_{0,l}, p_{\neg\text{finite},l}).$$

Part 3 - Hints and Helper

Capture every hidden activation without gradients and report scalar summaries. Flag large variance ratios between adjacent layers.

Part 4 - Python code skeleton

```
import torch

def E04(model, features, variance_ratio_limit=10.0):
    with torch.no_grad():
        _, states = model.forward_with_states(features)
    report = []
    previous_variance = features.float().var().item()
    for index, state in enumerate(states):
        values = state.float()
        variance = values.var().item()
        report.append({
            "layer": index,
            "mean": values.mean().item(),
            "variance": variance,
            "zero_ratio": (values == 0).float().mean().item(),
            "finite": torch.isfinite(values).all().item(),
            "unstable_ratio": variance / (previous_variance + 1e-12) > ...,
        })
        previous_variance = variance
    return report

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

13.6.6 Exercise 05 - Track Gradient Statistics to Detect Early Instability from Bad Initialization

Part 1 - Why this matters

Poor initialization can produce vanishing, exploding, highly sparse, or non-finite gradients on the first batch. Detecting these patterns before a long training run saves compute and identifies the problem before optimizer dynamics obscure its origin.

Gradient statistics should be interpreted by layer position and parameter type. A global norm alone can hide an early layer with no signal or one layer that dominates the entire update.

Part 2 - Mathematical form

$$G_l = (\|g_l\|_2, \|g_l\|_\infty, \mathbb{E}|g_l|, p_0(g_l), p_{\neg\text{finite}}(g_l)).$$

Part 3 - Hints and Helper

Run one backward pass before any update. Log every weight and bias separately and flag norms outside declared bounds.

Part 4 - Python code skeleton

```
import torch

def E05(model, lower=1e-10, upper=1e3):
    report = []
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        if gradient is None:
            report.append({"name": name, "status": "missing"})
            continue
        norm = gradient.norm().item()
        report.append({
            "name": name,
            "norm": norm,
            "max_abs": gradient.abs().max().item(),
            "zero_ratio": (gradient == 0).float().mean().item(),
            "finite": torch.isfinite(gradient).all().item(),
            "unstable": norm < lower or norm > upper,
        })
    return report

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

13.6.7 Exercise 06 - Demonstrate Training Collapse Caused by Extreme Initialization Scale

Part 1 - Why this matters

Weights initialized at an extreme scale can make activations and gradients explode, saturate bounded functions, or create non-finite loss values. Very small scales can instead collapse representations and weaken learning signals.

A controlled scale sweep should locate the transition from stable to unstable behavior. The objective is to explain collapse through measured signals, not simply to produce a NaN result.

Part 2 - Mathematical form

$$W_l = s\widetilde{W}_l, \qquad s \in \{10^{-k}, \ldots, 1, \ldots, 10^k\}, \qquad \text{stability} = F(s, L, \phi).$$

Part 3 - Hints and Helper

Reuse the same base random tensors and multiply them by each scale. Stop a run when loss, activations, gradients, or parameters become non-finite.

Part 4 - Python code skeleton

```
import copy
import torch

def E06(base_model, scales, train_steps):
    results = []
    for scale in scales:
        model = copy.deepcopy(base_model)
        with torch.no_grad():
            for parameter in model.weight_parameters():
                parameter.mul_(scale)
        history = train_steps(model, stop_on_nonfinite=True, ...)
        results.append({
            "scale": scale,
            "collapsed": not history["all_finite"],
            "first_failure_step": history.get("first_failure_step"),
            "history": history,
        })
    return results

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

13.6.8 Exercise 07 - Compare Training Speed Under Different Initializations Using the Same Dataset

Part 1 - Why this matters

Initialization changes the starting region of the loss landscape and the quality of early signal propagation. It can therefore affect how quickly otherwise identical models reach a target validation loss or accuracy.

Fair timing requires the same data order, optimizer, architecture, stopping rule, hardware, and seed schedule. Results should combine wall-clock time with optimization steps because one method may have identical computation per step but need fewer steps.

Part 2 - Mathematical form

$$T_m = \min\{t : \widehat{R}_{\text{val}}(\theta_t^{(m)}) \le \tau\}, \qquad m \in \mathcal{M}.$$

Part 3 - Hints and Helper

Repeat every initializer across seeds and record time and steps to a predetermined target. Report failures to reach the target within the budget.

Part 4 - Python code skeleton

```
import time
import torch

def E07(build_model, initializers, train_to_target, seeds):
    results = []
    for seed in seeds:
        for name, initializer in initializers.items():
            torch.manual_seed(seed)
            model = build_model()
            initializer(model)
            start = time.perf_counter()
            outcome = train_to_target(model, ...)
            elapsed = time.perf_counter() - start
            results.append({
                "seed": seed, "initializer": name,
                "elapsed": elapsed, **outcome,
            })
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

13.6.9 Exercise 08 - Analyze How Initialization Interacts with Activation Choice (ReLU vs Tanh)

Part 1 - Why this matters

ReLU and tanh have different output ranges and derivative behavior, so they do not respond identically to one weight scale. He initialization is designed around rectification, while Xavier often provides a more balanced starting scale for tanh.

The interaction should be tested factorially rather than by comparing one favored pair with one poor pair. Every activation-initializer combination must be evaluated under matched seeds and training conditions.

Part 2 - Mathematical form

$$Y = \mu + A_\phi + B_I + (AB)_{\phi,I} + \varepsilon.$$

Part 3 - Hints and Helper

Test ReLU and tanh with both Xavier and He initialization. Compare saturation, sparsity, activation variance, gradient flow, and training metrics.

Part 4 - Python code skeleton

```
import itertools
import torch

def E08(run_case, activations, initializers, seeds):
    results = []
    for activation, initializer, seed in itertools.product(
        activations, initializers, seeds
    ):
        torch.manual_seed(seed)
        metrics = run_case(activation, initializer, ...)
        results.append({
            "activation": activation,
            "initializer": initializer,
            "seed": seed,
            "metrics": metrics,
        })
    return results

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

13.6.10 Exercise 09 - Debug NaN Loss Caused by Unstable Initialization and Fix the Root Cause

Part 1 - Why this matters

A NaN loss is often detected far after the first invalid value appears. Excessive initial weights may create infinite pre-activations, invalid loss operations, or non-finite gradients that contaminate parameters during the first update.

Root-cause debugging locates the earliest non-finite tensor and corrects the initialization scale or formula. Lowering the learning rate or clipping gradients may delay failure without fixing an already invalid forward pass.

Part 2 - Mathematical form

$$k^* = \min\{k : T_k \notin \mathbb{R}^{\text{finite}}\}, \qquad \text{repair} \Rightarrow T_j \in \mathbb{R}^{\text{finite}} \ \forall j.$$

Part 3 - Hints and Helper

Check parameters, pre-activations, activations, loss, gradients, and updated parameters in order. Re-run the same batch after applying a justified initializer.

Part 4 - Python code skeleton

```
import torch

def E09(model, batch, loss_fn, stable_initializer):
    features, targets = batch
    output, states = model.forward_with_states(features)
    loss = loss_fn(output, targets)
    parameters_finite = all(
        torch.isfinite(parameter).all()
        for parameter in model.parameters()
    )
    diagnostics = {
        "parameters": parameters_finite,
        "states": [torch.isfinite(state).all().item() for state in states],
        "loss": torch.isfinite(loss).item(),
    }
    stable_initializer(model)
    fixed_output, fixed_states = model.forward_with_states(features)
    fixed_loss = loss_fn(fixed_output, targets)
    verified = torch.isfinite(fixed_loss).item() and all(
        torch.isfinite(state).all() for state in fixed_states
    )
    return diagnostics, verified

def main():
```

```
    print(E09(...))

if __name__ == "__main__":
    main()
```

13.6.11 Exercise 10 - Run Initialization Experiments on CUDA and Profile Startup Training Stability

Part 1 - Why this matters

CUDA enables larger initialization experiments but introduces asynchronous execution and device-specific memory constraints. Startup stability should be profiled with synchronized timing and all model, data, and generated parameters placed on the same device.

The first iterations may include one-time setup costs, so timing and mathematical stability should be reported separately. Peak memory, finite ratios, initial gradient norms, and early loss curves form a more useful profile than runtime alone.

Part 2 - Mathematical form

$$P_{m,D} = (t_{\text{warm}}, t_{\text{step}}, M_{\text{peak}}, p_{\text{finite}}, \|g_0\|).$$

Part 3 - Hints and Helper

Warm up CUDA before timing, synchronize around measurements, reset peak-memory statistics, and keep the initialized model on CUDA throughout the run.

Part 4 - Python code skeleton

```
import time
import torch

def E10(run_startup, initializer, device):
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats(device)
        torch.cuda.synchronize(device)
    start = time.perf_counter()
    result = run_startup(initializer, device, ...)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        peak = torch.cuda.max_memory_allocated(device)
    else:
        peak = None
    return {"elapsed": time.perf_counter() - start,
            "peak_memory": peak, **result}

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

13.6.12 Exercise 11 - Compare float32 vs mixed precision Training Stability for Each Initialization

Part 1 - Why this matters

Mixed precision reduces memory and can accelerate training, but its narrower numerical range may expose instability caused by poor initialization. Loss scaling protects small gradients, yet it cannot make non-finite forward activations valid.

Each initializer should be tested in full and mixed precision under the same seeds. The comparison must record skipped optimizer steps, scale changes, non-finite events, convergence, memory, and speed.

Part 2 - Mathematical form

$$\widetilde{\mathcal{L}} = s\mathcal{L}, \qquad \widetilde{g} = s\nabla\mathcal{L}, \qquad g = \widetilde{g}/s.$$

Part 3 - Hints and Helper

Use automatic mixed precision only on supported devices. Keep a full-precision control and report scaler behavior alongside loss values.

Part 4 - Python code skeleton

```
import torch

def E11(run_training, initializers, seeds):
    report = []
    for name, initializer in initializers.items():
        for seed in seeds:
            for precision in ("float32", "mixed"):
                outcome = run_training(
                    initializer=initializer,
                    seed=seed,
                    precision=precision,
                    ...
                )
                report.append({
                    "initializer": name,
                    "seed": seed,
                    "precision": precision,
                    "outcome": outcome,
                })
    return report

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

13.6.13 Exercise 12 - Implement Custom Parameter Initializer for Arbitrary Network Depth

Part 1 - Why this matters

A reusable initializer must discover all applicable modules regardless of network depth. It should compute fan values from each layer's actual shape, initialize weights according to a declared rule, and handle biases separately.

A custom initializer also needs validation and reproducibility. Unsupported modules, invalid gains, and accidental reinitialization of frozen or loaded parameters should be handled explicitly rather than silently.

Part 2 - Mathematical form

$$I(W_l; \phi_l, n_{\text{in}}, n_{\text{out}}, g), \qquad l = 1, \ldots, L.$$

Part 3 - Hints and Helper

Write a function suitable for model application, select the rule from activation metadata, and return a report of every modified module.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E12(model, rule, bias_value=0.0):
    report = []
    with torch.no_grad():
        for name, module in model.named_modules():
            if not isinstance(module, nn.Linear):
                continue
            if rule == "xavier":
                ...
            elif rule == "he":
                ...
            else:
                raise ValueError(...)
            if module.bias is not None:
                module.bias.fill_(bias_value)
            report.append((name, tuple(module.weight.shape), rule))
    return report

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

13.6.14 Exercise 13 - Measure Layer-Wise Signal Propagation Depth Before Saturation Occurs

Part 1 - Why this matters

Signal propagation depth is the number of layers through which an input remains informative before activations saturate, vanish, explode, or become non-finite. Initialization directly influences where this first failure appears.

A declared criterion is required because saturation differs by activation. Tracking variance and derivative magnitude gives a principled stopping point and supports comparisons across depth and initialization scale.

Part 2 - Mathematical form

$$L^* = \min\{l : s_l < \tau_s \ \vee \ s_l > \tau_e \ \vee \ p_{\text{sat},l} > \tau_p\}.$$

Part 3 - Hints and Helper

Use an untrained deep network, capture sequential states, and return both the first failing layer and all preceding statistics.

Part 4 - Python code skeleton

```
import torch

def E13(states, saturation_function, min_var, max_var, max_sat):
    report = []
    failure_depth = None
    for index, state in enumerate(states, start=1):
        variance = state.float().var().item()
        saturation = saturation_function(state)
        failed = (
            variance < min_var or variance > max_var
            or saturation > max_sat
            or not torch.isfinite(state).all()
        )
        report.append((index, variance, saturation, failed))
        if failed and failure_depth is None:
            failure_depth = index
    return failure_depth, report

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

13.6.15 Exercise 14 - Diagnose Dying ReLU Caused by Initialization and Apply LeakyReLU Fix

Part 1 - Why this matters

A biased or badly scaled initialization can place many ReLU units entirely in the negative region. Their outputs and local gradients become zero, preventing those units from recovering under ordinary updates.

LeakyReLU restores a negative-side gradient path, but the experiment should also correct the initialization root cause. Comparing ReLU, LeakyReLU, and repaired initialization separates symptom mitigation from a structurally healthier start.

Part 2 - Mathematical form

$$z_j^{(i)} < 0 \ \forall i \Rightarrow \mathrm{ReLU}'(z_j^{(i)}) = 0, \qquad \mathrm{LeakyReLU}'(z) = \alpha > 0 \text{ for } z < 0.$$

Part 3 - Hints and Helper

Measure dead-unit ratios and gradient norms before and after each intervention using the same batch and copied parameters.

Part 4 - Python code skeleton

```
import copy

def E14(model, batch, evaluate, repair_initialization):
    relu_case = copy.deepcopy(model)
    leaky_case = copy.deepcopy(model)
    repaired_case = copy.deepcopy(model)
    leaky_case.replace_relu_with_leaky_relu(negative_slope=...)
    repair_initialization(repaired_case)
    return {
        "relu": evaluate(relu_case, batch),
        "leaky_relu": evaluate(leaky_case, batch),
        "repaired_initialization": evaluate(repaired_case, batch),
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

13.6.16 Exercise 15 - Show How Bias Initialization Influences Early Learning and Decision Boundaries

Part 1 - Why this matters

Biases shift pre-activations independently of the input direction. Their initialization can control early activation rates and move decision boundaries before weights have learned useful orientations.

Zero bias is a common neutral choice, but small positive or class-informed biases can be useful in specific contexts. The reader should measure output prevalence, activation sparsity, initial loss, and boundary displacement rather than applying one value blindly.

Part 2 - Mathematical form

$$z = \mathbf{w}^\top \mathbf{x} + b, \qquad \mathcal{B} = \{\mathbf{x} : \mathbf{w}^\top \mathbf{x} + b = 0\}.$$

Part 3 - Hints and Helper

Hold weights fixed and sweep several bias values. Compare activation rates and predictions before any training, then observe the first updates.

Part 4 - Python code skeleton

```
import copy
import torch

def E15(base_model, bias_values, features, targets, loss_fn):
    report = []
    for value in bias_values:
        model = copy.deepcopy(base_model)
        with torch.no_grad():
            for parameter in model.bias_parameters():
                parameter.fill_(value)
        output, states = model.forward_with_states(features)
        report.append({
            "bias": value,
            "loss": loss_fn(output, targets).item(),
            "positive_output_ratio": (output > 0).float().mean().item(),
            "activation_zero_ratios": [
                (state == 0).float().mean().item() for state in states
            ],
        })
    return report

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

13.6.17 Exercise 16 - Compare Built-In PyTorch init Methods with Your Manual Implementations

Part 1 - Why this matters

Manual formulas explain initialization mathematics, while PyTorch methods provide tested implementations with explicit gain and fan conventions. Equivalence should be evaluated statistically because separate random draws are not expected to match element by element.

The comparison should validate bounds, means, variances, and reproducibility under controlled generators. A large tensor gives more reliable empirical moments than one small model layer.

Part 2 - Mathematical form

$$|\widehat{\mu} - \mu| < \varepsilon_{\mu}, \qquad |\widehat{\sigma}^2 - \sigma^2| < \varepsilon_{v}, \qquad \max|W| \leq a \text{ when bounded.}$$

Part 3 - Hints and Helper

Generate large manual and built-in samples with independent controlled seeds. Compare both against the theoretical distribution, not directly against each other.

Part 4 - Python code skeleton

```
import torch

def E16(manual_initializer, builtin_initializer, shape, seeds):
    results = []
    for seed in seeds:
        manual = torch.empty(shape)
        builtin = torch.empty(shape)
        torch.manual_seed(seed)
        manual_initializer(manual)
        torch.manual_seed(seed + 1)
        builtin_initializer(builtin)
        results.append({
            "seed": seed,
            "manual_mean": manual.mean().item(),
            "manual_variance": manual.var().item(),
            "builtin_mean": builtin.mean().item(),
            "builtin_variance": builtin.var().item(),
        })
    return results

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

13.6.18 Exercise 17 - Stress Test Initialization with Very Deep Networks and Monitor Memory Usage

Part 1 - Why this matters

Very deep networks magnify small variance errors and make initialization assumptions easier to test. They also retain many activations during backward, so mathematical instability and memory exhaustion must be measured separately.

A safe stress test increases depth gradually, uses bounded widths, records the last finite layer and peak memory, and stops before uncontrolled resource use. Failure depth is valuable evidence rather than an invitation to continue until the environment crashes.

Part 2 - Mathematical form

$$M_{\text{activation}} \propto B \sum_{l=1}^{L} d_l, \qquad s_l^2 \approx s_0^2 \prod_{k=1}^{l} r_k.$$

Part 3 - Hints and Helper

Sweep depth under a fixed memory budget. On CUDA, reset peak statistics and synchronize before reading memory values.

Part 4 - Python code skeleton

```
import torch

def E17(build_model, depths, width, batch, memory_limit):
    results = []
    for depth in depths:
        model, features = build_model(depth, width, batch)
        if features.is_cuda:
            torch.cuda.reset_peak_memory_stats(features.device)
        try:
            _, states = model.forward_with_states(features)
            finite_depth = next(
                (index for index, state in enumerate(states)
                 if not torch.isfinite(state).all()),
                len(states),
            )
            peak = ...
            results.append((depth, finite_depth, peak))
            if peak is not None and peak > memory_limit:
                break
        except RuntimeError as error:
            results.append((depth, None, str(error)))
            break
    return results

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

13.6.19 Exercise 18 - Create a Reproducible Initialization Benchmark Report with Controlled Seeds

Part 1 - Why this matters

A reproducible benchmark records enough information for another reader to reconstruct every initialization and training run. Seeds alone are insufficient without architecture, data split, software, device, precision, and deterministic settings.

The report should contain raw per-run results and aggregated conclusions. Preserving failures and uncertainty prevents a favorable average from hiding unstable seeds or unsupported claims.

Part 2 - Mathematical form

$$R = \Big(C, \mathcal{S}, \mathcal{M}, D, P, H, \{r_{m,s}\}, \text{aggregate}(r)\Big).$$

Part 3 - Hints and Helper

Store configuration before running experiments, use a fixed seed list, and verify that repeating one case reproduces metrics within declared tolerances.

Part 4 - Python code skeleton

```
import platform
import torch

def E18(configuration, run_case, initializers, seeds):
    runs = []
    for name, initializer in initializers.items():
        for seed in seeds:
            torch.manual_seed(seed)
            result = run_case(initializer, seed, configuration)
            runs.append({
                "initializer": name,
                "seed": seed,
                "result": result,
            })
    return {
        "configuration": configuration,

        "reproduction_check": ...,
    }

def main():
```

```
    print(E18(...))

if __name__ == "__main__":
    main()
```

13.6.20 Exercise 19 - Produce a Practical Initialization Selection Guide for Real Training Projects

Part 1 - Why this matters

A practical guide maps architecture, activation, output objective, precision, and depth to an initialization strategy supported by experiments. It should include defaults, diagnostics to run before training, and warning signs that require revision.

The guide must avoid universal claims. It should state tested conditions, explain interactions with bias and mixed precision, distinguish symptom fixes from root-cause repairs, and require new evidence when the project departs from benchmark conditions.

Part 2 - Mathematical form

$$I^*(c) = \arg\min_{I \in \mathcal{I}} \left(\widehat{R}(I, c) + \lambda_s U(I, c) + \lambda_t T(I, c) + \lambda_m M(I, c) \right).$$

Part 3 - Hints and Helper

Require a decision table, validation checklist, failure diagnostics, reproducibility rules, and evidence for every recommendation.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "project_context", "activation_initializer_map",
        "zero_initialization_warning", "xavier_guidance",
        "he_guidance", "bias_guidance",
        "pretraining_signal_checks", "gradient_checks",
        "mixed_precision_guidance", "cuda_profile",
        "failure_diagnostics", "reproducibility_protocol",
        "decision_table", "limitations", "retesting_conditions",
    }
    missing = sorted(required - sections.keys())
    unsupported = [
        item for item in sections.get("decision_table", [])
        if not item.get("evidence")
    ]
    return {
        "complete": not missing and not unsupported,
        "missing": missing,
        "unsupported_recommendations": unsupported,
        "guide": sections,
```

```
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

13.7 MLP05 - Optimizers and Learning Rate Dynamics

Models and Training

13.7.1 Exercise 00 - Implement Manual SGD Updates and Verify Parameter Changes Step by Step

Part 1 - Why this matters

Stochastic gradient descent changes each parameter in the direction opposite its current gradient. Implementing the update manually separates gradient computation from parameter mutation and reveals exactly what an optimizer step performs.

The update must occur without creating a new autograd graph, and gradients must be cleared before the next batch. Comparing the measured parameter difference with the predicted change verifies the sign, scale, and ordering of the step.

Part 2 - Mathematical form

$$\theta_{t+1} = \theta_t - \eta \nabla_\theta \mathcal{L}_t, \qquad \Delta\theta = -\eta g_t.$$

Part 3 - Hints and Helper

Clone parameters before the update, apply changes under a no-gradient context, and compare actual and expected differences.

Part 4 - Python code skeleton

```
import torch

def E00(model, loss, learning_rate):
    model.zero_grad(set_to_none=True)
    loss.backward()
    before = {n: p.detach().clone() for n, p in model.named_parameters()}
    gradients = {
        name: parameter.grad.detach().clone()
        for name, parameter in model.named_parameters()
    }
    with torch.no_grad():
        for parameter in model.parameters():
```

```
            parameter.add_(parameter.grad, alpha=-learning_rate)
    checks = {
        name: torch.allclose(parameter - before[name],
                             -learning_rate * gradients[name])
        for name, parameter in model.named_parameters()
    }
    return checks

def main():
    print(E00(...))

if __name__ == "__main__": main()
```

13.7.2 Exercise 01 - Compare SGD vs Momentum and Observe Convergence Differences

Part 1 - Why this matters

Momentum maintains a velocity that combines current and past gradients. It can accelerate movement along persistent descent directions and reduce oscillation across directions whose gradients repeatedly change sign.

A fair comparison must use identical initial parameters, data order, learning-rate budget, and stopping criteria. Loss curves, velocity norms, and steps to target reveal more than one final metric.

Part 2 - Mathematical form

$$v_t = \mu v_{t-1} + g_t, \qquad \theta_{t+1} = \theta_t - \eta v_t.$$

Part 3 - Hints and Helper

Clone one initial model for both optimizers and repeat across seeds. Record convergence speed and oscillation rather than selecting one favorable run.

Part 4 - Python code skeleton

```
import copy
import torch

def E01(model, train, learning_rate, momentum):
    sgd_model = copy.deepcopy(model)
    momentum_model = copy.deepcopy(model)
    sgd = torch.optim.SGD(sgd_model.parameters(), lr=learning_rate)
    mom = torch.optim.SGD(momentum_model.parameters(),
                          lr=learning_rate, momentum=momentum)
    return {
        "sgd": train(sgd_model, sgd, ...),
        "momentum": train(momentum_model, mom, ...),
```

```
    }

def main(): print(E01(...))
if __name__ == "__main__": main()
```

13.7.3 Exercise 02 - Implement Adam Optimizer and Track Bias Correction Behavior

Part 1 - Why this matters

Adam combines exponential averages of gradients and squared gradients to produce adaptive parameter-wise steps. Because both averages start at zero, their early values are biased toward zero and require time-dependent correction.

Implementing the equations exposes how the first and second moments, epsilon, and correction factors interact. The manual result should be compared with PyTorch using identical gradients and hyperparameters.

Part 2 - Mathematical form

$$m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t,\ v_t = \beta_2 v_{t-1} + (1-\beta_2) g_t^2,\ \hat{m}_t = \frac{m_t}{1-\beta_1^t},\ \hat{v}_t = \frac{v_t}{1-\beta_2^t}.$$

Part 3 - Hints and Helper

Initialize moments with zeros, increment the step before correction, and log raw and corrected moment norms at every update.

Part 4 - Python code skeleton

```
import torch

def E02(parameter, gradients, learning_rate, beta1, beta2, epsilon):
    first = torch.zeros_like(parameter)
    second = torch.zeros_like(parameter)
    history = []
    with torch.no_grad():
        for step, gradient in enumerate(gradients, start=1):
            first.mul_(beta1).add_(gradient, alpha=1 - beta1)
            second.mul_(beta2).addcmul_(gradient, gradient,
                                        value=1 - beta2)
            corrected_first = first / (...)
            corrected_second = second / (...)
            parameter.addcdiv_(corrected_first,
                               corrected_second.sqrt().add(epsilon),
                               value=-learning_rate)
            history.append((step, first.norm().item(),
                            corrected_first.norm().item()))
```

```
    return parameter, history

def main(): print(E02(...))
if __name__ == "__main__": main()
```

13.7.4 Exercise 03 - Compare Adam vs AdamW and Identify Weight Decay Differences in Practice

Part 1 - Why this matters

Adam with an L2 penalty adds a parameter-dependent term to the gradient before adaptive normalization. AdamW instead decouples weight decay from the loss gradient and applies direct shrinkage to parameters.

These procedures are not generally equivalent under adaptive scaling. A controlled one-step comparison should use the same parameters and gradient and isolate decay from all other optimizer differences.

Part 2 - Mathematical form

$$g_t^{L2} = g_t + \lambda\theta_t, \qquad \theta_{t+1}^{AdamW} = (1-\eta\lambda)\theta_t - \eta\frac{\hat{m}_t}{\sqrt{\hat{v}_t}+\varepsilon}.$$

Part 3 - Hints and Helper

Use copied models and identical gradients. Report parameter norms before and after one step and exclude biases from decay in a separate parameter group.

Part 4 - Python code skeleton

```
import copy
import torch

def E03(model, assign_gradients, learning_rate, decay):
    adam_model = copy.deepcopy(model)
    adamw_model = copy.deepcopy(model)
    assign_gradients(adam_model, ...)
    assign_gradients(adamw_model, ...)
    adam = torch.optim.Adam(adam_model.parameters(), lr=learning_rate,
                            weight_decay=decay)
    adamw = torch.optim.AdamW(adamw_model.parameters(), lr=learning_rate,
                              weight_decay=decay)
    adam.step(); adamw.step()
    return adam_model.state_dict(), adamw_model.state_dict()

def main(): print(E03(...))
if __name__ == "__main__": main()
```

13.7.5 Exercise 04 - Perform Learning Rate Sweep and Identify Divergence Threshold

Part 1 - Why this matters

The learning rate controls update magnitude and often separates useful progress from oscillation or divergence. A sweep across logarithmically spaced values reveals stable, slow, and unstable regions for one fixed training setup.

The divergence threshold depends on optimizer, batch size, initialization, and task. It must be defined using observable criteria such as non-finite loss, rapid growth, or failure to recover within a fixed budget.

Part 2 - Mathematical form

$$\eta \in \{10^a, \ldots, 10^b\}, \qquad \eta_{\text{div}} = \inf\{\eta : \text{unstable}(\eta)\}.$$

Part 3 - Hints and Helper

Restart from identical initial parameters for every rate. Stop unstable runs early and record the first divergence step.

Part 4 - Python code skeleton

```
import copy

def E04(base_model, learning_rates, run_training):
    results = []
    for rate in learning_rates:
        model = copy.deepcopy(base_model)
        outcome = run_training(model, learning_rate=rate,
                               stop_on_divergence=True, ...)
        results.append({"learning_rate": rate, **outcome})
    divergent = [r for r in results if r["diverged"]]
    threshold = min((r["learning_rate"] for r in divergent), default=None)
    return results, threshold

def main(): print(E04(...))
if __name__ == "__main__": main()
```

13.7.6 Exercise 05 - Implement Learning Rate Scheduler and Validate Step Timing and Effects

Part 1 - Why this matters

A scheduler changes the optimizer learning rate according to training progress. Calling it at the wrong time can shift the entire schedule, skip the intended initial rate, or make metric-driven schedules consume the wrong measurement.

Validation requires logging the rate used for each optimizer update, not merely the rate after scheduling. The exercise should distinguish per-step, per-epoch, and metric-based timing.

Part 2 - Mathematical form

$$\eta_t = S(t, \eta_0), \qquad \theta_{t+1} = \theta_t - \eta_t g_t.$$

Part 3 - Hints and Helper

Log the rate immediately before the optimizer step and immediately after the scheduler step. Compare the trace with the analytical schedule.

Part 4 - Python code skeleton

```
def E05(model, optimizer, scheduler, batches, loss_fn):
    trace = []
    for step, (features, targets) in enumerate(batches):
        optimizer.zero_grad(set_to_none=True)
        loss = loss_fn(model(features), targets)
        loss.backward()
        used_rate = optimizer.param_groups[0]["lr"]
        optimizer.step()
        scheduler.step(...)
        next_rate = optimizer.param_groups[0]["lr"]
        trace.append((step, used_rate, next_rate, loss.item()))
    return trace

def main(): print(E05(...))
if __name__ == "__main__": main()
```

13.7.7 Exercise 06 - Diagnose Slow Convergence Caused by Too-Low Learning Rate and Fix It

Part 1 - Why this matters

A learning rate that is too small produces updates that are valid but negligible relative to parameter scale. Loss may decrease monotonically while making so little progress that training appears stuck.

Diagnosis should compare gradient norms, update-to-parameter ratios, and loss slope. Increasing the rate must then be verified through faster progress without introducing instability.

Part 2 - Mathematical form

$$r_t = \frac{\|\Delta\theta_t\|}{\|\theta_t\| + \varepsilon} \approx \eta \frac{\|g_t\|}{\|\theta_t\| + \varepsilon}.$$

Part 3 - Hints and Helper

Measure update ratios before changing the rate, then resume copied runs with several larger values and the same batches.

Part 4 - Python code skeleton

```
def E06(run_training, low_rate, candidate_rates):
    baseline = run_training(low_rate, log_update_ratios=True, ...)
    candidates = {
        rate: run_training(rate, log_update_ratios=True, ...)
        for rate in candidate_rates
    }
    stable = {rate: result for rate, result in candidates.items()
              if not result["diverged"]}
    selected = min(stable, key=lambda rate: stable[rate]["final_loss"])
    return baseline, candidates, selected

def main(): print(E06(...))
if __name__ == "__main__": main()
```

13.7.8 Exercise 07 - Diagnose Divergence Caused by Too-High Learning Rate and Stabilize Training

Part 1 - Why this matters

An excessive learning rate can overshoot useful regions, create oscillating loss, expand parameter norms, and eventually produce non-finite values. Clipping may reduce one symptom while leaving the step size fundamentally inappropriate.

The root-cause test is to restore the same checkpoint and lower only the rate. Stability is confirmed when losses and parameter norms remain finite and progress resumes under the same data order.

Part 2 - Mathematical form

$$\eta > \eta_{\text{stable}} \Rightarrow \|\theta_{t+1} - \theta^*\| > \|\theta_t - \theta^*\| \text{ for repeated steps.}$$

Part 3 - Hints and Helper

Detect the first abnormal step, restore the last finite checkpoint, reduce the rate, and compare both trajectories.

Part 4 - Python code skeleton

```
def E07(checkpoint, run_training, high_rate, reduction_factor):
    unstable = run_training(checkpoint, high_rate,
                            stop_on_divergence=True, ...)
    stable_rate = high_rate * reduction_factor
    stabilized = run_training(checkpoint, stable_rate,
                              stop_on_divergence=True, ...)
```

```
    return {"unstable": unstable, "stable_rate": stable_rate,
            "stabilized": stabilized}

def main(): print(E07(...))
if __name__ == "__main__": main()
```

13.7.9 Exercise 08 - Implement Gradient Clipping and Measure Its Effect on Optimization Stability

Part 1 - Why this matters

Gradient clipping limits unusually large update directions before the optimizer step. Global norm clipping preserves direction while rescaling all gradients together when their combined norm exceeds a threshold.

The threshold should be evaluated experimentally. Excessive clipping can suppress learning, while rare clipping may protect against spikes without materially changing ordinary updates.

Part 2 - Mathematical form

$$\widetilde{g} = g \min(1, c/\|g\|_2), \qquad \|\widetilde{g}\|_2 \leq c.$$

Part 3 - Hints and Helper

Record pre-clipping norm, post-clipping norm, clipping frequency, loss, and update size across the run.

Part 4 - Python code skeleton

```
import torch

def E08(model, optimizer, loss, max_norm):
    optimizer.zero_grad(set_to_none=True)
    loss.backward()
    before = torch.nn.utils.clip_grad_norm_(model.parameters(), max_norm)
    after = torch.sqrt(sum(
        p.grad.pow(2).sum() for p in model.parameters() if p.grad is not None
    ))
    optimizer.step()
    return before.item(), after.item(), before.item() > max_norm

def main(): print(E08(...))
if __name__ == "__main__": main()
```

13.7.10 Exercise 09 - Compare Optimization Under Different Batch Sizes to Observe Noise Benefits

Part 1 - Why this matters

Small batches create noisier gradient estimates, which can help exploration but also increase update variability. Large batches reduce sampling noise and improve throughput on some hardware while requiring more memory.

A fair comparison uses mean loss reduction and considers both steps and processed samples. Learning-rate scaling must be declared because changing batch size without deciding how to change the rate alters two optimization factors.

Part 2 - Mathematical form

$$g_B = \frac{1}{B}\sum_{i=1}^{B} g_i, \qquad \mathrm{Var}(g_B) \approx \Sigma/B.$$

Part 3 - Hints and Helper

Track gradient variance, training loss, validation performance, throughput, and samples to target for every batch size.

Part 4 - Python code skeleton

```
def E09(run_training, batch_sizes, rate_policy, seeds):
    results = []
    for batch_size in batch_sizes:
        rate = rate_policy(batch_size)
        for seed in seeds:
            metrics = run_training(batch_size=batch_size,
                                   learning_rate=rate, seed=seed, ...)
            results.append({"batch_size": batch_size,
                            "learning_rate": rate,
                            "seed": seed, "metrics": metrics})
    return results

def main(): print(E09(...))
if __name__ == "__main__": main()
```

13.7.11 Exercise 10 - Execute Optimizer Steps on CUDA and Validate Parameter Device Placement

Part 1 - Why this matters

CUDA optimization requires model parameters, gradients, and optimizer state to remain on compatible devices. Creating an optimizer before or after moving the model can be valid,

but stale or replaced parameter objects can break the intended connection.

A placement report should verify parameters before backward, gradients after backward, and state tensors after the first optimizer step. The actual parameter change must also occur on CUDA.

Part 2 - Mathematical form

$$D(\theta) = D(g) = D(s_{\text{optimizer}}) = \text{CUDA}.$$

Part 3 - Hints and Helper

Run one full step, inspect every state tensor recursively, and compare parameter snapshots before and after the step.

Part 4 - Python code skeleton

```
import torch

def E10(model, optimizer, loss):
    before = [p.detach().clone() for p in model.parameters()]
    optimizer.zero_grad(set_to_none=True)
    loss.backward(); optimizer.step()
    parameter_devices = {str(p.device) for p in model.parameters()}
    gradient_devices = {str(p.grad.device) for p in model.parameters()
                        if p.grad is not None}
    state_devices = {str(value.device)
                     for state in optimizer.state.values()
                     for value in state.values()
                     if torch.is_tensor(value)}
    changed = [
        not torch.equal(old, new)
        for old, new in zip(before, model.parameters())
    ]
    return parameter_devices, gradient_devices, state_devices, changed

def main(): print(E10(...))
if __name__ == "__main__": main()
```

13.7.12 Exercise 11 - Profile Optimizer Overhead on GPU and Identify Bottlenecks in Update Step

Part 1 - Why this matters

An optimizer reads gradients, updates its state, and changes parameters. For small tensors or many parameter groups, repeated kernel launches and fragmented updates may dominate the step.

CUDA timing must be synchronized, warmed up, and separated from forward and backward time. Comparing optimizers also requires accounting for their different state memory and arithmetic.

Part 2 - Mathematical form

$$T_{\text{train}} = T_f + T_b + T_o + T_z, \qquad \rho_o = T_o / T_{\text{train}}.$$

Part 3 - Hints and Helper

Time the optimizer step in isolation after gradients exist. Report median latency, optimizer-state bytes, parameter count, and group count.

Part 4 - Python code skeleton

```
import time
import torch

def E11(optimizer, device, repeats):
    times = []
    for _ in range(repeats):
        if device.type == "cuda": torch.cuda.synchronize(device)
        start = time.perf_counter()
        optimizer.step()
        if device.type == "cuda": torch.cuda.synchronize(device)
        times.append(time.perf_counter() - start)
    state_bytes = sum(v.numel() * v.element_size()
                      for state in optimizer.state.values()
                      for v in state.values() if torch.is_tensor(v))
    return times, state_bytes

def main(): print(E11(...))
if __name__ == "__main__": main()
```

13.7.13 Exercise 12 - Compare Mixed Precision vs Full Precision Optimization Dynamics on the Same Task

Part 1 - Why this matters

Mixed precision changes numerical range, memory use, and throughput while usually retaining full-precision master parameters in standard training workflows. Dynamic loss scaling protects small gradients but may skip steps when non-finite values appear.

The comparison should begin from the same state and data order. Loss trajectory, gradient norms, skipped steps, scaler values, memory, speed, and validation performance together describe the optimization dynamics.

Part 2 - Mathematical form

$$\widetilde{\mathcal{L}} = s\mathcal{L}, \quad \widetilde{g} = sg, \quad g = \widetilde{g}/s.$$

Part 3 - Hints and Helper

Use matched checkpoints and seeds. Record scale changes and skipped updates rather than reporting only final accuracy.

Part 4 - Python code skeleton

```
def E12(run_training, checkpoint, seeds):
    results = []
    for seed in seeds:
        for precision in ("full", "mixed"):
            outcome = run_training(checkpoint=checkpoint, seed=seed,
                                   precision=precision, ...)
            results.append({"seed": seed, "precision": precision,
                            "outcome": outcome})
    return results

def main(): print(E12(...))
if __name__ == "__main__": main()
```

13.7.14 Exercise 13 - Implement Gradient Accumulation to Simulate Larger Batch Size on Limited GPU Memory

Part 1 - Why this matters

Gradient accumulation processes several micro-batches before one optimizer step, approximating a larger batch without storing all activations simultaneously. Each micro-loss must be scaled so the accumulated gradient matches the desired mean reduction.

The optimizer and scheduler should advance once per effective batch, not once per micro-batch. Incomplete accumulation at the end of an epoch also requires deliberate handling.

Part 2 - Mathematical form

$$g_{\text{eff}} = \frac{1}{K}\sum_{k=1}^{K} g_k, \qquad B_{\text{eff}} = KB_{\text{micro}}.$$

Part 3 - Hints and Helper

Divide each loss by the accumulation count, clear gradients before the cycle, and step only at the cycle boundary or final partial cycle.

Part 4 - Python code skeleton

```
def E13(model, optimizer, loader, loss_fn, accumulation_steps):
    optimizer.zero_grad(set_to_none=True)
    updates = 0
    for index, (features, targets) in enumerate(loader, start=1):
        loss = loss_fn(model(features), targets) / accumulation_steps
        loss.backward()
        boundary = index % accumulation_steps == 0
        final_batch = index == len(loader)
        if boundary or final_batch:
            optimizer.step()
            optimizer.zero_grad(set_to_none=True)
            updates += 1
    return updates

def main(): print(E13(...))
if __name__ == "__main__": main()
```

13.7.15 Exercise 14 - Verify Determinism and Reproducibility Under Fixed Seeds and Controlled Settings

Part 1 - Why this matters

A fixed seed controls pseudorandom sequences but does not automatically guarantee identical training. Data-loader workers, nondeterministic kernels, library versions, and asynchronous execution can still change results.

Reproducibility should be tested by repeating the full run and comparing losses, parameters, and metrics. The report must distinguish exact determinism from statistical reproducibility within a tolerance.

Part 2 - Mathematical form

$$R(C, s)_1 \stackrel{?}{=} R(C, s)_2, \qquad C = \text{complete controlled configuration.}$$

Part 3 - Hints and Helper

Centralize seed setup, enable deterministic algorithms where required, and record environment and configuration metadata.

Part 4 - Python code skeleton

```
import random
import torch

def E14(run_training, seed):
    def set_seed():
        random.seed(seed)
        torch.manual_seed(seed)
```

```
        if torch.cuda.is_available(): torch.cuda.manual_seed_all(seed)
        torch.use_deterministic_algorithms(...)
    set_seed(); first = run_training(...)
    set_seed(); second = run_training(...)
    return {
        "loss_match": first["losses"] == second["losses"],
        "parameter_match": ...,
        "first": first, "second": second,
    }

def main(): print(E14(...))
if __name__ == "__main__": main()
```

13.7.16 Exercise 15 - Detect and Fix Silent Training Bugs Caused by Missing zero_grad or Wrong Order

Part 1 - Why this matters

A training loop can run without exceptions while accumulating old gradients, stepping before backward, clearing gradients too late, or logging a loss detached from the update path. These ordering defects silently change the algorithm.

A correct iteration follows a testable state transition: clear gradients, forward, scalar loss, backward, optional clipping, optimizer step, and scheduler step at its defined frequency.

Part 2 - Mathematical form

$$\text{clear} \to \text{forward} \to \text{loss} \to \text{backward} \to \text{step}\,.$$

Part 3 - Hints and Helper

Instrument one iteration and assert gradient state and parameter changes after each stage. Compare the observed event order with the required sequence.

Part 4 - Python code skeleton

```
def E15(training_step):
    events, snapshots = training_step(instrument=True, ...)
    required = ["zero_grad", "forward", "loss", "backward",
                "optimizer_step"]
    problems = []
    if events[:len(required)] != required:
        problems.append("wrong_order")
    if snapshots["before_backward_has_gradients"]:
        problems.append("uncleared_gradients")
    if not snapshots["parameters_changed_after_step"]:
        problems.append("missing_update")
    return {"correct": not problems, "problems": problems,
```

```
            "events": events}

def main(): print(E15(...))
if __name__ == "__main__": main()
```

13.7.17 Exercise 16 - Implement Weight Decay Correctly and Demonstrate Difference from L2 Regularization

Part 1 - Why this matters

L2 regularization adds a squared-parameter penalty to the objective, while decoupled weight decay directly shrinks parameters during the optimizer step. They coincide for basic SGD under common conventions but differ for adaptive optimizers.

Implementation must also decide which parameters are decayed. Biases and normalization parameters are often excluded through explicit parameter groups rather than name-blind global settings.

Part 2 - Mathematical form

$$\mathcal{L}_{L2} = \mathcal{L} + \frac{\lambda}{2}\|\theta\|_2^2, \qquad \theta^+ = (1-\eta\lambda)\theta - \eta u(g).$$

Part 3 - Hints and Helper

Compare one step of manual L2, decoupled decay, Adam, and AdamW from identical parameters and gradients.

Part 4 - Python code skeleton

```
import torch

def E16(parameter, gradient, learning_rate, decay):
    l2_parameter = parameter.clone()
    decoupled_parameter = parameter.clone()
    with torch.no_grad():
        l2_parameter.add_(gradient + decay * l2_parameter,
                          alpha=-learning_rate)
        decoupled_parameter.mul_(1 - learning_rate * decay)
        decoupled_parameter.add_(gradient, alpha=-learning_rate)
    return (
        l2_parameter,
        decoupled_parameter,
        torch.allclose(l2_parameter, decoupled_parameter),
    )

def main(): print(E16(...))
if __name__ == "__main__": main()
```

13.7.18 Exercise 17 - Benchmark Convergence Speed for Multiple Optimizers and Summarize Results

Part 1 - Why this matters

Optimizer benchmarks should compare convergence in steps, processed samples, and wall-clock time because a method may require fewer updates while costing more per update. Final validation quality and failure rate must also be included.

Reliable conclusions require matched initialization, data order, tuning budgets, and multiple seeds. Each optimizer should receive a reasonable learning-rate search rather than one shared rate that favors a particular method.

Part 2 - Mathematical form

$$B_m = (T_{\tau,m}, S_{\tau,m}, R_{\text{val},m}, p_{\text{fail},m}, M_m).$$

Part 3 - Hints and Helper

Store raw runs, define the target before benchmarking, and summarize median values with variability and failures.

Part 4 - Python code skeleton

```
def E17(optimizer_factories, learning_rates, seeds, run_case):
    results = []
    for name, factory in optimizer_factories.items():
        for rate in learning_rates[name]:
            for seed in seeds:
                result = run_case(factory, rate, seed, ...)
                results.append({"optimizer": name, "rate": rate,
                                "seed": seed, "result": result})
    summary = ...
    return results, summary

def main(): print(E17(...))
if __name__ == "__main__": main()
```

13.7.19 Exercise 18 - Monitor Gradient Norms and Parameter Norms to Detect Impending Instability Early

Part 1 - Why this matters

Gradient and parameter norms often reveal instability before the loss becomes non-finite. Rapid growth, persistent collapse, or extreme update-to-parameter ratios provide actionable warning signals.

Monitoring should operate per layer and globally because one layer can fail while aggregate values appear normal. Thresholds should be based on baseline behavior and sustained changes rather than one harmless spike.

Part 2 - Mathematical form

$$r_t = \|g_t\|_2/(\|\theta_t\|_2 + \varepsilon), \qquad q_t = \|\Delta\theta_t\|_2/(\|\theta_t\|_2 + \varepsilon).$$

Part 3 - Hints and Helper

Log norms before each step, track rolling growth, and emit warnings for non-finite values or repeated threshold violations.

Part 4 - Python code skeleton

```
import torch

def E18(model, history, ratio_limit):
    records = []
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        if gradient is None: continue
        parameter_norm = parameter.detach().norm().item()
        gradient_norm = gradient.detach().norm().item()
        ratio = gradient_norm / (parameter_norm + 1e-12)
        records.append({"name": name, "parameter_norm": parameter_norm,
                        "gradient_norm": gradient_norm, "ratio": ratio,
                        "warning": ratio > ratio_limit or
                                   not torch.isfinite(gradient).all()})
    history.append(records)
    return records

def main(): print(E18(...))
if __name__ == "__main__": main()
```

13.7.20 Exercise 19 - Write an Optimization Debugging Checklist Covering All Common Training Failures

Part 1 - Why this matters

An optimization checklist converts experiments into a repeatable response to slow learning, divergence, noisy updates, stale gradients, incorrect decay, device errors, precision failures, and scheduler mistakes.

Each item should connect a symptom to a measurement, controlled test, correction, and verification step. The checklist must preserve evidence and avoid recommending clipping or optimizer replacement before the underlying cause is measured.

Part 2 - Mathematical form

$$\text{symptom} \to \text{evidence} \to \text{test} \to \text{fix} \to \text{verification}.$$

Part 3 - Hints and Helper

Include learning rate, gradient order, accumulation, batch size, clipping, decay, scheduler, CUDA, precision, determinism, and monitoring.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "learning_rate", "sgd_and_momentum", "adam_bias_correction",
        "adamw_and_decay", "scheduler_timing", "gradient_clipping",
        "batch_size_noise", "gradient_accumulation", "step_order",
        "cuda_placement", "mixed_precision", "determinism",
        "norm_monitoring", "benchmark_protocol", "decision_tree",
    }
    missing = sorted(required - sections.keys())
    unverified = [name for name, item in sections.items()
                  if isinstance(item, dict) and item.get("fix")
                  and not item.get("verification")]
    return {"complete": not missing and not unverified,
            "missing": missing, "unverified": unverified,
            "checklist": sections}

def main(): print(E19(...))
if __name__ == "__main__": main()
```

13.8 MLP06 - Loss Functions, Training Loop, and Logging

Models and Training

13.8.1 Exercise 00 - Build a Minimal Training Loop with Proper Train/Eval Separation and Correct Modes

Part 1 - Why this matters

A correct training loop changes model parameters only during training and evaluates learned behavior without constructing unnecessary gradient graphs. Training and evaluation modes also control modules whose behavior depends on phase, such as dropout and batch normalization.

Separating both phases prevents validation data from influencing optimization and makes reported metrics meaningful. The loop must restore the intended mode explicitly rather than assuming that one mode change affects only a single batch.

Part 2 - Mathematical form

$$\theta_{t+1} = \theta_t - \eta \nabla_\theta \mathcal{L}_{\text{train}}, \qquad \mathcal{L}_{\text{val}} = \ell(f_\theta(X_v), Y_v) \text{ without gradient tracking.}$$

Part 3 - Hints and Helper

Use model training mode inside the update loop and evaluation mode with inference context inside validation. Verify that validation leaves parameters unchanged.

Part 4 - Python code skeleton

```
import torch

def E00(model, train_loader, val_loader, optimizer, loss_fn):
    model.train()
    for features, targets in train_loader:
        optimizer.zero_grad(set_to_none=True)
        loss = loss_fn(model(features), targets)
        loss.backward(); optimizer.step()
    before = [p.detach().clone() for p in model.parameters()]
    model.eval()
    validation_losses = []
    with torch.inference_mode():
        for features, targets in val_loader:
            validation_losses.append(loss_fn(model(features), targets).item())
    unchanged = all(
        torch.equal(old, new)
        for old, new in zip(before, model.parameters())
    )
    return sum(validation_losses) / len(validation_losses), unchanged

def main(): print(E00(...))
if __name__ == "__main__": main()
```

13.8.2 Exercise 01 - Implement Classification Training Using CrossEntropyLoss and Validate Label Encoding

Part 1 - Why this matters

Multiclass cross-entropy in PyTorch expects unnormalized class logits and integer class indices. Applying softmax before the loss or passing incorrectly shaped one-hot labels changes or breaks the intended calculation.

Label validation should occur before training so range, data type, and shape errors cannot silently corrupt metrics. The output width must equal the number of classes, and every target must identify a valid class.

Part 2 - Mathematical form

$$\mathcal{L} = -\frac{1}{B}\sum_{i=1}^{B} \log \frac{e^{z_{i,y_i}}}{\sum_{c=1}^{C} e^{z_{i,c}}}, \qquad y_i \in \{0, \ldots, C-1\}.$$

Part 3 - Hints and Helper

Pass raw logits directly to the loss. Assert that labels are one-dimensional integer tensors and remain inside the class range.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E01(model, features, labels, optimizer, class_count):
    if labels.dtype != torch.long or labels.ndim != 1:
        raise ValueError(...)
    if labels.min() < 0 or labels.max() >= class_count:
        raise ValueError(...)
    logits = model(features)
    if logits.shape != (features.shape[0], class_count):
        raise ValueError(...)
    loss = nn.CrossEntropyLoss()(logits, labels)
    optimizer.zero_grad(set_to_none=True)
    loss.backward(); optimizer.step()
    return loss.item(), logits.argmax(dim=1)

def main(): print(E01(...))
if __name__ == "__main__": main()
```

13.8.3 Exercise 02 - Implement Regression Training Using MSELoss and Validate Output Shapes

Part 1 - Why this matters

Mean-squared error compares every predicted value with a corresponding continuous target. Accidental broadcasting can produce a valid scalar loss even when prediction and target shapes represent different structures.

Shape equality should therefore be verified before loss computation. The exercise should also preserve floating-point targets and distinguish a single-output batch from a one-dimensional tensor whose meaning is ambiguous.

Part 2 - Mathematical form

$$\mathcal{L}_{\mathrm{MSE}} = \frac{1}{N}\sum_{i=1}^{N}(\widehat{y}_i - y_i)^2, \qquad \mathrm{shape}(\widehat{Y}) = \mathrm{shape}(Y).$$

Part 3 - Hints and Helper

Require exact shape equality and floating-point targets. Use an explicit final dimension for single-output regression.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E02(model, features, targets, optimizer):
    predictions = model(features)
    if predictions.shape != targets.shape:
        raise ValueError(...)
    if not targets.is_floating_point():
        raise TypeError(...)
    loss = nn.MSELoss(reduction="mean")(predictions, targets)
    optimizer.zero_grad(set_to_none=True)
    loss.backward(); optimizer.step()
    return loss.item(), predictions.detach()

def main(): print(E02(...))
if __name__ == "__main__": main()
```

13.8.4 Exercise 03 - Add Accurate Metric Tracking and Ensure Metrics Match Ground Truth Calculations

Part 1 - Why this matters

Epoch metrics must aggregate samples correctly across batches of unequal size. Averaging batch means gives each batch equal weight and produces an error when the final batch is smaller.

Metric implementations should be compared with direct ground-truth calculations on stored predictions and targets. Classification counts and regression sums must use the correct denominator and avoid carrying gradient graphs into logging.

Part 2 - Mathematical form

$$\overline{L} = \frac{\sum_b B_b L_b}{\sum_b B_b}, \qquad \text{Accuracy} = \frac{\sum_b \text{correct}_b}{\sum_b B_b}.$$

Part 3 - Hints and Helper

Accumulate loss multiplied by batch size and total sample count. Verify the result against a direct calculation after concatenating detached outputs.

Part 4 - Python code skeleton

```
import torch

def E03(batch_records):
    loss_sum = 0.0; correct = 0; samples = 0
    predictions = []; targets = []
    for record in batch_records:
        size = record["targets"].shape[0]
```

```
        loss_sum += record["loss"] * size
        correct += (record["predictions"] == record["targets"]).sum().item()
        samples += size
        predictions.append(record["predictions"].detach().cpu())
        targets.append(record["targets"].detach().cpu())
    all_predictions = torch.cat(predictions)
    all_targets = torch.cat(targets)
    direct = (all_predictions == all_targets).float().mean().item()
    return {"loss": loss_sum / samples, "accuracy": correct / samples,
            "matches_direct": abs(correct / samples - direct) < 1e-12}

def main(): print(E03(...))
if __name__ == "__main__": main()
```

13.8.5 Exercise 04 - Implement Validation Loop and Detect Overfitting Using Train vs Val Curves

Part 1 - Why this matters

Training loss measures fit to examples used for updates, while validation loss estimates behavior on held-out data. A widening gap in which training improves and validation degrades is evidence of overfitting.

Both curves must be calculated with comparable reduction and recorded once per epoch. Validation must not shuffle labels into training, update parameters, or include data augmentation intended only for training unless the experiment explicitly requires it.

Part 2 - Mathematical form

$$G_t = \mathcal{L}_{\text{val},t} - \mathcal{L}_{\text{train},t}, \qquad \mathcal{L}_{\text{train}} \downarrow,\ \mathcal{L}_{\text{val}} \uparrow \Rightarrow \text{overfitting signal.}$$

Part 3 - Hints and Helper

Log train and validation curves with exact sample weighting. Detect a sustained validation increase rather than reacting to one noisy epoch.

Part 4 - Python code skeleton

```
def E04(train_epoch, validate_epoch, epochs, patience):
    history = []
    worsening = 0
    best_validation = float("inf")
    for epoch in range(epochs):
        train_metrics = train_epoch(...)
        validation_metrics = validate_epoch(...)
        value = validation_metrics["loss"]
        worsening = worsening + 1 if value > best_validation else 0
        best_validation = min(best_validation, value)
```

```
        history.append({"epoch": epoch, "train": train_metrics,
                        "validation": validation_metrics,
                        "overfitting_signal": worsening >= patience})
    return history

def main(): print(E04(...))
if __name__ == "__main__": main()
```

13.8.6 Exercise 05 - Add Early Stopping Logic and Confirm It Prevents Wasteful Training Iterations

Part 1 - Why this matters

Early stopping ends training when a monitored validation quantity has not improved for a declared patience period. It limits wasted computation and can reduce overfitting, but only if the best model state is preserved.

Minimum improvement, metric direction, patience semantics, and restoration behavior must be explicit. Testing with a synthetic metric sequence makes off-by-one errors visible before using the logic in real training.

Part 2 - Mathematical form

$$t_{\text{stop}} = \min\{t : t - t_{\text{best}} \geq p\}, \qquad m_t < m_{\text{best}} - \delta \text{ for loss improvement.}$$

Part 3 - Hints and Helper

Save the best state when improvement occurs, reset the counter, and restore that state when stopping triggers.

Part 4 - Python code skeleton

```
import copy

def E05(model, validation_losses, patience, min_delta):
    best = float("inf"); best_state = None; stale = 0
    stop_epoch = None
    for epoch, value in enumerate(validation_losses):
        if value < best - min_delta:
            best = value
            best_state = copy.deepcopy(model.state_dict())
            stale = 0
        else:
            stale += 1
        if stale >= patience:
            stop_epoch = epoch; break
    if best_state is not None: model.load_state_dict(best_state)
    return stop_epoch, best, model
```

```
def main(): print(E05(...))
if __name__ == "__main__": main()
```

13.8.7 Exercise 06 - Add Checkpoint Saving and Restore Training from Checkpoint Without Drift

Part 1 - Why this matters

A training checkpoint must preserve more than model weights when exact continuation matters. Optimizer state, epoch, random states, metrics, and relevant configuration all influence the next update.

Restoration should be verified by branching one controlled run: continue directly from a checkpoint and compare it with a save-load continuation using identical next batches. Any divergence identifies missing state.

Part 2 - Mathematical form

$$C_t = (\theta_t, S_t^{\text{opt}}, t, R_t^{\text{CPU}}, R_t^{\text{CUDA}}, H_t, C_{\text{config}}).$$

Part 3 - Hints and Helper

Save to a temporary path first and replace the final checkpoint atomically. Compare the first post-restore loss and parameter update with an uninterrupted control.

Part 4 - Python code skeleton

```
import random
import torch

def E06(path, model, optimizer, epoch, history):
    checkpoint = {
        "model": model.state_dict(), "optimizer": optimizer.state_dict(),
        "epoch": epoch, "history": history,
        "torch_rng": torch.get_rng_state(),
        "python_rng": random.getstate(),
        "cuda_rng": torch.cuda.get_rng_state_all()
                    if torch.cuda.is_available() else None,
    }
    torch.save(checkpoint, path)
    restored = torch.load(path, map_location=next(model.parameters()).device)
    model.load_state_dict(restored["model"])
    optimizer.load_state_dict(restored["optimizer"])
    return restored

def main(): print(E06(...))
if __name__ == "__main__": main()
```

13.8.8 Exercise 07 - Implement Resume Training with Scheduler and Optimizer State Preservation

Part 1 - Why this matters

Resuming only model weights restarts optimizer moments and learning-rate schedule, producing a different training trajectory. The scheduler state and the optimizer state must correspond to the same completed step or epoch.

The resume point should record the next epoch and global update count. A verification run must compare learning rate, optimizer state tensors, and the next parameter update with an uninterrupted control.

Part 2 - Mathematical form

$$C_t = (\theta_t, S_t^{\text{opt}}, S_t^{\text{sched}}, e_t, u_t).$$

Part 3 - Hints and Helper

Restore model, optimizer, and scheduler in a compatible order, then inspect the current learning rate before performing the next update.

Part 4 - Python code skeleton

```
import torch

def E07(checkpoint_path, model, optimizer, scheduler):
    state = torch.load(checkpoint_path,
                       map_location=next(model.parameters()).device)
    model.load_state_dict(state["model"])
    optimizer.load_state_dict(state["optimizer"])
    scheduler.load_state_dict(state["scheduler"])
    return {
        "next_epoch": state["epoch"] + 1,
        "global_step": state["global_step"],
        "learning_rates": [group["lr"] for group in optimizer.param_groups],
    }

def main(): print(E07(...))
if __name__ == "__main__": main()
```

13.8.9 Exercise 08 - Add Structured Logging and Verify Logs Are Correct for Every Epoch

Part 1 - Why this matters

Structured logs make experiments machine-readable and comparable. Every record should identify the epoch, phase, sample count, loss, metrics, learning rate, timing, and relevant diagnostic values with stable field names.

Logging correctness requires schema validation and consistency checks. Missing epochs, duplicate phases, impossible sample counts, or a learning rate recorded at the wrong time can mislead later analysis even when training itself is correct.

Part 2 - Mathematical form

$$R_{e,p} = \{e, p, N, L, M, \eta, T, D\}, \qquad p \in \{\text{train}, \text{validation}\}.$$

Part 3 - Hints and Helper

Append one record per phase and epoch, validate required fields and types, and compare logged metrics with the in-memory epoch result.

Part 4 - Python code skeleton

```
import json

def E08(path, records):
    required = {"epoch", "phase", "samples", "loss",
                "metrics", "learning_rate", "elapsed"}
    errors = []
    with open(path, "w", encoding="utf-8") as stream:
        for record in records:
            missing = required - record.keys()
            if missing: errors.append((record.get("epoch"), sorted(missing)))
            stream.write(json.dumps(record) + "
")
    expected = {(r["epoch"], r["phase"]) for r in records}
    complete = len(expected) == len(records) and not errors
    return complete, errors

def main(): print(E08(...))
if __name__ == "__main__": main()
```

13.8.10 Exercise 09 - Debug Training Loop Bugs That Produce Good Loss but Bad Accuracy

Part 1 - Why this matters

A decreasing loss with poor accuracy can be legitimate early in training, but persistent disagreement may indicate label mapping errors, wrong prediction axes, inappropriate thresholds, leakage, or a metric computed from probabilities incorrectly.

Debugging must recompute accuracy directly from logits and labels on a small known batch. Confusion matrices and sample-level predictions show whether the problem belongs to the model, label encoding, or metric pipeline.

Part 2 - Mathematical form

$$\widehat{y}_i = \arg\max_c z_{i,c}, \qquad \text{Accuracy} = B^{-1} \sum_i \mathbf{1}(\widehat{y}_i = y_i).$$

Part 3 - Hints and Helper

Inspect raw logits, target indices, predicted indices, class mapping, and confusion counts. Compare the logged accuracy with a direct tensor calculation.

Part 4 - Python code skeleton

```
import torch

def E09(logits, labels, logged_accuracy, class_count):
    predictions = logits.argmax(dim=1)
    direct = (predictions == labels).float().mean().item()
    confusion = torch.zeros(class_count, class_count, dtype=torch.long)
    for target, prediction in zip(labels.cpu(), predictions.cpu()):
        confusion[target, prediction] += 1
    problems = []
    if logits.ndim != 2: problems.append("wrong_logit_shape")
    if not 0 <= labels.min() or labels.max() >= class_count:
        problems.append("invalid_labels")
    if abs(direct - logged_accuracy) > 1e-12:
        problems.append("metric_mismatch")
    return direct, confusion, problems

def main(): print(E09(...))
if __name__ == "__main__": main()
```

13.8.11 Exercise 10 - Train Entire Pipeline on CUDA and Ensure Data, Model, and Loss Are on Same Device

Part 1 - Why this matters

A CUDA training pipeline requires every tensor participating in forward and loss computation to share the model device. Moving only the model leaves inputs or targets on the CPU and causes failure at the first mixed-device operation.

Device placement should be centralized rather than scattered across model code. The loop must validate model parameters, buffers, batches, outputs, loss, and gradients while avoiding repeated host-device transfers.

Part 2 - Mathematical form

$$D(X) = D(Y) = D(\theta) = D(\widehat{Y}) = D(\mathcal{L}) = D(\nabla\theta).$$

Part 3 - Hints and Helper

Choose one device, move each batch with appropriate non-blocking settings, and inspect devices after the first complete update.

Part 4 - Python code skeleton

```
import torch

def E10(model, loader, optimizer, loss_fn, device):
    model.to(device).train()
    report = []
    for features, targets in loader:
        features = features.to(device, non_blocking=True)
        targets = targets.to(device, non_blocking=True)
        optimizer.zero_grad(set_to_none=True)
        output = model(features); loss = loss_fn(output, targets)
        loss.backward(); optimizer.step()
        report.append({"features": str(features.device),
                       "targets": str(targets.device),
                       "output": str(output.device),
                       "loss": str(loss.device)})
        break
    return report

def main(): print(E10(...))
if __name__ == "__main__": main()
```

13.8.12 Exercise 11 - Measure GPU Utilization During Training and Identify Under-Utilization Root Causes

Part 1 - Why this matters

Low GPU utilization often indicates that the accelerator is waiting for data loading, CPU transformations, synchronization, or many tiny kernels. A faster GPU cannot help when the pipeline delivers work too slowly.

Diagnosis should separate data time, host-to-device transfer, forward, backward, and optimizer time. Utilization, throughput, and queue behavior must be observed over sustained training rather than one startup batch.

Part 2 - Mathematical form

$$T_{\text{step}} = T_{\text{data}} + T_{\text{transfer}} + T_f + T_b + T_o + T_{\text{sync}}.$$

Part 3 - Hints and Helper

Synchronize only around measured CUDA regions, warm up first, and compare the time fraction of each pipeline stage.

Part 4 - Python code skeleton

```
import time
import torch

def E11(run_profiled_step, steps, device):
    records = []
    for step in range(steps):
        if device.type == "cuda": torch.cuda.synchronize(device)
        start = time.perf_counter()
        timings = run_profiled_step(...)
        if device.type == "cuda": torch.cuda.synchronize(device)
        timings["total"] = time.perf_counter() - start
        records.append(timings)
    averages = {key: sum(r[key] for r in records) / len(records)
                for key in records[0]}
    bottleneck = max(averages, key=averages.get)
    return records, averages, bottleneck

def main(): print(E11(...))
if __name__ == "__main__": main()
```

13.8.13 Exercise 12 - Implement Mixed Precision Training with GradScaler and Detect Silent Overflow Issues

Part 1 - Why this matters

Automatic mixed precision accelerates supported CUDA operations and reduces activation memory. Gradient scaling protects small gradients from underflow, while the scaler skips optimizer updates when non-finite gradients are detected.

A training loop can appear to run while many steps are silently skipped. Monitoring scale changes, parameter updates, loss finiteness, and gradient norms is necessary to distinguish healthy scaling from persistent overflow.

Part 2 - Mathematical form

$$\widetilde{\mathcal{L}} = s\mathcal{L}, \qquad \widetilde{g} = sg, \qquad g = \widetilde{g}/s.$$

Part 3 - Hints and Helper

Use autocast for forward and loss, scale backward, unscale before clipping, then step and update the scaler. Log whether parameters actually changed.

Part 4 - Python code skeleton

```
import torch

def E12(model, batch, optimizer, loss_fn, scaler, device_type):
    features, targets = batch
    optimizer.zero_grad(set_to_none=True)
    before = [p.detach().clone() for p in model.parameters()]
    old_scale = scaler.get_scale()
    with torch.autocast(device_type=device_type, enabled=...):
        loss = loss_fn(model(features), targets)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    scaler.step(optimizer); scaler.update()
    changed = any(not torch.equal(a, b)
                  for a, b in zip(before, model.parameters()))
    return {"loss_finite": torch.isfinite(loss).item(),
            "old_scale": old_scale, "new_scale": scaler.get_scale(),
            "parameter_update": changed}

def main(): print(E12(...))
if __name__ == "__main__": main()
```

13.8.14 Exercise 13 - Create a Reproducible Experiment Template with Seeds, Configs, and Version Logs

Part 1 - Why this matters

A reproducible experiment records the complete conditions that generated a result. Seeds must be paired with immutable configuration, data identifiers, code version, library versions, device information, and deterministic settings.

The template should create a unique run directory and save configuration before training begins. Repeating a run should either reproduce outputs exactly or document the tolerated variation and its source.

Part 2 - Mathematical form

$$E = (C, s, V_{\text{code}}, V_{\text{libs}}, D, I_{\text{data}}, R).$$

Part 3 - Hints and Helper

Serialize the resolved configuration rather than defaults alone, log environment metadata, and perform a repeated-run verification.

Part 4 - Python code skeleton

```
import json
import platform
import torch
```

```
def E13(config, seed, code_version, data_id, output_path):
    torch.manual_seed(seed)
    metadata = {
        "config": config, "seed": seed,
        "code_version": code_version, "data_id": data_id,
        "torch_version": torch.__version__,
        "python_version": platform.python_version(),
        "cuda_version": torch.version.cuda,
        "device": torch.cuda.get_device_name(0)
                  if torch.cuda.is_available() else "cpu",
    }
    with open(output_path, "w", encoding="utf-8") as stream:
        json.dump(metadata, stream, indent=2, sort_keys=True)
    return metadata

def main(): print(E13(...))
if __name__ == "__main__": main()
```

13.8.15 Exercise 14 - Implement Gradient Accumulation in Training Loop and Validate Equivalent Results

Part 1 - Why this matters

Gradient accumulation combines several micro-batches before one optimizer step, reducing peak activation memory while approximating a larger effective batch. Loss scaling must match the intended mean reduction.

Equivalence should be tested without stochastic layers by comparing accumulated gradients and the resulting parameter update with one full-batch calculation. Unequal final micro-batches require weighting by sample count rather than dividing blindly.

Part 2 - Mathematical form

$$g_{\text{full}} = \frac{1}{N}\sum_{i=1}^{N} g_i, \qquad g_{\text{acc}} = \sum_{k} \frac{B_k}{N} g_k.$$

Part 3 - Hints and Helper

Use copied models, identical sample order, and no dropout. Compare gradients before stepping and parameters after stepping.

Part 4 - Python code skeleton

```
import copy
import torch

def E14(model, micro_batches, optimizer_factory, loss_fn):
```

```
    accumulated = copy.deepcopy(model)
    optimizer = optimizer_factory(accumulated.parameters())
    total = sum(targets.shape[0] for _, targets in micro_batches)
    optimizer.zero_grad(set_to_none=True)
    for features, targets in micro_batches:
        weight = targets.shape[0] / total
        loss = loss_fn(accumulated(features), targets) * weight
        loss.backward()
    gradients = [p.grad.detach().clone() for p in accumulated.parameters()]
    optimizer.step()
    full_batch_result = ...
    return gradients, full_batch_result, ...

def main(): print(E14(...))
if __name__ == "__main__": main()
```

13.8.16 Exercise 15 - Handle NaN Loss During Training by Adding Detection and Immediate Diagnostics

Part 1 - Why this matters

A non-finite loss should stop parameter updates immediately because one invalid step can contaminate optimizer state and every parameter. The visible NaN may be downstream from the first invalid activation or input.

Immediate diagnostics should preserve the failing batch and record input ranges, targets, outputs, activations, gradients, parameter norms, learning rate, precision, and recent losses. The system should fail loudly instead of continuing with corrupted state.

Part 2 - Mathematical form

$$\neg\,\mathrm{finite}(\mathcal{L}_t) \Rightarrow \text{abort step} \wedge \mathrm{capture}(D_t).$$

Part 3 - Hints and Helper

Check the loss before backward and gradients before stepping. Save detached diagnostic tensors without exposing sensitive raw data unnecessarily.

Part 4 - Python code skeleton

```
import torch

def E15(model, features, targets, optimizer, loss_fn):
    optimizer.zero_grad(set_to_none=True)
    output, states = model.forward_with_states(features)
    loss = loss_fn(output, targets)
    diagnostics = {"loss": loss.detach().cpu(),
                   "input_min": features.min().item(),
```

```
                    "input_max": features.max().item(),
                    "output_finite": torch.isfinite(output).all().item(),
                    "state_finite": [torch.isfinite(s).all().item()
                                     for s in states]}
    if not torch.isfinite(loss):
        return {"aborted": True, "diagnostics": diagnostics}
    loss.backward()
    gradients_finite = all(p.grad is None or torch.isfinite(p.grad).all()
                           for p in model.parameters())
    if gradients_finite: optimizer.step()
    return {"aborted": not gradients_finite,
            "diagnostics": diagnostics}

def main(): print(E15(...))
if __name__ == "__main__": main()
```

13.8.17 Exercise 16 - Implement Batch-Level Debug Mode to Inspect Failing Samples During Training

Part 1 - Why this matters

Batch-level debugging identifies which samples produce extreme loss, invalid outputs, or unexpected labels. Aggregate epoch metrics can hide a small group that repeatedly destabilizes training.

Debug mode should be opt-in because retaining per-sample information adds cost and may expose sensitive data. It should store sample identifiers and compact statistics rather than duplicating full datasets.

Part 2 - Mathematical form

$$i^* = \arg\max_i \ell_i, \qquad F = \{i : \neg\,\mathrm{finite}(\ell_i) \ \vee \ \ell_i > \tau\}.$$

Part 3 - Hints and Helper

Use an unreduced loss, rank samples by loss, and capture identifiers, labels, predictions, ranges, and finiteness for only the failing subset.

Part 4 - Python code skeleton

```
import torch

def E16(model, features, targets, sample_ids, elementwise_loss, threshold):
    outputs = model(features)
    losses = elementwise_loss(outputs, targets)
    per_sample = losses.reshape(losses.shape[0], -1).mean(dim=1)
    failing = (~torch.isfinite(per_sample)) | (per_sample > threshold)
```

```
    indices = failing.nonzero(as_tuple=False).flatten()
    report = []
    for index in indices.tolist():
        report.append({"sample_id": sample_ids[index],
                       "loss": per_sample[index].item(),
                       "target": targets[index].detach().cpu(),
                       "output": outputs[index].detach().cpu()})
    return report

def main(): print(E16(...))
if __name__ == "__main__": main()
```

13.8.18 Exercise 17 - Benchmark Training Throughput Under Different DataLoader Settings and Pin Memory

Part 1 - Why this matters

DataLoader configuration determines whether the accelerator receives batches fast enough. Worker count, pinned memory, prefetching, persistent workers, batch size, and transformation cost can each change throughput.

The benchmark must include steady-state training rather than data loading alone and should measure samples per second, data wait time, transfer time, and memory. Pinned memory is useful only when paired with compatible asynchronous transfers.

Part 2 - Mathematical form

$$Q = \frac{N_{\text{samples}}}{T_{\text{steady}}}, \qquad T_{\text{step}} = T_{\text{wait}} + T_{\text{transfer}} + T_{\text{compute}}.$$

Part 3 - Hints and Helper

Warm up workers and CUDA, hold the model computation fixed, and repeat each loader configuration several times.

Part 4 - Python code skeleton

```
import itertools

def E17(build_loader, benchmark, configurations, repeats):
    results = []
    for configuration in configurations:
        runs = []
        for _ in range(repeats):
            loader = build_loader(**configuration)
            use_non_blocking = configuration["pin_memory"]
            result = benchmark(
                loader, non_blocking=use_non_blocking, ...
```

```
            )
            runs.append(result)
        results.append({"configuration": configuration,
                        "runs": runs,
                        "mean_throughput": sum(r["throughput"] for r in runs)
                                           / len(runs)})
    return results

def main(): print(E17(...))
if __name__ == "__main__": main()
```

13.8.19 Exercise 18 - Validate End-to-End Training Correctness by Overfitting a Tiny Dataset on Purpose

Part 1 - Why this matters

A sufficiently expressive model should often fit a tiny clean dataset almost perfectly. Failure to do so is a powerful signal of bugs in labels, shapes, loss, gradient flow, optimizer order, learning rate, or model capacity.

This is a pipeline correctness test, not a generalization strategy. Regularization and augmentation should be disabled, the same examples repeated, and a strict target loss or accuracy declared before the run.

Part 2 - Mathematical form

$$\exists T : \mathcal{L}_{\text{tiny},T} < \varepsilon \ \wedge \ \text{Accuracy}_{\text{tiny},T} \approx 1.$$

Part 3 - Hints and Helper

Use a very small deterministic subset, verify labels manually, disable dropout and weight decay, and stop when the predefined target is reached.

Part 4 - Python code skeleton

```
def E18(model, tiny_loader, optimizer, loss_fn, max_steps, target):
    history = []
    iterator = iter(tiny_loader)
    for step in range(max_steps):
        try: features, labels = next(iterator)
        except StopIteration:
            iterator = iter(tiny_loader); features, labels = next(iterator)
        optimizer.zero_grad(set_to_none=True)
        logits = model(features); loss = loss_fn(logits, labels)
        loss.backward(); optimizer.step()
        accuracy = (logits.argmax(1) == labels).float().mean().item()
        history.append((step, loss.item(), accuracy))
        if loss.item() < target["loss"] and accuracy >= target["accuracy"]:
            return {"passed": True, "history": history}
```

```
    return {"passed": False, "history": history}

def main(): print(E18(...))
if __name__ == "__main__": main()
```

13.8.20 Exercise 19 - Produce a Full Training Loop Debugging and Verification Report

Part 1 - Why this matters

A complete report converts training-loop experiments into an auditable verification record. It should cover data contracts, modes, losses, metrics, updates, validation, checkpoint restoration, device placement, precision, throughput, and failure handling.

Every conclusion must cite an observed test and its result. The report should distinguish passed checks, unresolved risks, failed checks, corrective actions, and re-verification so that future changes can be evaluated against a stable baseline.

Part 2 - Mathematical form

$$\text{requirement} \rightarrow \text{test} \rightarrow \text{evidence} \rightarrow \text{status} \rightarrow \text{correction} \rightarrow \text{retest}.$$

Part 3 - Hints and Helper

Require evidence for all statuses and include the tiny-dataset overfit test as the final end-to-end verification.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "data_contracts", "train_eval_modes", "classification_loss",
        "regression_loss", "metric_validation", "validation_loop",
        "early_stopping", "checkpoint_restore", "resume_state",
        "structured_logs", "cuda_placement", "gpu_utilization",
        "mixed_precision", "reproducibility", "accumulation",
        "nan_diagnostics", "batch_debugging", "loader_benchmark",
        "tiny_dataset_overfit", "corrective_actions",
    }
    missing = sorted(required - sections.keys())
    unsupported = [name for name, result in sections.items()
                   if isinstance(result, dict) and result.get("status")
                   and not result.get("evidence")]
    return {"complete": not missing and not unsupported,
            "missing": missing, "unsupported": unsupported,
            "report": sections}

def main(): print(E19(...))
if __name__ == "__main__": main()
```

13.9 MLP07 - Regularization, Dropout, and Generalization

Models and Training

13.9.1 Exercise 00 - Demonstrate Overfitting in MLP by Training on Small Dataset Without Regularization

Part 1 - Why this matters

A high-capacity MLP can memorize a small training set while failing to learn patterns that transfer to unseen samples. Training performance continues to improve even as validation loss worsens, creating a growing generalization gap.

The experiment establishes an unregularized baseline before any remedy is introduced. Data splits, model capacity, and training duration must remain fixed so later regularization experiments can be compared with the same failure pattern.

Part 2 - Mathematical form

$$G_t = \mathcal{L}_{\text{val},t} - \mathcal{L}_{\text{train},t}, \qquad \mathcal{L}_{\text{train}} \downarrow,\ \mathcal{L}_{\text{val}} \uparrow .$$

Part 3 - Hints and Helper

Use a deliberately small training subset and a larger held-out set. Log both curves and identify the epoch with minimum validation loss.

Part 4 - Python code skeleton

```
def E00(train_epoch, validate_epoch, epochs):
    history = []
    for epoch in range(epochs):
        train = train_epoch(...)
        validation = validate_epoch(...)
        history.append({"epoch": epoch, "train": train,
                        "validation": validation,
                        "gap": validation["loss"] - train["loss"]})
    best_epoch = min(history, key=lambda item: item["validation"]["loss"])
    return history, best_epoch

def main(): print(E00(...))
if __name__ == "__main__": main()
```

13.9.2 Exercise 01 - Apply L2 Regularization and Measure Its Effect on Train vs Validation Gap

Part 1 - Why this matters

L2 regularization adds a penalty proportional to squared parameter magnitude. It discourages large weights and can reduce sensitivity, but excessive strength can prevent the model from fitting even the training data.

Its effect must be measured on both sides of the bias-variance trade-off. The reader should compare weight norms, training loss, validation loss, and the generalization gap across several penalty strengths.

Part 2 - Mathematical form

$$\mathcal{J}(\theta) = \mathcal{L}(\theta) + \frac{\lambda}{2} \sum_{\theta_i \in \Theta_w} \theta_i^2.$$

Part 3 - Hints and Helper

Apply the penalty to weights only unless a different policy is justified. Report the task loss separately from the regularized objective.

Part 4 - Python code skeleton

```
def E01(model, task_loss, strength):
    penalty = sum(parameter.pow(2).sum()
                  for name, parameter in model.named_parameters()
                  if "weight" in name)
    objective = task_loss + 0.5 * strength * penalty
    objective.backward()
    return {"task_loss": task_loss.item(),
            "penalty": penalty.item(),
            "objective": objective.item()}

def main(): print(E01(...))
if __name__ == "__main__": main()
```

13.9.3 Exercise 02 - Apply Weight Decay Correctly and Compare It Against L2 Regularization Implementation

Part 1 - Why this matters

Weight decay directly shrinks parameters during an optimizer update, whereas L2 regularization modifies the objective gradient. They can coincide for ordinary SGD but differ for adaptive optimizers because the added L2 gradient is adaptively scaled.

A controlled comparison should start from identical parameters and gradients. Parameter groups must make the decay policy explicit, particularly when biases should remain unregularized.

Part 2 - Mathematical form

$$g^{L2} = g + \lambda\theta, \qquad \theta^{+}_{WD} = (1 - \eta\lambda)\theta - \eta u(g).$$

Part 3 - Hints and Helper

Compare one update with SGD and one with Adam-style adaptation. Record parameter norms and exact element-wise differences.

Part 4 - Python code skeleton

```
import copy
import torch

def E02(model, loss_closure, learning_rate, decay):
    l2_model = copy.deepcopy(model)
    wd_model = copy.deepcopy(model)
    l2_loss = loss_closure(l2_model) + 0.5 * decay * sum(
        p.pow(2).sum() for p in l2_model.parameters())
    l2_loss.backward()
    l2_optimizer = torch.optim.Adam(l2_model.parameters(), lr=learning_rate)
    l2_optimizer.step()
    wd_loss = loss_closure(wd_model); wd_loss.backward()
    wd_optimizer = torch.optim.AdamW(wd_model.parameters(),
                                     lr=learning_rate, weight_decay=decay)
    wd_optimizer.step()
    return l2_model.state_dict(), wd_model.state_dict()

def main(): print(E02(...))
if __name__ == "__main__": main()
```

13.9.4 Exercise 03 - Implement Dropout Layer and Verify Behavior Differs Between Train and Eval Modes

Part 1 - Why this matters

Dropout randomly masks activations during training and rescales surviving values so their expectation is preserved. During evaluation it becomes the identity transformation, producing deterministic outputs.

Mode-dependent behavior must be verified explicitly. Repeated training passes should differ, repeated evaluation passes should match, and the average training output should approach the evaluation output over many samples.

Part 2 - Mathematical form

$$\widetilde{h} = \frac{m \odot h}{1 - p}, \quad m_i \sim \text{Bernoulli}(1 - p), \qquad \mathbb{E}[\widetilde{h}] = h.$$

Part 3 - Hints and Helper

Use the same input repeatedly in both modes. Measure zero ratio, determinism, and empirical mean preservation.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E03(values, probability, repeats=1000):
    dropout = nn.Dropout(probability)
    dropout.train()
    training_outputs = torch.stack([dropout(values) for _ in range(repeats)])
    dropout.eval()
    evaluation_a = dropout(values); evaluation_b = dropout(values)
    training_zero_ratio = (
        (training_outputs == 0).float().mean().item()
    )
    evaluation_deterministic = torch.equal(
        evaluation_a, evaluation_b
    )
    return {
        "training_zero_ratio": training_zero_ratio,
        "evaluation_deterministic": evaluation_deterministic,
        "mean_preserved": torch.allclose(
            training_outputs.mean(0), evaluation_a, atol=...
        ),
    }

def main(): print(E03(...))
if __name__ == "__main__": main()
```

13.9.5 Exercise 04 - Tune Dropout Probability and Identify Underfitting vs Overfitting Patterns

Part 1 - Why this matters

Dropout probability controls the strength of stochastic regularization. A low value may leave overfitting unchanged, while a high value can remove too much capacity and cause both training and validation performance to deteriorate.

Tuning should compare full learning curves across probabilities and seeds. The selected value should minimize held-out error, not maximize the gap reduction by making training uniformly poor.

Part 2 - Mathematical form

$$p^* = \arg\min_{p \in \mathcal{P}} \widehat{R}_{\text{val}}(p), \qquad p \in [0, 1).$$

Part 3 - Hints and Helper

Restart from matched initial conditions for every probability. Classify patterns using train loss, validation loss, and their gap together.

Part 4 - Python code skeleton

```
def E04(run_training, probabilities, seeds):
    results = []
    for probability in probabilities:
        for seed in seeds:
            metrics = run_training(dropout_probability=probability,
                                   seed=seed, ...)
            results.append({"probability": probability,
                            "seed": seed, "metrics": metrics})
    summary = ...
    selected = min(summary, key=lambda p: summary[p]["validation_loss"])
    return results, summary, selected

def main(): print(E04(...))
if __name__ == "__main__": main()
```

13.9.6 Exercise 05 - Combine Dropout with Weight Decay and Analyze Interaction Effects

Part 1 - Why this matters

Dropout regularizes activations stochastically, while weight decay constrains parameter magnitude. Combining them may improve generalization, have little added benefit, or over-regularize the same model.

Interaction cannot be inferred from separate one-factor tests. A factorial experiment must compare neither method, each method alone, and both together under identical data and seed conditions.

Part 2 - Mathematical form

$$Y = \mu + A_{\text{dropout}} + B_{\text{decay}} + (AB) + \varepsilon.$$

Part 3 - Hints and Helper

Use a grid of dropout probabilities and decay strengths. Report main effects, interaction, training fit, validation performance, and weight norms.

Part 4 - Python code skeleton

```
import itertools

def E05(run_case, dropout_values, decay_values, seeds):
    results = []
    for dropout, decay, seed in itertools.product(
        dropout_values, decay_values, seeds
    ):
        metrics = run_case(dropout=dropout, decay=decay,
                           seed=seed, ...)
        results.append({"dropout": dropout, "decay": decay,
                        "seed": seed, "metrics": metrics})
    interaction = ...
    return results, interaction

def main(): print(E05(...))
if __name__ == "__main__": main()
```

13.9.7 Exercise 06 - Implement Early Stopping and Compare Against Regularization Techniques

Part 1 - Why this matters

Early stopping limits effective training duration by restoring the model from the best validation epoch. Unlike explicit penalties, it does not alter the per-step objective or architecture.

Comparing early stopping with dropout and weight decay reveals whether controlling training time or constraining the model better addresses the observed overfitting. Compute cost and selected epoch should be reported alongside accuracy.

Part 2 - Mathematical form

$$t^* = \arg\min_t \mathcal{L}_{\text{val},t}, \qquad \theta_{\text{final}} = \theta_{t^*}.$$

Part 3 - Hints and Helper

Use the same maximum epoch budget and validation sequence. Restore the best state, then evaluate all methods on an untouched test set.

Part 4 - Python code skeleton

```
def E06(run_method, methods, seeds):
    results = []
    for method in methods:
        for seed in seeds:
            outcome = run_method(method, seed, restore_best=True, ...)
            results.append({"method": method, "seed": seed,
                            "best_epoch": outcome["best_epoch"],
                            "test_metrics": outcome["test_metrics"],
                            "training_time": outcome["training_time"]})
```

```
    return results

def main(): print(E06(...))
if __name__ == "__main__": main()
```

13.9.8 Exercise 07 - Study the Effect of Model Capacity (Depth/Width) on Generalization Behavior

Part 1 - Why this matters

Depth and width change the number and composition of functions an MLP can represent. Insufficient capacity causes underfitting, while excessive capacity can memorize small datasets unless data and regularization support it.

Capacity comparisons should include parameter count, training fit, validation performance, runtime, and memory. A larger model is not proven worse merely because it can overfit; its observed behavior under controlled training is what matters.

Part 2 - Mathematical form

$$P = \sum_{l=1}^{L} (d_{l-1} + 1)d_l, \qquad G(P) = R_{\text{val}}(P) - R_{\text{train}}(P).$$

Part 3 - Hints and Helper

Sweep controlled architectures and repeat seeds. Compare equal training budgets and separately consider roughly parameter-matched depth-width pairs.

Part 4 - Python code skeleton

```
def E07(build_model, train_and_evaluate, architectures, seeds):
    results = []
    for architecture in architectures:
        for seed in seeds:
            model = build_model(architecture, seed)
            metrics = train_and_evaluate(model, ...)
            parameters = sum(p.numel() for p in model.parameters())
            results.append({"architecture": architecture,
                            "seed": seed, "parameters": parameters,
                            "metrics": metrics})
    return results

def main(): print(E07(...))
if __name__ == "__main__": main()
```

13.9.9 Exercise 08 - Demonstrate Data Augmentation Concept for Non-Image Tabular Tasks

Part 1 - Why this matters

Tabular augmentation creates plausible training examples by perturbing continuous features, masking selected inputs, mixing compatible samples, or resampling within domain constraints. It must preserve the semantic meaning of the target.

Blind noise addition can create impossible records or leak information across splits. The augmentation must be fitted from training data only, respect feature types and bounds, and be validated against domain rules.

Part 2 - Mathematical form

$$\widetilde{x}_j = x_j + \epsilon_j, \quad \epsilon_j \sim \mathcal{N}(0, \sigma_j^2), \qquad \widetilde{y} = y \text{ only if label semantics are preserved.}$$

Part 3 - Hints and Helper

Select perturbable columns explicitly, scale noise by training statistics, and test constraint validity before adding samples to a batch.

Part 4 - Python code skeleton

```
import torch

def E08(features, labels, continuous_columns, scales, validator):
    augmented = features.clone()
    noise = torch.randn_like(augmented[:, continuous_columns])
    augmented[:, continuous_columns] += noise * scales
    valid = validator(augmented)
    if not valid.all():
        augmented = augmented[valid]
        augmented_labels = labels[valid]
    else:
        augmented_labels = labels.clone()
    return augmented, augmented_labels, valid.float().mean().item()

def main(): print(E08(...))
if __name__ == "__main__": main()
```

13.9.10 Exercise 09 - Debug Regularization Misuse That Causes Training Collapse or No Learning

Part 1 - Why this matters

Excessive decay, extreme dropout, a penalty applied twice, regularization of inappropriate parameters, or early stopping configured too aggressively can make a valid model appear incapable of learning.

Diagnosis begins by confirming that the unregularized model can fit a tiny dataset. Regularizers should then be reintroduced one at a time while logging task loss, penalty, active-unit ratio, gradient norms, and update magnitude.

Part 2 - Mathematical form

$$\mathcal{J} = \mathcal{L} + \lambda\Omega(\theta), \qquad \lambda\Omega \gg \mathcal{L} \text{ or } p \to 1 \Rightarrow \text{collapse risk.}$$

Part 3 - Hints and Helper

Disable every regularizer, establish a learning baseline, then add one mechanism per controlled run and identify the first failure.

Part 4 - Python code skeleton

```
def E09(run_case, regularization_config):
    baseline = run_case(dropout=0.0, decay=0.0,
                        early_stopping=False, ...)
    diagnostics = []
    for name in ("dropout", "decay", "early_stopping"):
        isolated = {"dropout": 0.0, "decay": 0.0,
                    "early_stopping": False}
        isolated[name] = regularization_config[name]
        result = run_case(**isolated, ...)
        diagnostics.append({"mechanism": name, "result": result})
    return baseline, diagnostics

def main(): print(E09(...))
if __name__ == "__main__": main()
```

13.9.11 Exercise 10 - Execute Regularized Training on CUDA and Measure Runtime Overhead of Dropout

Part 1 - Why this matters

Dropout adds random-mask generation and element-wise operations during CUDA training. Its relative overhead depends on tensor size, model compute, kernel behavior, and whether timing includes data transfer.

A valid benchmark compares identical networks with dropout disabled and enabled, keeps data on the GPU, warms up kernels, and synchronizes timed regions. Evaluation mode should show that dropout overhead disappears.

Part 2 - Mathematical form

$$O_{\text{drop}} = (T_p - T_0)/T_0, \qquad p > 0.$$

Part 3 - Hints and Helper

Measure forward-backward time in training mode and forward time in evaluation mode across several batch sizes.

Part 4 - Python code skeleton

```
import time
import torch

def E10(run_step, dropout_values, device, repeats):
    results = {}
    for probability in dropout_values:
        for _ in range(10): run_step(probability, ...)
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        for _ in range(repeats): run_step(probability, ...)
        torch.cuda.synchronize(device)
        results[probability] = (time.perf_counter() - start) / repeats
    baseline = results[0.0]
    overhead = {p: (value - baseline) / baseline
                for p, value in results.items()}
    return results, overhead

def main(): print(E10(...))
if __name__ == "__main__": main()
```

13.9.12 Exercise 11 - Compare Regularization Outcomes Under Mixed Precision Training

Part 1 - Why this matters

Mixed precision changes numerical behavior while dropout and weight decay alter optimization and capacity. Their interaction may affect gradient scaling, update skipping, and the effective strength of small penalties.

The comparison should use identical initial states, data order, and regularization settings in full and mixed precision. Validation performance, non-finite events, scaler history, norms, speed, and memory all belong in the result.

Part 2 - Mathematical form

$$R = F(p, \lambda, \text{precision}, \text{seed}).$$

Part 3 - Hints and Helper

Test each regularization configuration in both precision modes and repeat seeds. Track whether mixed-precision steps are skipped.

Part 4 - Python code skeleton

```
def E11(run_training, configurations, precisions, seeds):
    results = []
    for configuration in configurations:
        for precision in precisions:
            for seed in seeds:
```

```
                outcome = run_training(configuration=configuration,
                                       precision=precision,
                                       seed=seed, ...)
                results.append({"configuration": configuration,
                                "precision": precision,
                                "seed": seed, "outcome": outcome})
    return results

def main(): print(E11(...))
if __name__ == "__main__": main()
```

13.9.13 Exercise 12 - Analyze Generalization Under Label Noise and Apply Robust Training Strategies

Part 1 - Why this matters

Incorrect labels encourage a sufficiently flexible MLP to memorize contradictions. Training loss may eventually decrease while clean validation performance degrades, especially during long training.

Robust strategies can include early stopping, reduced capacity, label smoothing, sample reweighting, or verified data cleaning. Evaluation requires known clean validation labels and controlled noise injection only into the training split.

Part 2 - Mathematical form

$$\widetilde{y}_i = \begin{cases} y_i, & \text{with probability } 1-\rho, \\ c \neq y_i, & \text{with probability } \rho. \end{cases}$$

Part 3 - Hints and Helper

Sweep known noise rates and compare strategies across seeds. Preserve the clean labels separately so corrupted examples can be analyzed.

Part 4 - Python code skeleton

```
import torch

def E12(labels, noise_rate, class_count, generator):
    noisy = labels.clone()
    mask = torch.rand(labels.shape, generator=generator) < noise_rate
    offsets = torch.randint(1, class_count, labels.shape,
                            generator=generator)
    noisy[mask] = (labels[mask] + offsets[mask]) % class_count
    return noisy, mask

def run_experiment(noise_rates, strategies, seeds):
```

```
    return [...]

def main(): print(E12(...))
if __name__ == "__main__": main()
```

13.9.14 Exercise 13 - Study the Effect of Input Feature Normalization on Generalization Stability

Part 1 - Why this matters

Features with very different scales create poorly conditioned optimization and make some inputs dominate early gradients. Normalization can improve convergence stability and make regularization strength more comparable across features.

Statistics must be fitted on training data only and applied unchanged to validation and test sets. Recomputing them on held-out data leaks information and produces an unrealistic evaluation pipeline.

Part 2 - Mathematical form

$$\widetilde{x}_j = (x_j - \mu_j^{\text{train}})/(s_j^{\text{train}} + \varepsilon).$$

Part 3 - Hints and Helper

Fit means and standard deviations on the training split, handle constant columns, and compare seed-to-seed variation with and without normalization.

Part 4 - Python code skeleton

```
import torch

def E13(train_features, validation_features, epsilon=1e-8):
    mean = train_features.mean(dim=0)
    std = train_features.std(dim=0)
    safe_std = torch.where(std < epsilon, torch.ones_like(std), std)
    normalized_train = (train_features - mean) / safe_std
    normalized_validation = (validation_features - mean) / safe_std
    return {"train": normalized_train,
            "validation": normalized_validation,
            "mean": mean, "std": safe_std,
            "constant_columns": std < epsilon}

def main(): print(E13(...))
if __name__ == "__main__": main()
```

13.9.15 Exercise 14 - Implement K-Fold Cross Validation and Compare Model Stability Across Folds

Part 1 - Why this matters

K-fold cross validation rotates each partition through validation while training on the remaining partitions. It estimates how sensitive results are to one particular split and uses limited data more completely.

Every fold requires a newly initialized model and preprocessing fitted only on that fold's training portion. The final report should include per-fold metrics, mean, variation, and any fold whose data composition explains unusual behavior.

Part 2 - Mathematical form

$$\widehat{R}_{CV} = K^{-1} \sum_{k=1}^{K} R_k, \qquad s_{CV}^2 = (K-1)^{-1} \sum_{k} (R_k - \widehat{R}_{CV})^2.$$

Part 3 - Hints and Helper

Use disjoint validation indices whose union covers the dataset. Reinitialize model, optimizer, scheduler, and preprocessing for every fold.

Part 4 - Python code skeleton

```
import torch

def E14(folds, build_pipeline, train_and_evaluate):
    results = []
    validation_indices = []
    for fold, (train_indices, val_indices) in enumerate(folds):
        pipeline = build_pipeline(fold)
        metrics = train_and_evaluate(pipeline, train_indices,
                                     val_indices, ...)
        results.append({"fold": fold, "metrics": metrics})
        validation_indices.extend(val_indices.tolist())
    coverage = len(set(validation_indices)) == len(validation_indices)
    scores = torch.tensor([r["metrics"]["score"] for r in results])
    return results, scores.mean().item(), scores.std().item(), coverage

def main(): print(E14(...))
if __name__ == "__main__": main()
```

13.9.16 Exercise 15 - Diagnose Underfitting and Identify Whether It Comes from Regularization or Capacity Limits

Part 1 - Why this matters

Underfitting appears when training performance remains poor, but the cause may be insufficient model capacity, excessive regularization, inadequate optimization, or uninformative features. Validation performance alone cannot distinguish them.

A diagnostic experiment changes one constraint at a time. Removing regularization tests whether penalties are suppressing fit, while increasing capacity tests whether the hypothesis class is too limited.

Part 2 - Mathematical form

$$R_{\text{train}} \text{ high} \Rightarrow H_{\text{capacity}} \vee H_{\text{regularization}} \vee H_{\text{optimization}} \vee H_{\text{data}}.$$

Part 3 - Hints and Helper

First verify that optimization progresses, then run copied cases with regularization removed and capacity increased. Compare tiny-set fitting ability.

Part 4 - Python code skeleton

```
def E15(run_case, baseline_config):
    baseline = run_case(baseline_config, ...)
    no_regularization = dict(baseline_config)
    no_regularization.update({"dropout": 0.0, "decay": 0.0})
    larger = dict(baseline_config)
    larger["hidden_sizes"] = [size * 2
                              for size in baseline_config["hidden_sizes"]]
    tests = {"baseline": baseline,
             "no_regularization": run_case(no_regularization, ...),
             "larger_capacity": run_case(larger, ...),
             "tiny_set": run_case(baseline_config, tiny_set=True, ...)}
    cause = ...
    return tests, cause

def main(): print(E15(...))
if __name__ == "__main__": main()
```

13.9.17 Exercise 16 - Build a Generalization Report with Error Breakdown and Residual Analysis

Part 1 - Why this matters

Aggregate metrics can hide systematic errors affecting particular classes, target ranges, or subgroups. A generalization report decomposes failures so a model with an acceptable average cannot conceal a harmful pattern.

Classification requires class-wise confusion and error rates, while regression requires residual distributions, bias, scale, and relationships with features or predictions. Subgroup analysis must use meaningful groups and adequate sample counts.

Part 2 - Mathematical form

$$r_i = y_i - \widehat{y}_i, \qquad \mathbb{E}[r],\ \mathrm{Var}(r),\ \mathbb{E}[|r| \mid G = g].$$

Part 3 - Hints and Helper

Store detached predictions and targets, calculate global and subgroup metrics, and report uncertainty and low-count warnings.

Part 4 - Python code skeleton

```
import torch

def E16(predictions, targets, group_ids):
    residuals = targets - predictions
    report = {"mean_residual": residuals.mean().item(),
              "residual_std": residuals.std().item(),
              "mae": residuals.abs().mean().item(),
              "groups": {}}
    for group in torch.unique(group_ids):
        mask = group_ids == group
        group_residuals = residuals[mask]
        report["groups"][group.item()] = {
            "count": mask.sum().item(),
            "mae": group_residuals.abs().mean().item(),
            "bias": group_residuals.mean().item()}
    return report

def main(): print(E16(...))
if __name__ == "__main__": main()
```

13.9.18 Exercise 17 - Evaluate Robustness Under Distribution Shift and Document Observed Failure Patterns

Part 1 - Why this matters

Distribution shift occurs when deployment inputs or label relationships differ from training conditions. A model that generalizes within one random split may fail under changed scale, noise, missingness, subgroup prevalence, or time period.

Robustness evaluation should define realistic shifts and compare performance with the in-distribution baseline. Failure patterns must be documented by shift severity and subgroup rather than summarized as one worst-case number.

Part 2 - Mathematical form

$$\Delta R_s = R_{Q_s}(f) - R_P(f), \qquad Q_s \neq P.$$

Part 3 - Hints and Helper

Create controlled shift functions without changing labels incorrectly. Sweep severity and preserve both aggregate and sample-level errors.

Part 4 - Python code skeleton

```
def E17(model, dataset, shift_functions, evaluate, severities):
    baseline = evaluate(model, dataset)
    results = []
    for name, shift in shift_functions.items():
        for severity in severities:
            shifted = shift(dataset, severity)
            metrics = evaluate(model, shifted)
            results.append({"shift": name, "severity": severity,
                            "metrics": metrics,
                            "degradation": metrics["error"]
                                           - baseline["error"]})
    return baseline, results

def main(): print(E17(...))
if __name__ == "__main__": main()
```

13.9.19 Exercise 18 - Implement Model Ensembling of Multiple MLP Runs and Compare Generalization Gains

Part 1 - Why this matters

Models trained from different initializations may make partially independent errors. Averaging regression predictions or class probabilities can reduce variance and improve generalization when members are individually competent and sufficiently diverse.

Ensembling adds training, storage, and inference cost. The experiment should compare each member, the ensemble, prediction diversity, calibration, latency, and the marginal benefit of additional members.

Part 2 - Mathematical form

$$\widehat{y}_{\text{ens}} = M^{-1} \sum_{m=1}^{M} \widehat{y}_m, \qquad \operatorname{Var}(\widehat{y}_{\text{ens}}) \leq \operatorname{Var}(\widehat{y}_m) \text{ when errors are not perfectly correlated.}$$

Part 3 - Hints and Helper

Train members with controlled different seeds and the same data protocol. Average probabilities rather than class labels for classification.

Part 4 - Python code skeleton

```
import torch

def E18(models, features, task):
    for model in models: model.eval()
    with torch.inference_mode():
        outputs = torch.stack([model(features) for model in models])
        if task == "classification":
            member_values = outputs.softmax(dim=-1)
            ensemble = member_values.mean(dim=0)
            predictions = ensemble.argmax(dim=-1)
        else:
            member_values = outputs
            ensemble = outputs.mean(dim=0)
            predictions = ensemble
    diversity = member_values.var(dim=0).mean().item()
    return predictions, ensemble, diversity

def main(): print(E18(...))
if __name__ == "__main__": main()
```

13.9.20 Exercise 19 - Write a Practical Regularization Strategy Guide for Real Training Projects

Part 1 - Why this matters

A practical strategy guide selects regularization from evidence about dataset size, noise, model capacity, validation gaps, shift risk, compute budget, and deployment constraints. It should define a baseline before combining multiple mechanisms.

The guide must distinguish overfitting from underfitting and optimization failure. Each recommendation should state its expected signal, tuning range, controlled test, cost, failure mode, and verification condition.

Part 2 - Mathematical form

$$r^*(c) = \arg\min_{r \in \mathcal{R}} \left(\widehat{R}_{\text{val}}(r, c) + \lambda_c C(r) + \lambda_s S(r, c) \right).$$

Part 3 - Hints and Helper

Require a decision table, experiment order, misuse checks, shift tests, and evidence for every final recommendation.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "baseline_overfitting_test", "l2_and_weight_decay",
        "dropout", "early_stopping", "capacity_analysis",
        "tabular_augmentation", "misuse_diagnostics",
```

```
        "mixed_precision", "label_noise", "normalization",
        "cross_validation", "underfitting_diagnosis",
        "error_breakdown", "distribution_shift", "ensembling",
        "decision_table", "limitations", "retesting_conditions",
    }
    missing = sorted(required - sections.keys())
    unsupported = [item for item in sections.get("decision_table", [])
                   if not item.get("evidence")]
    return {"complete": not missing and not unsupported,
            "missing": missing, "unsupported": unsupported,
            "guide": sections}

def main(): print(E19(...))
if __name__ == "__main__": main()
```

13.10 MLP08 - Scaling, Profiling, and Production Readiness

Models and Training

13.10.1 Exercise 00 - Profile MLP Training Performance and Identify Whether Compute or Data Is the Bottleneck

Part 1 - Why this matters

Training throughput is limited by the slowest part of the pipeline. The accelerator may be busy computing forward and backward operations, or it may wait for data loading, preprocessing, transfer, synchronization, and Python control flow.

A profile must separate stages before optimization begins. Improving matrix computation cannot help a data-bound system, while adding workers cannot fix a model whose kernels already saturate the device.

Part 2 - Mathematical form

$$T_{\text{step}} = T_{\text{data}} + T_{\text{transfer}} + T_f + T_b + T_o + T_{\text{sync}}, \qquad Q = B/T_{\text{step}}.$$

Part 3 - Hints and Helper

Warm up the pipeline, profile representative steady-state steps, and classify the bottleneck from time fractions and device activity.

Part 4 - Python code skeleton

```
import time
import torch
```

```
def E00(profile_step, steps, device):
    records = []
    for _ in range(steps):
        if device.type == "cuda": torch.cuda.synchronize(device)
        start = time.perf_counter()
        record = profile_step(...)
        if device.type == "cuda": torch.cuda.synchronize(device)
        record["total"] = time.perf_counter() - start
        records.append(record)
    means = {key: sum(item[key] for item in records) / len(records)
             for key in records[0]}
    bottleneck = max(("data", "transfer", "forward", "backward", "optimizer"),
                     key=lambda key: means[key])
    return records, means, bottleneck

def main(): print(E00(...))
if __name__ == "__main__": main()
```

13.10.2 Exercise 01 - Measure DataLoader Impact Using num_workers and Pin Memory Configuration

Part 1 - Why this matters

DataLoader worker count determines how much data preparation can overlap with model computation. Pinned host memory can accelerate transfers to CUDA when batches use non-blocking copies, but it consumes system resources and is not automatically beneficial.

The best configuration depends on storage, CPU cores, transforms, batch size, and hardware. A benchmark should include startup and steady-state separately and guard against excessive workers or pinned-memory pressure.

Part 2 - Mathematical form

$$Q(w,p) = N/T_{\text{steady}}(w,p), \qquad w = \text{worker count},\ p \in \{0,1\}.$$

Part 3 - Hints and Helper

Sweep bounded worker counts and pin-memory settings. Repeat runs, preserve identical sample work, and report throughput and data-wait time.

Part 4 - Python code skeleton

```
import itertools

def E01(build_loader, benchmark, worker_counts, pin_options):
    results = []
    for workers, pin_memory in itertools.product(worker_counts, pin_options):
        loader = build_loader(num_workers=workers,
                              pin_memory=pin_memory,
```

```
                                persistent_workers=workers > 0)
            metrics = benchmark(loader, non_blocking=pin_memory, ...)
            results.append({"workers": workers, "pin_memory": pin_memory,
                            "metrics": metrics})
    best = max(results, key=lambda item: item["metrics"]["throughput"])
    return results, best

def main(): print(E01(...))
if __name__ == "__main__": main()
```

13.10.3 Exercise 02 - Implement Gradient Accumulation for Memory-Constrained GPUs and Validate Equivalence

Part 1 - Why this matters

Gradient accumulation divides an effective batch into micro-batches and delays the optimizer update. It reduces activation memory while preserving the desired mean gradient when each micro-batch contribution is weighted correctly.

Equivalence is exact only under controlled conditions without stochastic layers or batch-dependent behavior. The validation should compare gradients and updated parameters with a single full-batch step.

Part 2 - Mathematical form

$$g_{\text{eff}} = \sum_k \frac{B_k}{\sum_j B_j} g_k, \qquad B_{\text{eff}} = \sum_k B_k.$$

Part 3 - Hints and Helper

Use cloned models and identical samples. Keep stochastic behavior compatible with evaluation, and weight the loss by sample count when the final micro-batch is incomplete.

Part 4 - Python code skeleton

```
import copy
import torch

def E02(model, micro_batches, loss_fn, optimizer_factory):
    accumulated = copy.deepcopy(model)
    optimizer = optimizer_factory(accumulated.parameters())
    total = sum(targets.shape[0] for _, targets in micro_batches)
    optimizer.zero_grad(set_to_none=True)
    for features, targets in micro_batches:
        weight = targets.shape[0] / total
        (loss_fn(accumulated(features), targets) * weight).backward()
    gradients = [p.grad.detach().clone() for p in accumulated.parameters()]
    optimizer.step()
```

```
    full_batch_reference = ...
    return gradients, full_batch_reference, ...

def main(): print(E02(...))
if __name__ == "__main__": main()
```

13.10.4 Exercise 03 - Implement Mixed Precision Training and Quantify Speed vs Stability Tradeoffs

Part 1 - Why this matters

Mixed precision can improve tensor-core throughput and reduce memory, allowing larger batches. Its smaller numerical range can also introduce overflow, underflow, or skipped optimizer steps that alter training dynamics.

A useful comparison records throughput, peak memory, scaler history, non-finite events, skipped updates, convergence, and validation quality. Speed is valuable only when numerical stability and model quality remain acceptable.

Part 2 - Mathematical form

$$\text{benefit} = Q_{MP}/Q_{FP}, \qquad \text{cost} = R_{MP} - R_{FP} + p_{\text{skipped}}.$$

Part 3 - Hints and Helper

Start both modes from the same checkpoint and data order. Synchronize timing and compare several seeds.

Part 4 - Python code skeleton

```
def E03(run_training, checkpoint, precisions, seeds):
    results = []
    for precision in precisions:
        for seed in seeds:
            outcome = run_training(checkpoint=checkpoint,
                                   precision=precision,
                                   seed=seed, ...)
            results.append({"precision": precision,
                            "seed": seed, "outcome": outcome})
    tradeoff = ...
    return results, tradeoff

def main(): print(E03(...))
if __name__ == "__main__": main()
```

13.10.5 Exercise 04 - Compare Different Batch Sizes and Identify the Throughput-Optimal Configuration

Part 1 - Why this matters

Increasing batch size can improve device occupancy and amortize overhead until memory pressure, bandwidth, or computation reaches saturation. The largest batch that fits is not necessarily the one with the best throughput or latency.

Batch size also changes optimization noise, so systems throughput and model convergence should be reported separately. Production selection may optimize samples per second under a memory and quality constraint.

Part 2 - Mathematical form

$$B^* = \arg\max_{B \in \mathcal{B}} Q(B) \quad \text{subject to} \quad M(B) \le M_{\max},\ R(B) \le R_{\max}.$$

Part 3 - Hints and Helper

Warm up every size, synchronize measurements, track peak memory, and stop cleanly at out-of-memory configurations.

Part 4 - Python code skeleton

```
def E04(run_benchmark, batch_sizes, memory_limit):
    results = []
    for batch_size in batch_sizes:
        try:
            metrics = run_benchmark(batch_size, ...)
            results.append({"batch_size": batch_size,
                            "success": True, **metrics})
            if metrics["peak_memory"] > memory_limit: break
        except RuntimeError as error:
            results.append({"batch_size": batch_size,
                            "success": False, "error": str(error)})
            break
    valid = [item for item in results if item["success"]]
    best = max(valid, key=lambda item: item["throughput"])
    return results, best

def main(): print(E04(...))
if __name__ == "__main__": main()
```

13.10.6 Exercise 05 - Monitor GPU Utilization and Fix Under-Utilization Caused by Input Pipeline Issues

Part 1 - Why this matters

Low utilization with long data-wait intervals indicates that the GPU is starved by the input pipeline. Slow storage, expensive CPU transforms, insufficient workers, synchronous copies, or small batches can create this pattern.

The fix must target the measured cause. Increasing workers blindly can create contention, while caching or moving transforms may help only when the workload and memory budget support them.

Part 2 - Mathematical form

$$U \downarrow \wedge T_{\text{data}}/T_{\text{step}} \uparrow \Rightarrow \text{input starvation candidate.}$$

Part 3 - Hints and Helper

Establish a baseline, change one pipeline factor at a time, and verify higher utilization together with higher end-to-end throughput.

Part 4 - Python code skeleton

```
def E05(profile_pipeline, interventions):
    baseline = profile_pipeline({}, ...)
    results = []
    for name, configuration in interventions.items():
        profile = profile_pipeline(configuration, ...)
        results.append({"intervention": name,
                        "profile": profile,
                        "throughput_gain": profile["throughput"]
                                           / baseline["throughput"] - 1})
    successful = [r for r in results if r["throughput_gain"] > 0]
    return baseline, results, successful

def main(): print(E05(...))
if __name__ == "__main__": main()
```

13.10.7 Exercise 06 - Benchmark Inference Latency and Throughput for Production Deployment Settings

Part 1 - Why this matters

Inference latency measures the response time of individual requests, while throughput measures completed samples per unit time. They depend on batch size, concurrency, precision, device, compilation, and service overhead.

Averages hide tail behavior important to users. Production benchmarking should report warm and cold latency, median and high percentiles, throughput, memory, and output correctness under realistic input shapes.

Part 2 - Mathematical form

$$Q = N/T, \qquad L_{50} = P_{50}(L), \quad L_{95} = P_{95}(L), \quad L_{99} = P_{99}(L).$$

Part 3 - Hints and Helper

Use evaluation mode and inference context, warm up the model, synchronize device work, and exclude or include preprocessing explicitly.

Part 4 - Python code skeleton

```
import time
import torch

def E06(model, batches, device):
    model.eval(); latencies = []; samples = 0
    with torch.inference_mode():
        for batch in batches:
            if device.type == "cuda": torch.cuda.synchronize(device)
            start = time.perf_counter()
            output = model(batch)
            if device.type == "cuda": torch.cuda.synchronize(device)
            latencies.append(time.perf_counter() - start)
            samples += batch.shape[0]
    values = torch.tensor(latencies)
    return {"throughput": samples / values.sum().item(),
            "p50": values.quantile(0.50).item(),
            "p95": values.quantile(0.95).item(),
            "p99": values.quantile(0.99).item(), "last_output": output}

def main(): print(E06(...))
if __name__ == "__main__": main()
```

13.10.8 Exercise 07 - Export MLP Model Using TorchScript or torch.compile and Validate Output Parity

Part 1 - Why this matters

Model export or compilation can reduce Python overhead and enable optimized execution, but graph capture may impose shape, control-flow, or environment constraints. A successful export is not proof that behavior remains correct.

Parity tests should cover representative shapes, data types, devices, boundary values, and repeated calls. Differences must be evaluated with tolerances appropriate to precision, followed by latency and portability measurements.

Part 2 - Mathematical form

$$\max_X \|f_{\text{reference}}(X) - f_{\text{export}}(X)\|_\infty < \varepsilon.$$

Part 3 - Hints and Helper

Export in evaluation mode, test multiple inputs against the original model, save and reload the artifact when applicable, then benchmark.

Part 4 - Python code skeleton

```
import torch

def E07(model, example, test_inputs, method):
    model.eval()
    if method == "torchscript":
        exported = torch.jit.trace(model, example)
    elif method == "compile":
        exported = torch.compile(model)
    else:
        raise ValueError(...)
    parity = []
    with torch.inference_mode():
        for values in test_inputs:
            reference = model(values)
            candidate = exported(values)
            parity.append(torch.allclose(reference, candidate,
                                         atol=..., rtol=...))
    return exported, parity

def main(): print(E07(...))
if __name__ == "__main__": main()
```

13.10.9 Exercise 08 - Implement Checkpoint Rotation and Storage Strategy for Long Training Runs

Part 1 - Why this matters

Long runs can generate many large checkpoints and exhaust storage. Rotation preserves recent recovery points and selected milestones while removing redundant files according to an explicit retention policy.

Deletion must never remove the last known-good checkpoint or a file still being written. Atomic saves, integrity hashes, manifests, and separate best-model retention protect recovery from partial or corrupted state.

Part 2 - Mathematical form

$$K = K_{\text{recent}} \cup K_{\text{milestone}} \cup \{K_{\text{best}}\}, \qquad D = K_{\text{all}} \setminus K.$$

Part 3 - Hints and Helper

Write checkpoints atomically, verify them, update a manifest, then delete only files outside the retention set.

Part 4 - Python code skeleton

```
def E08(checkpoints, keep_recent, milestone_interval, best_id):
    ordered = sorted(checkpoints, key=lambda item: item["step"])
    keep = {item["id"] for item in ordered[-keep_recent:]}
    keep.update(item["id"] for item in ordered
                if item["step"] % milestone_interval == 0)
    keep.add(best_id)
    delete = [item for item in ordered
              if item["id"] not in keep and item["verified"]]
    manifest = {"keep": sorted(keep),
                "delete": [item["id"] for item in delete]}
    return manifest

def main(): print(E08(...))
if __name__ == "__main__": main()
```

13.10.10 Exercise 09 - Detect Memory Leaks and Unexpected GPU Growth Across Long Training Sessions

Part 1 - Why this matters

A memory leak occurs when references to computation graphs or tensors survive beyond their intended step. Appending losses without detaching, retaining graphs repeatedly, persistent hooks, or cached outputs can cause allocated memory to grow over time.

Caching by the allocator is not automatically a leak, so allocated, reserved, and peak memory must be distinguished. A leak test repeats identical work and examines sustained allocated growth after warm-up.

Part 2 - Mathematical form

$$\Delta M_t = M_{\text{allocated},t} - M_{\text{allocated},t-k}, \qquad \Delta M_t > 0 \text{ persistently} \Rightarrow \text{leak candidate.}$$

Part 3 - Hints and Helper

Log memory at fixed intervals, keep workload constant, and inspect collections for tensors that still have gradient functions.

Part 4 - Python code skeleton

```
import torch

def E09(run_step, steps, interval, device):
    records = []
    for step in range(steps):
        run_step(...)
```

```
        if step % interval == 0:
            torch.cuda.synchronize(device)
            records.append({"step": step,
                            "allocated": torch.cuda.memory_allocated(device),
                            "reserved": torch.cuda.memory_reserved(device),
                            "peak": torch.cuda.max_memory_allocated(device)})
    growth = records[-1]["allocated"] - records[0]["allocated"]
    return records, growth, growth > ...

def main(): print(E09(...))
if __name__ == "__main__": main()
```

13.10.11 Exercise 10 - Integrate Model Saving into Object Storage Workflow and Validate Retrieval Correctness

Part 1 - Why this matters

Object storage separates model artifacts from one machine and supports durable training and deployment workflows. A checkpoint should include metadata, a stable object key, integrity information, and a local atomic serialization step before upload.

Upload success alone is insufficient. The object must be retrieved, verified by hash, loaded into a compatible model, and tested for prediction parity with the pre-upload state.

Part 2 - Mathematical form

$$h_{\text{local}} = H(B_{\text{local}}), \qquad h_{\text{download}} = H(B_{\text{download}}), \qquad f_\theta(X) = f_{\theta'}(X).$$

Part 3 - Hints and Helper

Upload a versioned object without embedding credentials in code. Download to a new path, verify its hash, load it, and compare outputs.

Part 4 - Python code skeleton

```
import hashlib
import torch

def file_hash(path):
    digest = hashlib.sha256()
    with open(path, "rb") as stream:
        for block in iter(lambda: stream.read(1024 * 1024), b""):
            digest.update(block)
    return digest.hexdigest()

def E10(storage, local_path, object_key, download_path,
        model, model_factory, example):
    storage.upload(local_path, object_key)
    storage.download(object_key, download_path)
```

```
    integrity = file_hash(local_path) == file_hash(download_path)
    restored = model_factory()
    restored.load_state_dict(torch.load(download_path, map_location="cpu"))
    parity = torch.allclose(model.cpu()(example), restored(example), ...)
    return integrity, parity

def main(): print(E10(...))
if __name__ == "__main__": main()
```

13.10.12 Exercise 11 - Build a Minimal Inference API Wrapper and Validate Input Validation and Error Handling

Part 1 - Why this matters

An inference wrapper defines a stable contract between raw requests and the model. It must validate feature count, batch limits, data type, finite values, schema version, and device placement before execution.

Errors should be explicit and safe rather than exposing internal traces or producing silent coercions. Responses require version metadata and consistent output formatting so clients can interpret predictions correctly.

Part 2 - Mathematical form

$$\text{request} \xrightarrow{\text{validate}} X \xrightarrow{\text{preprocess}} \widetilde{X} \xrightarrow{f_\theta} \widehat{Y} \xrightarrow{\text{format}} \text{response}\,.$$

Part 3 - Hints and Helper

Separate validation, preprocessing, inference, and formatting functions. Test valid, malformed, oversized, and non-finite requests.

Part 4 - Python code skeleton

```
import torch

class InferenceWrapper:
    def __init__(self, model, feature_count, max_batch, version):
        self.model = model.eval()
        self.feature_count = feature_count
        self.max_batch = max_batch
        self.version = version

    def predict(self, payload):
        values = torch.as_tensor(payload, dtype=torch.float32)
        if values.ndim != 2 or values.shape[1] != self.feature_count:
            raise ValueError(...)
        oversized = values.shape[0] > self.max_batch
        invalid = not torch.isfinite(values).all()
```

```
        if oversized or invalid:
            raise ValueError(...)
        with torch.inference_mode(): output = self.model(values)
        return {"model_version": self.version,
                "predictions": output.cpu().tolist()}

def E11(wrapper, test_cases): return [...]
def main(): print(E11(...))
if __name__ == "__main__": main()
```

13.10.13 Exercise 12 - Implement Deterministic Training Controls and Explain Remaining Sources of Non-Determinism

Part 1 - Why this matters

Deterministic controls fix pseudorandom seeds and request deterministic algorithms, helping repeated runs reproduce results. They can reduce performance and do not control every external source such as hardware, driver, library, distributed timing, or data-order changes.

The experiment should repeat an entire short training run and compare losses and parameters. Any remaining difference must be documented with environment and operation evidence rather than attributed vaguely to the GPU.

Part 2 - Mathematical form

$$R(C, s)_1 \stackrel{?}{=} R(C, s)_2, \qquad C = \text{software, hardware, data, algorithm controls.}$$

Part 3 - Hints and Helper

Centralize seed setup, control loader workers, enable deterministic algorithms, and record operations that lack deterministic implementations.

Part 4 - Python code skeleton

```
import random
import torch

def E12(seed, run_training):
    def configure():
        random.seed(seed); torch.manual_seed(seed)
        if torch.cuda.is_available(): torch.cuda.manual_seed_all(seed)
        torch.use_deterministic_algorithms(True)
        torch.backends.cudnn.benchmark = False
    configure(); first = run_training(...)
    configure(); second = run_training(...)
    return {"losses_equal": first["losses"] == second["losses"],
            "parameters_equal": ...,
            "remaining_sources": [...]}
```

```
def main(): print(E12(...))
if __name__ == "__main__": main()
```

13.10.14 Exercise 13 - Add Full Experiment Tracking and Ensure Reproducibility Across Machines and GPUs

Part 1 - Why this matters

Cross-machine reproducibility requires more than a seed. The run must preserve resolved configuration, code revision, environment, data identity, model state, optimizer state, metrics, hardware, precision, and artifact hashes.

Exact numerical equality may not be possible across GPU architectures, so the experiment must define whether it requires bitwise determinism or metric parity within tolerance. A replay procedure should reconstruct the run from recorded artifacts.

Part 2 - Mathematical form

$$E = (C, V, D, H, P, s, A, M), \qquad \text{replay}(E) \approx R.$$

Part 3 - Hints and Helper

Create a run manifest before training, append immutable metrics, hash artifacts, and test replay on a second environment when available.

Part 4 - Python code skeleton

```
import platform
import torch

def E13(config, artifacts, metrics, code_revision, data_hash):
    manifest = {"config": config, "code_revision": code_revision,
                "data_hash": data_hash, "torch": torch.__version__,
                "cuda": torch.version.cuda,
                "python": platform.python_version(),
                "gpu": torch.cuda.get_device_name(0)
                       if torch.cuda.is_available() else "cpu",
                "artifacts": artifacts, "metrics": metrics,
                "artifact_hashes": ...}
    replay_result = ...
    return manifest, replay_result

def main(): print(E13(...))
if __name__ == "__main__": main()
```

13.10.15 Exercise 14 - Stress Test Training at Scale with Large Synthetic Dataset and Monitor System Limits

Part 1 - Why this matters

Synthetic data isolates system capacity from dataset storage and labeling concerns. It can reveal throughput ceilings, out-of-memory boundaries, host-memory pressure, thermal throttling, and long-run numerical instability.

A stress test must be bounded and recoverable. Load should increase gradually, monitoring should cover GPU and host resources, and the test should stop at defined safety thresholds rather than treating a crash as the target.

Part 2 - Mathematical form

$$S = (B, d, L, N, Q, M_{GPU}, M_{host}, T, \text{finite}).$$

Part 3 - Hints and Helper

Sweep one dimension at a time, record the last successful configuration, and separate system-limit failures from model numerical failures.

Part 4 - Python code skeleton

```
import torch

def E14(run_configuration, configurations, limits):
    results = []
    for configuration in configurations:
        try:
            metrics = run_configuration(configuration, ...)
            safe = (metrics["gpu_memory"] <= limits["gpu_memory"]
                    and metrics["host_memory"] <= limits["host_memory"]
                    and metrics["temperature"] <= limits["temperature"])
            results.append({"configuration": configuration,
                            "success": True, "safe": safe,
                            "metrics": metrics})
            if not safe: break
        except RuntimeError as error:
            results.append({"configuration": configuration,
                            "success": False, "error": str(error)})
            break
    return results

def main(): print(E14(...))
if __name__ == "__main__": main()
```

13.10.16 Exercise 15 - Validate Correctness by Intentionally Overfitting Tiny Dataset and Confirming Perfect Fit

Part 1 - Why this matters

A production pipeline should first prove that model, loss, labels, gradients, optimizer, and data flow can fit a tiny deterministic dataset. Failure indicates a correctness or capacity problem before scaling concerns matter.

The test is intentionally opposite to generalization. Augmentation and regularization should be disabled, a strict target set in advance, and the failing artifacts preserved if perfect fit is not reached.

Part 2 - Mathematical form

$$\exists T : \mathcal{L}_T < \varepsilon \ \wedge \ \text{Accuracy}_T = 1 \quad \text{on the tiny training set.}$$

Part 3 - Hints and Helper

Use a handful of verified examples and enough model capacity. Stop at the target or emit a full diagnostic report.

Part 4 - Python code skeleton

```
def E15(model, tiny_loader, optimizer, loss_fn, max_steps, target_loss):
    history = []
    for step in range(max_steps):
        for features, labels in tiny_loader:
            optimizer.zero_grad(set_to_none=True)
            logits = model(features); loss = loss_fn(logits, labels)
            loss.backward(); optimizer.step()
        accuracy = (logits.argmax(1) == labels).float().mean().item()
        history.append((step, loss.item(), accuracy))
        if loss.item() < target_loss and accuracy == 1.0:
            return {"passed": True, "history": history}
    return {"passed": False, "history": history,
            "diagnostics": ...}

def main(): print(E15(...))
if __name__ == "__main__": main()
```

13.10.17 Exercise 16 - Implement Regression Tests That Detect Training Quality Degradation After Refactors

Part 1 - Why this matters

Code refactors can preserve syntax and forward execution while changing initialization, loss scaling, data order, optimizer timing, or checkpoint behavior. Regression tests protect known training properties from silent degradation.

Tests should use small deterministic workloads and compare against toleranced baselines. They must cover functional correctness, short-run learning, tiny-set fit, numerical finiteness, throughput budgets, and serialization parity.

Part 2 - Mathematical form

$$|m_{\text{new}} - m_{\text{base}}| \le \tau_m, \qquad Q_{\text{new}} \ge (1 - \tau_q) Q_{\text{base}}.$$

Part 3 - Hints and Helper

Store baseline ranges rather than one fragile floating-point value and fail with a diagnostic diff that identifies the changed property.

Part 4 - Python code skeleton

```
def E16(run_suite, baseline, tolerances):
    current = run_suite(...)
    checks = {}
    for metric, expected in baseline.items():
        difference = current[metric] - expected
        checks[metric] = {"passed": abs(difference) <= tolerances[metric],
                          "expected": expected,
                          "current": current[metric],
                          "difference": difference}
    checks["all_finite"] = {"passed": current["all_finite"]}
    return {"passed": all(item["passed"] for item in checks.values()),
            "checks": checks}

def main(): print(E16(...))
if __name__ == "__main__": main()
```

13.10.18 Exercise 17 - Build a Production Readiness Checklist Covering Performance, Stability, and Monitoring

Part 1 - Why this matters

Production readiness requires verified behavior under realistic load and failure, not merely a good validation score. The system must meet latency, throughput, memory, stability, observability, security, rollback, and data-contract requirements.

A checklist should contain measurable acceptance criteria and evidence links. Unknown or failed items must block release when they concern correctness, recovery, or safety rather than being converted into optimistic assumptions.

Part 2 - Mathematical form

$$\text{release} = \bigwedge_{r \in R_{\text{critical}}} \text{pass}(r).$$

Part 3 - Hints and Helper

Classify requirements by severity, require evidence, identify owners, and keep rollback and monitoring tests in the release gate.

Part 4 - Python code skeleton

```
def E17(items):
    required = {"correctness", "latency", "throughput", "memory",
                "stability", "monitoring", "data_validation",
                "artifact_integrity", "rollback", "recovery",
                "security", "capacity_limits"}
    missing = sorted(required - items.keys())
    blockers = [name for name, item in items.items()
                if item.get("critical")
                and (item.get("status") != "passed"
                     or not item.get("evidence"))]
    return {"ready": not missing and not blockers,
            "missing": missing, "blockers": blockers, "items": items}

def main(): print(E17(...))
if __name__ == "__main__": main()
```

13.10.19 Exercise 18 - Simulate Failure Recovery by Resuming from Checkpoint After Forced Interruption

Part 1 - Why this matters

Recovery testing proves that a checkpoint can restore a run after process interruption. The recovered trajectory requires model, optimizer, scheduler, scaler, counters, random states, and data-sampler position to be preserved consistently.

A forced interruption should occur at a known step, followed by restoration in a fresh process-like state. The recovered next update must be compared with an uninterrupted control to detect drift.

Part 2 - Mathematical form

$$C_t \xrightarrow{\text{restore}} S_t, \qquad U(S_t, B_{t+1}) \stackrel{?}{=} U(S_t^{\text{control}}, B_{t+1}).$$

Part 3 - Hints and Helper

Save before interruption, discard in-memory objects, rebuild them, restore all states, and compare the next loss, learning rate, and parameters.

Part 4 - Python code skeleton

```
def E18(run_until, save_checkpoint, rebuild_and_restore,
        continue_training, interruption_step):
    control_state = run_until(interruption_step, ...)
    checkpoint_path = save_checkpoint(control_state, ...)
    control_next = continue_training(control_state, steps=1, ...)
    recovered_state = rebuild_and_restore(checkpoint_path, ...)
    recovered_next = continue_training(recovered_state, steps=1, ...)
    return {"loss_match": ...,
            "learning_rate_match": ...,
            "parameter_match": ...,
            "control": control_next,
            "recovered": recovered_next}

def main(): print(E18(...))
if __name__ == "__main__": main()
```

13.10.20 Exercise 19 - Produce a Final End-to-End MLP Engineering Report with Lessons Learned and Best Practices

Part 1 - Why this matters

The final engineering report connects mathematical correctness, training behavior, system performance, artifact management, inference reliability, monitoring, and recovery into one auditable account. It explains not only what worked but why the evidence supports deployment.

The report must preserve failures and lessons alongside successful results. Remaining risks, capacity boundaries, environment assumptions, rollback procedures, and future tests should be explicit so the MLP can evolve without losing verified behavior.

Part 2 - Mathematical form

$$\text{design} \to \text{train} \to \text{validate} \to \text{profile} \to \text{package} \to \text{deploy} \to \text{monitor} \to \text{recover}.$$

Part 3 - Hints and Helper

Require evidence for every major conclusion and include links to benchmarks, parity tests, regression tests, failure recovery, and the production gate.

Part 4 - Python code skeleton

```
def E19(sections):
    required = {
        "architecture", "training_correctness", "generalization",

Book 14

CNN (Convolutional Neural Networks)

14.1 Introduction

14.1.1 What will the book teach you

This book marks the transition from general-purpose feed-forward networks to models that are designed to reason about spatial structure. In an MLP, every input feature can be connected to every unit in the following layer. That approach is useful, but it ignores the fact that nearby pixels usually form local patterns and that the same pattern may appear in different positions. Convolutional Neural Networks introduce a stronger assumption: useful visual information can be detected locally with shared filters and combined gradually into more complex representations. The reader will learn why this inductive bias makes CNNs more parameter-efficient and better suited to images than a large fully connected network.

The book begins by making convolution completely visible. The reader will implement the operation with explicit loops, compare convolution with cross-correlation, follow a kernel as it moves across an image, and calculate every output dimension manually. Kernel size, stride, padding, dilation, channels, and batch dimensions will not be treated as isolated settings. Each one changes what information can be observed, how much spatial detail is preserved, and how expensive the computation becomes. Manual results will then be compared with PyTorch implementations so that library functions are used with understanding rather than memorization.

Particular attention will be given to tensor layout. Images commonly enter a PyTorch CNN in the form `(N,C,H,W)`, while convolutional kernels use the compact form `(Cout,Cin,kH,kW)` for output channels, input channels, and kernel height and width. The reader will learn how multiple input channels contribute to one output feature map and how multiple filters create several output channels. This foundation is essential because a CNN may run without an obvious error while still using incorrect channel order, normalization, or spatial dimensions. Shape reasoning will therefore remain a continuous responsibility throughout the book.

Feature maps and receptive fields will connect tensor operations to visual meaning. Early layers may respond to edges, orientations, colors, or textures, while deeper layers combine these responses over progressively larger regions. The reader will calculate receptive-field growth, create and inspect custom filters, capture intermediate activations, and test translation equivariance. The exercises will also show where this useful property can weaken because of padding, stride, downsampling, aliasing, or boundary effects. A feature map must be interpreted as a

learned response, not simply as another tensor produced by the network.

Downsampling will be studied as a deliberate information trade-off. Max pooling, average pooling, adaptive pooling, global average pooling, strided convolution, blur pooling, and anti-aliased alternatives will be compared in terms of output size, computational cost, invariance, and lost detail. Reducing resolution can enlarge the effective receptive field and lower memory usage, but aggressive reduction can destroy small or rare features before later layers can use them. The reader will learn to measure this loss and design a downsampling strategy according to the data rather than following a fixed architectural habit.

After the individual operations are understood, the reader will assemble a complete CNN forward architecture. Convolutional blocks, activation functions, normalization, pooling, classifier heads, global average pooling, dropout, and skip connections will be combined while every intermediate shape is verified. The book will compare explicit forward functions with `nn.Sequential` and configurable builders, inspect parameter counts and memory footprints, and use forward hooks to expose hidden states. The objective is to make architecture design explainable: every block must have a purpose, a valid tensor contract, and a measurable effect on representation or efficiency.

Training a CNN introduces interactions that are easy to overlook. The reader will construct complete training and validation loops, select loss functions that match the output representation, inspect layer-wise gradients, verify backpropagation numerically on small examples, and diagnose vanishing, exploding, or non-finite values. Learning-rate schedules, gradient clipping, gradient accumulation, mixed precision, checkpoint restoration, and CUDA execution will be tested as parts of one system. A decreasing loss will not be accepted as sufficient evidence of correctness; output shapes, labels, gradients, metrics, and deliberately overfitted tiny datasets will all be used to validate the pipeline.

The data pipeline receives its own chapter because a vision model can learn only from the images that actually reach it. The reader will load and normalize images, verify transformations visually, prevent leakage between dataset splits, and study random crops, flips, rotations, color changes, erasing, MixUp, and CutMix. Augmentation will be treated as an assumption about which changes should preserve a class label. An invalid transformation may silently teach the wrong task, while insufficient variation may encourage memorization. The exercises will therefore include ablation studies, corrupted-image checks, duplicate detection, balanced sampling, and DataLoader performance analysis.

Generalization and robustness will be examined beyond ordinary validation accuracy. The reader will compare weight decay, dropout, normalization, label smoothing, test-time augmentation, and ensembling, then observe performance under noise, blur, occlusion, lighting changes, color shifts, and adversarial-like perturbations. Reliability diagrams and calibration error will show that a confident prediction is not necessarily a correct or trustworthy prediction. Failure cases will be grouped and interpreted so that optimization failure, overfitting, data shift, and model sensitivity are not confused with one another.

Modern architectural patterns will explain how contemporary CNNs become deeper and more efficient. The reader will implement VGG-style blocks, residual connections, bottlenecks, grouped convolution, depthwise separable convolution, inverted residuals, squeeze-and-

excitation attention, stochastic depth, and DropPath. These designs will be compared using parameter count, computational operations, activation memory, GPU speed, accuracy, and stability. A block that uses fewer mathematical operations does not automatically run faster on every device, so theoretical efficiency and measured hardware behavior will be kept separate.

Finally, the book moves from a trained CNN to a model that can survive outside the notebook. The reader will benchmark latency and throughput, export models with TorchScript and ONNX, investigate `torch.compile`, compare numerical precision and quantization choices, and verify output parity against a trusted reference. Production exercises will cover preprocessing contracts, input validation, corrupt-batch handling, checkpoint integrity, model versioning, monitoring, distribution drift, rollback, A/B testing, memory leaks, and load testing. The final goal is not merely a CNN that achieves good accuracy once, but a system whose architecture, data, training behavior, performance, limitations, and recovery procedures can all be explained and tested.

14.1.2 Why this book comes after the MLP

The MLP established the central language of neural networks: layers transform representations, non-linear activations create expressive functions, backpropagation assigns credit, and optimizers update parameters. A CNN uses the same learning machinery, but changes the structure of the transformation. If an image with height H, width W, and C channels is flattened and passed to a fully connected layer with M outputs, the weight count grows as $MCHW$. A convolutional layer instead reuses a local kernel across spatial positions, allowing the same detector to respond wherever a pattern appears. This weight sharing preserves spatial relationships and usually requires far fewer parameters.

This progression matters because convolution should not feel like an unrelated collection of image functions. It is a specialized linear transformation placed inside the same forward, loss, backward, and optimization process already learned in the MLP book. The reader can therefore reuse knowledge about activations, gradients, initialization, optimizers, generalization, CUDA, and deployment while focusing on the new questions introduced by space: locality, channels, receptive fields, equivariance, downsampling, image preprocessing, and visual failure analysis.

14.1.3 How to study this book

Before implementing an operation, write down the input shape, kernel shape, stride, padding, expected output shape, parameter count, and receptive-field effect. For a two-dimensional convolution, the spatial output should be checked manually using

$$H_{\text{out}} = \left\lfloor \frac{H + 2P_h - D_h(K_h - 1) - 1}{S_h} + 1 \right\rfloor, \qquad W_{\text{out}} = \left\lfloor \frac{W + 2P_w - D_w(K_w - 1) - 1}{S_w} + 1 \right\rfloor.$$

After the code runs, inspect more than the final class label. Visualize inputs after preprocessing, check intermediate feature maps, record activation and gradient statistics, and verify devices, data types, memory use, and output parity. When comparing architectures or training settings, hold the dataset, split, seed, evaluation procedure, and computational budget constant. A speed comparison should include warm-up and synchronization, while an accuracy comparison should include repeated runs or clearly state its uncertainty.

The exercises intentionally include manual implementations, controlled experiments, CUDA measurements, and failure scenarios. Do not skip the manual work simply because PyTorch offers a ready-made layer. The manual version reveals the operation; the library version provides the efficient tool; and the comparison proves that both represent the same intended computation. Every failure should end with a root-cause explanation, a correction, and a test that would detect the same problem if it returned later.

14.1.4 The Chapters (CNN00 - CNN08) included in this book

- CNN00 - Convolution Concept and Intuition
- CNN01 - Feature Maps, Filters, and Receptive Fields
- CNN02 - Pooling, Downsampling, and Invariance
- CNN03 - CNN Forward Architecture and Implementation
- CNN04 - CNN Training Loop, Loss, and Backpropagation
- CNN05 - Data Pipeline and Augmentation for Vision
- CNN06 - Regularization, Normalization, and Robustness
- CNN07 - Modern CNN Blocks and Architectural Patterns
- CNN08 - Deployment, Export, and Production Readiness

14.2 CNN00 - Convolution Concept and Intuition

Models and Training

14.2.1 Exercise 00 - Understand Convolution as Local Pattern Detection Instead of Global Fully-Connected Mixing

Part 1 - Why this matters

A fully connected layer mixes every input location into every output unit, so it does not preserve locality by design. Convolution instead examines small neighborhoods and reuses the same detector across positions, making local structure an explicit assumption of the model.

This exercise asks you to compare both transformations on a tiny image. The goal is to explain parameter sharing, spatial output, and why the same edge or texture can be recognized at several locations without learning a separate weight for each location.

Part 2 - Mathematical form

$$Y_{n,o,i,j} = b_o + \sum_c \sum_u \sum_v X_{n,c,i+u,j+v} K_{o,c,u,v}.$$

Part 3 - Hints and Helper

Count how many weights are needed by each method, then move one local pattern to another valid position and compare the responses.

Part 4 - Python code skeleton

```
import torch

def E00(image, kernel):
    local_response = ...
    flattened = ...
    dense_weights = ...
    dense_response = ...
    return {
        "local": local_response,
        "dense": dense_response,
        "conv_parameters": ...,
        "dense_parameters": ...,
    }

def main():
    image = torch.tensor(..., dtype=torch.float32)
    kernel = torch.tensor(..., dtype=torch.float32)
    print(E00(image, kernel))

if __name__ == "__main__":
    main()
```

14.2.2 Exercise 01 - Implement a Simple 2D Convolution Using Explicit Nested Loops for Full Transparency

Part 1 - Why this matters

A manual implementation reveals exactly which input patch contributes to each output value. It makes indexing, kernel orientation, accumulation, and boundary assumptions visible before optimized library operations hide these details.

Implement one-channel mathematical convolution with valid boundaries and unit stride. Flip the kernel in both spatial dimensions, calculate every output element with nested loops, and retain enough intermediate information to inspect one selected patch.

Part 2 - Mathematical form

$$Y_{i,j} = \sum_{u=0}^{K_h-1} \sum_{v=0}^{K_w-1} X_{i+u,j+v} K_{K_h-1-u,K_w-1-v}.$$

Part 3 - Hints and Helper

Derive the output height and width first. For every output coordinate, extract a patch, multiply it by the flipped kernel, and sum all products.

Part 4 - Python code skeleton

```
import torch

def manual_convolution_2d(image, kernel):
    if image.ndim != 2 or kernel.ndim != 2:
        raise ValueError(...)
    out_h = ...
    out_w = ...
    flipped = ...
    output = torch.empty(...)
    for i in range(out_h):
        for j in range(out_w):
            patch = ...
            output[i, j] = ...
    return output

def E01():
    image = torch.tensor(..., dtype=torch.float32)
    kernel = torch.tensor(..., dtype=torch.float32)
    return manual_convolution_2d(image, kernel)

if __name__ == "__main__":
    print(E01())
```

14.2.3 Exercise 02 - Implement Cross-Correlation and Explain Why Deep Learning Calls It Convolution

Part 1 - Why this matters

Most deep-learning libraries implement cross-correlation: the kernel is applied without spatial flipping. It is commonly called convolution because the kernel is learned, so its orientation can adapt during training and the distinction rarely reduces model expressiveness.

Build convolution and cross-correlation from the same loop structure, compare their outputs with an asymmetric kernel, and verify which operation matches PyTorch. A symmetric kernel is a poor test because flipping it may leave it unchanged.

Part 2 - Mathematical form

$$Y_{i,j}^{\text{corr}} = \sum_{u,v} X_{i+u,j+v} K_{u,v}, \qquad Y_{i,j}^{\text{conv}} = \sum_{u,v} X_{i+u,j+v} K_{K_h-1-u,K_w-1-v}.$$

Part 3 - Hints and Helper

Use a kernel whose four corners have different values. Compare the manual results with `torch.nn.functional.conv2d` after adding batch and channel dimensions.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_operation(image, kernel, flip_kernel):
    selected_kernel = ... if flip_kernel else ...
    output = torch.empty(...)
    for i in range(...):
        for j in range(...):
            output[i, j] = ...
    return output

def E02(image, kernel):
    correlation = manual_operation(image, kernel, ...)
    convolution = manual_operation(image, kernel, ...)
    pytorch_output = F.conv2d(...).squeeze()
    return correlation, convolution, pytorch_output

if __name__ == "__main__":
    print(E02(torch.tensor(...), torch.tensor(...)))
```

14.2.4 Exercise 03 - Visualize How a Kernel Slides Over an Image and Produces a Feature Map

Part 1 - Why this matters

A feature-map value is meaningful only when it can be traced back to the receptive patch that produced it. Visualizing the sliding process connects output coordinates with input locations and exposes indexing errors immediately.

Record every valid patch, its element-wise products with the kernel, and the resulting sum. Create a figure that highlights the current patch in the image and places the computed response in the corresponding feature-map cell.

Part 2 - Mathematical form

$$P_{i,j} = X[i : i + K_h,\ j : j + K_w], \qquad Y_{i,j} = \langle P_{i,j}, K \rangle_F.$$

Part 3 - Hints and Helper

Separate computation from plotting. First return a trace containing coordinates, patches, products, and sums; then use that trace to construct reproducible frames.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def build_slide_trace(image, kernel):
    trace = []
    feature_map = torch.empty(...)
    for i in range(...):
        for j in range(...):
            patch = ...
            products = ...
            value = ...
            trace.append({...})
            feature_map[i, j] = value
    return feature_map, trace

def E03(image, kernel):
    feature_map, trace = build_slide_trace(image, kernel)
    fig, axes = plt.subplots(...)
    ...
    return fig, feature_map, trace
```

14.2.5 Exercise 04 - Verify Convolution Output Shape by Manual Calculation Using Kernel Size and Stride

Part 1 - Why this matters

Output-shape errors propagate into flattening, residual connections, classifier heads, and memory estimates. The shape must therefore be predicted before the convolution is executed rather than discovered from an exception afterward.

Implement a shape calculator for two spatial dimensions and validate it against several PyTorch convolutions. Include non-square inputs, kernels, strides, and padding so the calculation is not accidentally correct only for symmetric cases.

Part 2 - Mathematical form

$$H_{\text{out}} = \left\lfloor \frac{H + 2P_h - D_h(K_h - 1) - 1}{S_h} + 1 \right\rfloor, \quad W_{\text{out}} = \left\lfloor \frac{W + 2P_w - D_w(K_w - 1) - 1}{S_w} + 1 \right\rfloor.$$

Part 3 - Hints and Helper

Normalize every scalar or pair into a two-value tuple. Reject configurations that produce a non-positive output dimension.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def pair(value):
    return ...

def conv2d_output_shape(hw, kernel, stride=1, padding=0, dilation=1):
    h, w = ...
    kh, kw = ...
    sh, sw = ...
    ph, pw = ...
    dh, dw = ...
    out_h = ...
    out_w = ...
    return out_h, out_w

def E04(configs):
    checks = []
    for config in configs:
        predicted = conv2d_output_shape(...)
        actual = F.conv2d(...).shape[-2:]
        checks.append((predicted, actual, ...))
    return checks
```

14.2.6 Exercise 05 - Compare Different Kernel Sizes and Observe How Receptive Field Changes

Part 1 - Why this matters

Kernel size determines how much local context one layer can combine in a single response. Small kernels preserve locality and can be stacked, while larger kernels see wider regions immediately but require more parameters and computation.

Apply several normalized kernels to the same controlled image and compare their feature maps. Keep output dimensions comparable through appropriate padding, then distinguish the theoretical receptive field from the actual pattern response.

Part 2 - Mathematical form

$$R_1 = K, \qquad \#\theta = C_{\text{out}} C_{\text{in}} K_h K_w + C_{\text{out}}.$$

Part 3 - Hints and Helper

Use identical input and output channels for every trial. Report kernel size, parameter count, spatial output size, and response statistics.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def make_normalized_kernel(size, device):
    kernel = torch.ones(..., device=device)
    return ...

def E05(image, kernel_sizes):
    results = {}
    for size in kernel_sizes:
        kernel = make_normalized_kernel(size, image.device)
        padding = ...
        feature_map = F.conv2d(image, kernel, padding=padding)
        results[size] = {
            "output": feature_map,
            "parameters": ...,
            "mean": ...,
            "std": ...,
        }
    return results
```

14.2.7 Exercise 06 - Demonstrate the Effect of Stride on Downsampling and Information Loss

Part 1 - Why this matters

Stride controls how far the kernel moves between neighboring outputs. A larger stride reduces spatial resolution and computation, but it also skips overlapping observations and can make high-frequency structures disappear or alias into misleading patterns.

Compare stride values on smooth and rapidly alternating synthetic images. Measure output size, retained energy, and the error after a simple reconstruction so that information loss is demonstrated quantitatively as well as visually.

Part 2 - Mathematical form

$$Y_{i,j} = \sum_{u,v} X_{iS_h+u,jS_w+v} K_{u,v}, \qquad S > 1 \Rightarrow H_{\text{out}}, W_{\text{out}} \downarrow .$$

Part 3 - Hints and Helper

Use the same kernel for all trials. Upsample each reduced feature map back to a common size only for comparison; do not present interpolation as recovered information.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F
```

```
def evaluate_stride(image, kernel, stride):
    output = F.conv2d(image, kernel, stride=stride, padding=...)
    reconstructed = F.interpolate(
        output, size=image.shape[-2:], mode=...
    )
    return {
        "shape": tuple(output.shape),
        "output": output,
        "energy_ratio": ...,
        "reconstruction_error": ...,
    }

def E06(images, kernel, strides):
    return {...}
```

14.2.8 Exercise 07 - Demonstrate the Effect of Padding on Border Information Preservation and Output Size

Part 1 - Why this matters

Without padding, border pixels participate in fewer valid patches and spatial dimensions shrink after every layer. Padding can preserve size and give edge locations additional context, but the chosen padding values introduce their own assumptions outside the observed image.

Compare valid, zero, reflect, and replicate padding on an image containing strong border patterns. Count how often each original pixel contributes and inspect whether artificial edge responses are created by the padding mode.

Part 2 - Mathematical form

$$H_{\text{out}} = \left\lfloor \frac{H + 2P - K}{S} \right\rfloor + 1, \qquad P = \frac{K-1}{2} \text{ preserves size when } S = 1 \text{ and } K \text{ is odd.}$$

Part 3 - Hints and Helper

Apply non-zero padding modes explicitly with `F.pad`, then run convolution with zero internal padding. Compare center and border response statistics separately.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def convolve_with_padding(image, kernel, amount, mode):
    if mode == "constant":
        padded = F.pad(image, (...), mode=mode, value=...)
```

```
    else:
        padded = F.pad(image, (...), mode=mode)
    return F.conv2d(padded, kernel)

def E07(image, kernel, modes):
    results = {}
    for mode in modes:
        output = convolve_with_padding(image, kernel, ..., mode)
        results[mode] = {
            "output": output,
            "shape": tuple(output.shape),
            "border_mean": ...,
            "center_mean": ...,
        }
    return results
```

14.2.9 Exercise 08 - Implement Convolution with torch.nn.functional.conv2d and Validate It Against Manual Output

Part 1 - Why this matters

An optimized operation should be trusted only after its input convention and numerical result are matched to a transparent reference. PyTorch expects batched, channel-first tensors and implements cross-correlation rather than a flipped mathematical convolution.

Extend the manual implementation to batch, input-channel, and output-channel dimensions. Compare it with `conv2d` across several configurations using both absolute and relative tolerances, and report the largest disagreement.

Part 2 - Mathematical form

$$\text{close}(A, B) \iff |A - B| \leq \text{atol} + \text{rtol}|B|.$$

Part 3 - Hints and Helper

Start with stride one and no padding, then add options one at a time. Use float64 during the strictest reference test to reduce rounding ambiguity.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_conv2d(x, weight, bias=None, stride=1, padding=0):
    output = torch.empty(..., dtype=x.dtype, device=x.device)
    for n in range(...):
        for oc in range(...):
            for i in range(...):
```

```
                for j in range(...):
                    output[n, oc, i, j] = ...
    return output

def E08(x, weight, bias):
    manual = manual_conv2d(x, weight, bias, ...)
    library = F.conv2d(x, weight, bias, ...)
    return {
        "allclose": torch.allclose(manual, library, ...),
        "maximum_error": ...,
    }
```

14.2.10 Exercise 09 - Create Multiple Filters and Observe How Each Detects Different Visual Patterns

Part 1 - Why this matters

A convolutional layer produces multiple output channels because one filter cannot represent every useful local structure. Different filters may respond to horizontal, vertical, diagonal, bright-dark, or texture patterns in the same input.

Construct a bank of named filters and apply them in one convolution call. Use synthetic images with known structures, identify where each filter should respond strongly, and compare signed responses rather than keeping only their magnitudes.

Part 2 - Mathematical form

$$Y_o = \sum_{c=1}^{C_{\text{in}}} X_c \star K_{o,c} + b_o, \qquad o = 1, \ldots, C_{\text{out}}.$$

Part 3 - Hints and Helper

Stack filters along the output-channel dimension. Normalize their scales when response magnitudes must be compared fairly.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def build_filter_bank(dtype, device):
    horizontal = torch.tensor(..., dtype=dtype, device=device)
    vertical = torch.tensor(..., dtype=dtype, device=device)
    diagonal = torch.tensor(..., dtype=dtype, device=device)
    kernels = torch.stack([...]).unsqueeze(1)
    names = [...]
    return names, kernels
```

```
def E09(images):
    names, kernels = build_filter_bank(images.dtype, images.device)
    maps = F.conv2d(images, kernels, padding=...)
    summaries = {...}
    return names, maps, summaries
```

14.2.11 Exercise 10 - Move Convolution to CUDA and Confirm Numerical Parity with CPU Results

Part 1 - Why this matters

Moving a convolution to CUDA requires the input, weights, bias, and any related state to share a compatible device and data type. Device placement errors are explicit, while small floating-point differences may appear even when both computations are correct.

Run the same fixed convolution on CPU and CUDA, move the result back for comparison, and use a justified tolerance. Record device metadata and maximum error so parity is demonstrated rather than assumed.

Part 2 - Mathematical form

$$\Delta_{\max} = \max_i \left| Y_i^{\mathrm{CPU}} - Y_i^{\mathrm{GPU}} \right|.$$

Part 3 - Hints and Helper

Create the CPU tensors first, clone them to CUDA, and avoid generating separate random inputs on each device. Skip cleanly when CUDA is unavailable.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E10(x_cpu, weight_cpu, bias_cpu=None):
    if not torch.cuda.is_available():
        return {"available": False}
    y_cpu = F.conv2d(x_cpu, weight_cpu, bias_cpu, padding=...)
    x_gpu = ...
    weight_gpu = ...
    bias_gpu = ...
    y_gpu = F.conv2d(x_gpu, weight_gpu, bias_gpu, padding=...)
    difference = ...
    return {
        "available": True,
        "allclose": ...,
        "maximum_error": ...,
        "gpu_device": str(y_gpu.device),
    }
```

14.2.12 Exercise 11 - Benchmark CPU vs GPU Convolution Runtime for Small and Large Input Tensors

Part 1 - Why this matters

A GPU can execute large convolutions efficiently, but launch overhead, data transfer, synchronization, and insufficient parallel work can make it slower for small tensors. Performance claims must therefore be measured across realistic shapes.

Build a benchmark with warm-up, repeated measurements, and explicit CUDA synchronization. Time compute separately from host-to-device transfer and report latency, throughput, and memory for small and large cases.

Part 2 - Mathematical form

$$\text{throughput} = \frac{N_{\text{samples}}}{t}, \qquad \text{speedup} = \frac{t_{\text{CPU}}}{t_{\text{GPU}}}.$$

Part 3 - Hints and Helper

Reuse allocated tensors during the compute benchmark. Summarize a distribution of timings instead of reporting one potentially noisy observation.

Part 4 - Python code skeleton

```
import time
import torch
import torch.nn.functional as F

def synchronize(device):
    if device.type == "cuda":
        torch.cuda.synchronize(device)

def benchmark(x, weight, repeats, warmup):
    for _ in range(warmup):
        F.conv2d(x, weight, padding=...)
    times = []
    for _ in range(repeats):
        synchronize(x.device)
        start = time.perf_counter()
        ...
        synchronize(x.device)
        times.append(...)
    return {...}

def E11(cases):
    return [...]
```

14.2.13 Exercise 12 - Compare float32 and float16 Convolution Outputs and Detect Precision-Sensitive Cases

Part 1 - Why this matters

Lower precision can reduce memory use and increase GPU throughput, but float16 represents a smaller numeric range and fewer significant digits. Convolution sums many products, so scale, cancellation, and accumulation length influence the final error.

Generate controlled inputs at several magnitudes, compare float16 results with a float32 reference, and locate overflow, underflow, and relative-error growth. The exercise should identify when mixed precision is useful and when a sensitive operation needs higher precision.

Part 2 - Mathematical form

$$\epsilon_{\text{rel}} = \frac{|Y_{16} - Y_{32}|}{|Y_{32}| + \varepsilon}.$$

Part 3 - Hints and Helper

Perform the comparison on CUDA when supported. Include ordinary, very small, very large, and cancellation-heavy cases, and inspect finite values before computing summary errors.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def compare_precision(x32, w32):
    reference = F.conv2d(x32, w32, padding=...)
    low = F.conv2d(x32.half(), w32.half(), padding=...).float()
    absolute = ...
    relative = ...
    return {
        "finite": bool(torch.isfinite(low).all()),
        "max_absolute_error": ...,
        "max_relative_error": ...,
        "zero_fraction": ...,
    }

def E12(device):
    cases = {...}
    return {name: compare_precision(x, w) for name, (x, w) in cases.items()}
```

14.2.14 Exercise 13 - Understand Channels-First Format (N,C,H,W) and Debug Common Shape Mistakes

Part 1 - Why this matters

PyTorch convolution expects batch, channel, height, and width dimensions in that order. Image libraries may supply height, width, and channels instead, while a single image may omit its batch dimension entirely.

Create a validation and conversion function that accepts documented layouts and produces one canonical tensor. It must reject ambiguous shapes, verify the expected channel count, and preserve the association between images and batches.

Part 2 - Mathematical form

$$X_{\mathrm{NHWC}} \xrightarrow{\mathrm{permute}(0,3,1,2)} X_{\mathrm{NCHW}}.$$

Part 3 - Hints and Helper

Do not infer layout from shape alone when dimensions can share the same size. Require layout metadata and call `contiguous` when later operations need contiguous storage.

Part 4 - Python code skeleton

```
import torch

def to_nchw(x, layout, expected_channels):
    if layout == "HW":
        x = ...
    elif layout == "HWC":
        x = ...
    elif layout == "NHWC":
        x = ...
    elif layout == "NCHW":
        x = ...
    else:
        raise ValueError(...)
    if x.ndim != 4 or x.shape[1] != expected_channels:
        raise ValueError(...)
    return ...

def E13(test_cases):
    return [...]
```

14.2.15 Exercise 14 - Implement 1x1 Convolution and Explain Channel Mixing Without Spatial Mixing

Part 1 - Why this matters

A one-by-one convolution observes one spatial coordinate at a time but combines all input channels through a learned linear transformation. It can expand, compress, or reorganize channel representations without directly mixing neighboring pixels.

Implement the operation manually and verify that it matches matrix multiplication applied independently at every location. Compare parameter count with a larger spatial kernel and explain why one-by-one layers appear in bottlenecks and efficient architectures.

Part 2 - Mathematical form

$$Y_{n,:,i,j} = W X_{n,:,i,j} + b, \qquad W \in \mathbb{R}^{C_{\text{out}} \times C_{\text{in}}}.$$

Part 3 - Hints and Helper

Move the channel dimension to the end, apply one matrix multiplication to all positions, and permute the result back to channel-first form.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_pointwise(x, weight, bias):
    matrix = weight[..., 0, 0]
    positions = x.permute(...)
    mixed = ...
    if bias is not None:
        mixed = ...
    return mixed.permute(...).contiguous()

def E14(x, out_channels):
    weight = torch.randn(..., device=x.device)
    bias = torch.randn(..., device=x.device)
    manual = manual_pointwise(x, weight, bias)
    library = F.conv2d(x, weight, bias)
    return manual, library, ...
```

14.2.16 Exercise 15 - Demonstrate Convolution as Matrix Multiplication with im2col on a Tiny Example

Part 1 - Why this matters

The im2col view rearranges every receptive patch into a column so convolution can be expressed as a matrix multiplication. This reveals the algebra used by many implementations and explains the connection between convolutional and linear transformations.

Use a tiny tensor to build the patch matrix manually, flatten the filters into rows, multiply them, and reshape the result into a feature map. Compare the result with both `unfold` and `conv2d` while observing the temporary memory expansion.

Part 2 - Mathematical form

$$Y_{\text{matrix}} = K_{\text{rows}} X_{\text{cols}}, \qquad Y = \text{reshape}(Y_{\text{matrix}}).$$

Part 3 - Hints and Helper

Choose and document one column ordering. Verify each column against its original spatial patch before multiplying the matrices.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_im2col(x, kernel_size):
    columns = []
    coordinates = []
    for i in range(...):
        for j in range(...):
            patch = ...
            columns.append(...)
            coordinates.append((i, j))
    return torch.stack(columns, dim=...), coordinates

def E15(x, weight):
    columns, coordinates = manual_im2col(x, weight.shape[-2:])
    kernel_rows = ...
    matrix_output = ...
    feature_map = ...
    unfolded = F.unfold(x, kernel_size=...)
    direct = F.conv2d(x, weight)
    return {...}
```

14.2.17 Exercise 16 - Stress Test Convolution with Large Batches and Monitor GPU Memory Consumption

Part 1 - Why this matters

Convolution memory includes inputs, outputs, parameters, gradients, saved activations, and temporary workspaces. Increasing batch size may improve utilization until a sudden out-of-memory failure occurs, so usable capacity must be measured with safety margins.

Increase batch size systematically, record allocated and peak reserved GPU memory, and stop safely before destabilizing the process. Compare inference with training because backward propagation retains additional state and produces parameter gradients.

Part 2 - Mathematical form

$$M_{\text{peak}} = \max_t M_{\text{allocated}}(t), \qquad \text{bytes}(X) = \#X \cdot \text{bytes per element}.$$

Part 3 - Hints and Helper

Reset peak statistics before each trial and release references after it. Catch only CUDA out-of-memory errors, record the failed configuration, and avoid assuming reserved memory is a leak.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def run_trial(batch_size, shape, weight, training):
    torch.cuda.reset_peak_memory_stats()
    x = torch.randn((batch_size, *shape), device="cuda")
    x.requires_grad_(training)
    output = F.conv2d(x, weight, padding=...)
    if training:
        ...
    return {
        "batch_size": batch_size,
        "peak_allocated": torch.cuda.max_memory_allocated(),
        "peak_reserved": torch.cuda.max_memory_reserved(),
    }

def E16(batch_sizes, shape, weight, training):
    results = []
    for batch_size in batch_sizes:
        try:
            results.append(run_trial(...))
        except torch.cuda.OutOfMemoryError:
            ...
            break
    return results
```

14.2.18 Exercise 17 - Debug Device Mismatch and Non-Contiguous Tensor Issues in Convolution Pipelines

Part 1 - Why this matters

A convolution pipeline can fail when tensors are divided across CPU and GPU or when layout-changing operations produce unexpected strides. Non-contiguous tensors are valid for many operations, but some views or downstream kernels require a compatible memory layout.

Construct failing cases deliberately, inspect device, shape, stride, and contiguity, then repair the root cause without unnecessary copies. Distinguish a semantic layout error from a storage-contiguity problem because calling `contiguous` cannot correct swapped dimensions.

Part 2 - Mathematical form

stride(X) describes storage steps, shape(X) describes logical dimensions.

Part 3 - Hints and Helper

Create one diagnostic function that reports all tensor metadata before execution. Move related tensors through one chosen device and use `reshape` or `contiguous` only where justified.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def describe(name, tensor):
    return {
        "name": name,
        "shape": tuple(tensor.shape),
        "device": str(tensor.device),
        "stride": tensor.stride(),
        "contiguous": tensor.is_contiguous(),
    }

def safe_conv2d(x, weight, bias=None):
    target_device = ...
    x = ...
    weight = ...
    bias = ...
    if ...:
        x = ...
    return F.conv2d(x, weight, bias, padding=...)

def E17(failing_cases):
    return [...]
```

14.2.19 Exercise 18 - Validate Determinism Settings and Observe When CUDA Convolution Becomes Non-Deterministic

Part 1 - Why this matters

Repeated CNN runs can differ because of random initialization, sampling, stochastic layers, asynchronous execution, or nondeterministic CUDA algorithms. Setting one seed controls only part of this system.

Run identical convolution experiments under controlled and uncontrolled settings, compare outputs and gradients bitwise and numerically, and record the software and hardware environment. Explain the performance cost and the limits of deterministic guarantees.

Part 2 - Mathematical form

$$\text{bitwise deterministic: } Y^{(1)} = Y^{(2)}, \qquad \text{numerically stable: } \|Y^{(1)} - Y^{(2)}\| \le \tau.$$

Part 3 - Hints and Helper

Use `torch.use_deterministic_algorithms`, fixed seeds, and documented backend settings. Test repeated execution in one process separately from independent process runs.

Part 4 - Python code skeleton

```
import os
import random
import torch

def configure(seed, deterministic):
    random.seed(seed)
    torch.manual_seed(seed)
    torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(deterministic)
    ...

def one_run(seed, deterministic, device):
    configure(seed, deterministic)
    x = torch.randn(..., device=device, requires_grad=True)
    layer = torch.nn.Conv2d(...).to(device)
    output = layer(x)
    output.sum().backward()
    return output.detach().cpu(), x.grad.detach().cpu()

def E18(repeats, seed, device):
    runs = [one_run(seed, ..., device) for _ in range(repeats)]
    return {...}
```

14.2.20 Exercise 19 - Write a Conceptual Report Explaining Why Convolution Is the Core Inductive Bias for Vision

Part 1 - Why this matters

An inductive bias is a structural preference that guides learning toward some solutions more easily than others. Convolution favors local connectivity and shared detectors, reflecting the observation that nearby pixels interact strongly and visual patterns can recur across positions.

The final report must connect locality, weight sharing, translation equivariance, hierarchical composition, parameter efficiency, and computational behavior. It must also identify limitations, including boundary effects, loss of exact invariance, restricted global context, and cases where another architecture may be more appropriate.

Part 2 - Mathematical form

$$f(T_\delta X) = T_\delta f(X) \text{ for ideal translation equivariance}, \qquad \#\theta_{\text{conv}} \ll \#\theta_{\text{dense}}.$$

Part 3 - Hints and Helper

Support every major claim with one earlier experiment. Separate equivariance from invariance, and describe when padding, stride, pooling, or finite image boundaries weaken the ideal property.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED_SECTIONS = [
    "Locality",
    "Weight Sharing",
    "Translation Equivariance",
    "Hierarchical Features",
    "Efficiency",
    "Limitations",
    "Experimental Evidence",
]

def validate_report(report):
    missing = ...
    evidence_count = ...
    return {
        "missing_sections": missing,
        "evidence_count": evidence_count,
        "ready": ...,
    }

def E19(experiment_summaries, output_path):
    report = ...
    checks = validate_report(report)
    Path(output_path).write_text(..., encoding="utf-8")
    return checks
```

14.3 CNN01 - Feature Maps, Filters, and Receptive Fields

Models and Training

14.3.1 Exercise 00 - Compute Feature Map Dimensions for Multiple Conv Layers Using Manual Step-by-Step Formula

Part 1 - Why this matters

A CNN changes spatial size layer by layer, and one incorrect prediction can break a classifier head, skip connection, or memory estimate. Shape reasoning must therefore follow the complete stack rather than examining each layer only after execution.

Calculate height, width, and channel count after every convolution. Record the values substituted into the formula, then verify the entire trace against PyTorch using both square and non-square configurations.

Part 2 - Mathematical form

$$H_l = \left\lfloor \frac{H_{l-1} + 2P_l - D_l(K_l - 1) - 1}{S_l} + 1 \right\rfloor, \qquad C_l = C_{\text{out},l}.$$

Part 3 - Hints and Helper

Normalize scalar settings into pairs and reject a layer when either predicted spatial dimension is non-positive.

Part 4 - Python code skeleton

```
import torch

def output_size(size, kernel, stride, padding, dilation):
    return ...

def E00(input_shape, layer_specs):
    n, channels, height, width = input_shape
    trace = []
    for index, spec in enumerate(layer_specs):
        height = output_size(height, ...)
        width = output_size(width, ...)
        channels = ...
        trace.append({"layer": index, "shape": (...)})
    x = torch.randn(input_shape)
    model = torch.nn.Sequential(...)
    actual = ...
    return trace, actual
```

14.3.2 Exercise 01 - Visualize How Receptive Field Grows with Depth Using a Simple Layer Stack

Part 1 - Why this matters

A deep unit can depend on a wide input region even when every kernel is small. Receptive-field growth explains how local detectors become capable of representing larger structures as information passes through several layers.

Track receptive-field size and the spacing between neighboring receptive centers through a controlled stack. Visualize the input locations that influence one selected output and compare the calculation with an empirical gradient mask.

Part 2 - Mathematical form

$$R_l = R_{l-1} + (K_l - 1)J_{l-1}, \qquad J_l = J_{l-1}S_l, \qquad R_0 = J_0 = 1.$$

Part 3 - Hints and Helper

Calculate the jump before updating it. Backpropagate from one output scalar and mark input pixels with non-zero gradients.

Part 4 - Python code skeleton

```
import torch

def receptive_field_trace(layer_specs):
    receptive_field, jump = 1, 1
    trace = []
    for spec in layer_specs:
        receptive_field = ...
        jump = ...
        trace.append((receptive_field, jump))
    return trace

def empirical_mask(model, input_shape, output_index):
    x = torch.randn(input_shape, requires_grad=True)
    y = model(x)
    y[output_index].backward()
    return ...

def E01(layer_specs, model):
    return receptive_field_trace(layer_specs), empirical_mask(...)
```

14.3.3 Exercise 02 - Show How Increasing Channels Raises Representation Capacity Without Increasing Resolution

Part 1 - Why this matters

Spatial resolution describes where responses occur, while channel count describes how many learned response types are stored at each location. Increasing channels can represent more patterns without changing feature-map height or width.

Compare layers with identical spatial settings and different output-channel counts. Measure output shape, parameter count, activation memory, and diversity between channel responses instead of assuming that more channels automatically provide useful capacity.

Part 2 - Mathematical form

$$Y \in \mathbb{R}^{N \times C_{\text{out}} \times H' \times W'}, \qquad \#\theta = C_{\text{out}}(C_{\text{in}} K_h K_w + 1).$$

Part 3 - Hints and Helper

Keep kernels, stride, padding, input, and seed controlled. Use channel correlation or rank as one imperfect indicator of redundant responses.

Part 4 - Python code skeleton

```
import torch

def channel_summary(output, layer):
    flattened = output.flatten(start_dim=2)
    correlation = ...
    return {
        "shape": tuple(output.shape),
        "parameters": ...,
        "activation_bytes": ...,
        "mean_channel_correlation": ...,
    }

def E02(x, channel_options):
    results = {}
    for out_channels in channel_options:
        torch.manual_seed(...)
        layer = torch.nn.Conv2d(...)
        results[out_channels] = channel_summary(layer(x), layer)
    return results
```

14.3.4 Exercise 03 - Implement Multi-Channel Convolution and Explain the Channel Summation Mechanism Clearly

Part 1 - Why this matters

Each output channel combines every input channel with a separate spatial kernel and then sums those contributions. Omitting that summation or confusing channel order changes the mathematical operation even when spatial indexing is correct.

Implement batch and multi-channel cross-correlation with explicit loops. Preserve each input-channel contribution temporarily, verify that their sum plus bias creates one output channel, and compare the result with PyTorch.

Part 2 - Mathematical form

$$Y_{n,o,i,j} = b_o + \sum_{c=1}^{C_{\text{in}}} \sum_{u,v} X_{n,c,i+u,j+v} K_{o,c,u,v}.$$

Part 3 - Hints and Helper

Test with channels containing visibly different patterns and weights. A one-channel test cannot verify the summation mechanism.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_multi_channel(x, weight, bias=None):
    output = torch.empty(...)
    contributions = torch.empty(...)
    for n in range(...):
        for oc in range(...):
            for i in range(...):
                for j in range(...):
                    for ic in range(...):
                        contributions[...] = ...
                    output[n, oc, i, j] = ...
    return output, contributions

def E03(x, weight, bias):
    manual, parts = manual_multi_channel(x, weight, bias)
    reference = F.conv2d(x, weight, bias)
    return manual, parts, torch.allclose(manual, reference)
```

14.3.5 Exercise 04 - Verify Kernel Tensor Shape (out_channels,in_channels,kH,kW) and Debug Wrong Ordering Bugs

Part 1 - Why this matters

PyTorch stores convolution weights by output channel, input channel, kernel height, and kernel width. A weight tensor built in another ordering may fail immediately or silently attach the wrong filter to each channel after an incorrect reshape.

Create a validator that checks the expected dimensions and interprets every axis. Demonstrate why permutation is required when converting from a documented external layout and why reshaping alone cannot exchange semantic axes.

Part 2 - Mathematical form

$$K \in \mathbb{R}^{C_{\text{out}} \times C_{\text{in}} \times K_h \times K_w}.$$

Part 3 - Hints and Helper

Fill each logical channel pair with a distinct constant so an ordering mistake remains visible in the output.

Part 4 - Python code skeleton

```
import torch

def validate_kernel(weight, in_channels, out_channels, kernel_hw):
    expected = (...)
    if tuple(weight.shape) != expected:
        raise ValueError(...)
    return True

def convert_kernel(weight, source_layout):
    if source_layout == "HWIO":
        return weight.permute(...).contiguous()
    if source_layout == "OIHW":
        return ...
    raise ValueError(...)

def E04(weight_cases):
    return [...]
```

14.3.6 Exercise 05 - Compare Edge-Detector Kernels on Synthetic Pattern Images and Observe Their Responses

Part 1 - Why this matters

Hand-designed edge filters provide an interpretable example of feature-map behavior. Their positive and negative lobes respond to intensity changes with particular orientations, while flat regions ideally produce responses near zero.

Apply several edge detectors to vertical, horizontal, diagonal, constant, and noisy images. Compare signed maps, magnitude maps, and peak locations so orientation selectivity and noise sensitivity are both visible.

Part 2 - Mathematical form

$$G_x = X \star K_x, \qquad G_y = X \star K_y, \qquad M = \sqrt{G_x^2 + G_y^2}.$$

Part 3 - Hints and Helper

Normalize image scale, keep padding consistent, and do not discard response sign before explaining what it represents.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def edge_kernels(dtype, device):
    sobel_x = torch.tensor(..., dtype=dtype, device=device)
    sobel_y = torch.tensor(..., dtype=dtype, device=device)
```

```
    prewitt_x = torch.tensor(..., dtype=dtype, device=device)
    return torch.stack([...]).unsqueeze(1)

def E05(images):
    kernels = edge_kernels(images.dtype, images.device)
    responses = F.conv2d(images, kernels, padding=...)
    magnitude = ...
    peaks = ...
    return responses, magnitude, peaks
```

14.3.7 Exercise 06 - Create Custom Kernels to Detect Horizontal, Vertical, and Diagonal Structures

Part 1 - Why this matters

Designing a kernel turns a visual hypothesis into weights. The location and signs of the weights determine which local arrangement is reinforced, which is suppressed, and how the response changes when contrast is reversed.

Construct custom kernels for three orientations, test them on controlled patterns, and revise them using measured responses. Require each detector to respond more strongly to its target orientation than to non-target patterns.

Part 2 - Mathematical form

$$s(K, X) = \max_{i,j} |(X \star K)_{i,j}|, \qquad s(K, X_{\text{target}}) > s(K, X_{\text{other}}).$$

Part 3 - Hints and Helper

Use zero-sum kernels for contrast transitions and normalize their norms before comparing selectivity.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def design_kernels():
    horizontal = torch.tensor(..., dtype=torch.float32)
    vertical = torch.tensor(..., dtype=torch.float32)
    diagonal = torch.tensor(..., dtype=torch.float32)
    kernels = torch.stack([...]).unsqueeze(1)
    return kernels / ...

def selectivity_matrix(images, kernels):
    responses = F.conv2d(images, kernels, padding=...)
    return responses.abs().amax(dim=(-2, -1))
```

```
def E06(images):
    scores = selectivity_matrix(images, design_kernels())
    return scores, ...
```

14.3.8 Exercise 07 - Demonstrate Translation Equivariance by Shifting Input and Observing Shifted Feature Maps

Part 1 - Why this matters

An ideal convolution is translation equivariant: shifting the input shifts the feature map by the corresponding amount. This property allows one shared detector to recognize a pattern at several locations.

Shift a synthetic image without wrapping content across boundaries, apply the same convolution before and after the shift, and align the feature maps for comparison. Evaluate only locations whose receptive fields remain valid in both cases.

Part 2 - Mathematical form

$$f(T_\delta X) = T_\delta f(X).$$

Part 3 - Hints and Helper

Use an interior comparison mask so pixels introduced or removed at the boundary do not invalidate the intended test.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def translate_without_wrap(x, dy, dx, fill=0.0):
    shifted = torch.full_like(x, fill)
    source_slices = ...
    target_slices = ...
    shifted[target_slices] = x[source_slices]
    return shifted

def E07(x, weight, shift):
    base = F.conv2d(x, weight, padding=...)
    moved_input = translate_without_wrap(x, *shift)
    moved_output = F.conv2d(moved_input, weight, padding=...)
    expected = translate_without_wrap(base, *shift)
    mask = ...
    return (moved_output - expected)[mask], ...
```

14.3.9 Exercise 08 - Demonstrate When Translation Equivariance Breaks Due to Padding or Stride Choices

Part 1 - Why this matters

Finite images, padding rules, and subsampling weaken the ideal translation behavior of convolution. A one-pixel input shift may interact with a different sampling phase when stride is larger than one, while borders receive artificial context from padding.

Repeat the equivariance test across valid, zero, reflect, and strided configurations. Separate boundary error from interior sampling error and explain which transformations remain approximately equivariant.

Part 2 - Mathematical form

$$f_S(T_\delta X) = T_{\delta/S} f_S(X) \text{ only when the shift is compatible with stride } S.$$

Part 3 - Hints and Helper

Test shifts that are and are not multiples of the stride. Report interior and border errors separately.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def equivariance_error(x, weight, shift, stride, pad_mode):
    padded = ...
    base = F.conv2d(padded, weight, stride=stride)
    shifted_x = ...
    shifted_output = F.conv2d(...)
    expected = ...
    interior_mask = ...
    return {
        "interior_error": ...,
        "border_error": ...,
        "shape": tuple(base.shape),
    }

def E08(x, weight, configurations):
    return [equivariance_error(x, weight, **c) for c in configurations]
```

14.3.10 Exercise 09 - Analyze How Stride Impacts Aliasing and Feature Map Quality Using Visual Examples

Part 1 - Why this matters

Strided convolution samples a filtered signal on a coarser grid. If the input contains frequencies above what that grid can represent, distinct patterns may produce similar or distorted feature maps through aliasing.

Create checkerboards and sinusoidal patterns at several frequencies, then compare direct strided convolution with a low-pass-filtered alternative. Visualize the maps and quantify how strongly results change under a one-pixel phase shift.

Part 2 - Mathematical form

$$f_{\text{input}} > \frac{f_{\text{sample}}}{2} \;\Rightarrow\; \text{aliasing risk.}$$

Part 3 - Hints and Helper

Keep downsampling factor fixed and vary pattern frequency. Blur before subsampling rather than after information has already been discarded.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def low_pass_then_stride(x, blur_kernel, stride):
    smoothed = F.conv2d(x, blur_kernel, padding=...)
    return smoothed[..., ::stride, ::stride]

def phase_sensitivity(a, b):
    return ...

def E09(patterns, conv_kernel, blur_kernel, stride):
    results = []
    for pattern in patterns:
        direct = F.conv2d(pattern, conv_kernel, stride=stride)
        antialiased = low_pass_then_stride(pattern, blur_kernel, stride)
        shifted = ...
        results.append({...})
    return results
```

14.3.11 Exercise 10 - Run Feature Map Extraction on CUDA and Verify Output Shape and Device Placement

Part 1 - Why this matters

Feature extraction on CUDA succeeds only when the model, input, and relevant state share the intended device. Correct device placement must be checked together with feature-map shapes because moving computation does not repair architectural mistakes.

Capture outputs from selected convolutional layers on CUDA, compare their shapes with manual predictions, and verify that hooks do not retain computational graphs unnecessarily during analysis.

Part 2 - Mathematical form

$$X \in \text{CUDA},\ \theta \in \text{CUDA} \implies f_\theta(X) \in \text{CUDA}.$$

Part 3 - Hints and Helper

Register hooks before the forward pass, detach captured outputs, and remove every hook afterward.

Part 4 - Python code skeleton

```
import torch

def extract_features(model, x, layer_names):
    captured, handles = {}, []
    for name, module in model.named_modules():
        if name in layer_names:
            handles.append(module.register_forward_hook(...))
    try:
        with torch.inference_mode():
            output = model(x)
    finally:
        for handle in handles:
            handle.remove()
    return output, captured

def E10(model, x, expected_shapes):
    if not torch.cuda.is_available():
        return {"available": False}
    model, x = ...
    output, maps = extract_features(model, x, ...)
    return {"available": True, "checks": ...}
```

14.3.12 Exercise 11 - Benchmark Different Kernel Sizes and Strides on GPU to Measure Real Performance Differences

Part 1 - Why this matters

Kernel size and stride change mathematical work, output size, memory traffic, and the algorithms selected by the CUDA backend. Parameter count or FLOPs alone cannot predict the fastest configuration on a specific GPU.

Benchmark a controlled grid of kernel and stride choices with warm-up and synchronization. Report latency, throughput, output shape, estimated operations, and peak memory while keeping batch and channel dimensions fixed.

Part 2 - Mathematical form

$$\text{MACs} = NH'W'C_{\text{out}}C_{\text{in}}K_hK_w.$$

Part 3 - Hints and Helper

Allocate each layer before timing, reuse tensors, and summarize repeated measurements rather than one call.

Part 4 - Python code skeleton

```
import time
import torch

def benchmark_layer(layer, x, warmup, repeats):
    for _ in range(warmup):
        layer(x)
    times = []
    for _ in range(repeats):
        torch.cuda.synchronize()
        start = time.perf_counter()
        output = layer(x)
        torch.cuda.synchronize()
        times.append(time.perf_counter() - start)
    return output, ...

def E11(x, configurations):
    results = []
    for config in configurations:
        layer = torch.nn.Conv2d(...).cuda()
        output, timing = benchmark_layer(layer, x, ..., ...)
        results.append({...})
    return results
```

14.3.13 Exercise 12 - Investigate Numerical Differences Between CPU and GPU Feature Maps Under Various Seeds

Part 1 - Why this matters

CPU and GPU convolution may use different floating-point instruction orders or algorithms, producing small numerical differences without indicating a logical error. Seeds control generated inputs and parameters but do not make all hardware arithmetic identical.

Repeat matched CPU and GPU feature extraction under several seeds. Record absolute and relative errors per layer, determine whether discrepancies grow with depth, and distinguish reproducibility within one device from parity across devices.

Part 2 - Mathematical form

$$\Delta_l = \max_i |F_{l,i}^{\mathrm{CPU}} - F_{l,i}^{\mathrm{GPU}}|.$$

Part 3 - Hints and Helper

Clone one initialized CPU state to GPU for each seed; do not initialize the two models independently.

Part 4 - Python code skeleton

```
import copy
import torch

def layerwise_features(model, x):
    features = {}
    handles = [...]
    with torch.inference_mode():
        model(x)
    for handle in handles:
        handle.remove()
    return features

def compare_seed(model_factory, x_factory, seed):
    torch.manual_seed(seed)
    cpu_model = model_factory().eval()
    gpu_model = copy.deepcopy(cpu_model).cuda().eval()
    x_cpu = x_factory()
    cpu_maps = layerwise_features(cpu_model, x_cpu)
    gpu_maps = layerwise_features(gpu_model, x_cpu.cuda())
    return {...}

def E12(seeds, model_factory, x_factory):
    return [compare_seed(model_factory, x_factory, s) for s in seeds]
```

14.3.14 Exercise 13 - Implement Depthwise Convolution Manually and Explain How It Differs from Standard Convolution

Part 1 - Why this matters

Depthwise convolution applies separate spatial filters to individual input channels instead of summing across all channels for every output. It extracts channel-specific spatial patterns but does not perform general channel mixing by itself.

Implement the operation manually for a depth multiplier, compare it with grouped PyTorch convolution, and contrast its parameter count and connectivity with a standard convolution having the same output channels.

Part 2 - Mathematical form

$$C_{\text{out}} = mC_{\text{in}}, \qquad \#\theta_{\text{depthwise}} = mC_{\text{in}}K_hK_w.$$

Part 3 - Hints and Helper

Map each output channel to its source input channel using integer division by the depth multiplier.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_depthwise(x, weight, multiplier):
    output = torch.empty(...)
    for n in range(...):
        for oc in range(...):
            source_channel = ...
            for i in range(...):
                for j in range(...):
                    output[n, oc, i, j] = ...
    return output

def E13(x, weight, multiplier):
    manual = manual_depthwise(x, weight, multiplier)
    reference = F.conv2d(x, weight, groups=x.shape[1])
    return manual, reference, {
        "depthwise_parameters": ...,
        "standard_parameters": ...,
    }
```

14.3.15 Exercise 14 - Implement Grouped Convolution and Prove It Reduces Parameters While Preserving Some Representation Power

Part 1 - Why this matters

Grouped convolution partitions input and output channels into independent channel groups. It retains full spatial filtering within each group while removing connections between groups, reducing parameters and computation at the cost of restricted channel interaction.

Implement grouped convolution by slicing channels and concatenating independent group outputs. Validate it against PyTorch, calculate connectivity, and construct an input perturbation that proves which outputs cannot be affected across group boundaries.

Part 2 - Mathematical form

$$\#\theta_{\text{grouped}} = \frac{C_{\text{out}} C_{\text{in}} K_h K_w}{G}.$$

Part 3 - Hints and Helper

Require both channel counts to be divisible by the group count and test forbidden cross-group influence explicitly.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_grouped_conv(x, weight, groups):
    in_per_group = ...
    out_per_group = ...
    outputs = []
    for group in range(groups):
        x_group = ...
        w_group = ...
        outputs.append(F.conv2d(x_group, w_group))
    return torch.cat(outputs, dim=1)

def E14(x, weight, groups):
    manual = manual_grouped_conv(x, weight, groups)
    reference = F.conv2d(x, weight, groups=groups)
    influence_test = ...
    return manual, reference, influence_test
```

14.3.16 Exercise 15 - Compare Standard, Depthwise, and Grouped Convolutions in Parameters, Speed, and Feature Quality

Part 1 - Why this matters

Standard, depthwise, and grouped convolutions make different connectivity assumptions. Lower parameter count can improve efficiency, but runtime depends on hardware kernels and restricted connectivity may reduce feature quality for a particular task.

Build comparable blocks with matched input and output shapes, benchmark them, and evaluate their feature maps on a controlled prediction task. Separate depthwise-only filtering from depthwise plus pointwise channel mixing.

Part 2 - Mathematical form

$$\text{compression ratio} = \frac{\#\theta_{\text{variant}}}{\#\theta_{\text{standard}}}.$$

Part 3 - Hints and Helper

Control initialization, training budget, and evaluation data. Compare parameters, latency, peak memory, and task metric in one table.

Part 4 - Python code skeleton

```
import time
import torch

def build_variants(in_channels, out_channels, kernel_size, groups):
    standard = torch.nn.Conv2d(...)
    depthwise_separable = torch.nn.Sequential(...)
    grouped = torch.nn.Conv2d(...)
    return {...}

def profile_block(block, x):
    parameters = sum(p.numel() for p in block.parameters())
    timing = ...
    output = ...
    quality = ...
    return {
        "parameters": parameters,
        "latency": timing,
        "quality": quality,
        "shape": tuple(output.shape),
    }

def E15(x, configuration):
    return {name: profile_block(block, x) for name, block in ...}
```

14.3.17 Exercise 16 - Detect and Fix Shape Errors When Switching Between RGB and Grayscale Inputs

Part 1 - Why this matters

RGB images normally provide three channels while grayscale images provide one. A convolution configured for one format cannot consume the other without an explicit conversion or architectural change.

Design a preprocessing contract that validates layout and channel count, then compare grayscale-to-RGB replication, RGB-to-luminance conversion, and first-layer weight adaptation. Explain which transformations preserve compatibility and which change learned behavior.

Part 2 - Mathematical form

$$X_{\text{gray}} = \alpha R + \beta G + \gamma B, \qquad C_{\text{gray}} = 1,\ C_{\text{RGB}} = 3.$$

Part 3 - Hints and Helper

Never repair the error with an arbitrary reshape. Channel conversion must describe how values are transformed.

Part 4 - Python code skeleton

```
import torch

def convert_channels(x, target_channels):
    if x.ndim != 4:
        raise ValueError(...)
    if x.shape[1] == target_channels:
        return x
    if x.shape[1] == 1 and target_channels == 3:
        return ...
    if x.shape[1] == 3 and target_channels == 1:
        coefficients = x.new_tensor(...).view(1, 3, 1, 1)
        return ...
    raise ValueError(...)

def adapt_first_layer(weight, target_channels):
    return ...

def E16(model, test_inputs):
    return [...]
```

14.3.18 Exercise 17 - Stress Test a Very Deep Conv Stack and Monitor Activation Magnitudes for Stability Issues

Part 1 - Why this matters

Repeated convolution and activation can cause signals to shrink, grow, saturate, or become non-finite with depth. The final output alone cannot reveal where the instability began.

Build a configurable deep stack and capture layer-wise mean, standard deviation, norm, zero fraction, and finite-value status. Compare initialization and activation choices under controlled inputs and stop safely when failure is detected.

Part 2 - Mathematical form

$$\mu_l = \mathbb{E}[A_l], \qquad \sigma_l^2 = \mathrm{Var}(A_l), \qquad r_l = \frac{\|A_l\|_2}{\|A_{l-1}\|_2}.$$

Part 3 - Hints and Helper

Detach statistics immediately instead of storing full graphs. Use fixed seeds and identical depth when comparing initialization strategies.

Part 4 - Python code skeleton

```
import torch

def activation_statistics(tensor):
    return {
        "mean": ...,
        "std": ...,
        "norm": ...,
        "zero_fraction": ...,
        "finite": ...,
    }

def run_with_monitoring(model, x):
    records, handles = [], []
    for name, module in model.named_modules():
        if isinstance(module, ...):
            handles.append(module.register_forward_hook(...))
    try:
        output = model(x)
    finally:
        for handle in handles:
            handle.remove()
    return output, records

def E17(depths, initializers, input_tensor):
    return {...}
```

14.3.19 Exercise 18 - Build a Receptive Field Calculator and Validate It Against Empirical Behavior

Part 1 - Why this matters

A reusable receptive-field calculator prevents vague claims about how much context a unit can see. It must track receptive size, effective jump, and center offset through convolutions and pooling layers.

Implement the calculator from layer specifications, then validate selected output units by differentiating them with respect to an input. Compare predicted receptive bounds with the empirical non-zero gradient support.

Part 2 - Mathematical form

$$R_l = R_{l-1} + (K_l - 1)D_l J_{l-1}, \quad J_l = J_{l-1} S_l, \quad O_l = O_{l-1} + \left(\frac{K_l - 1}{2} D_l - P_l\right) J_{l-1}.$$

Part 3 - Hints and Helper

Track height and width independently. Use simple non-zero weights and avoid activations that can accidentally block the gradient during validation.

Part 4 - Python code skeleton

```
import torch

def receptive_field_calculator(layer_specs):
    state = {
        "rf": (1, 1),
        "jump": (1, 1),
        "offset": (0.5, 0.5),
    }
    trace = []
    for spec in layer_specs:
        state = ...
        trace.append(state.copy())
    return trace

def empirical_support(model, input_shape, output_coordinate):
    x = torch.ones(input_shape, requires_grad=True)
    y = model(x)
    y[output_coordinate].backward()
    coordinates = torch.nonzero(...)
    return ...

def E18(layer_specs, model, cases):
    predicted = receptive_field_calculator(layer_specs)
    empirical = [...]
    return predicted, empirical, ...
```

14.3.20 Exercise 19 - Produce a Receptive Field and Feature Map Interpretation Guide for Future Debugging

Part 1 - Why this matters

Feature maps should not be interpreted only by their shapes, and receptive fields should not be confused with proof that every location inside them contributes equally. A debugging guide must connect theoretical coverage with observed activations and gradients.

Create a structured guide covering shape traces, receptive-field calculations, channel semantics, visualization, numerical statistics, equivariance tests, grouped connectivity, device parity, and common failure patterns. Every recommendation should point to evidence produced in earlier exercises.

Part 2 - Mathematical form

theoretical receptive field $\supseteq$ effective influential region measured for a particular input.

Part 3 - Hints and Helper

Include a symptom, diagnostic measurement, likely causes, and verification test for every failure pattern.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED_TOPICS = [
    "Shape Trace",
    "Receptive Field",
    "Channel Interpretation",
    "Equivariance",
    "Numerical Stability",
    "Connectivity",
    "Debugging Checklist",
]

def validate_guide(text, evidence):
    missing = [topic for topic in REQUIRED_TOPICS if topic not in text]
    linked_evidence = ...
    return {
        "missing": missing,
        "linked_evidence": linked_evidence,
        "ready": ...,
    }

def E19(experiment_records, output_path):
    guide = ...
    checks = validate_guide(guide, experiment_records)
    Path(output_path).write_text(guide, encoding="utf-8")
    return checks
```

14.4 CNN02 - Pooling, Downsampling, and Invariance

Models and Training

14.4.1 Exercise 00 - Implement Max Pooling Manually and Verify It Matches torch.nn.functional.max_pool2d

Part 1 - Why this matters

Max pooling divides each feature map into local windows and retains the largest value from each window. A manual version makes window placement, stride, padding, overlap, and boundary behavior explicit before an optimized implementation is trusted.

Implement batched channel-first max pooling with explicit loops, calculate its output shape, and compare values with PyTorch. Include negative inputs so incorrect zero padding cannot silently replace the true maximum near a boundary.

Part 2 - Mathematical form

$$Y_{n,c,i,j} = \max_{0 \le u < K_h, 0 \le v < K_w} X_{n,c,iS_h+u,jS_w+v}.$$

Part 3 - Hints and Helper

Begin with no padding and equal kernel and stride, then add overlapping windows. Use negative infinity when mathematical max padding is required.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_max_pool2d(x, kernel_size, stride):
    out_h, out_w = ...
    output = torch.empty(..., dtype=x.dtype, device=x.device)
    for n in range(...):
        for c in range(...):
            for i in range(out_h):
                for j in range(out_w):
                    window = ...
                    output[n, c, i, j] = ...
    return output

def E00(x):
    manual = manual_max_pool2d(x, ..., ...)
    reference = F.max_pool2d(x, ..., ...)
    return manual, reference, torch.allclose(manual, reference)
```

14.4.2 Exercise 01 - Implement Average Pooling and Compare Its Behavior to Max Pooling on the Same Input

Part 1 - Why this matters

Average pooling summarizes the complete window, whereas max pooling preserves only its strongest activation. Their outputs therefore respond differently to noise, sparse peaks, uniform regions, and distributed evidence.

Implement average pooling manually and compare both methods on synthetic feature maps with known structures. Measure changes in mean, variance, peak preservation, and sensitivity to one extreme value.

Part 2 - Mathematical form

$$Y_{i,j}^{\text{avg}} = \frac{1}{K_h K_w} \sum_{u,v} X_{iS_h+u,jS_w+v}.$$

Part 3 - Hints and Helper

Use identical windows and stride for both methods. Include constant, sparse, noisy, and smoothly varying inputs.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def manual_average_pool2d(x, kernel_size, stride):
    output = torch.empty(...)
    for i in range(...):
        for j in range(...):
            output[..., i, j] = ...
    return output

def summarize(tensor):
    return {"mean": ..., "std": ..., "maximum": ...}

def E01(x):
    average = manual_average_pool2d(x, ..., ...)
    maximum = F.max_pool2d(x, ..., ...)
    return average, maximum, summarize(average), summarize(maximum)
```

14.4.3 Exercise 02 - Explain and Demonstrate Why Pooling Introduces Local Translation Invariance

Part 1 - Why this matters

A small translation within one pooling window may leave the pooled value unchanged, especially when the same maximum remains inside that window. This creates limited local invariance, not complete invariance to arbitrary image shifts.

Move a distinctive activation through several positions inside and across pooling windows. Compare pooled outputs and identify exactly which shifts are ignored and which change the sampled region or output coordinate.

Part 2 - Mathematical form

$$p(T_\delta X) \approx p(X) \text{ for some small local shifts, but not for every } \delta.$$

Part 3 - Hints and Helper

Test within-window and cross-window shifts separately. Avoid describing convolutional equivariance and pooling invariance as the same property.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def place_peak(shape, row, column, value):
    x = torch.zeros(shape)
    x[..., row, column] = value
    return x

def E02(positions, pool_size):
    outputs = []
    for row, column in positions:
        x = place_peak(...)
        pooled = F.max_pool2d(x, pool_size, pool_size)
        outputs.append({"position": (row, column), "output": pooled})
    invariance_matrix = ...
    return outputs, invariance_matrix
```

14.4.4 Exercise 03 - Compare Pooling and Strided Convolution for Downsampling and Measure Quality Differences

Part 1 - Why this matters

Pooling uses a fixed summary rule, while strided convolution learns a spatial filter during downsampling. The learned method may preserve task-relevant information, but it introduces parameters and can alias if sampling occurs without suitable filtering.

Construct max-pooling, average-pooling, and strided-convolution branches with matched output shapes. Compare reconstruction error, downstream task quality, parameters, feature statistics, and sensitivity to shifts.

Part 2 - Mathematical form

$$Y_{\text{pool}} = p(X), \qquad Y_{\text{stride}} = X \star_S K.$$

Part 3 - Hints and Helper

Match output channels and spatial dimensions before comparing. Train the convolution branch only when the experiment explicitly evaluates learned downsampling.

Part 4 - Python code skeleton

```
import torch

def build_downsamplers(channels):
    return {
        "max": torch.nn.MaxPool2d(...),
        "average": torch.nn.AvgPool2d(...),
        "strided_conv": torch.nn.Conv2d(...),
    }

def evaluate(name, module, x, target):
    reduced = module(x)
    reconstructed = ...
    return {
        "name": name,
        "shape": tuple(reduced.shape),
        "parameters": ...,
        "quality": ...,
    }

def E03(x, target):
    modules = build_downsamplers(x.shape[1])
    results = []
    for name, module in modules.items():
        results.append(evaluate(name, module, x, target))
    return results
```

14.4.5 Exercise 04 - Analyze Pooling Window Size, Information Loss, and Classification Performance

Part 1 - Why this matters

A larger pooling window compresses a wider region into one value, reducing memory and increasing local invariance while discarding more spatial detail. The effect depends on whether the task relies on large structures or small localized evidence.

Sweep window sizes under a controlled classifier and dataset. Record spatial compression, retained signal, accuracy, latency, and failure cases, keeping the remaining architecture and training budget fixed.

Part 2 - Mathematical form

$$\rho = \frac{H'W'}{HW}, \qquad \text{information loss generally increases as } \rho \downarrow .$$

Part 3 - Hints and Helper

Include a dataset where small objects determine the label and another dominated by broad patterns. Do not infer information quality from output size alone.

Part 4 - Python code skeleton

```
import torch

def run_experiment(window_size, train_loader, val_loader, seed):
    torch.manual_seed(seed)
    model = torch.nn.Sequential(...)
    history = ...
    metrics = ...
    return {
        "window": window_size,
        "compression": ...,
        "accuracy": ...,
        "latency": ...,
        "history": history,
    }

def E04(window_sizes, train_loader, val_loader):
    results = []
    for size in window_sizes:
        result = run_experiment(size, train_loader, val_loader, ...)
        results.append(result)
    return results
```

14.4.6 Exercise 05 - Visualize Aliasing from Aggressive Downsampling Without Anti-Aliasing

Part 1 - Why this matters

Downsampling removes sample locations. When a feature map contains frequencies too high for the reduced grid, different structures can collapse into distorted or misleading patterns known as aliases.

Generate checkerboards and sinusoidal inputs at several frequencies, downsample them aggressively, and compare direct sampling with low-pass filtering before reduction. Visualize phase-dependent artifacts and quantify reconstruction or shift error.

Part 2 - Mathematical form

$$f_{\max} > \frac{f_s}{2} \implies \text{aliasing can occur after sampling.}$$

Part 3 - Hints and Helper

Change the phase by one pixel while preserving frequency. Large output changes reveal sampling sensitivity.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def downsample_direct(x, factor):
    return x[..., ::factor, ::factor]

def downsample_filtered(x, blur, factor):
    smooth = F.conv2d(x, blur, padding=...)
    return smooth[..., ::factor, ::factor]

def E05(patterns, blur, factor):
    records = []
    for pattern in patterns:
        direct = downsample_direct(pattern, factor)
        filtered = downsample_filtered(pattern, blur, factor)
        records.append({...})
    figure = ...
    return figure, records
```

14.4.7 Exercise 06 - Implement Global Average Pooling and Explain Its Role in Modern CNN Classifier Heads

Part 1 - Why this matters

Global average pooling replaces every spatial feature map with its mean, producing one value per channel. This creates an input-size-tolerant representation and can remove a large fully connected layer from the classifier head.

Implement it manually, verify it against PyTorch, and compare parameter count with flattening followed by a dense layer. Explain what spatial information is intentionally discarded and how channels become global evidence summaries.

Part 2 - Mathematical form

$$z_{n,c} = \frac{1}{HW} \sum_{i=1}^{H} \sum_{j=1}^{W} X_{n,c,i,j}.$$

Part 3 - Hints and Helper

Average only spatial axes and preserve batch and channel axes. Test several input resolutions with the same classifier.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F
```

```
def manual_global_average_pool(x):
    if x.ndim != 4:
        raise ValueError(...)
    return ...

def E06(x, class_count):
    manual = manual_global_average_pool(x)
    reference = F.adaptive_avg_pool2d(x, 1).flatten(1)
    global_head = torch.nn.Linear(x.shape[1], class_count)
    dense_head = torch.nn.Linear(..., class_count)
    return {
        "allclose": ...,
        "global_parameters": ...,
        "dense_parameters": ...,
    }
```

14.4.8 Exercise 07 - Demonstrate Adaptive Pooling with Variable Input Image Sizes

Part 1 - Why this matters

Adaptive pooling chooses window boundaries so different input sizes produce a requested output size. It allows a later network stage to receive a stable tensor shape without requiring every image to share one spatial resolution.

Apply adaptive max and average pooling to several non-square inputs, verify output dimensions, and inspect how uneven partitions affect which input locations contribute. Compare adaptive pooling with resizing before feature extraction.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{N \times C \times H \times W} \xrightarrow{\text{adaptive pool}} Y \in \mathbb{R}^{N \times C \times H_t \times W_t}.$$

Part 3 - Hints and Helper

Use one fixed target shape and record source-to-output region boundaries for at least one irregular input size.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def region_bounds(index, input_size, output_size):
    start = ...
    end = ...
    return start, end
```

```
def E07(inputs, target_hw):
    results = []
    for x in inputs:
        average = F.adaptive_avg_pool2d(x, target_hw)
        maximum = F.adaptive_max_pool2d(x, target_hw)
        regions = ...
        results.append({"input": tuple(x.shape), "average": average,
                        "maximum": maximum, "regions": regions})
    return results
```

14.4.9 Exercise 08 - Compare Feature Map Statistics Before and After Pooling to Understand Signal Compression

Part 1 - Why this matters

Pooling changes more than shape. Max pooling often raises local response magnitude and sparsity, while averaging reduces variance and smooths peaks. These changes influence later normalization, activation, and gradient behavior.

Measure mean, variance, norm, sparsity, extrema, entropy estimate, and channel correlation before and after several pooling methods. Interpret which statistics reflect compression and which depend strongly on the input distribution.

Part 2 - Mathematical form

$$\Delta\mu = \mu(Y) - \mu(X), \qquad \Delta\sigma^2 = \mathrm{Var}(Y) - \mathrm{Var}(X).$$

Part 3 - Hints and Helper

Compute statistics per channel before aggregating. A global summary can hide collapse in only a subset of channels.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def statistics(x):
    return {
        "mean_per_channel": ...,
        "variance_per_channel": ...,
        "norm_per_channel": ...,
        "zero_fraction": ...,
        "minimum": ...,
        "maximum": ...,
    }

def E08(x):
```

```
    variants = {
        "before": x,
        "max": F.max_pool2d(x, ...),
        "average": F.avg_pool2d(x, ...),
    }
    return {name: statistics(value) for name, value in variants.items()}
```

14.4.10 Exercise 09 - Debug Output Shape Mistakes from Pooling and Stride Interactions in Complex Networks

Part 1 - Why this matters

Several reductions in one architecture can shrink feature maps faster than expected, create fractional predictions that are floored, or make a later kernel larger than its input. The visible failure may occur many layers after the original mistake.

Build a shape tracer for convolution and pooling modules and compare predicted shapes with forward-hook observations. Report the first mismatching layer with its complete configuration instead of only showing the final exception.

Part 2 - Mathematical form

$$H_l = \left\lfloor \frac{H_{l-1} + 2P_l - D_l(K_l - 1) - 1}{S_l} + 1 \right\rfloor .$$

Part 3 - Hints and Helper

Trace height and width independently and include ceil mode when it is enabled. Validate every transition before running expensive training.

Part 4 - Python code skeleton

```
import torch

def predict_transition(shape, module):
    if isinstance(module, torch.nn.Conv2d):
        return ...
    if isinstance(module, (torch.nn.MaxPool2d, torch.nn.AvgPool2d)):
        return ...
    return shape

def E09(model, input_shape):
    predicted, observed = [], []
    shape = input_shape
    handles = []
    for name, module in model.named_modules():
        shape = predict_transition(shape, module)
        predicted.append((name, shape))
```

```
        handles.append(...)
    model(torch.randn(input_shape))
    ...
    return predicted, observed, ...
```

14.4.11 Exercise 10 - Run Pooling on CUDA and Confirm Correctness and Speed
Benefits

Part 1 - Why this matters

Pooling is usually inexpensive compared with convolution, so GPU acceleration depends on tensor size and transfer overhead. Correctness and speed must be measured separately using identical inputs and synchronized timings.

Compare CPU and CUDA outputs for several pooling modes, then benchmark small and large tensors with warm-up. Keep transfer timing separate from compute timing and justify numerical tolerances.

Part 2 - Mathematical form

$$\text{speedup} = t_{\text{CPU}}/t_{\text{GPU}}, \qquad \Delta_{\max} = \max |Y_{\text{CPU}} - Y_{\text{GPU}}|.$$

Part 3 - Hints and Helper

Synchronize CUDA immediately before starting and after finishing each timed region. Reuse already transferred tensors.

Part 4 - Python code skeleton

```
import time
import torch
import torch.nn.functional as F

def benchmark(operation, x, repeats):
    times = []
    for _ in range(...):
        operation(x)
    for _ in range(repeats):
        if x.is_cuda: torch.cuda.synchronize()
        start = time.perf_counter()
        y = operation(x)
        if x.is_cuda: torch.cuda.synchronize()
        times.append(time.perf_counter() - start)
    return y, ...

def E10(x_cpu, operation):
    if not torch.cuda.is_available(): return {"available": False}
    cpu_output, cpu_time = benchmark(operation, x_cpu, ...)
```

```
    gpu_output, gpu_time = benchmark(operation, x_cpu.cuda(), ...)
    return {...}
```

14.4.12 Exercise 11 - Benchmark Pooling and Strided Convolution Runtime and GPU Memory Usage

Part 1 - Why this matters

Pooling has no trainable weights, while strided convolution performs learned multiply-accumulate operations and stores parameter gradients during training. Their real memory and runtime differences depend on shape, backend, precision, and whether backward is included.

Benchmark matched-output variants in inference and training. Report forward and backward time, allocated and peak memory, parameter count, and output size so the comparison separates computation from representational flexibility.

Part 2 - Mathematical form

$$M_{\text{peak}} = \max_t M_{\text{allocated}}(t), \qquad \#\theta_{\text{pool}} = 0.$$

Part 3 - Hints and Helper

Reset peak memory statistics for each isolated trial and clear references between variants.

Part 4 - Python code skeleton

```
import torch

def profile(module, x, training):
    torch.cuda.reset_peak_memory_stats()
    x = x.detach().requires_grad_(training)
    output = module(x)
    if training:
        output.mean().backward()
    return {
        "parameters": sum(p.numel() for p in module.parameters()),
        "peak_memory": torch.cuda.max_memory_allocated(),
        "output_shape": tuple(output.shape),
        "time": ...,
    }

def E11(x, channels):
    variants = {"max": ..., "average": ..., "strided_conv": ...}
    results = {}
    for name, module in variants.items():
        results[name] = profile(module, x, ...)
    return results
```

14.4.13 Exercise 12 - Investigate Pooling Precision Under float16 Mixed Precision Settings

Part 1 - Why this matters

Max pooling selects an existing value and is usually insensitive to accumulation precision, while average pooling sums values and divides, making it more vulnerable to rounding, underflow, or overflow in low precision.

Compare float16 outputs and gradients with float32 references across normal, tiny, large, and cancellation-heavy inputs. Test both max and average pooling and report non-finite values separately from finite numerical error.

Part 2 - Mathematical form

$$\epsilon_{\text{rel}} = \frac{|Y_{16} - Y_{32}|}{|Y_{32}| + \varepsilon}.$$

Part 3 - Hints and Helper

Run on hardware that supports float16 pooling and convert low-precision results to float32 before error calculation.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def compare_precision(x32, operation):
    x32 = x32.detach().requires_grad_(True)
    reference = operation(x32)
    reference.sum().backward()
    grad32 = x32.grad.detach().clone()
    x16 = x32.detach().half().requires_grad_(True)
    low = operation(x16)
    low.sum().backward()
    return {
        "output_error": ...,
        "gradient_error": ...,
        "finite": ...,
    }

def E12(cases):
    operations = {"max": ..., "average": ...}
    return {...}
```

14.4.14 Exercise 13 - Implement Anti-Aliased Pooling and Compare It with Standard Pooling

Part 1 - Why this matters

Anti-aliased pooling applies a low-pass filter before reducing the sampling rate. It suppresses frequencies that the coarser output grid cannot represent, trading some sharpness and computation for improved shift stability.

Construct a normalized blur kernel, filter each channel independently, and then downsample. Compare it with standard pooling on high-frequency patterns, shifted inputs, and a controlled classification task.

Part 2 - Mathematical form

$$Y = \downarrow_S (h \star X), \qquad \sum_{u,v} h_{u,v} = 1.$$

Part 3 - Hints and Helper

Apply the same blur independently to every channel by using grouped convolution. Compare phase sensitivity and accuracy, not only visual smoothness.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def blur_kernel_2d(coefficients, channels, device, dtype):
    vector = torch.tensor(coefficients, device=device, dtype=dtype)
    kernel = torch.outer(vector, vector)
    kernel = kernel / kernel.sum()
    return kernel.view(1, 1, *kernel.shape).repeat(channels, 1, 1, 1)

def anti_aliased_pool(x, kernel, stride):
    smooth = F.conv2d(x, kernel, padding=..., groups=x.shape[1])
    return smooth[..., ::stride, ::stride]

def E13(x, shifted_x):
    kernel = blur_kernel_2d(...)
    standard = F.avg_pool2d(x, ...)
    antialiased = anti_aliased_pool(x, kernel, ...)
    return standard, antialiased, ...
```

14.4.15 Exercise 14 - Implement Blur Pooling and Measure Its Effect on Robustness

Part 1 - Why this matters

Blur pooling is one practical anti-aliasing design that separates smoothing from subsampling. It aims to reduce prediction changes caused by small translations or corruptions that interact badly with a coarse sampling grid.

Insert blur pooling into a small CNN and compare it with the original downsampling path. Evaluate clean accuracy, shifted accuracy, noise and blur robustness, latency, and memory so robustness gains are weighed against their cost.

Part 2 - Mathematical form

$$\mathcal{R}_{\text{shift}} = \mathbb{E}_{\delta} \| f(X) - f(T_{\delta} X) \|.$$

Part 3 - Hints and Helper

Copy shared model weights before changing the downsampling block and evaluate both models on identical perturbations.

Part 4 - Python code skeleton

```
import torch

class BlurPool(torch.nn.Module):
    def __init__(self, channels, stride=2):
        super().__init__()
        self.register_buffer("kernel", ...)
        self.stride = stride

    def forward(self, x):
        return ...

def robustness_suite(model, batches):
    return {
        "clean": ...,
        "shifted": ...,
        "noisy": ...,
        "blurred": ...,
    }

def E14(baseline, blur_model, batches):
    baseline_results = robustness_suite(baseline, batches)
    blur_results = robustness_suite(blur_model, batches)
    return baseline_results, blur_results
```

14.4.16 Exercise 15 - Analyze When Pooling Helps or Hurts Based on Dataset Structure

Part 1 - Why this matters

Pooling is beneficial when exact location is less important than the presence of a pattern and when moderate compression removes redundancy. It can be harmful when labels depend on tiny objects, precise coordinates, counts, or fine boundaries.

Create controlled datasets representing location-invariant detection, small-object recognition, and spatial-relation tasks. Compare no pooling, mild pooling, and aggressive pooling under the same architecture budget.

Part 2 - Mathematical form

$$\text{utility of pooling} = \text{task invariance benefit} - \text{lost spatial information}.$$

Part 3 - Hints and Helper

Inspect per-task errors and examples. One average accuracy cannot reveal which structural assumption succeeded or failed.

Part 4 - Python code skeleton

```
import torch

def build_model(pooling_strategy, task):
    return torch.nn.Sequential(...)

def controlled_run(task_data, strategy, seed):
    torch.manual_seed(seed)
    model = build_model(strategy, task_data.name)
    train_metrics = ...
    test_metrics = ...
    failure_examples = ...
    return {
        "task": task_data.name,
        "strategy": strategy,
        "train": train_metrics,
        "test": test_metrics,
        "failures": failure_examples,
    }

def E15(tasks, strategies):
    results = []
    for task in tasks:
        for strategy in strategies:
            results.append(controlled_run(task, strategy, ...))
    return results
```

14.4.17 Exercise 16 - Stress Test Deep Downsampling Stacks and Detect Feature Collapse or Excessive Information Loss

Part 1 - Why this matters

Repeated downsampling can reduce a feature map to a tiny grid before the network has extracted enough useful structure. Activation variance, rank, spatial diversity, or class separability may collapse even when tensor shapes remain valid.

Build stacks with increasing numbers of reduction stages and monitor shape, variance, norm, unique-value ratio, and representation quality after every stage. Detect the earliest point where compression becomes destructive.

Part 2 - Mathematical form

$$H_L \approx H_0 \prod_{l=1}^{L} \frac{1}{S_l}, \qquad W_L \approx W_0 \prod_{l=1}^{L} \frac{1}{S_l}.$$

Part 3 - Hints and Helper

Use hooks and detached summaries instead of retaining all computational graphs. Define collapse thresholds before viewing results.

Part 4 - Python code skeleton

```
import torch

def stage_statistics(x):
    return {
        "shape": tuple(x.shape),
        "variance": ...,
        "norm": ...,
        "spatial_diversity": ...,
        "finite": ...,
    }

def E16(x, stage_factory, maximum_depth):
    records = []
    current = x
    for depth in range(maximum_depth):
        stage = stage_factory(depth)
        current = stage(current)
        record = stage_statistics(current)
        records.append(record)
        if ...:
            break
    return records
```

14.4.18 Exercise 17 - Build a Shape-Tracking Utility for Spatial Changes Through a CNN Pipeline

Part 1 - Why this matters

A reusable shape tracker converts architecture inspection from guesswork into a recorded contract. It should show which module changed channels or spatial dimensions and whether the observed output matches a manual prediction.

Attach temporary hooks to relevant modules, run a dry input, and log input shape, output shape, kernel, stride, padding, dilation, and ceil mode. Export the trace in a form that can be compared across architecture revisions.

Part 2 - Mathematical form

$$S_l = (N_l, C_l, H_l, W_l), \qquad \text{trace} = \{S_0 \to S_1 \to \cdots \to S_L\}.$$

Part 3 - Hints and Helper

Handle modules with tuple outputs and remove hooks in a finally block. Do not store full tensors in the log.

Part 4 - Python code skeleton

```
import torch

def module_config(module):
    return {"kernel": ..., "stride": ..., "padding": ...}

def track_shapes(model, example):
    records, handles = [], []
    def make_hook(name):
        def hook(module, inputs, output):
            records.append({"name": name,
                            "input": tuple(inputs[0].shape),
                            "output": tuple(output.shape),
                            "config": module_config(module)})
        return hook
    try:
        for name, module in model.named_modules():
            if isinstance(module, ...):
                handles.append(module.register_forward_hook(make_hook(name)))
        model(example)
    finally:
        for handle in handles: handle.remove()
    return records

def E17(models, example):
    return {...}
```

14.4.19 Exercise 18 - Create a Downsampling Strategy Comparison Report Using Multiple Configurations

Part 1 - Why this matters

Choosing a downsampling strategy requires evidence across information quality, task accuracy, robustness, speed, memory, and implementation complexity. A report prevents one attractive metric from hiding an unacceptable trade-off elsewhere.

Evaluate pooling, strided convolution, adaptive pooling, and anti-aliased alternatives using a shared protocol. Record configurations and seeds, aggregate repeated runs, and state which conclusions are task-specific.

Part 2 - Mathematical form

$$\text{decision score} = \sum_m w_m \, \widetilde{q}_m, \qquad \sum_m w_m = 1.$$

Part 3 - Hints and Helper

Keep raw metrics in the report even if a weighted summary is used. Document weights before ranking methods.

Part 4 - Python code skeleton

```
from pathlib import Path

def aggregate_runs(records):
    return {
        "accuracy_mean": ...,
        "accuracy_std": ...,
        "latency_median": ...,
        "peak_memory": ...,
        "shift_robustness": ...,
    }

def rank_strategies(summaries, weights):
    normalized = ...
    return ...

def E18(experiment_records, weights, output_path):
    summaries = aggregate_runs(experiment_records)
    ranking = rank_strategies(summaries, weights)
    report = ...
    Path(output_path).write_text(report, encoding="utf-8")
    return summaries, ranking
```

14.4.20 Exercise 19 - Write a Practical Guide for Selecting Pooling, Stride, or Global Pooling in Real CNNs

Part 1 - Why this matters

No downsampling method is universally correct. The selection should follow the task's spatial requirements, expected invariances, input resolution, compute budget, robustness needs,

and deployment constraints.

Write a decision guide that distinguishes local pooling, learned strided reduction, anti-aliased reduction, adaptive pooling, and global pooling. Include warning signs, validation experiments, and recovery steps for information loss, aliasing, shape errors, and feature collapse.

Part 2 - Mathematical form

$$\text{method} = g(\text{task geometry, resolution, invariance, accuracy, latency, memory}).$$

Part 3 - Hints and Helper

For every recommendation, provide a condition, trade-off, measurement, and failure test rather than a rule without evidence.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED_SECTIONS = [
    "Task Requirements",
    "Pooling Options",
    "Aliasing",
    "Shape Validation",
    "Performance",
    "Failure Tests",
    "Decision Checklist",
]

def validate_guide(text, evidence):
    missing = []
    for section in REQUIRED_SECTIONS:
        if section not in text:
            missing.append(section)
    return {"missing": missing, "evidence_links": ..., "ready": ...}

def E19(experiments, output_path):
    guide = ...
    validation = validate_guide(guide, experiments)
    Path(output_path).write_text(guide, encoding="utf-8")
    return validation
```

14.5 CNN03 - CNN Forward Architecture and Implementation

Models and Training

14.5.1 Exercise 00 - Build a Minimal CNN Classifier and Verify Forward Pass Output Dimensions

Part 1 - Why this matters

A minimal classifier connects convolutional feature extraction to class logits and exposes the complete tensor path. Every transformation must preserve the batch dimension and produce exactly one score vector per sample.

Build a small network with convolution, activation, downsampling, and a classifier head. Predict each intermediate shape manually, then verify the predictions with a dry forward pass before any training begins.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{N \times C \times H \times W} \xrightarrow{f_\theta} Z \in \mathbb{R}^{N \times K}.$$

Part 3 - Hints and Helper

Start with one documented input resolution and assert the final shape. Record intermediate shapes rather than checking only the logits.

Part 4 - Python code skeleton

```
import torch

class MinimalCNN(torch.nn.Module):
    def __init__(self, in_channels, class_count):
        super().__init__()
        self.conv1 = torch.nn.Conv2d(...)
        self.conv2 = torch.nn.Conv2d(...)
        self.pool = torch.nn.MaxPool2d(...)
        self.classifier = torch.nn.Linear(...)

    def forward(self, x):
        x = ...
        x = ...
        x = ...
        return self.classifier(x)

def E00(input_shape, class_count):
    model = MinimalCNN(input_shape[1], class_count)
    output = model(torch.randn(input_shape))
    return tuple(output.shape), ...
```

14.5.2 Exercise 01 - Implement CNN with nn.Sequential and Compare It to Explicit Forward Function Style

Part 1 - Why this matters

Sequential composition is concise for a single linear path, while an explicit forward method makes branching, reused outputs, debugging, and custom control flow easier to express. Both styles should implement identical mathematics when their modules and order match.

Create equivalent models in both styles, copy one state dictionary into the other, and compare outputs and intermediate observability. Explain which architecture changes would no longer fit a simple sequential container.

Part 2 - Mathematical form

$$f(x) = f_L \circ f_{L-1} \circ \cdots \circ f_1(x).$$

Part 3 - Hints and Helper

Use named ordered blocks or matching parameter keys, then switch both models to evaluation mode before parity testing.

Part 4 - Python code skeleton

```
import torch

class ExplicitCNN(torch.nn.Module):
    def __init__(self):
        super().__init__()
        self.conv = torch.nn.Conv2d(...)
        self.activation = torch.nn.ReLU()
        self.pool = torch.nn.MaxPool2d(...)

    def forward(self, x):
        x = self.conv(x)
        x = ...
        return ...

def build_sequential():
    return torch.nn.Sequential(...)

def E01(x):
    explicit, sequential = ExplicitCNN(), build_sequential()
    sequential.load_state_dict(...)
    return explicit(x), sequential(x), ...
```

14.5.3 Exercise 02 - Add ReLU Between Conv Layers and Confirm Non-Linearity Changes Representation

Part 1 - Why this matters

Several convolutional layers without non-linear activation collapse into one linear transformation apart from boundary details. ReLU prevents this collapse by suppressing negative responses and creating input-dependent activation patterns.

Compare a two-layer linear convolutional stack with the same stack containing ReLU. Test scaling and additivity, inspect zero fractions, and demonstrate a pair of inputs for which the activated model violates linear superposition.

Part 2 - Mathematical form

$$\mathrm{ReLU}(z) = \max(0, z), \qquad f(aX + bY) \neq af(X) + bf(Y) \text{ in general.}$$

Part 3 - Hints and Helper

Copy identical convolution weights between variants. Test additivity with controlled inputs containing positive and negative pre-activations.

Part 4 - Python code skeleton

```
import copy
import torch

def build_variants():
    linear = torch.nn.Sequential(...)
    nonlinear = torch.nn.Sequential(...)
    ...
    return linear, nonlinear

def superposition_error(model, x, y, a, b):
    combined = model(a * x + b * y)
    separate = a * model(x) + b * model(y)
    return ...

def E02(x, y):
    linear, nonlinear = build_variants()
    return {"linear": superposition_error(...),
            "nonlinear": superposition_error(...),
            "zero_fraction": ...}
```

14.5.4 Exercise 03 - Implement Flatten Correctly and Debug Batch Dimension Mistakes

Part 1 - Why this matters

Flattening converts spatial features into vectors for a dense head, but the batch axis must remain separate. Flattening the entire tensor merges samples, while using a fixed view can fail on different batch sizes or non-contiguous storage.

Implement safe flattening, compare it with incorrect alternatives, and validate feature count for several batch sizes. Detect the first point where sample identity or expected classifier input is lost.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{N \times C \times H \times W} \mapsto X' \in \mathbb{R}^{N \times CHW}.$$

Part 3 - Hints and Helper

Use flatten starting at dimension one or reshape with the current batch size. Do not hard-code the batch dimension.

Part 4 - Python code skeleton

```
import torch

def safe_flatten(x):
    if x.ndim < 2:
        raise ValueError(...)
    return ...

def validate_flatten(x, expected_features):
    flattened = safe_flatten(x)
    if flattened.shape != (x.shape[0], expected_features):
        raise ValueError(...)
    return flattened

def E03(shapes):
    results = []
    for shape in shapes:
        x = torch.randn(shape)
        results.append(validate_flatten(x, ...).shape)
    return results
```

14.5.5 Exercise 04 - Replace Flatten and Fully Connected Head with Global Average Pooling and Compare Cost

Part 1 - Why this matters

A flatten-plus-dense head assigns separate weights to every spatial position and can dominate parameter count. Global average pooling summarizes each channel before classification, reducing parameters and allowing variable spatial sizes.

Build matched CNN bodies with both heads and compare logits shape, parameter count, activation memory, latency, and validation performance. Explain what spatial information the global head removes.

Part 2 - Mathematical form

$$z_c = \frac{1}{HW}\sum_{i,j} X_{c,i,j}, \qquad \#\theta_{\text{GAP head}} = CK + K.$$

Part 3 - Hints and Helper

Keep the feature extractor identical and use adaptive average pooling to one spatial cell.

Part 4 - Python code skeleton

```
import copy
import torch

class GlobalHead(torch.nn.Module):
    def __init__(self, channels, classes):
        super().__init__()
        self.pool = torch.nn.AdaptiveAvgPool2d(1)
        self.fc = torch.nn.Linear(channels, classes)

    def forward(self, x):
        return self.fc(...)

def E04(backbone, example, classes):
    dense_model = ...
    global_model = ...
    return {"dense_parameters": ...,
            "global_parameters": ...,
            "output_shapes": ...,
            "latency": ...}
```

14.5.6 Exercise 05 - Add Dropout to the CNN Classifier Head and Verify Train and Eval Behavior

Part 1 - Why this matters

Dropout randomly suppresses activations during training and rescales surviving values, creating stochastic subnetworks. During evaluation it must become inactive so repeated inference is stable.

Insert dropout in the classifier head, perform repeated forward passes in both modes, and compare output variance and zero fractions. Also verify that changing mode does not disable gradient tracking by itself.

Part 2 - Mathematical form

$$\widetilde{h}_i = \frac{m_i}{1-p} h_i, \qquad m_i \sim \text{Bernoulli}(1-p).$$

Part 3 - Hints and Helper

Use the same input repeatedly. Call train and eval explicitly and separate mode behavior from inference-mode behavior.

Part 4 - Python code skeleton

```
import torch

class DropoutHead(torch.nn.Module):
    def __init__(self, features, classes, probability):
        super().__init__()
        self.dropout = torch.nn.Dropout(probability)
        self.linear = torch.nn.Linear(features, classes)

    def forward(self, x):
        return self.linear(self.dropout(x))

def repeated_outputs(model, x, repeats):
    return torch.stack([...])

def E05(model, x):
    model.train()
    train_outputs = repeated_outputs(model, x, ...)
    model.eval()
    eval_outputs = repeated_outputs(model, x, ...)
    return {"train_variance": ..., "eval_variance": ...}
```

14.5.7 Exercise 06 - Implement Batch Normalization and Verify Running Statistics and Mode Switching

Part 1 - Why this matters

Batch normalization uses current batch statistics during training while updating running estimates for evaluation. Incorrect mode switching can make validation depend on batch composition and produce unstable predictions.

Insert BatchNorm after convolution, inspect learned parameters and buffers, and observe running mean and variance across controlled batches. Verify that evaluation uses stored statistics without updating them.

Part 2 - Mathematical form

$$\widehat{x} = \frac{x - \mu_B}{\sqrt{\sigma_B^2 + \varepsilon}}, \qquad y = \gamma \widehat{x} + \beta.$$

Part 3 - Hints and Helper

Record buffers before and after each pass. Use deliberately shifted batches so statistic updates remain visible.

Part 4 - Python code skeleton

```
import torch

class NormalizedBlock(torch.nn.Module):
    def __init__(self, in_channels, out_channels):
        super().__init__()
        self.conv = torch.nn.Conv2d(...)
        self.norm = torch.nn.BatchNorm2d(out_channels)
        self.activation = torch.nn.ReLU()

    def forward(self, x):
        return ...

def snapshot(norm):
    return {"mean": norm.running_mean.clone(),
            "variance": norm.running_var.clone()}

def E06(block, batches):
    before = snapshot(block.norm)
    block.train(); ...
    after_train = snapshot(block.norm)
    block.eval(); ...
    after_eval = snapshot(block.norm)
    return before, after_train, after_eval
```

14.5.8 Exercise 07 - Add a Residual-Like Skip Connection and Verify Shape Compatibility

Part 1 - Why this matters

A skip connection adds an earlier representation to a transformed path, providing a direct route for information and gradients. Addition is valid only when batch, channel, and spatial dimensions are compatible.

Implement an identity skip and a projection skip for changed channels or stride. Check shapes before addition and compare parameter count and output behavior for both cases.

Part 2 - Mathematical form

$$Y = F(X) + P(X), \qquad \text{shape}(F(X)) = \text{shape}(P(X)).$$

Part 3 - Hints and Helper

Use an identity projection only when all dimensions already match; otherwise use a one-by-one convolution with appropriate stride.

Part 4 - Python code skeleton

```
import torch

class ResidualLikeBlock(torch.nn.Module):
    def __init__(self, in_channels, out_channels, stride=1):
        super().__init__()
        self.main = torch.nn.Sequential(...)
        self.skip = ...

    def forward(self, x):
        main = self.main(x)
        skip = self.skip(x)
        if main.shape != skip.shape:
            raise ValueError(...)
        return ...

def E07(configurations):
    return [...]
```

14.5.9 Exercise 08 - Inspect Intermediate Feature Maps with Forward Hooks and Save Them for Debugging

Part 1 - Why this matters

Forward hooks expose module outputs without rewriting the model's forward method. They are useful for locating shape changes, dead activations, non-finite values, and unexpected feature distributions.

Register hooks on selected layers, store detached CPU copies or compact statistics, and remove every handle after one diagnostic pass. Save metadata that links each feature map to its module and input.

Part 2 - Mathematical form

$$\mathcal{H}_l : (M_l, X_l, Y_l) \mapsto \text{diagnostic}(Y_l).$$

Part 3 - Hints and Helper

Do not retain graph-connected GPU tensors across batches. Use a context-managed pattern so hooks cannot accumulate accidentally.

Part 4 - Python code skeleton

```
import torch

def capture_features(model, x, selected_names, save_full=False):
    records, handles = {}, []
    def make_hook(name):
        def hook(module, inputs, output):
            records[name] = {
                "shape": tuple(output.shape),
                "mean": ...,
                "std": ...,
                "values": output.detach().cpu() if save_full else None,
            }
        return hook
    try:
        for name, module in model.named_modules():
            if name in selected_names:
                handles.append(module.register_forward_hook(make_hook(name)))
        model(x)
    finally:
        for handle in handles: handle.remove()
    return records

def E08(model, x):
    return capture_features(model, x, ..., ...)
```

14.5.10 Exercise 09 - Debug CNN Forward Failures: Shape Mismatch, NaNs, and Wrong Channel Ordering

Part 1 - Why this matters

Forward failures often appear far from their cause. A wrong channel layout may reach the first convolution, a bad scale may create non-finite values later, and an incorrect spatial prediction may break only at the classifier.

Build a diagnostic forward routine that validates input contract and records shape, device, dtype, finite status, and value range layer by layer. Return the first violated invariant with actionable context.

Part 2 - Mathematical form

$$\text{valid}(A_l) = \text{shape ok} \wedge \text{finite}(A_l) \wedge \text{device ok}\,.$$

Part 3 - Hints and Helper

Fail at the earliest invalid layer. Do not repair wrong channel order with an arbitrary reshape.

Part 4 - Python code skeleton

```
import torch

def validate_tensor(name, tensor, expected_channels=None):
    checks = {
        "shape": tuple(tensor.shape),
        "dtype": str(tensor.dtype),
        "device": str(tensor.device),
        "finite": bool(torch.isfinite(tensor).all()),
    }
    if expected_channels is not None and tensor.shape[1] != expected_channels:
        raise ValueError(...)
    if not checks["finite"]:
        raise FloatingPointError(...)
    return checks

def E09(model, failing_inputs):
    reports = []
    for case in failing_inputs:
        try: reports.append(...)
        except Exception as error: reports.append({...})
    return reports
```

14.5.11 Exercise 10 - Move a Full CNN Forward Pass to CUDA and Confirm Shared Device Placement

Part 1 - Why this matters

Moving only the input or only the model creates a device mismatch. A complete CUDA forward path includes parameters, buffers, inputs, and newly created tensors inside the model.

Move a model and batch to one selected CUDA device, audit all parameter and buffer devices, and compare output shape and numerical parity with a copied CPU reference.

Part 2 - Mathematical form

$$\text{device}(X) = \text{device}(\theta) = \text{device}(B) = \text{device}(Y).$$

Part 3 - Hints and Helper

Create constants from existing tensors or register them as buffers. Do not call CUDA blindly inside forward.

Part 4 - Python code skeleton

```
import copy
import torch

def audit_devices(model):
    devices = {str(p.device) for p in model.parameters()}
    devices.update(str(b.device) for b in model.buffers())
    return devices

def E10(model, x_cpu):
    if not torch.cuda.is_available():
        return {"available": False}
    cpu_model = copy.deepcopy(model).eval()
    gpu_model = copy.deepcopy(model).cuda().eval()
    with torch.inference_mode():
        cpu_output = cpu_model(x_cpu)
        gpu_output = gpu_model(x_cpu.cuda())
    return {"available": True, "devices": audit_devices(gpu_model),
            "shape": tuple(gpu_output.shape), "maximum_error": ...}
```

14.5.12 Exercise 11 - Benchmark Forward Throughput and Identify Expensive Layers on GPU

Part 1 - Why this matters

End-to-end latency shows whether a model meets a target, but it does not identify which layers consume time. Layer profiling reveals compute-heavy operations, synchronization costs, and unexpected bottlenecks.

Measure warmed-up end-to-end latency and per-layer CUDA time across batch sizes. Report throughput and each layer's share while avoiding hook overhead in the final production benchmark.

Part 2 - Mathematical form

$$\text{throughput} = N/t, \qquad q_l = t_l / \sum_j t_j.$$

Part 3 - Hints and Helper

Use CUDA events or a profiler and synchronize measurement boundaries. Repeat enough times to summarize stable timing distributions.

Part 4 - Python code skeleton

```
import torch

def profile_forward(model, x, warmup, repeats):
    for _ in range(warmup): model(x)
```

```
    layer_times = {}
    handles = [...]
    for _ in range(repeats):
        ...
    for handle in handles: handle.remove()
    return {"latency": ..., "throughput": ...,
            "layer_times": layer_times}

def E11(model, batch_shapes):
    model = model.cuda().eval()
    results = []
    for shape in batch_shapes:
        x = torch.randn(shape, device="cuda")
        results.append(profile_forward(model, x, ..., ...))
    return results
```

14.5.13 Exercise 12 - Compare float32 and Mixed Precision Forward Outputs and Detect Sensitive Layers

Part 1 - Why this matters

Mixed precision can accelerate convolution and reduce activation memory, but some layers or input scales may lose accuracy or become non-finite. End-to-end error alone cannot reveal where divergence begins.

Capture matched layer outputs in float32 and autocast execution, then calculate absolute and relative errors per layer. Include extreme input scales and identify the first precision-sensitive transformation.

Part 2 - Mathematical form

$$\epsilon_l = \frac{\|A_l^{\text{mixed}} - A_l^{32}\|}{\|A_l^{32}\| + \varepsilon}.$$

Part 3 - Hints and Helper

Use one model state and identical input. Convert captured mixed outputs to float32 before comparison.

Part 4 - Python code skeleton

```
import torch

def forward_features(model, x, use_autocast):
    records, handles = {}, [...]
    with torch.autocast("cuda", enabled=use_autocast):
        output = model(x)
    for handle in handles: handle.remove()
```

```
    return output, records

def E12(model, x):
    model = model.cuda().eval()
    x = x.cuda()
    reference, maps32 = forward_features(model, x, False)
    mixed, maps_mixed = forward_features(model, x, True)
    errors = {...}
    return reference, mixed, errors
```

14.5.14 Exercise 13 - Implement a Configurable CNN Builder from a Layer Specification List

Part 1 - Why this matters

A configuration-driven builder makes architecture experiments reproducible and prevents repeated hand editing. It must validate channel flow, supported layer types, arguments, and output contracts before constructing modules.

Define a small explicit schema for convolution, activation, pooling, normalization, and adaptive pooling. Build named modules in order, track predicted shape, and reject invalid or ambiguous specifications.

Part 2 - Mathematical form

$$\mathcal{A} = \left[(t_1, \phi_1), \ldots, (t_L, \phi_L)\right] \xrightarrow{\text{build}} f_\theta.$$

Part 3 - Hints and Helper

Avoid evaluating arbitrary strings. Map approved type names to constructors and validate every field.

Part 4 - Python code skeleton

```
import torch

LAYER_TYPES = {
    "conv": torch.nn.Conv2d,
    "relu": torch.nn.ReLU,
    "max_pool": torch.nn.MaxPool2d,
    "batch_norm": torch.nn.BatchNorm2d,
    "adaptive_average": torch.nn.AdaptiveAvgPool2d,
}

def build_cnn(specifications, input_shape):
    modules = []
    shape = input_shape
    trace = []
```

```
    for index, spec in enumerate(specifications):
        layer_type = spec.get("type")
        if layer_type not in LAYER_TYPES:
            raise ValueError(...)
        module = LAYER_TYPES[layer_type](...)
        shape = ...
        modules.append(module)
        trace.append((index, shape))
    return torch.nn.Sequential(*modules), trace

def E13(specifications, input_shape):
    return build_cnn(specifications, input_shape)
```

14.5.15 Exercise 14 - Validate Parameter Count and Memory Footprint for Multiple CNN Architecture Variants

Part 1 - Why this matters

Two CNNs with similar output accuracy can differ greatly in parameter storage, activation memory, and temporary workspaces. Parameter count alone does not predict training memory because saved activations often dominate.

Compare architecture variants with manual and programmatic parameter counts. Measure parameter bytes, buffer bytes, output activation bytes, and peak CUDA memory in inference and training.

Part 2 - Mathematical form

$$M_{\text{parameters}} = \sum_{p} \#p \cdot \text{bytes}(p), \qquad M_{\text{peak}} \geq M_{\text{parameters}} + M_{\text{activations}}.$$

Part 3 - Hints and Helper

Reset CUDA peak statistics for each isolated model and include gradients and optimizer state only when the scenario requires them.

Part 4 - Python code skeleton

```
import torch

def model_storage(model):
    parameter_bytes = sum(p.numel() * p.element_size()
                          for p in model.parameters())
    buffer_bytes = sum(b.numel() * b.element_size()
                       for b in model.buffers())
    return parameter_bytes, buffer_bytes

def profile_memory(model, x, training):
```

```
    ...
    return {"parameters": ..., "buffers": ...,
            "peak_memory": ..., "output_bytes": ...}

def E14(variants, x):
    results = {}
    for name, model in variants.items():
        results[name] = profile_memory(model, x, ...)
    return results
```

14.5.16 Exercise 15 - Test CNN Forward Robustness Across Input Sizes with Adaptive Pooling

Part 1 - Why this matters

A CNN with adaptive pooling can accept several spatial sizes while preserving a fixed classifier input. Earlier convolutions still impose minimum-size and aspect-ratio constraints that must be tested.

Run one model on square, rectangular, small, and large inputs. Validate output shape, finite values, memory, and consistency of preprocessing, then document the smallest supported dimensions.

Part 2 - Mathematical form

$$H, W \text{ variable} \xrightarrow{\text{adaptive pool}} H_t, W_t \text{ fixed.}$$

Part 3 - Hints and Helper

Keep channel count and normalization contract fixed. Catch invalid small inputs with a clear pre-forward validation error.

Part 4 - Python code skeleton

```
import torch

def validate_input(x, channels, minimum_hw):
    if x.ndim != 4 or x.shape[1] != channels:
        raise ValueError(...)
    if x.shape[-2] < minimum_hw[0] or x.shape[-1] < minimum_hw[1]:
        raise ValueError(...)

def E15(model, shapes, class_count):
    results = []
    model.eval()
    for shape in shapes:
        try:
            x = torch.randn(shape)
```

```
            validate_input(x, ..., ...)
            output = model(x)
            results.append({"shape": shape, "output": tuple(output.shape),
                            "finite": ...})
        except Exception as error:
            results.append({"shape": shape, "error": str(error)})
    return results
```

14.5.17 Exercise 16 - Create Unit Tests for Output Shapes and Dtypes at Every CNN Layer

Part 1 - Why this matters

Layer-level tests detect architectural regressions before training hides them behind slow failures. Shapes, data types, devices, and finite-value expectations form a practical forward contract.

Create parameterized tests for supported input sizes and precisions, capture intermediate outputs, and compare them with an expected specification. Include deliberately invalid inputs and verify informative failures.

Part 2 - Mathematical form

$$\forall l : \ \text{shape}(A_l) = S_l \wedge \text{dtype}(A_l) = D_l.$$

Part 3 - Hints and Helper

Test the architecture in evaluation mode and keep expected values independent of the implementation being tested.

Part 4 - Python code skeleton

```
import torch

def collect_layer_metadata(model, x):
    records, handles = {}, [...]
    model(x)
    for handle in handles: handle.remove()
    return records

def assert_contract(actual, expected):
    for name, contract in expected.items():
        assert actual[name]["shape"] == contract["shape"]
        assert actual[name]["dtype"] == contract["dtype"]
        assert actual[name]["finite"]

def E16(model, test_cases):
    for case in test_cases:
```

```
        actual = collect_layer_metadata(model, case["input"])
        assert_contract(actual, case["expected"])
    return True
```

14.5.18 Exercise 17 - Stress Test CNN Forward with Large Batches and Monitor GPU Memory Peaks

Part 1 - Why this matters

Increasing batch size improves parallel work until activation and workspace memory approach device capacity. A safe stress test must find practical limits without repeatedly destabilizing the CUDA process.

Increase batch size systematically, record latency, throughput, allocated memory, reserved memory, and failure point, and compare full precision with mixed precision under inference mode.

Part 2 - Mathematical form

$$M_{\text{peak}}(B) \approx M_{\text{fixed}} + B\, M_{\text{sample}}.$$

Part 3 - Hints and Helper

Reset peak statistics per trial and stop after the first out-of-memory result. Keep a safety margin below the largest successful batch.

Part 4 - Python code skeleton

```
import torch

def one_trial(model, batch_size, sample_shape, mixed):
    torch.cuda.reset_peak_memory_stats()
    x = torch.randn((batch_size, *sample_shape), device="cuda")
    with torch.inference_mode(), torch.autocast("cuda", enabled=mixed):
        output = model(x)
    return {"batch": batch_size,
            "peak": torch.cuda.max_memory_allocated(),
            "throughput": ..., "shape": tuple(output.shape)}

def E17(model, batch_sizes, sample_shape):
    results = []
    for batch_size in batch_sizes:
        try: results.append(one_trial(model, batch_size, sample_shape, ...))
        except torch.cuda.OutOfMemoryError:
            results.append({"batch": batch_size, "failed": True})
            break
    return results
```

14.5.19 Exercise 18 - Implement a Minimal CNN Inference Wrapper and Validate Preprocessing Requirements

Part 1 - Why this matters

An inference wrapper protects the model from malformed images and ensures that resizing, channel order, value range, normalization, device, and batch rules match training. Silent preprocessing drift can invalidate an otherwise correct model.

Create separate validation, preprocessing, inference, and formatting stages. Test valid images, wrong channels, non-finite values, unsupported sizes, and oversized batches with explicit error messages.

Part 2 - Mathematical form

$$\text{request} \to \text{validate} \to \text{preprocess} \to f_\theta \to \text{response}\,.$$

Part 3 - Hints and Helper

Store preprocessing configuration with the model version and run inference without gradient tracking.

Part 4 - Python code skeleton

```
import torch

class CNNInferenceWrapper:
    def __init__(self, model, config, device):
        self.model = model.to(device).eval()
        self.config = config
        self.device = device

    def validate(self, images):
        ...

    def preprocess(self, images):
        ...

    def predict(self, images):
        self.validate(images)
        batch = self.preprocess(images).to(self.device)
        with torch.inference_mode():
            logits = self.model(batch)
        return {"version": ..., "predictions": ...}

def E18(wrapper, test_cases):
    return [...]
```

14.5.20 Exercise 19 - Produce a CNN Forward Design Report Explaining Architecture Choices and Their Effects

Part 1 - Why this matters

A forward architecture is a chain of assumptions about locality, resolution, channels, normalization, regularization, and classifier structure. A design report makes these assumptions reviewable and connects them to measurable consequences.

Document the tensor trace, receptive-field progression, parameter and memory budget, non-linearities, normalization, downsampling, skip paths, supported inputs, CUDA behavior, precision limits, and known failure cases. Support choices with evidence from earlier exercises.

Part 2 - Mathematical form

$$\mathcal{D} = \{\text{shape}, \text{capacity}, \text{receptive field}, \text{latency}, \text{memory}, \text{robustness}\}.$$

Part 3 - Hints and Helper

For each architectural choice, state its purpose, alternative, measured effect, and verification test.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED_SECTIONS = [
    "Input Contract", "Shape Trace", "Feature Extractor",
    "Classifier Head", "Parameters and Memory", "CUDA and Precision",
    "Failure Modes", "Verification Checklist",
]

def validate_report(report, evidence):
    missing = []
    for section in REQUIRED_SECTIONS:
        if section not in report:
            missing.append(section)
    return {"missing": missing, "evidence_links": ..., "ready": ...}

def E19(experiment_records, output_path):
    report = ...
    checks = validate_report(report, experiment_records)
    Path(output_path).write_text(report, encoding="utf-8")
    return checks
```

14.6 CNN04 - CNN Training Loop, Loss, and Backpropagation

Models and Training

14.6.1 Exercise 00 - Build a Complete CNN Training Loop with Correct Train/Eval Modes and Loss Computation

Part 1 - Why this matters

A correct training loop coordinates model mode, device transfer, forward computation, scalar loss, gradient clearing, backward propagation, and parameter updates. Validation must disable gradient tracking and aggregate metrics over the complete dataset.

Implement separate training and evaluation functions. Weight accumulated loss by batch size, count correct predictions from logits, and verify that dropout and normalization receive the intended mode.

Part 2 - Mathematical form

$$\bar{L} = \frac{\sum_b n_b L_b}{\sum_b n_b}, \qquad \text{accuracy} = \frac{\sum_b \text{correct}_b}{\sum_b n_b}.$$

Part 3 - Hints and Helper

Call `zero_grad` before backward, never update during validation, and divide accumulated totals only after the loader finishes.

Part 4 - Python code skeleton

```
import torch

def run_epoch(model, loader, loss_fn, device, optimizer=None):
    training = optimizer is not None
    model.train(training)
    total_loss = total_correct = total_samples = 0
    context = torch.enable_grad() if training else torch.inference_mode()
    with context:
        for images, labels in loader:
            images, labels = images.to(device), labels.to(device)
            if training: optimizer.zero_grad(set_to_none=True)
            logits = model(images)
            loss = loss_fn(logits, labels)
            if training:
                loss.backward(); optimizer.step()
            batch_size = labels.shape[0]
            total_loss += ...
            total_correct += ...
            total_samples += batch_size
    return {"loss": ..., "accuracy": ...}

def E00(model, train_loader, val_loader, optimizer, loss_fn, device):
    return run_epoch(...), run_epoch(...)
```

14.6.2 Exercise 01 - Overfit a Tiny Dataset to Validate End-to-End CNN Correctness

Part 1 - Why this matters

A sufficiently expressive CNN should memorize a very small clean dataset. Failure to do so is a strong sign of a bug in labels, output shape, loss, gradients, optimizer order, preprocessing, or model capacity.

Select a fixed tiny subset, disable unnecessary regularization and augmentation, and train until loss approaches zero and accuracy approaches perfection. Record diagnostics if the target is not reached.

Part 2 - Mathematical form

$$\text{tiny-set accuracy} \to 100\%, \qquad L \to 0.$$

Part 3 - Hints and Helper

Use deterministic samples and inspect every label. This is a pipeline test, not evidence of generalization.

Part 4 - Python code skeleton

```
import torch

def E01(model, tiny_loader, optimizer, loss_fn, epochs, target_accuracy):
    history = []
    for epoch in range(epochs):
        metrics = ...
        history.append(metrics)
        if metrics["accuracy"] >= target_accuracy:
            break
    return {"passed": ..., "history": history,
            "final_parameters_finite": ...}
```

14.6.3 Exercise 02 - Compare CrossEntropyLoss and BCEWithLogitsLoss for Binary Image Classification

Part 1 - Why this matters

Binary classification can use two logits with integer class labels and cross-entropy, or one logit with floating binary targets and binary cross-entropy. Mixing output shapes, target encodings, or an extra sigmoid produces incorrect training.

Implement both valid formulations on the same batch, inspect loss and gradients, and map logits to class predictions correctly. Compare parameter count in the final layer without claiming the objectives are numerically identical.

Part 2 - Mathematical form

$$L_{\mathrm{BCE}} = -y \log \sigma(z) - (1-y)\log(1-\sigma(z)), \qquad L_{\mathrm{CE}} = -\log \mathrm{softmax}(z)_y.$$

Part 3 - Hints and Helper

Pass raw logits to both PyTorch losses. BCE targets must match the single-logit shape and use floating type.

Part 4 - Python code skeleton

```
import torch

def binary_formulation(features, labels, head):
    logits = head(features).squeeze(1)
    loss = torch.nn.BCEWithLogitsLoss()(logits, labels.float())
    predictions = (logits >= 0).long()
    return loss, predictions

def two_class_formulation(features, labels, head):
    logits = head(features)
    loss = torch.nn.CrossEntropyLoss()(logits, labels.long())
    return loss, logits.argmax(dim=1)

def E02(features, labels):
    return binary_formulation(...), two_class_formulation(...)
```

14.6.4 Exercise 03 - Inspect Layer-Wise Gradients and Detect Vanishing or Exploding Patterns

Part 1 - Why this matters

Layer-wise gradient statistics show whether the loss can influence early and late parameters. Extremely small norms may indicate blocked or vanishing paths, while rapidly growing or non-finite norms can destabilize updates.

After one backward pass, record norm, maximum magnitude, mean, zero fraction, and finite status for every trainable parameter. Compare layers and repeat across several steps to distinguish one noisy batch from a persistent pattern.

Part 2 - Mathematical form

$$g_l = \|\nabla_{\theta_l} L\|_2, \qquad r_l = g_l / (\|\theta_l\|_2 + \varepsilon).$$

Part 3 - Hints and Helper

Check for a missing gradient separately from a zero gradient. Log before optimizer.step and after backward.

Part 4 - Python code skeleton

```
import torch

def gradient_report(model):
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        report[name] = {"missing": gradient is None,
                        "norm": ... if gradient is not None else None,
                        "maximum": ...,
                        "finite": ...}
    return report

def E03(model, batch, loss_fn):
    model.zero_grad(set_to_none=True)
    loss = loss_fn(model(batch[0]), batch[1])
    loss.backward()
    return loss.item(), gradient_report(model)
```

14.6.5 Exercise 04 - Validate Backpropagation with Finite Differences on a Tiny CNN

Part 1 - Why this matters

Finite differences provide an independent numerical approximation of a selected derivative. Comparing them with autograd can expose detached tensors, wrong custom operations, and incorrect gradient assumptions.

Use a tiny float64 CNN and deterministic input, perturb selected parameter elements in both directions, and compare the central-difference estimate with autograd. Keep the network smooth around tested points.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial \theta_i} \approx \frac{L(\theta_i + \epsilon) - L(\theta_i - \epsilon)}{2\epsilon}.$$

Part 3 - Hints and Helper

Disable dropout, avoid ReLU points near zero, restore each parameter after perturbation, and choose epsilon appropriate for float64.

Part 4 - Python code skeleton

```
import torch

def finite_difference(model, loss_fn, inputs, targets, parameter, index, eps):
    original = parameter[index].item()
    with torch.no_grad(): parameter[index] = original + eps
    plus = loss_fn(model(inputs), targets).item()
    with torch.no_grad(): parameter[index] = original - eps
    minus = loss_fn(model(inputs), targets).item()
    with torch.no_grad(): parameter[index] = original
    return ...

def E04(model, inputs, targets, checks):
    model.zero_grad(); loss = ...; loss.backward()
    return [...]
```

14.6.6 Exercise 05 - Debug NaN Loss by Checking Inputs, Initialization, and Learning Rate

Part 1 - Why this matters

A non-finite loss is a symptom rather than a diagnosis. It may originate in corrupt inputs, unstable normalization, extreme initialization, invalid labels, excessive learning rate, or an earlier non-finite activation or gradient.

Build a diagnostic step that checks finite values at input, logits, loss, gradients, and updated parameters. Stop at the first failure and attach layer statistics so the root cause is localized.

Part 2 - Mathematical form

$$\text{finite}(X) \wedge \text{finite}(Z) \wedge \text{finite}(L) \wedge \text{finite}(\nabla L).$$

Part 3 - Hints and Helper

Never continue optimizer updates after a non-finite loss. Reproduce the failing batch before changing several settings at once.

Part 4 - Python code skeleton

```
import torch

def require_finite(name, tensor):
    if not torch.isfinite(tensor).all():
        raise FloatingPointError(name)

def diagnostic_step(model, batch, loss_fn, optimizer):
    images, labels = batch
    require_finite("images", images)
    optimizer.zero_grad(set_to_none=True)
```

```
    logits = model(images); require_finite("logits", logits)
    loss = loss_fn(logits, labels); require_finite("loss", loss)
    loss.backward()
    for name, parameter in model.named_parameters():
        if parameter.grad is not None: require_finite(name, parameter.grad)
    ...
    return ...

def E05(failing_cases):
    return [...]
```

14.6.7 Exercise 06 - Implement Gradient Clipping and Measure Its Stabilizing Effect

Part 1 - Why this matters

Gradient clipping limits an update when its norm or individual values become excessive. It can prevent a transient spike from destroying training, but constant clipping may hide a bad learning rate or unstable architecture.

Compare identical runs with and without global norm clipping. Record pre-clip norm, returned norm, post-clip norm, loss, and parameter change, then calculate how often clipping activates.

Part 2 - Mathematical form

$$g \leftarrow g \min\left(1, \frac{\tau}{\|g\|_2}\right).$$

Part 3 - Hints and Helper

Clip after backward and before optimizer.step. Diagnose the cause if nearly every step is clipped.

Part 4 - Python code skeleton

```
import torch

def train_step(model, batch, optimizer, loss_fn, threshold):
    optimizer.zero_grad(set_to_none=True)
    loss = loss_fn(model(batch[0]), batch[1])
    loss.backward()
    before = ...
    returned = torch.nn.utils.clip_grad_norm_(model.parameters(), threshold)
    after = ...
    optimizer.step()
    return {"loss": loss.item(), "before": before,
            "returned": returned.item(), "after": after,
```

```
            "clipped": ...}

def E06(controlled_runs):
    return {...}
```

14.6.8 Exercise 07 - Implement Learning Rate Scheduling and Verify Step Timing and Outcome

Part 1 - Why this matters

A scheduler changes the optimizer learning rate according to epoch, update, or validation behavior. Calling it at the wrong frequency or position produces a different schedule from the intended one.

Implement one epoch-based and one metric-based schedule. Log the learning rate used for every update and verify the trace against a manually calculated expectation.

Part 2 - Mathematical form

$$\eta_t = s(t, \eta_0, \text{metrics}), \qquad \theta_{t+1} = \theta_t - \eta_t g_t.$$

Part 3 - Hints and Helper

Decide whether scheduling occurs before or after an optimizer step based on the scheduler contract, and resume its state from checkpoints.

Part 4 - Python code skeleton

```
import torch

def E07(model, loader, optimizer, scheduler, loss_fn, epochs):
    history = []
    for epoch in range(epochs):
        learning_rate_used = optimizer.param_groups[0]["lr"]
        train_metrics = ...
        validation_metrics = ...
        if isinstance(scheduler, torch.optim.lr_scheduler.ReduceLROnPlateau):
            scheduler.step(...)
        else:
            scheduler.step()
        history.append({
            "epoch": epoch,
            "lr": learning_rate_used,
            "train": train_metrics,
            "validation": validation_metrics,
        })
    return history, ...
```

14.6.9 Exercise 08 - Compare SGD and Adam on the Same CNN and Explain Outcome Differences

Part 1 - Why this matters

SGD applies one shared learning-rate scale, while Adam normalizes updates using running first and second moments. Their early speed, final generalization, memory cost, and sensitivity to hyperparameters can differ.

Run controlled experiments from identical initial weights and data order. Compare loss, accuracy, gradient and update norms, runtime, optimizer-state memory, and final validation behavior.

Part 2 - Mathematical form

$$\text{SGD} : \Delta\theta = -\eta g, \qquad \text{Adam} : \Delta\theta = -\eta \frac{\widehat{m}}{\sqrt{\widehat{v}} + \epsilon}.$$

Part 3 - Hints and Helper

Clone the model state before constructing optimizers and tune learning rates fairly instead of forcing identical values.

Part 4 - Python code skeleton

```
import copy
import torch

def controlled_run(model, loader, optimizer_factory, seed):
    torch.manual_seed(seed)
    optimizer = optimizer_factory(model.parameters())
    history = ...
    state_bytes = ...
    return {"history": history, "state_bytes": state_bytes,
            "final_state": copy.deepcopy(model.state_dict())}

def E08(base_model, loader):
    sgd_model = copy.deepcopy(base_model)
    adam_model = copy.deepcopy(base_model)
    sgd_results = controlled_run(sgd_model, loader, ...)
    adam_results = controlled_run(adam_model, loader, ...)
    return sgd_results, adam_results
```

14.6.10 Exercise 09 - Debug Training Where Loss Improves but Accuracy Does Not Improve

Part 1 - Why this matters

Loss can decrease while accuracy remains unchanged because confidence improves without crossing class boundaries. It can also signal wrong target encoding, metric logic, thresholding, class imbalance, or mismatched sample aggregation.

Inspect logits, predictions, labels, confusion matrix, confidence, per-class loss, and metric code on a fixed batch. Recalculate accuracy manually and test whether decision thresholds or label mappings are correct.

Part 2 - Mathematical form

$$\widehat{y} = \arg\max_k z_k, \qquad \text{accuracy} = N^{-1} \sum_i \mathbf{1}[\widehat{y}_i = y_i].$$

Part 3 - Hints and Helper

Confirm that loss and metric consume the same semantic task. Aggregate correct counts and sample counts, not unweighted batch accuracies.

Part 4 - Python code skeleton

```
import torch

def diagnostic_metrics(logits, labels):
    predictions = logits.argmax(dim=1)
    confusion = ...
    return {"accuracy": ...,
            "confidence": logits.softmax(dim=1).amax(dim=1),
            "confusion": confusion,
            "predictions": predictions}

def E09(model, fixed_batch, loss_fn):
    logits = model(fixed_batch[0])
    loss = loss_fn(logits, fixed_batch[1])
    report = diagnostic_metrics(logits, fixed_batch[1])
    return loss.item(), report, ...
```

14.6.11 Exercise 10 - Train CNN on CUDA with Correct DataLoader Transfer and Pinned Memory

Part 1 - Why this matters

Efficient CUDA training requires model placement, pinned host buffers, non-blocking copies, and enough input-pipeline throughput. Pinning does not move data to the GPU and may not help when the source or workload is unsuitable.

Configure a DataLoader, transfer each batch to the selected device, and verify parameter, buffer, input, target, and output devices. Benchmark blocking and non-blocking paths under controlled settings.

Part 2 - Mathematical form

$$X_{\text{CPU,pinned}} \xrightarrow{\text{non-blocking}} X_{\text{CUDA}}.$$

Part 3 - Hints and Helper

Enable `pin_memory` only for CUDA use, and measure a full pipeline rather than timing an asynchronous copy without synchronization.

Part 4 - Python code skeleton

```
import torch

def cuda_epoch(model, loader, optimizer, loss_fn, device):
    model.train()
    for images, labels in loader:
        images = images.to(device, non_blocking=True)
        labels = labels.to(device, non_blocking=True)
        optimizer.zero_grad(set_to_none=True)
        logits = model(images)
        loss = loss_fn(logits, labels)
        loss.backward(); optimizer.step()
        assert logits.device == device
    return ...

def E10(dataset, model):
    loader = torch.utils.data.DataLoader(dataset, batch_size=...,
        shuffle=True, num_workers=..., pin_memory=True)
    return cuda_epoch(model.cuda(), loader, ..., ..., torch.device("cuda"))
```

14.6.12 Exercise 11 - Profile GPU Utilization and Fix Training Under-Utilization Bottlenecks

Part 1 - Why this matters

Low utilization may come from slow loading, CPU augmentation, small batches, synchronization, or insufficient computation. The correct fix depends on whether time is spent waiting for data, forward, backward, or optimizer work.

Instrument the training step into data-wait and compute intervals, profile representative batches, and change one pipeline factor at a time. Report throughput and utilization before and after the measured fix.

Part 2 - Mathematical form

$$t_{\text{step}} = t_{\text{data}} + t_{\text{transfer}} + t_{\text{forward}} + t_{\text{backward}} + t_{\text{update}}.$$

Part 3 - Hints and Helper

Warm up first and avoid unnecessary item calls or synchronizations inside the hot loop.

Part 4 - Python code skeleton

```
import time
import torch

def profiled_epoch(model, loader, optimizer, loss_fn):
    records = []
    previous_end = time.perf_counter()
    for images, labels in loader:
        data_wait = time.perf_counter() - previous_end
        ...
        records.append({"data_wait": data_wait,
                        "transfer": ..., "forward": ...,
                        "backward": ..., "update": ...})
        previous_end = time.perf_counter()
    return records

def E11(configurations):
    return [...]
```

14.6.13 Exercise 12 - Implement Mixed Precision CNN Training and Detect Silent Overflow or Underflow

Part 1 - Why this matters

Autocast selects lower precision for suitable operations, while gradient scaling protects small gradients from underflow. A skipped optimizer update or falling scale may reveal overflow even when no visible exception occurs.

Implement mixed precision with the current PyTorch scaling API, log scale changes, skipped steps, finite gradients, memory, and throughput, and compare training quality with float32.

Part 2 - Mathematical form

$$L_s = sL, \qquad \nabla L = s^{-1}\nabla L_s.$$

Part 3 - Hints and Helper

Unscale before clipping or gradient inspection. Check whether the optimizer actually advanced when overflow is detected.

Part 4 - Python code skeleton

```
import torch

def mixed_step(model, batch, optimizer, loss_fn, scaler):
```

```
    optimizer.zero_grad(set_to_none=True)
    old_scale = scaler.get_scale()
    with torch.autocast("cuda", dtype=torch.float16):
        loss = loss_fn(model(batch[0]), batch[1])
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_finite = ...
    scaler.step(optimizer); scaler.update()
    new_scale = scaler.get_scale()
    return {"loss": loss.item(), "old_scale": old_scale,
            "new_scale": new_scale, "possible_skip": ...,
            "gradient_finite": gradient_finite}

def E12(training_inputs):
    return [...]
```

14.6.14 Exercise 13 - Validate Determinism Options and Explain CNN Training Non-Determinism

Part 1 - Why this matters

Reproducible CNN training depends on seeds, data order, augmentation workers, dropout, backend algorithms, floating-point reduction order, and hardware. One seed does not control all sources.

Run repeated experiments under strict and relaxed settings, compare batches, initial states, losses, final parameters, and metrics, and record the environment and performance cost of deterministic algorithms.

Part 2 - Mathematical form

$$\Delta_\theta = \max_i |\theta_i^{(1)} - \theta_i^{(2)}|.$$

Part 3 - Hints and Helper

Control DataLoader generators and worker seeds, and distinguish repeatability on one system from reproducibility across systems.

Part 4 - Python code skeleton

```
import random
import torch

def configure(seed, deterministic):
    random.seed(seed); torch.manual_seed(seed)
    torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(deterministic)
```

```
    ...

def one_run(seed, deterministic, factory, loader_factory):
    configure(seed, deterministic)
    model = factory().cuda()
    history = ...
    return history, {k: v.cpu() for k, v in model.state_dict().items()}

def E13(repeats, seed):
    runs = [one_run(seed, True, ..., ...) for _ in range(repeats)]
    return {...}
```

14.6.15 Exercise 14 - Implement Checkpoint Resume with Optimizer and Scheduler State Preservation

Part 1 - Why this matters

A training checkpoint must preserve more than model weights. Optimizer moments, scheduler position, scaler state, epoch, best metric, and random states influence whether resumed training continues consistently.

Save atomically, load into freshly constructed objects, restore all states, and compare a continuous run with an interrupted-and-resumed run. Validate keys and devices before continuing.

Part 2 - Mathematical form

$$C_t = (\theta_t, O_t, S_t, G_t, R_t, t).$$

Part 3 - Hints and Helper

Write to a temporary path and rename after success. Call optimizer state loading after constructing it for the restored model.

Part 4 - Python code skeleton

```
import torch

def save_checkpoint(path, model, optimizer, scheduler, scaler, epoch):
    state = {"model": model.state_dict(),
             "optimizer": optimizer.state_dict(),
             "scheduler": scheduler.state_dict(),
             "scaler": scaler.state_dict() if scaler else None,
             "epoch": epoch, "rng": torch.get_rng_state(),
             "cuda_rng": torch.cuda.get_rng_state_all()}
    temporary = str(path) + ".tmp"
    torch.save(state, temporary)
    ...
```

```
def load_checkpoint(path, model, optimizer, scheduler, scaler):
    state = torch.load(path, map_location=...)
    ...
    return state["epoch"]

def E14(continuous_run, resumed_run):
    return {...}
```

14.6.16 Exercise 15 - Benchmark Training Throughput Across Batch Sizes and Find the Best Trade-Off

Part 1 - Why this matters

Larger batches can improve GPU utilization and samples per second but consume more memory and change gradient noise. The throughput-optimal batch may not provide the best convergence or validation result.

Benchmark forward, backward, and update time after warm-up across feasible batch sizes. Record peak memory, throughput, loss progress per sample, and failure point, then select according to an explicit objective.

Part 2 - Mathematical form

$$\text{throughput}(B) = B/t_{\text{step}}(B), \qquad \text{efficiency} = \text{throughput}/M_{\text{peak}}.$$

Part 3 - Hints and Helper

Keep model, precision, workers, and input shape fixed. Synchronize CUDA timing and leave memory headroom.

Part 4 - Python code skeleton

```
import torch

def benchmark_batch(model, batch_size, sample_shape, repeats):
    torch.cuda.reset_peak_memory_stats()
    times = []
    for _ in range(repeats):
        batch = ...
        torch.cuda.synchronize(); start = ...
        ...
        torch.cuda.synchronize(); times.append(...)
    return {"batch": batch_size, "throughput": ...,
            "peak_memory": torch.cuda.max_memory_allocated(),
            "median_step": ...}

def E15(batch_sizes):
    results = []
```

```
    for size in batch_sizes:
        try: results.append(benchmark_batch(...))
        except torch.cuda.OutOfMemoryError: break
    return results, ...
```

14.6.17 Exercise 16 - Implement Gradient Accumulation for Memory-Constrained Large-Batch Training

Part 1 - Why this matters

Gradient accumulation divides one effective batch into micro-batches and delays the optimizer update. Correct scaling must preserve a sample-weighted mean, especially when the final micro-batch has a different size.

Compare one full-batch step with accumulated micro-batches from cloned models. Disable stochastic and batch-dependent differences during strict equivalence testing, then measure memory savings.

Part 2 - Mathematical form

$$g_{\text{eff}} = \sum_k \frac{n_k}{\sum_j n_j} g_k.$$

Part 3 - Hints and Helper

Clear gradients once per effective batch and update once after all contributions. Weight by samples rather than blindly dividing by micro-batch count.

Part 4 - Python code skeleton

```
import torch

def accumulated_step(model, micro_batches, optimizer, loss_fn):
    optimizer.zero_grad(set_to_none=True)
    total_samples = sum(labels.shape[0] for _, labels in micro_batches)
    for images, labels in micro_batches:
        loss = loss_fn(model(images), labels)
        scaled_loss = loss * labels.shape[0] / total_samples
        scaled_loss.backward()
    optimizer.step()
    return ...

def E16(base_model, full_batch, micro_batches):
    full_model = ...
    accumulated_model = ...
    ...
    return {"parameter_error": ..., "gradient_error": ...,
            "memory_reduction": ...}
```

14.6.18 Exercise 17 - Build Debug Mode That Saves Misclassified Images and Confidence Scores

Part 1 - Why this matters

Aggregate metrics reveal that errors exist but not what the model is confusing. Saving misclassified samples with labels, predictions, confidence, and identifiers supports visual and subgroup analysis.

Create an evaluation-only debug mode that reverses display normalization, limits storage, avoids duplicates, and writes metadata beside image artifacts. Group errors by true and predicted class.

Part 2 - Mathematical form

$$c_i = \max_k \operatorname{softmax}(z_i)_k, \qquad \mathcal{E} = \{i : \widehat{y}_i \neq y_i\}.$$

Part 3 - Hints and Helper

Preserve sample identifiers and never use augmented training views as if they were original evidence unless explicitly marked.

Part 4 - Python code skeleton

```
from pathlib import Path
import torch

def collect_errors(model, loader, device, maximum):
    model.eval(); errors = []
    with torch.inference_mode():
        for images, labels, identifiers in loader:
            logits = model(images.to(device))
            probabilities = logits.softmax(dim=1)
            predictions = probabilities.argmax(dim=1)
            for index in torch.nonzero(predictions.cpu() != labels).flatten():
                errors.append({...})
                if len(errors) >= maximum: return errors
    return errors

def E17(model, loader, output_directory):
    errors = collect_errors(model, loader, ..., ...)
    Path(output_directory).mkdir(...)
    ...
    return errors
```

14.6.19 Exercise 18 - Validate Training by Reaching Near-Perfect Accuracy on a Simple Synthetic Task

Part 1 - Why this matters

A synthetic task with a known visual rule isolates the learning pipeline from uncertain real data. A small CNN should solve a clean separable pattern task; failure indicates an implementation or optimization problem.

Generate labeled images from a deterministic rule, split without leakage, train, and require near-perfect train and validation accuracy. Add controlled noise only after the clean task succeeds.

Part 2 - Mathematical form

$$y = \mathbf{1}[\text{known pattern is present in } X].$$

Part 3 - Hints and Helper

Visualize samples and verify labels before training. Keep train and validation generators independent.

Part 4 - Python code skeleton

```
import torch

def make_synthetic_dataset(count, image_size, seed):
    generator = torch.Generator().manual_seed(seed)
    images = torch.zeros(...)
    labels = torch.randint(..., generator=generator)
    for index, label in enumerate(labels):
        if label == 1: ...
        else: ...
    return torch.utils.data.TensorDataset(images, labels)

def E18(model_factory):
    train_data = make_synthetic_dataset(..., seed=...)
    validation_data = make_synthetic_dataset(..., seed=...)
    model = model_factory()
    history = ...
    return {"history": history, "passed": ...,
            "train_accuracy": ..., "validation_accuracy": ...}
```

14.6.20 Exercise 19 - Produce a Full CNN Training Debugging Playbook Covering Common Failure Scenarios

Part 1 - Why this matters

CNN training failures span data, shapes, losses, gradients, optimization, precision, performance, reproducibility, checkpointing, and evaluation. A playbook converts these recurring failures into an ordered diagnostic process.

Write symptom-driven procedures for no learning, NaN loss, low accuracy, overfitting, vanishing or exploding gradients, CUDA under-utilization, out-of-memory, mixed-precision skips, nondeterminism, and resume drift. Link each procedure to evidence from earlier exercises.

Part 2 - Mathematical form

$$\text{symptom} \rightarrow \text{measurement} \rightarrow \text{hypothesis} \rightarrow \text{controlled test} \rightarrow \text{fix} \rightarrow \text{regression test}.$$

Part 3 - Hints and Helper

Begin with one batch and one tiny dataset before tuning the full run. Every fix needs a test that would detect recurrence.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED = ["Data", "Forward Pass", "Loss", "Gradients", "Optimizer",
            "CUDA", "Mixed Precision", "Checkpoints", "Evaluation",
            "Reproducibility", "Regression Tests"]

def validate_playbook(text, evidence):
    missing = [name for name in REQUIRED if name not in text]
    return {"missing": missing, "evidence_links": ...,
            "ready": len(missing) == 0 and ...}

def E19(experiment_records, output_path):
    playbook = ...
    checks = validate_playbook(playbook, experiment_records)
    Path(output_path).write_text(playbook, encoding="utf-8")
    return checks
```

14.7 CNN05 - Data Pipeline and Augmentation for Vision

Models and Training

14.7.1 Exercise 00 - Implement Image Dataset Loading with Correct Normalization and Tensor Conversion

Part 1 - Why this matters

Image loading must produce consistent channel-first floating tensors, labels, and identifiers. Incorrect ranges, channel order, alpha handling, or normalization can silently change the learning problem.

Build a Dataset that decodes files, validates image mode and size, converts values to a documented range, and applies channel-wise normalization. Test grayscale, RGB, corrupt, and unusual-sized samples.

Part 2 - Mathematical form

$$X'_{c,h,w} = \frac{X_{c,h,w} - \mu_c}{\sigma_c}.$$

Part 3 - Hints and Helper

Calculate statistics from training data only and return a stable sample identifier for debugging.

Part 4 - Python code skeleton

```
class ImageDataset(torch.utils.data.Dataset):
    def __init__(self, records, transform): ...
    def __len__(self): return ...
    def __getitem__(self, index):
        image, label, identifier = ...
        tensor = ...
        if tensor.ndim != 3: raise ValueError(...)
        return tensor, label, identifier

def E00(records):
    dataset = ImageDataset(records, ...)
    return dataset, [...\]
```

14.7.2 Exercise 01 - Validate Channel Ordering and Normalization by Visualizing a Preprocessed Batch

Part 1 - Why this matters

A tensor may have the expected shape while its colors or scale are wrong. Visual inspection after reversing normalization exposes swapped channels, clipping, unexpected value ranges, and transforms that destroy semantic content.

Load one batch, report per-channel statistics, denormalize a copy, convert it to display layout, and create a labeled grid. Verify that displayed images correspond to their source identifiers.

Part 2 - Mathematical form

$$X_{\text{display}} = \text{clip}(X'\sigma + \mu, 0, 1).$$

Part 3 - Hints and Helper

Never modify the training batch in place during denormalization, and permute from channel-first to channel-last for display.

Part 4 - Python code skeleton

```
def denormalize(batch, mean, std):
    mean = batch.new_tensor(mean).view(1, -1, 1, 1)
    std = batch.new_tensor(std).view(1, -1, 1, 1)
    return ...

def E01(batch, labels, identifiers, mean, std):
    restored = denormalize(batch.clone(), mean, std)
    statistics = {...}
    figure = ...
    return figure, statistics
```

14.7.3 Exercise 02 - Implement Train and Test Splits and Confirm No Data Leakage

Part 1 - Why this matters

Leakage occurs when the same source, duplicate, subject, time group, or derived image appears across splits. It creates optimistic evaluation even when file names differ.

Split with a fixed seed and group-aware rule, then compare identifiers, content hashes, and relevant metadata across partitions. Fit normalization and augmentation decisions from the training split only.

Part 2 - Mathematical form

$$D_{\text{train}} \cap D_{\text{test}} = \varnothing.$$

Part 3 - Hints and Helper

Define the leakage unit before splitting; for medical or video data it may be a patient or sequence rather than one image.

Part 4 - Python code skeleton

```
def split_records(records, test_fraction, seed, group_key):
    groups = ...
    train_groups, test_groups = ...
    return ..., ...

def leakage_report(train_records, test_records):
    id_overlap = ...
    hash_overlap = ...
```

```
    group_overlap = ...
    return {"ids": id_overlap, "hashes": hash_overlap,
            "groups": group_overlap, "passed": ...}

def E02(records):
    train, test = split_records(records, ..., ..., ...)
    return train, test, leakage_report(train, test)
```

14.7.4 Exercise 03 - Implement Random Crop and Horizontal Flip and Measure Generalization Impact

Part 1 - Why this matters

Crop and flip encode assumptions that partial views and horizontal reflection should preserve the label. They can improve generalization only when those transformations are valid for the dataset.

Implement stochastic transforms for training and deterministic preprocessing for validation. Compare controlled runs, visualize transformed samples, and measure accuracy and failure categories.

Part 2 - Mathematical form

$$\widetilde{X} = T(X), \qquad y(T(X)) = y(X) \text{ must be a valid assumption.}$$

Part 3 - Hints and Helper

Seed comparison runs, keep the validation pipeline fixed, and check classes whose meaning changes under reflection.

Part 4 - Python code skeleton

```
def build_transforms(training):
    if training:
        return ...  # crop, flip, tensor, normalize
    return ...      # deterministic resize, tensor, normalize

def E03(dataset, seeds):
    baseline = ...
    augmented = ...
    examples = ...
    return {"baseline": baseline, "augmented": augmented,
            "examples": examples, "difference": ...}
```

14.7.5 Exercise 04 - Implement Color Jitter and Analyze When It Helps or Hurts Specific Datasets

Part 1 - Why this matters

Color jitter changes brightness, contrast, saturation, or hue and can discourage reliance on incidental lighting. It harms tasks where exact color is a label-defining signal or when transformed colors become unrealistic.

Apply controlled jitter strengths to color-dependent and color-invariant tasks. Inspect class-conditional examples and compare clean accuracy, shifted-light accuracy, calibration, and confusion patterns.

Part 2 - Mathematical form

$$\widetilde{X} = T_{b,c,s,h}(X).$$

Part 3 - Hints and Helper

Begin with plausible parameter ranges and test one color component at a time before combining them.

Part 4 - Python code skeleton

```
def color_jitter_experiment(dataset, strengths, seed):
    results = []
    for strength in strengths:
        transform = ...
        examples = ...
        metrics = ...
        results.append({"strength": strength, "metrics": metrics,
                        "examples": examples})
    return results

def E04(datasets):
    return {...}
```

14.7.6 Exercise 05 - Implement Random Rotation and Analyze Its Effect on Model Invariance

Part 1 - Why this matters

Rotation is appropriate when object identity is orientation-independent, but it can change labels for digits, directional signs, text, or gravity-dependent scenes. Interpolation and empty corners also introduce artifacts.

Compare rotation ranges and fill strategies on tasks with different orientation semantics. Measure accuracy by angle and inspect whether artifacts rather than objects become predictive.

Part 2 - Mathematical form

$$T_\theta(X)(p) = X(R_{-\theta}p).$$

Part 3 - Hints and Helper

Use label-preserving angles, document interpolation, and visualize boundary artifacts before training.

Part 4 - Python code skeleton

```
def rotation_suite(image, angles, interpolation, fill):
    outputs = []
    for angle in angles:
        outputs.append((angle, ...))
    return outputs

def E05(train_data, validation_by_angle):
    model = ...
    history = ...
    angle_metrics = {...}
    return history, angle_metrics, rotation_suite(...)
```

14.7.7 Exercise 06 - Implement Random Erasing or Cutout and Evaluate Its Regularization Effect

Part 1 - Why this matters

Random erasing hides a region and encourages the model to use distributed evidence rather than one highly predictive patch. Excessive occlusion can remove the object or create unrealistic training samples.

Implement area and aspect-ratio sampling, visualize masks, and compare robustness to occlusion with clean accuracy. Track how often the erased region overlaps the task-defining feature in synthetic data.

Part 2 - Mathematical form

$$\widetilde{X} = X \odot (1 - M) + vM.$$

Part 3 - Hints and Helper

Bound the number of sampling attempts and preserve the original image when no valid rectangle is found.

Part 4 - Python code skeleton

```
def random_erasing(image, generator, scale, ratio, fill):
    height, width = image.shape[-2:]
    for _ in range(...):
        erase_h, erase_w = ...
        if erase_h < height and erase_w < width:
            output = image.clone(); output[..., ...\] = fill
            return output, ...
    return image, None

def E06(dataset):
    return {"examples": ..., "clean_metric": ...,
            "occlusion_metric": ...}
```

14.7.8 Exercise 07 - Implement MixUp or CutMix and Compare with Standard Augmentation

Part 1 - Why this matters

MixUp combines images and soft labels globally, while CutMix inserts one image region into another and weights labels by visible area. Both change the target representation and therefore require compatible loss computation.

Implement one method, verify lambda and label mixing, visualize batches, and compare calibration, robustness, and accuracy with standard augmentation under the same training budget.

Part 2 - Mathematical form

$$\widetilde{X} = \lambda X_a + (1-\lambda)X_b, \quad \widetilde{y} = \lambda y_a + (1-\lambda)y_b.$$

Part 3 - Hints and Helper

Apply the same permutation to images and labels, and recompute CutMix lambda from the clipped rectangle area.

Part 4 - Python code skeleton

```
def mixup(images, labels, alpha, generator):
    permutation = ...
    lam = ...
    mixed_images = ...
    return mixed_images, labels, labels[permutation], lam

def mixed_loss(loss_fn, logits, y_a, y_b, lam):
    return ...

def E07(batch):
    mixed = mixup(*batch, ..., ...)
    return mixed, ...
```

14.7.9 Exercise 08 - Optimize DataLoader with num_workers and pin_memory and Benchmark It

Part 1 - Why this matters

Worker count, persistent workers, prefetching, pinning, storage speed, and transform cost determine whether data arrives before the GPU needs it. More workers can eventually add contention instead of speed.

Benchmark complete epochs across controlled DataLoader configurations. Record throughput, startup time, steady-state batch wait, CPU memory, failures, and GPU idle time.

Part 2 - Mathematical form

$$\text{loader throughput} = N_{\text{samples}}/t_{\text{epoch}}.$$

Part 3 - Hints and Helper

Run multiple epochs to separate worker startup from steady state, and change one setting at a time.

Part 4 - Python code skeleton

```
def benchmark_loader(dataset, config, epochs):
    loader = torch.utils.data.DataLoader(dataset, **config)
    epoch_times, batch_waits = [], []
    for epoch in range(epochs):
        start = ...
        for batch in loader: ...
        epoch_times.append(...)
    return {"config": config, "epoch_times": epoch_times,
            "throughput": ..., "batch_waits": batch_waits}

def E08(dataset, configurations):
    return [benchmark_loader(dataset, c, ...) for c in configurations]
```

14.7.10 Exercise 09 - Debug Data Pipeline Bugs Causing Wrong Labels or Broken Image Tensors

Part 1 - Why this matters

A pipeline may pair images with wrong labels, normalize twice, return inconsistent shapes, mutate cached samples, or fail only on one corrupt record. Batch-level errors often hide the responsible source item.

Add validation at dataset and collate boundaries, preserve identifiers, and build a debug loader that isolates failing samples. Check label range, tensor contract, determinism expectations, and image-label correspondence.

Part 2 - Mathematical form

$$\text{valid}(x, y) = \text{shape ok} \wedge \text{finite}(x) \wedge y \in \{0, \ldots, K-1\}.$$

Part 3 - Hints and Helper

Inspect samples with shuffling disabled first and report the exact index and path on failure.

Part 4 - Python code skeleton

```
def validate_sample(sample, class_count):
    image, label, identifier = sample
    if image.ndim != 3 or not torch.isfinite(image).all():
        raise ValueError(identifier)
    if not 0 <= int(label) < class_count: raise ValueError(identifier)
    return True

def E09(dataset, class_count):
    failures = []
    for index in range(len(dataset)):
        try: validate_sample(dataset[index], class_count)
        except Exception as error: failures.append({...})
    return failures
```

14.7.11 Exercise 10 - Move the Data Pipeline to CUDA Efficiently and Measure Transfer Overhead

Part 1 - Why this matters

Input tensors normally remain on CPU until each batch is transferred. Efficient overlap requires pinned memory, non-blocking copies, suitable batch sizes, and enough compute to hide transfer latency.

Measure synchronous and asynchronous host-to-device paths with correct synchronization. Separate decoding, collation, transfer, and model time and verify that targets and inputs reach the same device.

Part 2 - Mathematical form

$$t_{\text{step}} = t_{\text{load}} + t_{\text{H2D}} + t_{\text{compute}} - t_{\text{overlap}}.$$

Part 3 - Hints and Helper

Never time an asynchronous copy without synchronizing its completion, and avoid moving data to CUDA inside worker processes.

Part 4 - Python code skeleton

```
def transfer_batch(batch, device, non_blocking):
    images, labels = batch
    return (images.to(device, non_blocking=non_blocking),
            labels.to(device, non_blocking=non_blocking))

def benchmark_transfer(loader, device, non_blocking):
    records = []
    for batch in loader:
        torch.cuda.synchronize(); start = ...
        moved = transfer_batch(batch, device, non_blocking)
        torch.cuda.synchronize(); records.append(...)
    return {...}

def E10(loader): return benchmark_transfer(...), benchmark_transfer(...)
```

14.7.12 Exercise 11 - Implement Prefetching and Compare It with a Baseline DataLoader

Part 1 - Why this matters

Prefetching prepares a future batch while the current batch is being computed, reducing visible data wait when transfer and compute can overlap. Incorrect stream synchronization can expose incomplete tensors or add overhead.

Implement a CUDA prefetcher with a dedicated stream, compare it with the same baseline loader, and verify output parity, ordering, throughput, and memory.

Part 2 - Mathematical form

$$t_{\text{pipeline}} \approx \max(t_{\text{prepare}}, t_{\text{compute}}) \text{ under effective overlap.}$$

Part 3 - Hints and Helper

Make the current stream wait for the prefetch stream before consuming a batch and benchmark after warm-up.

Part 4 - Python code skeleton

```
class CUDAPrefetcher:
    def __init__(self, loader, device):
        self.iterator = iter(loader); self.device = device
        self.stream = torch.cuda.Stream(); self.next_batch = None
        self.preload()
    def preload(self): ...
    def next(self): ...
```

```
def E11(loader, model):
    baseline = ...
    prefetched = ...
    return {"baseline": baseline, "prefetched": prefetched,
            "parity": ...}
```

14.7.13 Exercise 12 - Analyze Image Resolution Trade-Offs in Accuracy, Speed, and GPU Memory

Part 1 - Why this matters

Higher resolution can preserve small objects and fine boundaries but increases activation area, computation, transfer, and memory. Resizing may also distort aspect ratio or remove details before the model sees them.

Train or evaluate controlled resolution variants, recording accuracy by object size, throughput, peak memory, and preprocessing cost. Keep architecture adaptation and crop policy explicit.

Part 2 - Mathematical form

$$\text{activation area} \propto HW, \qquad \text{conv cost} \propto HWC_{\text{in}}C_{\text{out}}K^2.$$

Part 3 - Hints and Helper

Use the same split and evaluation protocol and inspect small-object failures rather than reporting only overall accuracy.

Part 4 - Python code skeleton

```
def resolution_experiment(resolution, model_factory, loaders):
    model = model_factory(resolution)
    history = ...
    torch.cuda.reset_peak_memory_stats()
    metrics = ...
    return {"resolution": resolution, "metrics": metrics,
            "throughput": ..., "peak_memory": ...,
            "small_object_metric": ...}

def E12(resolutions):
    return [resolution_experiment(r, ..., ...) for r in resolutions]
```

14.7.14 Exercise 13 - Detect Augmentation Bugs That Destroy Class Semantics or Introduce Label Noise

Part 1 - Why this matters

An augmentation is valid only if the transformed sample still supports its assigned target. Direction changes, cropped-away objects, impossible colors, or geometric label mismatches can silently inject supervision errors.

Define class-specific invariance rules, run deterministic transform audits, and compare labels before and after transformations using metadata or synthetic ground truth. Save violations for review.

Part 2 - Mathematical form

$$y(T(X)) = y(X) \text{ is an assumption that must be tested.}$$

Part 3 - Hints and Helper

Audit each transform alone before composing it, and record random parameters so failures can be reproduced.

Part 4 - Python code skeleton

```
def audit_transform(sample, transform, semantic_validator, trials):
    violations = []
    for trial in range(trials):
        transformed, parameters = ...
        if not semantic_validator(sample, transformed, parameters):
            violations.append({...})
    return violations

def E13(dataset, transform_specs):
    report = {}
    for name, transform in transform_specs.items():
        report[name] = [...\]
    return report
```

14.7.15 Exercise 14 - Implement Balanced Sampling for Imbalanced Image Datasets

Part 1 - Why this matters

Random sampling follows the observed class distribution and may provide few minority examples per epoch. Weighted sampling can rebalance exposure, but it does not create new information and may increase overfitting to repeated minority samples.

Compute sample weights from training labels, build a weighted sampler, and compare observed batch and epoch distributions. Evaluate per-class recall and duplication frequency rather than only overall accuracy.

Part 2 - Mathematical form

$$w_i \propto 1/n_{y_i}.$$

Part 3 - Hints and Helper

Calculate weights from the training split only and decide whether sampling is with replacement.

Part 4 - Python code skeleton

```
def sample_weights(labels):
    counts = torch.bincount(labels)
    class_weights = ...
    return class_weights[labels]

def E14(dataset, labels, batch_size):
    weights = sample_weights(labels)
    sampler = torch.utils.data.WeightedRandomSampler(... )
    loader = torch.utils.data.DataLoader(dataset, batch_size=batch_size,
                                         sampler=sampler)
    observed = ...
    return loader, {"expected": ..., "observed": observed,
                    "duplication": ...}
```

14.7.16 Exercise 15 - Build an Augmentation Ablation Study and Identify What Actually Helps

Part 1 - Why this matters

Combining many augmentations can improve, harm, or mask each other's effects. An ablation study isolates contributions under a shared training budget and prevents conclusions based on one lucky run.

Define a baseline and controlled additions or removals, repeat seeds, and report mean and variation for clean, shifted, and per-class metrics. Preserve exact configurations and transformed examples.

Part 2 - Mathematical form

$$\Delta_m = q(\mathcal{T}) - q(\mathcal{T} \setminus \{m\}).$$

Part 3 - Hints and Helper

Change one planned factor per comparison and keep validation preprocessing identical for all runs.

Part 4 - Python code skeleton

```
def controlled_run(config, seed):
    model = ...; history = ...; metrics = ...
    return {"config": config, "seed": seed,
            "history": history, "metrics": metrics}

def E15(configurations, seeds):
    records = []
    for config in configurations:
        for seed in seeds:
            records.append(controlled_run(config, seed))
    summary = ...
    return records, summary
```

14.7.17 Exercise 16 - Compare Per-Dataset and Per-Image Normalization Strategies

Part 1 - Why this matters

Per-dataset normalization preserves relative brightness differences using training-set statistics. Per-image normalization removes each image's global scale and may help some acquisition shifts while destroying absolute intensity information.

Implement both strategies with numerical safeguards and compare channel distributions, accuracy, calibration, and performance under lighting shifts. Prevent validation statistics from influencing dataset normalization.

Part 2 - Mathematical form

$$X'_{\text{dataset}} = (X - \mu_D)/\sigma_D, \qquad X'_{\text{image}} = (X - \mu_X)/(\sigma_X + \varepsilon).$$

Part 3 - Hints and Helper

State the axes used for statistics and handle nearly constant images without division instability.

Part 4 - Python code skeleton

```
def dataset_normalize(x, mean, std): return ...
def image_normalize(x, epsilon):
    mean = x.mean(dim=(-2, -1), keepdim=True)
    std = x.std(dim=(-2, -1), keepdim=True)
    return ...

def E16(train_data, shifted_validation):
    training_stats = ...
    variants = {"dataset": ..., "per_image": ...}
    return {name: ... for name in variants}
```

14.7.18 Exercise 17 - Create a Data Quality Report for Corruption, Duplicates, and Outliers

Part 1 - Why this matters

A training-ready dataset requires readable files, valid dimensions and channels, consistent labels, controlled duplicates, and an understood distribution. Corruption or duplicates can bias training and leak into evaluation.

Scan every record safely, compute exact and perceptual fingerprints, summarize dimensions and value statistics, flag outliers, and separate confirmed errors from samples needing human review.

Part 2 - Mathematical form

$$z_i = (s_i - \text{median}(s))/\,\text{MAD}(s).$$

Part 3 - Hints and Helper

Never delete automatically from a heuristic flag. Preserve paths, identifiers, reasons, and thresholds in the report.

Part 4 - Python code skeleton

```
def inspect_record(record):
    try:
        image = ...
        return {"id": ..., "readable": True, "shape": ...,
                "hash": ..., "perceptual_hash": ...,
                "statistics": ...}
    except Exception as error:
        return {"id": ..., "readable": False, "error": str(error)}

def E17(records, output_path):
    inspections = [inspect_record(r) for r in records]
    duplicates = ...; outliers = ...; summary = ...
    ...
    return summary
```

14.7.19 Exercise 18 - Stress Test DataLoader Throughput and Debug Crashes or Deadlocks

Part 1 - Why this matters

High worker counts, corrupt decoders, excessive shared memory, non-picklable transforms, and worker exceptions can cause stalls or intermittent failure. A stress test must preserve

enough context to reproduce the last successful batch.

Run long controlled iterations across worker settings with timeouts, deterministic identifiers, memory monitoring, and exception capture. Distinguish slow batches from a true deadlock and isolate failing records with a single worker.

Part 2 - Mathematical form

$$t_{\text{wait},b} > \tau \;\Rightarrow\; \text{investigate stall rather than assume deadlock immediately.}$$

Part 3 - Hints and Helper

Begin with zero workers for correctness, then increase gradually; avoid CUDA operations inside workers.

Part 4 - Python code skeleton

```
def stress_loader(loader, maximum_batches, stall_threshold):
    records = []; previous = ...
    for index, batch in enumerate(loader):
        wait = ...
        records.append({"batch": index, "wait": wait,
                        "identifiers": ...})
        if wait > stall_threshold: ...
        if index + 1 >= maximum_batches: break
    return records

def E18(dataset, configurations):
    results = []
    for config in configurations:
        try: results.append(stress_loader(...))
        except Exception as error: results.append({...})
    return results
```

14.7.20 Exercise 19 - Produce a Practical Vision Data Pipeline Checklist for Training-Ready Datasets

Part 1 - Why this matters

A reliable pipeline joins data provenance, split integrity, decoding, labels, preprocessing, augmentation semantics, sampling, performance, reproducibility, and monitoring. A checklist converts these requirements into evidence before expensive training begins.

Create gates for leakage, corrupt data, tensor contracts, normalization, augmentation audits, class balance, loader stability, throughput, CUDA transfer, and reproducible configuration. Link every pass condition to a generated report or test.

Part 2 - Mathematical form

$$\text{ready} = \bigwedge_i \text{gate}_i(\text{evidence}).$$

Part 3 - Hints and Helper

Use pass, fail, and needs-review states; do not mark a gate complete without an artifact or measured threshold.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED = ["Provenance", "Split Integrity", "Labels",
            "Tensor Contract", "Normalization", "Augmentation",
            "Class Balance", "Performance", "Reproducibility"]

def validate_checklist(text, evidence):
    missing = [name for name in REQUIRED if name not in text]
    failed_gates = ...
    return {"missing": missing, "failed": failed_gates,
            "ready": not missing and not failed_gates}

def E19(reports, output_path):
    checklist = ...
    result = validate_checklist(checklist, reports)
    Path(output_path).write_text(checklist, encoding="utf-8")
    return result
```

14.8 CNN06 - Regularization, Normalization, and Robustness

Models and Training

14.8.1 Exercise 00 - Demonstrate CNN Overfitting Without Regularization and Observe the Generalization Gap

Part 1 - Why this matters

A high-capacity CNN can continue improving on training data while validation loss worsens. This gap separates memorization from reliable performance on unseen samples.

Train an unregularized model on a small dataset, log train and validation curves, and identify the first epoch where the gap expands persistently.

Part 2 - Mathematical form

$$G_t = L_{\text{val},t} - L_{\text{train},t}.$$

Part 3 - Hints and Helper

Keep the split fixed and inspect both loss and accuracy; one metric alone can hide the pattern.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    baseline = ...
    history = ...
    gap = ...
    return {"history": history, "gap": gap, "overfit_epoch": ...}
```

14.8.2 Exercise 01 - Apply Weight Decay and Quantify Training Stability and Validation Performance

Part 1 - Why this matters

Weight decay discourages unbounded parameter growth and can improve generalization, but excessive decay limits useful capacity. Its effect depends on optimizer, learning rate, and which parameters are decayed.

Sweep controlled decay values and record validation performance, parameter norms, gradient norms, and convergence speed from identical initial states.

Part 2 - Mathematical form

$$\theta_{t+1} = (1 - \eta\lambda)\theta_t - \eta g_t.$$

Part 3 - Hints and Helper

Consider excluding normalization scales and biases, and distinguish decoupled decay from adding an L2 term.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    for decay in decay_values:
        model = ...
        history = ...
        results.append({"decay": decay, "history": history,
                        "parameter_norm": ...})
    return results
```

14.8.3 Exercise 02 - Compare Dropout in the Classifier Head and Convolutional Blocks

Part 1 - Why this matters

Head dropout regularizes global features, while spatial dropout inside convolutional blocks can remove whole feature channels. Element-wise dropout may create noisy spatial patterns with different effects.

Compare matched probabilities and placements, verify train/eval behavior, and measure activation sparsity, convergence, and validation performance.

Part 2 - Mathematical form

$$\widetilde{A} = A \odot M/(1-p).$$

Part 3 - Hints and Helper

Change only placement in each run and inspect whether early-feature dropout prevents learning.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    variants = {"head": ..., "block": ..., "spatial": ...}
    return {name: ... for name, model in variants.items()}
```

14.8.4 Exercise 03 - Implement BatchNorm and Explain Its Effect on Optimization and Gradient Flow

Part 1 - Why this matters

BatchNorm standardizes channel activations using batch statistics and learns scale and shift. It can smooth optimization behavior, but it makes training dependent on batch composition and running estimates.

Compare activation and gradient statistics with and without BatchNorm, then inspect running buffers and small-batch behavior.

Part 2 - Mathematical form

$$y = \gamma \frac{x - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} + \beta.$$

Part 3 - Hints and Helper

Place normalization consistently, switch modes correctly, and do not confuse improved optimization with guaranteed regularization.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    plain, normalized = ...
    plain_stats = ...
    normalized_stats = ...
    return plain_stats, normalized_stats, ...
```

14.8.5 Exercise 04 - Compare BatchNorm and LayerNorm in CNN Settings and Explain When Each Fits

Part 1 - Why this matters

BatchNorm aggregates each channel across batch and spatial positions, while LayerNorm normalizes selected dimensions within each sample. Their behavior differs under small batches, variable distributions, and deployment.

Build matched CNN variants, state the normalized axes, and compare stability across batch sizes and distribution shifts.

Part 2 - Mathematical form

$$\text{BN} : \mu_c \text{ across } N, H, W; \qquad \text{LN} : \mu \text{ within each sample.}$$

Part 3 - Hints and Helper

Verify tensor shape required by LayerNorm and avoid claiming the methods are interchangeable.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    for batch_size in batch_sizes:
        results.append({"batch": batch_size, "batch_norm": ...,
                        "layer_norm": ...})
    return results
```

14.8.6 Exercise 05 - Diagnose Instability from Wrong Normalization Placement and Fix the Root Cause

Part 1 - Why this matters

Normalization before or after activation changes the distribution seen by the next operation. Duplicate, missing, or dimensionally incorrect normalization can suppress signals or make running statistics misleading.

Create failing placements deliberately, capture layer statistics, locate the first unstable block, and fix one cause at a time.

Part 2 - Mathematical form

$$A_l = \phi(\text{Norm}(W_l A_{l-1})) \text{ is not identical to } \text{Norm}(\phi(W_l A_{l-1})).$$

Part 3 - Hints and Helper

Track mean, variance, zero fraction, gradient norm, and finite status for each placement.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    records = ...  # hooks for activations and gradients
    first_unstable = ...
    fixed_model = ...
    return records, first_unstable, fixed_model
```

14.8.7 Exercise 06 - Evaluate Robustness to Input Noise and Blurring and Compare Degradation Patterns

Part 1 - Why this matters

Noise corrupts local pixel values while blur removes high-frequency structure. Different degradation curves reveal whether the CNN depends on texture, edges, or broader shapes.

Evaluate fixed severity levels without retraining, preserve clean references, and report overall and per-class performance with confidence changes.

Part 2 - Mathematical form

$$X_{\text{noise}} = X + \sigma\epsilon, \qquad X_{\text{blur}} = h_s \star X.$$

Part 3 - Hints and Helper

Clip to the valid range and apply perturbations before the same normalization used for clean inputs.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    for severity in severities:
        noisy = ...; blurred = ...
        results.append({"severity": severity, "noise": ..., "blur": ...})
    return results
```

14.8.8 Exercise 07 - Evaluate Random Occlusion and Test Use of Global Context

Part 1 - Why this matters

Occlusion reveals whether predictions depend on one small discriminative region or distributed context. Random masks can also remove the object entirely, so mask position and area must be recorded.

Measure accuracy and confidence across occlusion sizes and locations, then create sensitivity maps and inspect class-specific failures.

Part 2 - Mathematical form

$$\Delta_c(M) = p_c(X) - p_c(X \odot (1 - M) + vM).$$

Part 3 - Hints and Helper

Compare central, random, and sliding masks, and distinguish evidence removal from artificial mask artifacts.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    for mask in masks:
        occluded = ...
        records.append({"mask": mask, "confidence_change": ...,
                        "correct": ...})
    return records
```

14.8.9 Exercise 08 - Implement Label Smoothing and Measure Overconfidence and Calibration

Part 1 - Why this matters

Label smoothing replaces one-hot certainty with a softened target, often reducing extreme logits. It may improve calibration while slightly changing accuracy or harming tasks requiring sharp separation.

Implement the target distribution manually, validate against PyTorch, and compare negative log-likelihood, confidence, accuracy, and calibration error.

Part 2 - Mathematical form

$$q_k = (1 - \epsilon)\mathbf{1}[k = y] + \epsilon/K.$$

Part 3 - Hints and Helper

Use raw logits and verify how smoothing mass is distributed across classes.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    smoothed_targets = ...
    loss = ...
    metrics = {"accuracy": ..., "ece": ..., "nll": ...}
    return loss, smoothed_targets, metrics
```

14.8.10 Exercise 09 - Debug Regularization Misconfiguration Causing Underfitting or Failure to Learn

Part 1 - Why this matters

Several strong techniques combined can make a CNN appear broken: excessive decay, dropout, augmentation, smoothing, or early stopping may suppress learning. The symptom can resemble low capacity or optimizer failure.

Build an ordered diagnostic that removes regularizers, overfits a tiny set, and restores one technique at a time while monitoring gradients and train accuracy.

Part 2 - Mathematical form

$$\text{observed failure} = f(\text{capacity, optimization, data, regularization}).$$

Part 3 - Hints and Helper

Establish an unregularized learning baseline before tuning multiple regularizers.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    baseline = ...
    for regularizer in regularizers:
        diagnostics = ...
        ...
    return {"baseline": baseline, "diagnostics": ...}
```

14.8.11 Exercise 10 - Train Regularized CNN on CUDA and Measure Technique Runtime and Memory Overhead

Part 1 - Why this matters

Regularization methods have different hardware costs. Weight decay mainly affects updates, dropout adds masks, normalization stores statistics and activations, and augmentation may bottleneck the CPU pipeline.

Profile isolated techniques with a matched model, batch, precision, and dataset. Report throughput, peak memory, and validation gain.

Part 2 - Mathematical form

$$\text{overhead} = (t_{\text{regularized}} - t_{\text{base}})/t_{\text{base}}.$$

Part 3 - Hints and Helper

Warm up CUDA, synchronize timing boundaries, and separate data-pipeline cost from model cost.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    torch.cuda.reset_peak_memory_stats()
    start = ...
    metrics = ...
    return {"time": ..., "peak_memory": ..., "metrics": metrics}
```

14.8.12 Exercise 11 - Compare Mixed Precision Stability With and Without Normalization Layers

Part 1 - Why this matters

Normalization can keep activation scales in a range favorable to mixed precision, yet reductions and small variances may themselves be precision-sensitive. Gradient scaling does not repair non-finite forward values.

Compare matched runs with layer-wise finite checks, scaler history, gradient norms, skipped steps, and validation performance.

Part 2 - Mathematical form

$$\epsilon_l = \|A_l^{16} - A_l^{32}\| / (\|A_l^{32}\| + \varepsilon).$$

Part 3 - Hints and Helper

Unscale gradients before inspection and find the first layer where divergence becomes significant.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    with torch.autocast("cuda", dtype=torch.float16):
        loss = ...
    ...
    return {"scale_history": ..., "layer_errors": ..., "skipped_steps": ...}
```

14.8.13 Exercise 12 - Perform a Regularization Ablation Study and Identify What Actually Helps

Part 1 - Why this matters

Ablation isolates the contribution of one technique within a fixed experimental context. Interactions mean the value of a method alone may differ from its value inside a combination.

Run repeated seeds for baseline, additions, removals, and selected combinations; summarize clean, robust, calibration, and cost metrics.

Part 2 - Mathematical form

$$\Delta_m = q(\mathcal{R}) - q(\mathcal{R} \setminus \{m\}).$$

Part 3 - Hints and Helper

Predefine comparisons and keep training budget, split, initialization policy, and evaluation identical.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    records = []
    for config in configurations:
        for seed in seeds:
            records.append(...)
    return records, ...
```

14.8.14 Exercise 13 - Detect Distribution Shift Under Changed Lighting or Color and Measure Generalization Failure

Part 1 - Why this matters

A model may perform well on its source distribution yet fail when illumination, color balance, or sensor response changes. Confidence can remain high even as accuracy falls.

Create controlled shift severities, compare input and feature statistics, and report accuracy, confidence, calibration, and class-specific degradation.

Part 2 - Mathematical form

$$P_{\text{train}}(X) \neq P_{\text{deploy}}(X).$$

Part 3 - Hints and Helper

Use held-out transformations and avoid tuning on the final shift test set.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    for shift, severity in shift_cases:
        shifted = ...
        results.append({
            "shift": shift,
            "severity": severity,
            "metrics": ...,
            "feature_drift": ...,
        })
    return results
```

14.8.15 Exercise 14 - Implement Test-Time Augmentation and Decide Whether It Adds Robustness or Noise

Part 1 - Why this matters

Test-time augmentation averages predictions from label-preserving views. It can reduce variance but increases latency and fails when a transform changes semantics or produces correlated errors.

Aggregate probabilities or logits consistently, compare single-view and multi-view accuracy, calibration, robustness, and latency, and inspect cases made worse.

Part 2 - Mathematical form

$$p(y \mid X) = M^{-1} \sum_{m=1}^{M} p(y \mid T_m(X)).$$

Part 3 - Hints and Helper

Use deterministic approved transforms and reverse geometric outputs when the task requires spatial predictions.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    views = [transform(images) for transform in transforms]
    probabilities = [model(view).softmax(dim=1) for view in views]
    combined = torch.stack(probabilities).mean(dim=0)
    return combined, ...
```

14.8.16 Exercise 15 - Evaluate Adversarial-Like Perturbations and Document CNN Sensitivity Patterns

Part 1 - Why this matters

Small gradient-informed or structured perturbations can expose locally sensitive decision boundaries. This exercise studies sensitivity and failure patterns rather than claiming a complete security evaluation.

Generate bounded perturbations, verify their magnitude and valid range, then measure accuracy, confidence, transfer across models, and visual detectability.

Part 2 - Mathematical form

$$X' = \text{clip}(X + \epsilon \, \text{sign}(\nabla_X L)).$$

Part 3 - Hints and Helper

Keep the model in evaluation mode, clear input gradients, and report epsilon in the original pixel scale.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    images = images.detach().requires_grad_(True)
    loss = loss_fn(model(images), labels); loss.backward()
    perturbed = ...
    return perturbed, {"magnitude": ..., "metrics": ...}
```

14.8.17 Exercise 16 - Build a Robustness Report Grouping Misclassifications by Failure Type and Confidence

Part 1 - Why this matters

One robustness score hides whether failures come from blur, noise, occlusion, shift, small objects, or ambiguous labels. Grouped examples connect aggregate degradation to observable causes.

Store sample identifiers, corruption metadata, labels, predictions, and confidence; produce per-group metrics and galleries of high-confidence errors.

Part 2 - Mathematical form

$$\mathcal{E}_g = \{i : \widehat{y}_i \neq y_i \wedge \text{type}(i) = g\}.$$

Part 3 - Hints and Helper

Preserve original and perturbed versions together and cap stored examples per group.

Part 4 - Python code skeleton

```
from pathlib import Path
import torch

def E16(model, data, config):
    errors = ...
    groups = ...
    report = {name: ... for name, samples in groups.items()}
    ...
    return report
```

14.8.18 Exercise 17 - Analyze Calibration Error and Build a Reliability Diagram for Overconfidence

Part 1 - Why this matters

Calibration asks whether predictions made with confidence near a value are correct at approximately that rate. Accuracy alone cannot reveal systematically overconfident probabilities.

Bin predictions by confidence, calculate accuracy and confidence per bin, plot reliability, and compare ECE, NLL, and Brier score across clean and shifted data.

Part 2 - Mathematical form

$$\mathrm{ECE} = \sum_b \frac{|B_b|}{N} |\operatorname{acc}(B_b) - \operatorname{conf}(B_b)|.$$

Part 3 - Hints and Helper

State binning choices and include counts; empty or tiny bins can mislead.

Part 4 - Python code skeleton

```
from pathlib import Path
import torch

def E17(model, data, config):
    confidence, prediction = probabilities.max(dim=1)
    bins = ...
    ece = ...
    figure = ...
    return ece, figure, ...
```

14.8.19 Exercise 18 - Implement CNN Ensembling and Quantify Accuracy and Robustness Improvements

Part 1 - Why this matters

Models trained with different seeds may make partially independent errors. Averaging their predictive distributions can improve accuracy and robustness, but multiplies storage and inference cost.

Train or load genuinely independent members, measure disagreement and error overlap, and compare probability averaging with a single model on clean and corrupted sets.

Part 2 - Mathematical form

$$p_{\mathrm{ens}}(y \mid X) = M^{-1} \sum_m p_m(y \mid X).$$

Part 3 - Hints and Helper

Keep class order and preprocessing identical across members and report latency and memory alongside gains.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    member_probabilities = [model(images).softmax(dim=1) for model in models]
    ensemble = torch.stack(member_probabilities).mean(dim=0)
    disagreement = ...
    return ensemble, disagreement, ...
```

14.8.20 Exercise 19 - Write a Practical CNN Regularization Strategy Guide for Training and Deployment

Part 1 - Why this matters

Regularization should respond to measured failure modes rather than being enabled by habit. Training fit, validation gap, calibration, robustness, batch size, shift risk, and deployment cost all influence the strategy.

Create a decision guide covering diagnosis, technique selection, ablations, CUDA cost, calibration, shift evaluation, rollback criteria, and monitoring evidence.

Part 2 - Mathematical form

$$\text{strategy} = g(\text{fit gap, robustness, calibration, cost, deployment shift}).$$

Part 3 - Hints and Helper

For every recommendation include trigger, expected effect, trade-off, experiment, and regression test.

Part 4 - Python code skeleton

```
from pathlib import Path
import torch

def E19(model, data, config):
    guide = ...
    required = [...]
    missing = [section for section in required if section not in guide]
    Path(output_path).write_text(guide, encoding="utf-8")
    return {"missing": missing, "ready": not missing}
```

14.9 CNN07 - Modern CNN Blocks and Architectural Patterns

Models and Training

14.9.1 Exercise 00 - Implement a VGG-Style Block and Analyze Parameters and Feature Behavior

Part 1 - Why this matters

A VGG-style block stacks small convolutions and activations before reducing resolution. Repeated local transformations expand the effective receptive field while increasing channels and activation cost.

Build a configurable block, predict every shape, count parameters, and inspect activation statistics after each layer.

Part 2 - Mathematical form

$$\#\theta = \sum_{l}(C_{l-1}C_lK_l^2 + C_l).$$

Part 3 - Hints and Helper

Compare two small kernels with one larger kernel using matched input and output shapes.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    block = torch.nn.Sequential(...)
    output, feature_stats = ...
    return output, {"parameters": ..., "stats": feature_stats}
```

14.9.2 Exercise 01 - Implement a Residual Block and Explain Improved Gradient Flow

Part 1 - Why this matters

Residual blocks learn a transformation added to an identity or projected path. The skip route allows information and gradients to bypass difficult transformations.

Implement a basic block, compare gradient norms with a plain stack, and test identity behavior when the residual branch is near zero.

Part 2 - Mathematical form

$$Y = F(X) + X, \qquad \partial Y/\partial X = \partial F/\partial X + I.$$

Part 3 - Hints and Helper

Use projection only when channels or spatial size change.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    residual = ...
    plain = ...
    return {"residual_output": ..., "plain_output": ...,
            "gradient_norms": ...}
```

14.9.3 Exercise 02 - Validate Residual Addition Shapes and Debug Channel Mismatch Errors

Part 1 - Why this matters

Residual addition requires equal batch, channel, height, and width dimensions. Stride or channel changes on only one path cause invalid addition or incorrect alignment.

Build a shape validator and projection shortcut, then test identity, channel expansion, and spatial reduction cases.

Part 2 - Mathematical form

$$\text{shape}(F(X)) = \text{shape}(P(X)).$$

Part 3 - Hints and Helper

Check both paths immediately before addition and report their configurations.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    main, skip = ...
    if main.shape != skip.shape: raise ValueError(...)
    return main + skip, ...
```

14.9.4 Exercise 03 - Implement a Bottleneck Residual Block and Compare Its Efficiency with a Standard Block

Part 1 - Why this matters

A bottleneck uses one-by-one layers to compress and restore channels around an expensive spatial convolution. Efficiency depends on the bottleneck width and hardware execution.

Compare standard and bottleneck blocks in parameters, FLOPs, latency, memory, and feature statistics under matched output shapes.

Part 2 - Mathematical form

$$C \xrightarrow{1\times1} C_b \xrightarrow{3\times3} C_b \xrightarrow{1\times1} C'.$$

Part 3 - Hints and Helper

Do not call a block efficient from parameter count alone; benchmark the target GPU.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    standard, bottleneck = ...
    return {"standard": profile(...), "bottleneck": profile(...)}
```

14.9.5 Exercise 04 - Implement Depthwise Separable Convolution and Quantify Parameter and FLOPs Reduction

Part 1 - Why this matters

Depthwise separable convolution splits spatial filtering by channel from one-by-one channel mixing. It greatly reduces theoretical work but restricts connectivity in the depthwise stage.

Implement both stages, validate against their mathematical decomposition, and compare with standard convolution.

Part 2 - Mathematical form

$$\#\theta_{\text{sep}} = C_{in}K^2 + C_{in}C_{out}.$$

Part 3 - Hints and Helper

Report depthwise-only and complete separable outputs separately.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    depthwise = torch.nn.Conv2d(..., groups=...)
    pointwise = torch.nn.Conv2d(..., kernel_size=1)
    return pointwise(depthwise(data)), {...}
```

14.9.6 Exercise 05 - Implement a MobileNetV2-Style Inverted Residual and Explain the Expansion Ratio

Part 1 - Why this matters

An inverted residual expands a narrow input, applies depthwise filtering, and projects back to a compact output. The expansion ratio controls hidden capacity and cost.

Build the block with a linear projection, conditional skip, and variable expansion; compare accuracy, latency, and memory.

Part 2 - Mathematical form

$$C \xrightarrow{1\times1} tC \xrightarrow{DW} tC \xrightarrow{1\times1} C'.$$

Part 3 - Hints and Helper

Use the skip only when stride is one and endpoint shapes match.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    expanded = ...
    depthwise = ...
    projected = ...
    return projected + data if ... else projected
```

14.9.7 Exercise 06 - Implement Squeeze-and-Excitation Attention and Measure Feature Selectivity

Part 1 - Why this matters

SE attention summarizes each channel globally and predicts channel gates. It adapts feature strength to the input without directly modeling new spatial locations.

Implement squeeze, reduction, expansion, and sigmoid gating; inspect gate distributions and class-conditional selectivity.

Part 2 - Mathematical form

$$s_c = (HW)^{-1} \sum_{i,j} X_{cij}, \qquad Y_c = g_c X_c.$$

Part 3 - Hints and Helper

Choose a non-zero reduced width and measure added parameters and latency.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    summary = data.mean(dim=(-2, -1))
    gates = ...
    return data * gates[..., None, None], gates
```

14.9.8 Exercise 07 - Compare Standard, Depthwise Separable, and Grouped Convolution Speed on GPU

Part 1 - Why this matters

Theoretical FLOPs do not translate directly to GPU speed because kernel launch, memory traffic, tensor shape, and backend support matter.

Benchmark warmed-up variants across batch and channel sizes, reporting latency, throughput, parameters, FLOPs, and peak memory.

Part 2 - Mathematical form

$$\text{speedup} = t_{standard}/t_{variant}.$$

Part 3 - Hints and Helper

Synchronize timing boundaries and keep input-output shapes identical.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    variants = {...}
    results = {}
    for name, module in variants.items():
        results[name] = benchmark(module, data)
    return results
```

14.9.9 Exercise 08 - Build a Small CNN with Modern Blocks and Validate Its Forward Pass

Part 1 - Why this matters

Combining modern blocks requires a coherent channel and stride plan. A valid collection of individual modules can still create an invalid network when transitions disagree.

Build a compact staged CNN, trace all shapes, verify logits, parameter count, finite activations, and supported input sizes.

Part 2 - Mathematical form

$$X \to \text{stem} \to \text{stages} \to \text{global pool} \to \text{logits}.$$

Part 3 - Hints and Helper

Document the contract at every stage boundary before training.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    model = torch.nn.Sequential(...)
    trace = ...
    logits = model(data)
    return logits, trace, ...
```

14.9.10 Exercise 09 - Debug Stride Placement and Residual Path Misalignment Bugs

Part 1 - Why this matters

Moving stride between branches or layers changes sampling, receptive-field centers, and tensor alignment. Matching final shape alone may not guarantee corresponding spatial content.

Construct failing stride variants, trace both paths, compare impulse responses, and repair alignment deliberately.

Part 2 - Mathematical form

$$J_l = J_{l-1} S_l.$$

Part 3 - Hints and Helper

Use a synthetic impulse image to reveal spatial offsets hidden by ordinary inputs.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    main_trace, skip_trace = ...
    impulse_outputs = ...
    return {"main": main_trace, "skip": skip_trace,
            "alignment": ...}
```

14.9.11 Exercise 10 - Train a Modern-Block CNN on CUDA and Benchmark It Against a Simple Baseline

Part 1 - Why this matters

Modern blocks should be judged by learning behavior and hardware cost, not novelty. A smaller model may train slower if its operations are poorly utilized.

Train matched baseline and modern models from controlled seeds, comparing accuracy, convergence, throughput, memory, and stability.

Part 2 - Mathematical form

$$\text{value} = f(\text{accuracy}, \text{speed}, \text{memory}, \text{stability}).$$

Part 3 - Hints and Helper

Use equal data, epochs, optimizer policy, precision, and evaluation protocol.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    baseline, modern = ...
    return controlled_train(baseline, ...), controlled_train(modern, ...)
```

14.9.12 Exercise 11 - Profile GPU Utilization and Identify Block-Level Bottlenecks

Part 1 - Why this matters

Block profiling locates expensive operations and reveals whether compute, memory, or launch overhead dominates. End-to-end utilization alone cannot name the cause.

Profile representative training steps and aggregate CUDA time, calls, shapes, and memory by block type.

Part 2 - Mathematical form

$$q_b = t_b / \sum_j t_j.$$

Part 3 - Hints and Helper

Warm up first and profile only a limited representative window.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    with torch.profiler.profile(...) as profile:
        ...
    return summarize_by_block(profile)
```

14.9.13 Exercise 12 - Compare Memory Usage of VGG-Style and Residual Architectures

Part 1 - Why this matters

Residual models store branch activations for later addition, while VGG-style stacks may use wide high-resolution maps. Training memory includes saved activations, gradients, and workspaces.

Profile matched-depth models in inference and training, recording parameter bytes, activation estimates, and peak CUDA memory.

Part 2 - Mathematical form

$$M_{peak} \geq M_{params} + M_{saved\ activations} + M_{workspace}.$$

Part 3 - Hints and Helper

Reset peak statistics and isolate one model per trial.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    for model in models:
        results.append(memory_profile(model, data, ...))
    return results
```

14.9.14 Exercise 13 - Implement Stochastic Depth and Observe Regularization in Deep Residual Networks

Part 1 - Why this matters

Stochastic depth skips residual branches for selected samples or batches during training while keeping all blocks active during evaluation. It shortens expected training paths and regularizes depth.

Implement survival probabilities across depth, verify expectation scaling and modes, then compare generalization and convergence.

Part 2 - Mathematical form

$$Y = X + \frac{m}{p}F(X), \qquad m \sim Bernoulli(p).$$

Part 3 - Hints and Helper

Never drop the identity path, and test deterministic evaluation explicitly.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    if model.training and ...:
        residual = residual * ...
    return identity + residual
```

14.9.15 Exercise 14 - Implement DropPath and Verify It Activates Only During Training

Part 1 - Why this matters

DropPath removes complete residual contributions rather than independent elements. Its mask shape must broadcast over non-batch dimensions so one path decision applies consistently per sample.

Implement the operation, verify empirical survival rate, expectation, train/eval behavior, device, and dtype.

Part 2 - Mathematical form

$$\widetilde{X} = X\, m/p.$$

Part 3 - Hints and Helper

Return the input unchanged when disabled, in evaluation mode, or survival is one.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    if not training or drop_probability == 0: return data
    mask = ...
    return data * mask / ...
```

14.9.16 Exercise 15 - Compare Accuracy and Robustness Across Architectural Pattern Choices

Part 1 - Why this matters

Architectures encode different biases about depth, connectivity, channel mixing, and efficiency. Clean accuracy alone cannot identify robustness or deployment suitability.

Compare controlled models on clean data, noise, blur, occlusion, shift, calibration, latency, and memory.

Part 2 - Mathematical form

$$\mathcal{Q} = \{acc, robustness, ECE, latency, memory\}.$$

Part 3 - Hints and Helper

Match training budget and report uncertainty across seeds.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    for name, model in models.items():
        results[name] = evaluation_suite(model, data)
    return results
```

14.9.17 Exercise 16 - Build an Ablation Study Removing One Block Type at a Time and Measure Impact

Part 1 - Why this matters

Ablation tests whether a block contributes beyond the rest of the architecture. Removing it may also change parameter count or depth, so the comparison must state resulting differences.

Create a full model and planned removals or replacements, repeat seeds, and measure quality, cost, gradient flow, and stability.

Part 2 - Mathematical form

$$\Delta_b = q(M) - q(M \setminus b).$$

Part 3 - Hints and Helper

Predefine replacements and preserve tensor compatibility.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    for configuration in ablations:
        for seed in seeds: records.append(run(...))
    return records, ...
```

14.9.18 Exercise 17 - Create an Architecture Summary with Parameters, FLOPs, Speed, and Accuracy

Part 1 - Why this matters

A structured summary prevents selection by one metric and exposes trade-offs between theoretical and measured efficiency.

Collect shapes, parameters, FLOPs, CUDA latency, throughput, peak memory, clean accuracy, and robustness into one validated table.

Part 2 - Mathematical form

$$\text{efficiency} = \text{quality}/\text{measured cost}.$$

Part 3 - Hints and Helper

Use identical benchmark settings and label estimated metrics separately from measured ones.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    rows = [summarize(name, model, data) for name, model in models.items()]
    return rows, validate_rows(rows)
```

14.9.19 Exercise 18 - Stress Test a Deep Modern CNN for NaNs, Instability, and Memory Blowups

Part 1 - Why this matters

Deep networks can fail from activation growth, broken skips, unstable normalization, precision limits, or excessive saved state. Failure may begin long before the final loss becomes non-finite.

Increase depth and batch systematically while logging layer activations, gradients, memory, scaler behavior, and first failure.

Part 2 - Mathematical form

$$r_l = \|A_l\|/(\|A_{l-1}\| + \varepsilon).$$

Part 3 - Hints and Helper

Stop on the first non-finite value and retain its exact configuration and batch.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    records = monitor_layers(model, data)
    first_failure = ...
    return records, first_failure
```

14.9.20 Exercise 19 - Produce a Modern CNN Architecture Guide for Efficient Vision Models

Part 1 - Why this matters

Efficient design balances representation, optimization, hardware behavior, data, robustness, and deployment constraints. No block is universally superior.

Write a decision guide connecting task requirements to block choice, channel plan, downsampling, attention, regularization, benchmarking, and failure tests.

Part 2 - Mathematical form

$$design = g(task, data, hardware, latency, memory, robustness).$$

Part 3 - Hints and Helper

For each recommendation include purpose, alternative, measured trade-off, and verification test.

Part 4 - Python code skeleton

```
from pathlib import Path
import torch

def E19(model, data, config):
    guide = ...
    Path(output_path).write_text(guide, encoding="utf-8")
    return validate_guide(guide, evidence)
```

14.10 CNN08 - Deployment, Export, and Production Readiness

Models and Training

14.10.1 Exercise 00 - Benchmark CNN Inference Latency and Throughput Under Production-Like Batch and Precision Settings

Part 1 - Why this matters

A fast experiment is not automatically a fast production system. Warm-up, synchronization, batch size, precision, preprocessing, and request arrival patterns can change the measured latency dramatically.

Build a controlled benchmark that separates warm-up from measured iterations and reports latency percentiles as well as throughput. Treat the benchmark configuration as part of the result.

Part 2 - Mathematical form

$$\text{throughput} = \frac{NB}{\sum_{i=1}^{N} t_i}, \qquad p_q = \text{Quantile}_q(t_1, \ldots, t_N).$$

Part 3 - Hints and Helper

Synchronize CUDA before starting and stopping the timer. Report median and tail latency, not only the arithmetic mean.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    model.eval()
    with torch.inference_mode():
        for _ in range(...):
            _ = model(sample)
        times = ...
    return {"p50_ms": ..., "p99_ms": ..., "samples_per_s": ...}
```

14.10.2 Exercise 01 - Export CNN Using TorchScript and Validate Output Parity Across Exported and Native Models

Part 1 - Why this matters

Export changes the execution representation of a model and may expose unsupported control flow, device assumptions, or mode-dependent behavior. A successful save operation alone does not prove correctness.

Export an evaluation-mode CNN, reload it independently, and compare its outputs with the native model over several fixed and randomized inputs. Record both absolute and relative error.

Part 2 - Mathematical form

$$e_{\max} = \max_i |y_i - \hat{y}_i|, \qquad y \approx \hat{y} \iff e_{\max} \le a + r \max_i |y_i|.$$

Part 3 - Hints and Helper

Use the same weights, preprocessing, device, dtype, and evaluation mode on both paths. Test more than one input.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    model.eval()
    example = ...
    exported = torch.jit.trace(model, example)
    exported.save(...)
    reloaded = ...
    return {"max_abs_error": ..., "parity": ...}
```

14.10.3 Exercise 02 - Export CNN Using ONNX and Validate Correctness Across Different Runtime Backends

Part 1 - Why this matters

ONNX separates the model from the training framework, but operator conversion and runtime implementations may introduce shape or numerical differences. Portability must therefore be demonstrated with evidence.

Export the CNN with an explicit input contract, load it in available runtimes, and compare every backend against the PyTorch reference. Include dynamic-batch tests when the deployment contract permits them.

Part 2 - Mathematical form

$$\Delta_b = \max_i |f_{\mathrm{PT}}(x_b)_i - f_{\mathrm{ONNX}}(x_b)_i| \,.$$

Part 3 - Hints and Helper

Name the input and output tensors, declare only genuinely dynamic axes, and validate several batch sizes.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    torch.onnx.export(model, example, output_path, input_names=[...],
                      output_names=[...], dynamic_axes=...)
    reference = model(example)
    backend_outputs = ...
    return compare_backends(reference, backend_outputs)
```

14.10.4 Exercise 03 - Use torch.compile for CNN and Measure Speed Gains vs Compilation Overhead

Part 1 - Why this matters

Compilation can reduce steady-state execution time, yet its startup cost may outweigh the gain for short jobs or changing input shapes. Benchmarking only the fastest repeated call hides this trade-off.

Measure eager execution, first compiled call, and steady compiled execution separately. Calculate the number of requests required to recover compilation cost and verify output parity.

Part 2 - Mathematical form

$$T_c(n) = T_{\mathrm{compile}} + n\, t_c, \qquad n_{\mathrm{break}} = \frac{T_{\mathrm{compile}}}{t_e - t_c}.$$

Part 3 - Hints and Helper

Keep input shapes controlled, synchronize device timings, and report graph recompilations when shapes change.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    compiled = torch.compile(model)
    eager_ms = benchmark(model, inputs)
    first_call_ms = ...
    compiled_ms = benchmark(compiled, inputs)
    return {"eager_ms": eager_ms, "first_ms": ..., "break_even": ...}
```

14.10.5 Exercise 04 - Implement Quantization Conceptually and Measure Accuracy Drop vs Performance Gain

Part 1 - Why this matters

Quantization replaces expensive high-precision values with a smaller numerical representation. It can reduce memory and latency, but calibration errors and sensitive layers may damage accuracy.

Implement the quantize–dequantize idea on tensors, then evaluate a supported model quantization path. Compare model size, latency, and task metric against the floating-point baseline.

Part 2 - Mathematical form

$$q = \text{clip}(\text{round}(x/s) + z, q_{\min}, q_{\max}), \qquad \hat{x} = s(q - z).$$

Part 3 - Hints and Helper

Use representative calibration data. Measure end-to-end behavior and identify layers responsible for the largest error.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    def fake_quantize(x, scale, zero_point, qmin, qmax):
        q = ...
        return ...

    baseline = evaluate(model, loader)
    quantized = ...
    return compare_quality_size_latency(baseline, quantized)
```

14.10.6 Exercise 05 - Implement Batch Inference Pipeline with Efficient Transfer and Memory Reuse

Part 1 - Why this matters

Production throughput depends on the entire input-to-output path, not solely on the CNN kernel. Repeated allocation, blocking transfers, and tiny batches can leave an accelerator idle.

Build a batch inference pipeline that validates inputs, groups requests, uses efficient host-to-device transfer, and reuses buffers where safe. Preserve the mapping from every output to its request.

Part 2 - Mathematical form

$$T_{\text{batch}} = T_{\text{prep}} + T_{H\to D} + T_{\text{model}} + T_{D\to H}.$$

Part 3 - Hints and Helper

Use pinned memory with non-blocking transfer only when the environment supports it. Never reuse a buffer before its work is complete.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    def infer_batch(requests, model, device, buffers):
        request_ids, host_batch = ...
        device_batch = host_batch.to(device, non_blocking=...)
        with torch.inference_mode():
            output = model(device_batch)
        return restore_request_order(request_ids, output)
```

14.10.7 Exercise 06 - Build a Minimal Inference Service Wrapper with Input Validation and Error Handling

Part 1 - Why this matters

A correct model can still fail as a service when requests contain the wrong shape, dtype, range, encoding, or size. Validation turns uncontrolled tensor failures into explicit API behavior.

Create a framework-neutral service wrapper that validates a request, preprocesses it, runs inference without gradient tracking, and returns a versioned response or a structured error.

Part 2 - Mathematical form

$$\mathcal{S}(r) = \text{serialize}(f_\theta(P(V(r)))) \,.$$

Part 3 - Hints and Helper

Separate validation errors from internal failures. Do not expose stack traces or silently reshape malformed data.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    class InferenceService:
        def predict(self, request):
            validated = ...
```

```
    tensor = ...
    with torch.inference_mode():
        output = self.model(tensor)
    return {"model_version": ..., "prediction": ...}
```

14.10.8 Exercise 07 - Implement Model Versioning and Backward-Compatible Checkpoint Loading

Part 1 - Why this matters

Weights are meaningful only together with architecture, preprocessing, labels, and format version. An unversioned checkpoint can load successfully while producing semantically wrong predictions.

Define checkpoint metadata and a migration path from an older schema. Reject incompatible artifacts clearly, and test that a migrated checkpoint preserves reference predictions.

Part 2 - Mathematical form

$$C_v = \{\theta, v, \mathcal{A}, P, L, m\}, \qquad M_{v \to v+1}(C_v) = C_{v+1}.$$

Part 3 - Hints and Helper

Store schema version, model identifier, class mapping, preprocessing signature, and integrity information.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    def load_versioned_checkpoint(path, model):
        checkpoint = ...
        version = checkpoint["schema_version"]
        if version < CURRENT_VERSION:
            checkpoint = ...
        validate_compatibility(checkpoint, model)
        return ...
```

14.10.9 Exercise 08 - Add Monitoring Hooks for Confidence Drift and Data Distribution Shift

Part 1 - Why this matters

Production labels often arrive late, so accuracy cannot be the only early warning signal. Changes in input statistics, predicted classes, confidence, and invalid-request rate can reveal

drift sooner.

Collect privacy-aware aggregate signals over time windows and compare them with a reference baseline. Trigger an alert only through an explicit threshold and persistence rule.

Part 2 - Mathematical form

$$\mathrm{PSI} = \sum_j (p_j - q_j) \log \frac{p_j + \epsilon}{q_j + \epsilon}, \qquad \bar{c} = \frac{1}{N} \sum_i \max_k p_{ik}.$$

Part 3 - Hints and Helper

Monitor trends and sample counts alongside scores. A drift alert indicates investigation, not automatic proof that the model is wrong.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    class DriftMonitor:
        def update(self, probabilities, input_stats):
            self.confidence.update(...)
            self.predicted_classes.update(...)
        def report(self, reference):
            return {"psi": ..., "mean_confidence": ..., "alert": ...}
```

14.10.10 Exercise 09 - Build Batch Failure Handling That Skips Corrupt Inputs Without Breaking the Pipeline

Part 1 - Why this matters

One corrupt image should not erase every valid result in a batch. At the same time, silently dropping records breaks traceability and can hide a systematic data problem.

Validate each item, infer on the valid subset, restore original ordering, and return per-item success or error records. Confirm that one failure cannot shift predictions onto the wrong identifiers.

Part 2 - Mathematical form

$$I_v = \{i : V(x_i) = 1\}, \qquad R_i = \begin{cases} f(x_i), & i \in I_v, \\ e_i, & i \notin I_v. \end{cases}$$

Part 3 - Hints and Helper

Keep immutable request IDs through filtering and batching. Count failure types and set a batch-level failure-rate limit.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    def safe_batch_predict(records, model):
        valid, errors = validate_each(records)
        outputs = model(stack_valid(valid)) if valid else ...
        results = restore_by_request_id(outputs, errors)
        return results, {"failure_rate": ...}
```

14.10.11 Exercise 10 - Run Deployment-Oriented CUDA Inference and Measure Real GPU Utilization Under Load

Part 1 - Why this matters

A CUDA model can remain slow when the workload is too small, transfers are serialized, or the input pipeline starves the device. Utilization must be interpreted together with latency and throughput.

Generate controlled concurrent load, measure device utilization and memory, and relate those measurements to request latency. Find the saturation point rather than maximizing utilization blindly.

Part 2 - Mathematical form

$$U = \frac{T_{\text{busy}}}{T_{\text{wall}}}, \qquad \lambda_{\max} = \max\{\lambda : p_{99}(\lambda) \le S\}.$$

Part 3 - Hints and Helper

Warm up first and synchronize only at measurement boundaries. Record queue time separately from model execution time.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    load_generator = ...
    with gpu_monitor() as samples:
        responses = run_concurrent_load(service, load_generator, rate=...)
    return {"gpu_utilization": ..., "queue_ms": ..., "p99_ms": ...}
```

14.10.12 Exercise 11 - Compare float32, float16, and int8 Inference Accuracy and Performance Trade-Offs

Part 1 - Why this matters

Lower precision can improve speed and memory use, but gains depend on hardware, operators, batch size, and calibration. A format is useful only if it satisfies both quality and service objectives.

Evaluate all supported precision paths with identical data and report quality, latency, throughput, memory, and numerical disagreement. Mark unsupported combinations rather than inventing results.

Part 2 - Mathematical form

$$S_p = \frac{t_{32}}{t_p}, \qquad \Delta M_p = M_{32} - M_p, \qquad \Delta Q_p = Q_{32} - Q_p.$$

Part 3 - Hints and Helper

Use the same warm-up and measurement protocol. Include tail latency and per-class quality when class sensitivity matters.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    results = {}
    precisions = ...
    for precision in precisions:
        candidate = prepare_model(model, precision)
        results[precision] = evaluate_precision(
            candidate, loader
        )
    return compare_precision_results(results)
```

14.10.13 Exercise 12 - Build a Reproducible Deployment Benchmark Suite with Fixed Inputs and Seeds

Part 1 - Why this matters

A benchmark is useful only when another run can explain or reproduce its result. Hidden changes in data, software, hardware, warm-up, or timing rules can create false performance regressions.

Package fixed inputs, seeds, environment metadata, correctness tolerances, and timing procedures into one suite. Produce a machine-readable result record and compare it with a stored baseline.

Part 2 - Mathematical form

$$R = F(H, S, D, C, W, N), \qquad \delta = \frac{R_{\text{new}} - R_{\text{base}}}{R_{\text{base}}}.$$

Part 3 - Hints and Helper

Hash the input fixture and configuration. Separate correctness failures from statistically meaningful performance regressions.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    set_all_seeds(config.seed)
    assert sha256_file(inputs_path) == config.input_hash
    result = run_benchmark(config, inputs_path)
    record = {"environment": ..., "config": ..., "result": result}
    return compare_with_baseline(record, baseline)
```

14.10.14 Exercise 13 - Implement Checkpoint Integrity Verification and Detect Corrupted Weight Files Early

Part 1 - Why this matters

A truncated or modified checkpoint must be rejected before it reaches the model. Loading without integrity and compatibility checks can turn a storage fault into unpredictable inference behavior.

Create a manifest containing size, cryptographic digest, version, and expected tensor metadata. Verify the artifact before deserialization and fail closed on any mismatch.

Part 2 - Mathematical form

$$h = \mathrm{SHA256}(B), \qquad \mathrm{valid}(B) = [h = h^*] \wedge [|B| = n^*].$$

Part 3 - Hints and Helper

Compute the digest as a stream for large files. Test bit modification, truncation, wrong version, and wrong tensor shape.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    def verify_checkpoint(path, manifest):
        actual_hash = sha256_stream(path)
        if actual_hash != manifest["sha256"]:
            raise ...
        checkpoint = ...
        validate_tensor_metadata(checkpoint, manifest)
        return checkpoint
```

14.10.15 Exercise 14 - Simulate NaN Production Incident and Build an Automatic Rollback Strategy

Part 1 - Why this matters

Non-finite outputs can spread into ranking, billing, or downstream decisions. Recovery needs a tested health gate and a known-good artifact, not an improvised response after impact begins.

Inject a controlled NaN failure, detect it at the service boundary, stop promotion, and atomically return traffic to the previous healthy version. Preserve evidence for root-cause analysis.

Part 2 - Mathematical form

$$H(y) = \mathbf{1}[\text{isfinite}(y)]\mathbf{1}[m \geq m_{\min}], \qquad H = 0 \Rightarrow v \leftarrow v_{\text{stable}}.$$

Part 3 - Hints and Helper

Use consecutive-failure or rate thresholds to avoid flapping. Rollback must include preprocessing and configuration, not weights alone.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    output = candidate_service.predict(canary_batch)
    healthy = torch.isfinite(output).all() and metrics_pass(...)
    if not healthy:
        traffic_router.activate(stable_version)
        incident_log.write(...)
    return {"healthy": bool(healthy), "active_version": ...}
```

14.10.16 Exercise 15 - Validate Training–Serving Preprocessing Parity and Detect Silent Mismatch Bugs

Part 1 - Why this matters

A production model may receive different resizing, channel order, normalization, or label mapping from training. Such mismatches often produce plausible outputs and evade ordinary exception handling.

Represent preprocessing as a versioned contract and run golden samples through both training and serving paths. Fail deployment when tensors or predictions exceed a justified tolerance.

Part 2 - Mathematical form

$$d_P = \max_i |P_{\text{train}}(x)_i - P_{\text{serve}}(x)_i|.$$

Part 3 - Hints and Helper

Check resize semantics, color space, value range, channel order, normalization constants, and class-index mapping.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    train_tensor = training_preprocess(golden_image)
    serve_tensor = serving_preprocess(golden_image)
    max_error = ...
    assert max_error <= tolerance
    return {"tensor_error": ..., "prediction_parity": ...}
```

14.10.17 Exercise 16 - Implement A/B Testing for Two CNN Models on the Same Input Stream

Part 1 - Why this matters

Offline improvement does not guarantee online value. A controlled A/B test estimates the effect of a new model while preventing routing rules or unequal traffic from biasing the comparison.

Assign requests deterministically, log model version and outcome, and compare guardrail and primary metrics. Include a stop rule and verify that each user remains in one group.

Part 2 - Mathematical form

$$\widehat{\Delta} = \bar{m}_B - \bar{m}_A, \qquad z = \frac{\widehat{\Delta}}{\sqrt{s_A^2/n_A + s_B^2/n_B}}.$$

Part 3 - Hints and Helper

Hash a stable unit such as user ID for assignment. Do not route retries independently or declare success from an unplanned metric.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    def assign_variant(stable_id):
        return ...
```

```
    variant = assign_variant(request.user_id)
    result = services[variant].predict(request)
    log_exposure(variant, result, ...)
    return analyze_ab_metrics(exposures, outcomes)
```

14.10.18 Exercise 17 - Create an End-to-End Production Readiness Checklist for Performance, Monitoring, and Stability

Part 1 - Why this matters

Release confidence comes from evidence across correctness, performance, resilience, security, observability, and recovery. A checklist converts vague confidence into explicit release gates and accountable evidence.

Build a machine-checkable readiness record whose items name an owner, result, artifact, threshold, and expiration. A critical failed gate must block release.

Part 2 - Mathematical form

$$\text{ready} = \bigwedge_{j \in \mathcal{C}} g_j, \qquad g_j \in \{0, 1\}.$$

Part 3 - Hints and Helper

Distinguish mandatory gates from advisory findings. Link every passing claim to a test result rather than a verbal assertion.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    required_gates = load_readiness_spec(...)
    results = {gate.name: run_gate(gate) for gate in required_gates}
    ready = all(r.passed for r in results.values() if r.critical)
    return {"ready": ready, "evidence": ...}
```

14.10.19 Exercise 18 - Stress Test Inference Service for Memory Leaks and Tail Latency Spikes

Part 1 - Why this matters

A service that survives a short benchmark may degrade after thousands of requests. Memory growth, queue buildup, allocator fragmentation, and rare slow inputs often appear only under sustained load.

Drive a staged workload through the service, sample latency and memory over time, and detect sustained growth after warm-up. Include bursts, corrupt inputs, and recovery periods.

Part 2 - Mathematical form

$$s_M = \frac{\sum_i (t_i - \bar{t})(M_i - \bar{M})}{\sum_i (t_i - \bar{t})^2}, \qquad \text{leak suspected if } s_M > \tau.$$

Part 3 - Hints and Helper

Use bounded queues and a fixed test duration. Keep allocator caching distinct from unreachable-memory growth before diagnosing a leak.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    samples = []
    for stage in workload_plan:
        responses = drive_load(service, stage)
        samples.append(sample_latency_memory(responses))
    trend = fit_memory_slope(samples)
    return {"memory_slope": trend, "p99_spikes": ..., "passed": ...}
```

14.10.20 Exercise 19 - Produce a Final CNN Engineering Report Covering Architecture, Training, Deployment, and Failures

Part 1 - Why this matters

A final model artifact does not preserve the reasoning, experiments, limitations, or operational knowledge required to maintain it. An engineering report makes the system reproducible and reviewable.

Create an evidence-based report linking architecture and data decisions to training results, deployment benchmarks, monitoring, incidents, and unresolved risks. Reject the report if required evidence is missing.

Part 2 - Mathematical form

$$\mathcal{R} = \{A, D, T, E, P, O, F, L\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

Include exact artifact versions, experiment references, acceptance thresholds, known failure modes, rollback instructions, and next actions.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    sections = collect_evidence(
        architecture=..., data=..., training=..., evaluation=...,
        deployment=..., operations=..., failures=..., limitations=...)
    report = render_report(sections)
    validate_required_evidence(report)
    return report
```

Book 15

RNN (Recurrent Neural Networks)

15.1 Introduction

15.1.1 What will the book teach you

Previous models in this volume processed an input and produced an output without maintaining an explicit memory of what had appeared before it. A linear model receives features, a multilayer perceptron transforms them through hidden layers, and a convolutional neural network searches for spatial patterns inside an image. These models are powerful, but many real problems cannot be understood by examining each input independently. Language, rainfall, energy demand, financial prices, sensor readings, audio signals, and user activity are sequences in which the meaning of the current observation may depend on observations that occurred earlier.

This book introduces recurrent neural networks, or RNNs, as the first models in this volume designed explicitly to process ordered information through time. Instead of treating every time step as an isolated sample, an RNN carries a hidden state from one step to the next. This hidden state acts as a compact and continuously updated representation of the past. The model therefore does not only ask, "What is the current input?" It also asks, "What information from the previous steps should influence the current computation?"

The central recurrence of a simple RNN can be written as:

$$\mathbf{h}_t = \phi\left(\mathbf{W}_{xh}\mathbf{x}_t + \mathbf{W}_{hh}\mathbf{h}_{t-1} + \mathbf{b}_h\right)$$

and the output may be computed as:

$$\mathbf{y}_t = \mathbf{W}_{hy}\mathbf{h}_t + \mathbf{b}_y$$

Here, $\mathbf{x}_t$ is the input at time step t, $\mathbf{h}_{t-1}$ is the hidden state received from the previous time step, and $\mathbf{h}_t$ is the updated memory. The matrix $\mathbf{W}_{xh}$ controls how the current input influences the hidden state, while $\mathbf{W}_{hh}$ controls how previous memory influences new memory. The activation function ϕ, commonly `tanh` in a vanilla RNN, introduces non-linearity. The matrices and biases are shared across all time steps, allowing the same transition rule to process sequences of different lengths.

This weight sharing is one of the defining properties of recurrent computation. An RNN does not create a separate set of parameters for the first, second, and third observations. It repeatedly applies the same transformation while the hidden state changes over time. As a

result, the model can learn temporal rules that are not tied to one fixed position. However, sharing weights also means that errors in the recurrent transformation are repeated. A slightly unstable update may grow across a long sequence, while a transformation that repeatedly weakens information may cause earlier observations to disappear from memory.

The book begins by making recurrent computation completely visible. You will represent sequences as ordered time steps, implement the recurrence using pure Python, translate the same process into PyTorch tensor operations, and manually unroll the network. You will compare one-step prediction, full-sequence prediction, many-to-one classification, and many-to-many sequence labeling. These experiments will show that an RNN output is not determined only by its current input; it is also determined by the hidden state produced by the entire preceding computation.

Tensor dimensions require special attention in recurrent models. A typical RNN input may follow the structure:

$$(\text{sequence length}, \text{batch size}, \text{input size})$$

or, when `batch_first=True`:

$$(\text{batch size}, \text{sequence length}, \text{input size})$$

The hidden state adds another structure containing the number of recurrent layers, directional components, batch size, and hidden size. A tensor can have valid numerical values and still represent the wrong temporal organization. For this reason, the exercises will repeatedly require the reader to predict shapes, inspect dimensions, preserve batch and time axes, and debug hidden-state placement on both the CPU and CUDA devices.

The hidden state will then be studied as a dynamic system rather than an unexplained tensor returned by PyTorch. You will visualize how it changes over time, test different initial states, create learnable initial states, compare hidden sizes, stack multiple recurrent layers, and build bidirectional networks. You will probe hidden representations to discover whether earlier information remains encoded or has been forgotten. This investigation is important because the hidden state is not guaranteed to contain a perfect record of the past. It has limited capacity and is repeatedly transformed as new observations arrive.

A bidirectional RNN processes a sequence in two directions. One recurrence moves from the beginning toward the end, while another moves from the end toward the beginning. Their representations can be combined to give each position information about both earlier and later observations:

$$\mathbf{h}_t = \left[\overrightarrow{\mathbf{h}}_t; \overleftarrow{\mathbf{h}}_t\right]$$

This can improve sequence labeling when the complete sequence is available, but it is not appropriate for every forecasting or real-time problem. A forecasting model cannot use future observations that do not yet exist. The reader must therefore learn that architectural capability and valid problem design are not the same thing.

Training an RNN introduces backpropagation through time, commonly called BPTT. When the recurrent computation is unrolled, the network becomes a deep computational graph whose

depth depends on the sequence length. A loss produced at a later time step may send gradients backward through many earlier states. The gradient therefore contains repeated products of recurrent Jacobians:

$$\frac{\partial \mathbf{h}_T}{\partial \mathbf{h}_t} = \prod_{k=t+1}^{T} \frac{\partial \mathbf{h}_k}{\partial \mathbf{h}_{k-1}}$$

If these repeated factors usually have magnitudes below one, the gradient can shrink until the model receives almost no information about distant events. If they repeatedly have magnitudes above one, the gradient can grow rapidly and destabilize training. These are the vanishing-gradient and exploding-gradient problems, and they are central limitations of the vanilla RNN rather than rare implementation mistakes.

You will inspect gradients across time, deliberately produce vanishing and exploding behavior, apply gradient clipping, and verify a tiny RNN with finite-difference calculations. You will also implement truncated backpropagation through time, in which the sequence is divided into shorter computational segments. Truncation can reduce memory and runtime, but it limits how far gradients can travel. Detaching the hidden state too early breaks necessary learning paths, while failing to detach it at the correct boundary can retain an increasingly large graph. The goal is to understand this trade-off experimentally instead of copying a hidden-state detachment pattern without knowing its effect.

Sequence data preparation creates another class of challenges. Unlike ordinary tabular batches, sequences may have different lengths and may require padding, masks, packing, or carefully aligned sliding windows. You will construct sequence datasets, implement custom batching, use `pack_padded_sequence`, create padding masks, and ensure that padded positions do not contribute to the loss. You will also detect incorrect target shifts, temporal leakage, and invalid train-validation splits. In time-dependent data, randomly moving future observations into the training set can produce impressive results that are completely misleading.

The book applies vanilla RNNs to two major problem families. The first is character-level language modeling, where the model predicts the next character from the preceding sequence. You will build a vocabulary, create input-target pairs, train a small language model, and generate text autoregressively. Temperature and top-k sampling will demonstrate that generation is controlled not only by learned probabilities but also by the strategy used to select the next token. Perplexity, repetition, novelty, and long-term coherence will be examined instead of judging generated text by appearance alone.

The second application is time-series forecasting. You will convert a time series into supervised windows, scale features without leaking future information, and compare one-step with multi-step forecasting. In autoregressive forecasting, predicted values may be returned to the model as later inputs, causing small errors to accumulate across the forecast horizon. Teacher forcing can make training easier by providing true previous values, but it can also create a difference between training and inference known as exposure bias. The exercises will make this difference visible through controlled experiments.

Evaluation must respect temporal structure. Standard random splitting may be unsuitable when the future must be predicted from the past. You will therefore use chronological splits and walk-forward validation, measure errors across multiple forecast horizons, and compare

MAE and MSE. A single average error may hide the fact that accuracy deteriorates severely at longer horizons, during unusual events, or after a distribution shift. Results must be examined over time and under the same conditions in which the model is expected to operate.

Training stability will be investigated through dropout, weight decay, recurrent initialization, layer normalization, learning-rate schedules, early stopping, gradient clipping, and optimizer selection. These methods will not be presented as automatic improvements. Each method changes the learning process and may help, have no measurable effect, or make the model worse. You will conduct ablation experiments in which one factor is changed at a time and use observed evidence to decide which stabilization methods are appropriate.

CUDA and computational performance are integrated throughout the book. You will compare CPU and GPU execution, analyze sequence length and hidden-size scaling, measure memory consumption during BPTT, examine packed and padded sequences, and profile data-transfer and kernel costs. Recurrent computation is sequential across time steps, which limits parallelism compared with many convolutional operations. A GPU may therefore provide little benefit for a tiny RNN or a short sequence, while larger batches and hidden states may use it more effectively. Performance conclusions must be based on synchronized, reproducible measurements rather than assumptions.

Mixed precision introduces additional trade-offs. Lower precision can reduce memory use and improve throughput, but recurrent state updates are repeated many times. Small numerical differences may accumulate across a long sequence, and unstable gradients may overflow or underflow. You will compare precision modes, monitor non-finite values, use gradient scaling where appropriate, and identify conditions in which additional speed is not worth the loss of numerical reliability.

The final chapters will expose the theoretical and practical boundary of the vanilla RNN. You will build controlled memory tasks in which relevant information appears far before the required prediction and measure when the model begins to forget. You will then examine gated recurrent units and long short-term memory networks as engineering responses to this limitation. Their gates create learned paths that regulate which information is written, preserved, exposed, or forgotten.

This transition is important because the book is not intended to make the reader believe that a vanilla RNN is the best model for every sequential problem. Its purpose is to reveal the fundamental ideas of recurrence, temporal state, weight sharing, BPTT, autoregressive prediction, and long-term dependency failure. Once these mechanisms and limitations are understood directly, LSTM and GRU architectures become logical solutions to observed problems rather than collections of equations that must be memorized.

By the end of this book, the reader should be able to construct and train an RNN, explain its tensor shapes and temporal computation, prepare variable-length sequence data, inspect hidden states and gradients, evaluate language and forecasting tasks, diagnose instability, profile CUDA performance, and identify when a vanilla RNN is no longer suitable. More importantly, the reader should be able to support every conclusion with an experiment.

15.1.2 How to study this book

Every exercise should be treated as a controlled temporal experiment. Before running the code, predict the input shape, output shape, hidden-state shape, device placement, and expected behavior across time. When changing sequence length, hidden size, precision, learning rate, or truncation length, keep the remaining conditions fixed. Otherwise, it becomes impossible to identify which change caused the observed result.

Begin with very short sequences whose recurrence can be calculated manually. Print or visualize the hidden state at every time step and compare it with your own calculations. Only after the CPU implementation is understood should the same experiment be moved to CUDA. GPU execution must always be verified against a controlled reference before performance is measured.

Never shuffle time-series data without first asking whether the operation leaks information from the future. Never calculate scaling statistics using validation or test observations. Never allow padded positions to affect the loss. Never carry a hidden state from one unrelated sequence into another unless the experiment intentionally uses stateful training. These errors may not produce exceptions, but they can invalidate the entire experiment.

When studying long-term dependencies, do not rely only on the final loss. Inspect gradients at different time steps, probe hidden states, vary dependency distance, and measure where performance begins to collapse. When comparing RNN, GRU, and LSTM models, control parameter count, training data, optimization settings, and evaluation procedure as carefully as possible. A fair comparison requires more than placing three final accuracy values in a table.

For every completed challenge, the reader should be able to answer five questions: What information arrives at the current time step? What information is carried from the past? How is the hidden state transformed? How does the error travel backward through time? What evidence demonstrates that the model learned a temporal relationship rather than exploiting leakage or an accidental shortcut? If these questions cannot be answered, the experiment should be repeated before continuing.

15.1.3 The Chapters (RNN00 - RNN08) included in this book

- RNN00 - Sequence Modeling and Core RNN Intuition
- RNN01 - Hidden State Dynamics and Temporal Behavior
- RNN02 - Backpropagation Through Time (BPTT)
- RNN03 - Sequence Data Preparation and Batching
- RNN04 - Language Modeling with Vanilla RNN
- RNN05 - Time Series Forecasting with Vanilla RNN
- RNN06 - Regularization and Stabilization for RNNs
- RNN07 - Efficiency, Profiling, and CUDA Performance
- RNN08 - Transition to Gated RNNs (Why LSTM Exists)

15.2 RNN00 - Sequence Modeling and Core RNN Intuition

Models and Training

15.2.1 Exercise 00 - Understand Why Sequence Data Requires Memory Beyond Standard Feed-Forward Networks

Part 1 - Why this matters

A feed-forward network maps each input to an output without carrying an explicit record of earlier inputs. This assumption fails when the correct interpretation of the current value depends on what appeared before it.

Construct two sequences that end with the same current input but require different outputs because their histories differ. Use the experiment to prove why an independent feed-forward mapping cannot solve the task reliably.

Part 2 - Mathematical form

$$\hat{y}_t = f(x_t) \quad \text{versus} \quad \hat{y}_t = g(x_t, h_{t-1}).$$

Part 3 - Hints and Helper

Keep the final input identical in both sequences. If the desired outputs differ, the missing variable is information from history.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    sequences = ...
    targets = ...
    current_only = ...
    with_history = ...
    return {"current_only": current_only, "with_history": with_history}
```

15.2.2 Exercise 01 - Represent a Sequence as Time Steps and Define the Input–Output Mapping Precisely

Part 1 - Why this matters

A sequence is not merely a longer tensor. Its axes describe time, samples, and features, while the target may correspond to one step, the next step, or the entire sequence.

Represent a small sequence explicitly as time steps and state the mapping being learned. Verify that every input time step and target index correspond to the intended task.

Part 2 - Mathematical form

$$X = (x_1, x_2, \ldots, x_T), \qquad F : X \mapsto Y.$$

Part 3 - Hints and Helper

Write down whether the task is many-to-one, one-step forecasting, or many-to-many before creating tensors.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    sequence = ...
    time_steps = ...
    target = ...
    assert sequence.shape == (...)
    return time_steps, target
```

15.2.3 Exercise 02 - Implement a Simple RNN Forward Pass Using Pure Python Recurrence

Part 1 - Why this matters

Implementing recurrence without PyTorch layers reveals the exact order of temporal computation. Each new state must depend on both the current input and the state produced one step earlier.

Use Python scalars or lists to process a short sequence one element at a time. Save every hidden state so the complete recurrence can be checked manually.

Part 2 - Mathematical form

$$h_t = \tanh(w_x x_t + w_h h_{t-1} + b).$$

Part 3 - Hints and Helper

Initialize the hidden state once before the loop. Do not reset it inside the sequence.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    import math

    def recurrence(sequence, wx, wh, bias):
        hidden = ...
        states = []
        for value in sequence:
            hidden = ...
            states.append(hidden)
        return states
```

15.2.4 Exercise 03 - Translate the RNN Recurrence Equation into PyTorch Tensor Operations

Part 1 - Why this matters

Tensor implementation extends the scalar recurrence to batches and hidden vectors while preserving the same mathematical rule. Shape mistakes can silently change which features are combined.

Implement one recurrent cell with matrix multiplication, bias addition, and a non-linearity. Unroll it across a tensor sequence and compare the result with a manually calculated tiny example.

Part 2 - Mathematical form

$$\mathbf{h}_t = \tanh(\mathbf{x}_t \mathbf{W}_{xh}^\mathsf{T} + \mathbf{h}_{t-1} \mathbf{W}_{hh}^\mathsf{T} + \mathbf{b}_h).$$

Part 3 - Hints and Helper

Annotate the expected shape after every matrix multiplication before executing the code.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    batch, steps, input_size = data.shape
    hidden = torch.zeros(batch, config.hidden_size)
    states = []
    for t in range(steps):
        hidden = ...
        states.append(hidden)
    return torch.stack(states, dim=...)
```

15.2.5 Exercise 04 - Explain Hidden State as Compact Memory and Test Its Effect on Output Prediction

Part 1 - Why this matters

The hidden state is a fixed-size summary updated as the sequence is read. It is not a perfect archive, so its content depends on the learned transition and its limited capacity.

Run the same current input with different preceding histories and compare the hidden states and predictions. Then reset the state to demonstrate what information is lost.

Part 2 - Mathematical form

$$h_t = \Phi(x_t, h_{t-1}), \qquad \hat{y}_t = \Psi(h_t).$$

Part 3 - Hints and Helper

Control the final input and model weights. Change only the history or the initial hidden state.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    history_a, history_b, current = ...
    h_a = run_history(model, history_a)
    h_b = run_history(model, history_b)
    y_a = model.step(current, h_a)
    y_b = ...
    return {"state_distance": ..., "outputs": (y_a, y_b)}
```

15.2.6 Exercise 05 - Demonstrate Weight Sharing Across Time Steps and Explain Why It Matters

Part 1 - Why this matters

An RNN reuses the same input and recurrent weights at every time step. This gives the model a consistent transition rule and prevents parameter count from growing with sequence length.

Apply one cell repeatedly, verify that the parameter objects remain identical, and compare shared recurrence with an intentionally unshared construction.

Part 2 - Mathematical form

$$h_t = \phi(W_x x_t + W_h h_{t-1} + b), \qquad \theta_t = \theta \ \forall t.$$

Part 3 - Hints and Helper

Distinguish changing hidden-state values from shared parameter values. Shared weights receive gradient contributions from all time steps.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    cell = ...
    parameter_ids = []
    hidden = initial_hidden
    for x_t in sequence:
        parameter_ids.append(id(cell.weight_hh))
        hidden = ...
    assert len(set(parameter_ids)) == ...
    return hidden
```

15.2.7 Exercise 06 - Build a Tiny Synthetic Sequence Task Where History Is Required to Predict Correctly

Part 1 - Why this matters

A controlled synthetic task isolates temporal memory from unrelated data complexity. It allows you to know exactly which earlier event should determine the target.

Create sequences whose label depends on a marker shown several steps before the final input. Train simple baselines and confirm that a history-aware model outperforms a current-step-only model.

Part 2 - Mathematical form

$$y = \mathbf{1}[x_{T-d} = m], \qquad d > 0.$$

Part 3 - Hints and Helper

Balance the labels and prevent the final input from revealing the marker. Increase the delay to test memory difficulty.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    def make_memory_dataset(samples, steps, delay):
        x = ...
        marker = ...
        y = ...
```

```
        hide_marker_from_last_step(x)
        return x, y

    train_data = make_memory_dataset(...)
    return train_and_compare(train_data, models=...)
```

15.2.8 Exercise 07 - Compare One-Step Prediction vs Full-Sequence Prediction in a Controlled Experiment

Part 1 - Why this matters

One-step prediction consumes a limited context to predict a specific target, while full-sequence prediction returns an output aligned with every time step. Their output shapes and loss alignment are different.

Use the same sequence to produce a final-step prediction and a prediction at every step. Define aligned targets and compare the amount of supervision each formulation provides.

Part 2 - Mathematical form

$$F_{1:T} : X_{1:T} \mapsto \hat{y}_T, \qquad G_{1:T} : X_{1:T} \mapsto (\hat{y}_1, \ldots, \hat{y}_T).$$

Part 3 - Hints and Helper

Do not compare losses until both reductions and numbers of supervised positions are defined consistently.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    outputs, hidden = model(sequence)
    last_prediction = ...
    sequence_predictions = ...
    last_loss = criterion(last_prediction, last_target)
    full_loss = ...
    return last_loss, full_loss
```

15.2.9 Exercise 08 - Implement Many-to-One RNN for Sequence Classification and Validate Output Shapes

Part 1 - Why this matters

Many-to-one models compress a complete sequence into one representation for classification. Selecting the wrong axis or padded final state can make the classifier use an unintended time

step.

Build an RNN classifier that converts a batch of sequences into one logit vector per sample. Validate intermediate and final tensor shapes with assertions.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{B\times T\times D} \longrightarrow H \in \mathbb{R}^{B\times T\times H} \longrightarrow Z \in \mathbb{R}^{B\times C}.$$

Part 3 - Hints and Helper

For equal-length sequences, use the last relevant state. Preserve the batch dimension even when the batch contains one sample.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    rnn = torch.nn.RNN(..., batch_first=True)
    classifier = torch.nn.Linear(...)
    outputs, final_hidden = rnn(data)
    representation = ...
    logits = classifier(representation)
    assert logits.shape == (...)
    return logits
```

15.2.10 Exercise 09 - Implement Many-to-Many RNN for Sequence Labeling and Validate Temporal Alignment

Part 1 - Why this matters

Sequence labeling requires one prediction for each relevant input position. An off-by-one shift can produce a valid loss while teaching the model to label the wrong time step.

Project every recurrent output to class logits and verify that input positions, target positions, and output positions remain aligned. Include a deliberately shifted target as a failure comparison.

Part 2 - Mathematical form

$$X_{1:T} \mapsto H_{1:T} \mapsto Z_{1:T}, \qquad Z \in \mathbb{R}^{B\times T\times C}.$$

Part 3 - Hints and Helper

Flatten batch and time only for the loss, then confirm that the same ordering is used for logits and targets.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    outputs, _ = rnn(data)
    logits = classifier(outputs)
    assert logits.shape[:2] == targets.shape
    loss = criterion(logits.reshape(...), targets.reshape(...))
    shifted_loss = ...
    return loss, shifted_loss
```

15.2.11 Exercise 10 - Move RNN Forward Computation to CUDA and Validate Output Parity with CPU Results

Part 1 - Why this matters

Moving an RNN to CUDA requires its parameters, inputs, and initial hidden state to share one device. Correct execution must be established before speed is measured.

Clone identical weights into CPU and CUDA models, run both in evaluation mode, and compare their outputs and final states after returning CUDA results to the CPU.

Part 2 - Mathematical form

$$e_{\max} = \max_i |y_i^{\text{CPU}} - y_i^{\text{CUDA}}|.$$

Part 3 - Hints and Helper

Use identical inputs and tolerances appropriate for the dtype. Availability of CUDA should be checked explicitly.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    device = torch.device("cuda" if torch.cuda.is_available() else "cpu")
    cpu_model = ...
    gpu_model = ...
    gpu_model.load_state_dict(cpu_model.state_dict())
    y_cpu, h_cpu = cpu_model(cpu_input)
    y_gpu, h_gpu = ...
    return torch.allclose(y_cpu, y_gpu.cpu(), atol=..., rtol=...)
```

15.2.12 Exercise 11 - Benchmark RNN Forward Speed on CPU vs GPU for Different Sequence Lengths

Part 1 - Why this matters

RNNs contain a sequential dependency across time, so GPU acceleration depends on sequence length, batch size, hidden size, and transfer cost. Small workloads may be faster on the CPU.

Benchmark several sequence lengths with fixed feature and hidden sizes. Separate warm-up from timed iterations and synchronize CUDA around measurements.

Part 2 - Mathematical form

$$S(T) = \frac{t_{\mathrm{CPU}}(T)}{t_{\mathrm{GPU}}(T)}, \qquad \text{throughput} = \frac{BT}{t}.$$

Part 3 - Hints and Helper

Generate inputs before timing and report median latency. Include end-to-end transfer cost as a separate measurement.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    results = {}
    for steps in config.sequence_lengths:
        cpu_input = torch.randn(...)
        gpu_input = cpu_input.to("cuda")
        cpu_ms = benchmark(...)
        gpu_ms = benchmark(..., synchronize=True)
        results[steps] = ...
    return results
```

15.2.13 Exercise 12 - Compare float32 vs float16 RNN Forward Outputs and Identify Precision-Sensitive Cases

Part 1 - Why this matters

Recurrent updates repeatedly reuse earlier numerical results, allowing small precision differences to accumulate across time. Lower precision may therefore behave differently as sequences grow.

Run matched float32 and float16 models over several lengths and input scales. Measure output error, hidden-state error, and the first appearance of non-finite values.

Part 2 - Mathematical form

$$e_T = \frac{\|h_T^{(32)} - h_T^{(16)}\|_2}{\|h_T^{(32)}\|_2 + \epsilon}.$$

Part 3 - Hints and Helper

Copy the same weights before casting. Compare on supported hardware and treat overflow as a result rather than hiding it.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    reference = model.float()
    candidate = copy_model(model).half().to(device)
    errors = []
    for steps in config.sequence_lengths:
        y32, h32 = ...
        y16, h16 = ...
        errors.append({"steps": steps, "relative_error": ..., "finite": ...})
    return errors
```

15.2.14 Exercise 13 - Understand Tensor Shapes for RNN Inputs (seq_len, batch, input_size) and Debug Mistakes

Part 1 - Why this matters

The standard PyTorch RNN layout places time before batch unless configured otherwise. Confusing these axes may run without an immediate exception when their sizes happen to be compatible.

Construct a tensor with uniquely identifiable values for every time, batch, and feature index. Permute axes intentionally, inspect slices, and create assertions that detect the wrong layout.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{T \times B \times D}, \qquad Y \in \mathbb{R}^{T \times B \times H}.$$

Part 3 - Hints and Helper

Use different values for T, B, and D so an accidental permutation cannot hide behind equal dimensions.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    seq_len, batch, input_size = ...
    x = torch.arange(...).reshape(seq_len, batch, input_size)
    validate_layout(x, expected=...)
    wrong = x.permute(...)
    try:
```

```
        validate_layout(wrong, expected=...)
    except ...:
        ...
    return x
```

15.2.15 Exercise 14 - Implement RNN with batch_first Option and Verify Shape Conversions Correctly

Part 1 - Why this matters

The `batch_first` option changes the layout of input and output tensors, but it does not change the hidden-state layout. Assuming that every tensor changes creates subtle bugs.

Run equivalent batch-first and time-first models with shared weights. Convert only the required axes and verify output and hidden-state parity.

Part 2 - Mathematical form

$$X_{BTD} = \text{permute}(X_{TBD}, 1, 0, 2), \qquad h_n \in \mathbb{R}^{L \times B \times H}.$$

Part 3 - Hints and Helper

Transpose the sequence outputs back before comparison. Do not transpose the final hidden state merely because batch-first is enabled.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    time_model = torch.nn.RNN(..., batch_first=False)
    batch_model = torch.nn.RNN(..., batch_first=True)
    batch_model.load_state_dict(time_model.state_dict())
    x_batch = x_time.permute(...)
    y_time, h_time = time_model(x_time)
    y_batch, h_batch = ...
    return {"output_parity": ..., "hidden_parity": ...}
```

15.2.16 Exercise 15 - Implement a Manual Unroll of RNN Over Time and Compare to torch.nn.RNN Behavior

Part 1 - Why this matters

A manual unroll connects the recurrence equation to PyTorch's optimized RNN module. Matching both implementations proves that weight orientation, bias terms, and time ordering are understood.

Extract weights from a one-layer `torch.nn.RNN`, reproduce every step manually, and compare the complete output sequence and final hidden state.

Part 2 - Mathematical form

$$h_t = \tanh(x_t W_{ih}^{\mathsf{T}} + b_{ih} + h_{t-1} W_{hh}^{\mathsf{T}} + b_{hh}).$$

Part 3 - Hints and Helper

Use one layer, one direction, zero dropout, and the same initial hidden state before extending the experiment.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    module = torch.nn.RNN(..., nonlinearity="tanh")
    module_output, module_hidden = module(sequence, initial_hidden)
    hidden = initial_hidden[0]
    manual_states = []
    for t in range(sequence.shape[0]):
        hidden = ...
        manual_states.append(hidden)
    manual_output = torch.stack(manual_states)
    return compare(module_output, manual_output, module_hidden, hidden)
```

15.2.17 Exercise 16 - Stress Test RNN Forward with Long Sequences and Monitor GPU Memory and Runtime

Part 1 - Why this matters

Long sequences increase recurrent work and retain more intermediate activations when gradients are enabled. A configuration that works for a short example may exceed practical memory or latency limits.

Increase sequence length gradually, measure runtime and peak GPU memory, and stop safely before an out-of-memory failure. Compare inference mode with gradient-enabled forward execution.

Part 2 - Mathematical form

$$\text{activation memory} = O(TBLH), \qquad \text{recurrent work} = O(TBH^2).$$

Part 3 - Hints and Helper

Reset peak-memory statistics between trials and record failed configurations explicitly. Do not allocate every test tensor at once.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    records = []
    for steps in config.sequence_lengths:
        torch.cuda.reset_peak_memory_stats()
        sample = torch.randn(..., device=device)
        try:
            elapsed = ...
            peak = torch.cuda.max_memory_allocated()
            record = {"steps": steps, "ms": elapsed,
                      "peak_bytes": peak}
            records.append(record)
        except torch.cuda.OutOfMemoryError:
            ...
    return records
```

15.2.18 Exercise 17 - Debug Device Mismatch and Hidden-State Placement Errors in CUDA RNN Pipelines

Part 1 - Why this matters

An RNN may fail even when its model and input are on CUDA if the initial hidden state remains on the CPU. Creating state from global defaults also risks dtype mismatch.

Reproduce device and dtype failures deliberately, inspect every participating tensor, and implement a safe hidden-state constructor derived from the input or model parameters.

Part 2 - Mathematical form

$$\text{device}(X) = \text{device}(h_0) = \text{device}(\theta).$$

Part 3 - Hints and Helper

Create hidden state with `x.new_zeros` or explicit device and dtype. Avoid fixing errors by moving tensors repeatedly inside the time loop.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    def initial_state(model, x, layers, hidden_size):
        return x.new_zeros(...)

    model = model.to(device)
    x = data.to(device)
    h0 = initial_state(model, x, ..., ...)
    assert_same_device_dtype(model, x, h0)
    return model(x, h0)
```

15.2.19 Exercise 18 - Validate Determinism Settings and Observe When CUDA RNN Becomes Non-Deterministic

Part 1 - Why this matters

Reproducibility requires more than setting one random seed. Initialization, data order, backend algorithms, precision, and device behavior can all influence repeated RNN outputs.

Run the same forward experiment several times under controlled seeds and deterministic settings. Compare exact equality and tolerance-based equality, then document remaining environmental constraints.

Part 2 - Mathematical form

$$d_r = \max_i |y_i^{(r)} - y_i^{(0)}|, \qquad \text{deterministic if } d_r = 0 \ \forall r.$$

Part 3 - Hints and Helper

Recreate the model and inputs after resetting every seed. Record software, hardware, dtype, and backend configuration with the result.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    def run_once(seed, deterministic):
        set_all_seeds(seed)
        torch.use_deterministic_algorithms(deterministic)
        model, sample = ...
        return model(sample)[0].detach().cpu()

    runs = [run_once(config.seed, True) for _ in range(...)]
    return compare_repeated_runs(runs)
```

15.2.20 Exercise 19 - Write a Conceptual Report Explaining RNN Memory, Weight Sharing, and Temporal Computation

Part 1 - Why this matters

A complete understanding of recurrence must connect equations, tensor shapes, experiments, and failure cases. A final report makes this reasoning explicit before the book advances to BPTT and longer dependencies.

Produce an evidence-based report explaining how state flows forward, how parameters are reused, how task mappings differ, and where vanilla RNN forward computation fails. Link each claim to an experiment from this chapter.

Part 2 - Mathematical form

$$\mathcal{R} = \{\text{recurrence}, \text{state}, \text{sharing}, \text{mapping}, \text{shapes}, \text{evidence}, \text{limits}\}.$$

Part 3 - Hints and Helper

Include at least one manual calculation, one shape trace, one CPU–CUDA comparison, and one observed failure or limitation.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    sections = {
        "recurrence": ...,
        "hidden_state": ...,
        "weight_sharing": ...,
        "experiments": ...,
        "limitations": ...,
    }
    report = render_report(sections)
    validate_required_evidence(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.3 RNN01 - Hidden State Dynamics and Temporal Behavior

Models and Training

15.3.1 Exercise 00 - Visualize Hidden State Evolution Over Time for a Simple Repeating Pattern Sequence

Part 1 - Why this matters

A hidden state changes at every time step even when the same recurrent parameters are reused. Visualizing its components exposes cycles, saturation, drift, and responses to repeated input patterns.

Feed a controlled repeating sequence into a small RNN, retain every hidden state, and plot selected dimensions over time. Relate repeating or changing state patterns to the input period.

Part 2 - Mathematical form

$$h_t = \phi(W_{xh}x_t + W_{hh}h_{t-1} + b), \qquad H = (h_1, \ldots, h_T).$$

Part 3 - Hints and Helper

Use fixed weights and a short period first. Plot input and hidden dimensions against the same time axis.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    pattern = ...
    sequence = pattern.repeat(...)
    outputs, hidden = model(sequence)
    states = outputs.detach().cpu()
    figure = plot_state_trajectories(sequence, states, dimensions=...)
    return states, figure
```

15.3.2 Exercise 01 - Analyze How Initial Hidden State Choice Affects Early Predictions and Convergence

Part 1 - Why this matters

The initial hidden state supplies the memory available before the first input arrives. Its influence is often strongest near the beginning and may decay, persist, or destabilize later states.

Run identical sequences from zero, random, and fixed nonzero initial states. Compare prediction differences across time and, during training, compare convergence under controlled seeds.

Part 2 - Mathematical form

$$\Delta_t = \|h_t^{(a)} - h_t^{(b)}\|_2.$$

Part 3 - Hints and Helper

Keep model parameters and inputs identical. Plot Δ_t to determine whether initialization influence disappears.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    initial_states = {"zero": ..., "random": ..., "fixed": ...}
    runs = {}
```

```
    for name, h0 in initial_states.items():
        outputs, hidden = model(data, h0)
        runs[name] = ...
    differences = ...
    return runs, differences
```

15.3.3 Exercise 02 - Implement Learnable Initial Hidden State and Compare Against Zero Initialization

Part 1 - Why this matters

A learnable initial state can encode a useful task-level prior before any observation is processed. It also adds parameters that may overfit or become tied to a fixed batch assumption.

Register one initial-state parameter, expand it safely across the current batch, and compare it with zero initialization using the same data and training protocol.

Part 2 - Mathematical form

$$h_0 = \mathbf{c}, \qquad \mathbf{c} \in \mathbb{R}^{LD \times 1 \times H}, \qquad \mathbf{c} \text{ is trainable.}$$

Part 3 - Hints and Helper

Use `expand` rather than storing one parameter per batch element. Confirm that the parameter appears in the state dictionary and receives a gradient.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    class LearnableStateRNN(torch.nn.Module):
        def __init__(self, input_size, hidden_size, layers=1):
            super().__init__()
            self.rnn = torch.nn.RNN(...)
            self.h0 = torch.nn.Parameter(...)
        def forward(self, x):
            batch = x.shape[0]
            initial = ...
            return self.rnn(x, initial)

    return compare_initialization_strategies(...)
```

15.3.4 Exercise 03 - Demonstrate Information Decay Over Long Sequences Using Hidden State Probing

Part 1 - Why this matters

A vanilla RNN may gradually lose information that appeared far in the past. Final accuracy alone does not show when or how the stored signal disappears.

Insert a known marker, increase the delay before probing the hidden state, and train a simple decoder to recover the marker. Plot probe accuracy against distance.

Part 2 - Mathematical form

$$A(d) = \Pr(q(h_{t+d}) = m_t)\,.$$

Part 3 - Hints and Helper

Use a balanced marker and a simple probe. Freeze the RNN while training the probe so the measurement does not alter the representation.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    distances = ...
    probe_scores = {}
    with torch.no_grad():
        hidden_sequences = collect_states(model, data)
    for distance in distances:
        features, marker_targets = ...
        probe = train_probe(features, marker_targets)
        probe_scores[distance] = ...
    return probe_scores
```

15.3.5 Exercise 04 - Compare Single-Layer vs Multi-Layer RNN Hidden State Representations

Part 1 - Why this matters

Stacked recurrent layers build representations at different levels. Lower layers respond directly to sequence inputs, while higher layers receive transformed temporal features from below.

Train matched one-layer and multi-layer RNNs, inspect states from every layer, and compare probe accuracy, state norms, parameter counts, and task performance.

Part 2 - Mathematical form

$$h_t^{(l)} = \phi\Big(W_{xh}^{(l)} h_t^{(l-1)} + W_{hh}^{(l)} h_{t-1}^{(l)} + b^{(l)}\Big)\,.$$

Part 3 - Hints and Helper

A fair comparison should report the increased parameter count. Do not treat the final-layer state as if it contains every layer.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    single = torch.nn.RNN(..., num_layers=1, batch_first=True)
    stacked = torch.nn.RNN(..., num_layers=config.layers, batch_first=True)
    single_result = analyze_model(single, data)
    stacked_result = analyze_model(stacked, data)
    return compare_representations(single_result, stacked_result)
```

15.3.6 Exercise 05 - Implement Stacked RNN and Confirm Correct Hidden State Shape at Each Layer

Part 1 - Why this matters

In a stacked RNN, every layer maintains its own recurrent state. Confusing the layer axis with the batch or time axis can produce incorrect initialization and state reuse.

Construct a multi-layer RNN, create the correct initial state, and use assertions or a manual stack to confirm the state associated with each layer.

Part 2 - Mathematical form

$$h_n \in \mathbb{R}^{L\times B\times H}, \qquad Y \in \mathbb{R}^{B\times T\times H}.$$

Part 3 - Hints and Helper

With a unidirectional RNN, the first hidden-state axis has length `num_layers`, not sequence length.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    layers, batch, hidden_size = ...
    h0 = data.new_zeros(layers, batch, hidden_size)
    rnn = torch.nn.RNN(..., num_layers=layers, batch_first=True)
    outputs, h_n = rnn(data, h0)
    assert h_n.shape == (...)
    layer_states = ...
    return outputs, layer_states
```

15.3.7 Exercise 06 - Investigate the Effect of Hidden Size on Memory Capacity and Sequence Accuracy

Part 1 - Why this matters

Hidden size limits the dimensional space available for temporal representation. Too little capacity may discard useful history, while excessive capacity increases cost and can overfit.

Train several hidden sizes on the same delayed-memory task. Compare accuracy by delay, parameter count, runtime, and memory rather than selecting the largest model automatically.

Part 2 - Mathematical form

$$P(H) = HD + H^2 + H, \qquad C_{\text{step}} = O(B(HD + H^2)).$$

Part 3 - Hints and Helper

Reuse the dataset split, seed policy, optimizer budget, and evaluation procedure for every hidden size.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    results = {}
    for hidden_size in config.hidden_sizes:
        candidate = build_rnn(hidden_size=hidden_size)
        history = train(candidate, train_loader, ...)
        results[hidden_size] = {
            "accuracy_by_delay": ...,
            "parameters": ...,
            "runtime_ms": ...,
        }
    return results
```

15.3.8 Exercise 07 - Implement Bidirectional RNN and Verify Forward and Backward State Concatenation

Part 1 - Why this matters

A bidirectional RNN produces one state from past-to-future processing and another from future-to-past processing. PyTorch interleaves directional states within the layer axis.

Build a one-layer bidirectional RNN, separate both directions, concatenate them explicitly, and verify agreement with the returned sequence output and final state layout.

Part 2 - Mathematical form

$$y_t = [\overrightarrow{h}_t; \overleftarrow{h}_t] \in \mathbb{R}^{2H}, \qquad h_n \in \mathbb{R}^{2L \times B \times H}.$$

Part 3 - Hints and Helper

For each layer, index forward direction at $2l$ and backward direction at $2l + 1$.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    rnn = torch.nn.RNN(..., bidirectional=True, batch_first=True)
    outputs, h_n = rnn(data)
    forward_output, backward_output = outputs.split(
        config.hidden_size, dim=-1
    )
    forward_final = h_n[...]
    backward_final = ...
    assert outputs.shape == (...)
    return forward_output, backward_output, forward_final, backward_final
```

15.3.9 Exercise 08 - Compare Bidirectional vs Unidirectional RNN for a Sequence Labeling Task

Part 1 - Why this matters

Future context can improve a label at the current position when the entire sequence is available. That advantage is invalid in causal or streaming settings where later observations are unknown.

Train both directions under comparable capacity on a labeling task whose correct label sometimes requires future context. Compare accuracy, latency, parameters, and causal validity.

Part 2 - Mathematical form

$$\hat{y}_t^{\text{uni}} = f(x_{1:t}), \qquad \hat{y}_t^{\text{bi}} = g(x_{1:T}).$$

Part 3 - Hints and Helper

Create a task where future context has a measurable role, then state explicitly why the bidirectional model cannot be used online.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    models = {"unidirectional": ..., "bidirectional": ...}
    results = {}
    for name, candidate in models.items():
        train(candidate, train_loader, ...)
        results[name] = evaluate_sequence_labels(candidate, test_loader)
        results[name]["parameters"] = ...
        results[name]["latency_ms"] = ...
    return results
```

15.3.10 Exercise 09 - Debug Hidden State Shape Bugs in Multi-Layer and Bidirectional RNN Setups

Part 1 - Why this matters

Layer count, direction count, batch size, and hidden size all appear in the hidden-state tensor. Multiplying or ordering them incorrectly produces common recurrent pipeline failures.

Create a validator for RNN configuration and initial-state shape. Test it against correct states and deliberately malformed layer, direction, batch, and hidden dimensions.

Part 2 - Mathematical form

$$\text{shape}(h_0) = (LD, B, H), \qquad D \in \{1, 2\}.$$

Part 3 - Hints and Helper

Derive D from `bidirectional`; never infer it from output width after an error has occurred.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    def expected_hidden_shape(rnn, batch):
        directions = ...
        return (...)

    def validate_hidden(rnn, x, h0):
        expected = expected_hidden_shape(rnn, x.shape[0])
        if h0.shape != expected:
            raise ValueError(...)
        return True

    return run_shape_failure_tests(validate_hidden, cases=...)
```

15.3.11 Exercise 10 - Move Hidden State Analysis to CUDA Without Excess Host–Device Transfers

Part 1 - Why this matters

Copying every time-step state to the CPU inside the recurrent loop can synchronize execution repeatedly and destroy GPU throughput. Analysis should collect tensors on-device before transferring only the required summary.

Run hidden-state extraction on CUDA, compute selected statistics on the device, and perform one controlled transfer for visualization. Compare it with a deliberately inefficient per-step transfer.

Part 2 - Mathematical form

$$T_{\text{total}} = T_{\text{compute}} + N_{\text{copy}} T_{D \to H} + T_{\text{sync}}.$$

Part 3 - Hints and Helper

Detach states before analysis but keep them on CUDA until aggregation is complete. Transfer small summaries instead of full histories when possible.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    model = model.to(device)
    batch = data.to(device, non_blocking=True)
    with torch.inference_mode():
        states, final_hidden = model(batch)
        summary_gpu = compute_state_statistics(states)
    summary_cpu = ...
    return summary_cpu
```

15.3.12 Exercise 11 - Benchmark Hidden State Computation Cost for Increasing Hidden Size on GPU

Part 1 - Why this matters

Recurrent weight multiplication grows approximately quadratically with hidden size. The measured curve also reflects GPU occupancy, memory traffic, and fixed launch overhead.

Benchmark matched RNNs across hidden sizes after warm-up. Record latency, throughput, parameter count, and peak memory to build an empirical scaling curve.

Part 2 - Mathematical form

$$C(H) = O(TB(HD + H^2)), \qquad P(H) = HD + H^2 + H.$$

Part 3 - Hints and Helper

Allocate each candidate independently and synchronize around timing. Keep batch size, sequence length, dtype, and device fixed.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    records = []
    for hidden_size in config.hidden_sizes:
        candidate = build_rnn(hidden_size).to(device)
        sample = torch.randn(..., device=device)
        warmup(candidate, sample)
        latency = benchmark(candidate, sample, synchronize=True)
        records.append({"hidden_size": hidden_size,
                        "latency_ms": latency, "peak_memory": ...})
    return records
```

15.3.13 Exercise 12 - Compare Floating-Point Precision Effects on Hidden State Stability and Temporal Drift

Part 1 - Why this matters

Rounding error enters every recurrent update and may accumulate over many time steps. Precision differences that appear harmless early can change later states substantially.

Run identical float64, float32, and float16 recurrences over increasing lengths. Compare state trajectories to the highest-precision reference and detect saturation or non-finite values.

Part 2 - Mathematical form

$$d_t^{(p)} = \frac{\|h_t^{(64)} - h_t^{(p)}\|_2}{\|h_t^{(64)}\|_2 + \epsilon}.$$

Part 3 - Hints and Helper

Use identical weights and inputs before casting. Plot drift over time instead of reporting only the final difference.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    precisions = ...
    trajectories = {}
    for dtype in precisions:
        candidate = copy_model(model).to(device=device, dtype=dtype)
        sample = data.to(device=device, dtype=dtype)
        trajectories[str(dtype)] = candidate(sample)[0].detach()
    reference = trajectories[...]
    return compute_temporal_drift(reference, trajectories)
```

15.3.14 Exercise 13 - Use Forward Hooks to Save Hidden States and Build a Visualization Pipeline

Part 1 - Why this matters

Instrumentation should observe internal behavior without rewriting the main model. Hooks are useful, but careless storage can retain computational graphs and cause memory growth.

Register hooks on recurrent components, detach and store selected outputs, remove all hook handles, and convert the captured states into a reproducible visualization.

Part 2 - Mathematical form

$$\mathcal{C}_l = \{\text{detach}(H^{(l)})\}, \qquad l = 1, \ldots, L.$$

Part 3 - Hints and Helper

A standard RNN hook receives a tuple containing sequence output and final state. Save only what the analysis requires.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    captured = {}
    handles = []

    def save_state(name):
        def hook(module, inputs, output):
            sequence_output, final_state = output
            captured[name] = ...
        return hook

    for name, module in selected_modules(model):
        handles.append(module.register_forward_hook(save_state(name)))
```

```
    _ = model(data)
    for handle in handles:
        ...
    return build_visualization(captured)
```

15.3.15 Exercise 14 - Probe Hidden States to Detect Whether Past Information Is Encoded or Forgotten

Part 1 - Why this matters

A probe tests whether a specific property of the past can be recovered from a hidden representation. This provides stronger evidence about memory than inspecting state magnitude alone.

Freeze an RNN, collect hidden states at different delays, and train simple linear probes to predict a past attribute. Compare against majority and shuffled-label baselines.

Part 2 - Mathematical form

$$q_d^* = \arg\min_q \sum_i \ell(q(h_{t+d}^{(i)}), a_t^{(i)}).$$

Part 3 - Hints and Helper

Keep the probe simple and separate its training and test sets. High probe capacity may learn patterns that the representation does not expose directly.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    with torch.no_grad():
        states, attributes = collect_probe_dataset(model, loader)
    results = {}
    for delay in config.delays:
        x_probe, y_probe = align_probe_data(states, attributes, delay)
        probe = train_linear_probe(x_probe, y_probe)
        results[delay] = evaluate_probe(probe, ...)
    results["shuffled_baseline"] = ...
    return results
```

15.3.16 Exercise 15 - Implement Teacher Forcing Conceptually and Observe Its Impact on Sequence Generation

Part 1 - Why this matters

During teacher forcing, the decoder receives the true previous target instead of its own previous prediction. This can accelerate learning but changes the distribution of inputs seen during training.

Implement an autoregressive loop with a configurable teacher-forcing ratio. Compare training loss and free-running generation quality under several ratios.

Part 2 - Mathematical form

$$u_t = \begin{cases} y_{t-1}, & z_t = 1, \\ \hat{y}_{t-1}, & z_t = 0, \end{cases} \qquad z_t \sim \text{Bernoulli}(r).$$

Part 3 - Hints and Helper

Sample the teacher-forcing decision explicitly and detach discrete sampled predictions before reusing them as inputs.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    hidden = initial_hidden
    input_t = start_token
    outputs = []
    for t in range(targets.shape[1]):
        logits, hidden = decoder.step(input_t, hidden)
        outputs.append(logits)
        use_teacher = ...
        predicted = ...
        input_t = targets[:, t] if use_teacher else predicted
    return torch.stack(outputs, dim=1)
```

15.3.17 Exercise 16 - Investigate Exposure Bias in Autoregressive Sequence Generation with RNN

Part 1 - Why this matters

A teacher-forced model trains on correct prefixes but generates from prefixes containing its own mistakes. This train–inference mismatch can cause errors to compound over long outputs.

Evaluate the same model with true-prefix and free-running generation. Measure accuracy by generation step and quantify how the gap grows after the first error.

Part 2 - Mathematical form

$$\Delta_t = \mathbb{E}[\ell_t^{\text{free}}] - \mathbb{E}[\ell_t^{\text{teacher}}].$$

Part 3 - Hints and Helper

Use the same starting context. Record the first-error position and later recovery rather than only complete-sequence accuracy.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    teacher_outputs = generate(model, data, mode="teacher_forced")
    free_outputs = generate(model, data, mode="free_running")
    teacher_error = error_by_step(teacher_outputs, targets)
    free_error = ...
    first_errors = ...
    return {"gap_by_step": free_error - teacher_error,
            "first_error_positions": first_errors}
```

15.3.18 Exercise 17 - Stress Test Very Long Sequences and Identify Practical Limits for Vanilla RNN Memory

Part 1 - Why this matters

A vanilla RNN may execute on a long sequence while failing to preserve the information needed from its beginning. Computational feasibility and usable temporal memory are different limits.

Increase dependency distance and sequence length while measuring probe accuracy, task accuracy, state similarity, runtime, and memory. Identify where information and engineering limits occur.

Part 2 - Mathematical form

$$d_{\text{memory}} = \max\{d : A(d) \geq \tau_A\}, \qquad T_{\text{system}} = \max\{T : M(T) \leq M_{\max}\}.$$

Part 3 - Hints and Helper

Report the memory horizon separately from the longest sequence that merely fits in memory.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    records = []
    for length in config.sequence_lengths:
        sample, target, marker = make_long_memory_batch(length, ...)
        states, _ = model(sample.to(device))
        records.append({
```

```
            "length": length,
            "probe_accuracy": ...,
            "task_accuracy": ...,
            "runtime_ms": ...,
            "peak_memory": ...,
        })
    return identify_practical_limits(records, thresholds=...)
```

15.3.19 Exercise 18 - Build a Hidden State Debugging Checklist for Shapes, Devices, and Temporal Alignment

Part 1 - Why this matters

Recurrent bugs often produce plausible tensors while mixing layers, directions, batches, or time steps. A repeatable checklist prevents debugging from depending on intuition alone.

Create executable checks for configuration, state shapes, devices, dtypes, finite values, state-reset rules, padding alignment, temporal ordering, and expected gradient behavior.

Part 2 - Mathematical form

$$\text{valid} = S \wedge D \wedge P \wedge F \wedge A \wedge R.$$

Part 3 - Hints and Helper

Each failed check should name the expected and observed condition and point to the exact tensor or time boundary.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    checks = {
        "shape": check_hidden_shapes(...),
        "device_dtype": check_device_dtype(...),
        "finite": check_finite_states(...),
        "alignment": check_temporal_alignment(...),
        "reset_policy": check_state_reset(...),
        "padding": check_padding_behavior(...),
    }
    failed = ...
    return {"passed": not failed, "checks": checks, "failed": failed}
```

15.3.20 Exercise 19 - Produce a Detailed Report Explaining Hidden State Dynamics and Their Failure Modes

Part 1 - Why this matters

A hidden-state analysis is complete only when observations are connected to temporal equations, controlled experiments, practical limits, and debugging evidence. The report consolidates those conclusions for later BPTT work.

Write a reproducible report covering state evolution, initialization, depth, directionality, capacity, precision, probing, generation mismatch, long-memory limits, and observed failures.

Part 2 - Mathematical form

$$\mathcal{R} = \{E, I, L, D, C, P, Q, G, M, F\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

Include plots and configuration metadata, distinguish evidence from interpretation, and state what the experiments cannot prove.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    sections = collect_evidence(
        evolution=..., initialization=..., depth=..., directionality=...,
        capacity=..., precision=..., probes=..., generation=...,
        memory_limits=..., failures=...)
    report = render_report(sections)
    validate_required_evidence(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.4 RNN02 - Backpropagation Through Time (BPTT)

Models and Training

15.4.1 Exercise 00 - Define Backpropagation Through Time and Explain How It Extends Standard Backprop

Part 1 - Why this matters

An RNN reuses one transition across many time steps, but its loss depends on the chain of states produced by those repeated applications. Backpropagation through time exposes that recurrent chain as one deep computational graph.

Unroll a tiny RNN on paper and in code, mark every dependency from the loss to earlier states, and explain how shared parameters collect gradient contributions from multiple time steps.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial W_{hh}} = \sum_{t=1}^{T} \frac{\partial L}{\partial h_t} \frac{\partial h_t}{\partial W_{hh}}, \qquad \frac{\partial h_T}{\partial h_t} = \prod_{k=t+1}^{T} \frac{\partial h_k}{\partial h_{k-1}}.$$

Part 3 - Hints and Helper

Distinguish copies of an operation in the unrolled graph from the single shared parameter tensor used by every copy.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    sequence = ...
    hidden = initial_hidden
    states = []
    for x_t in sequence:
        hidden = recurrent_step(x_t, hidden, parameters=...)
        states.append(hidden)
    loss = compute_loss(states, targets=...)
    graph_description = trace_dependencies(loss, states)
    return loss, graph_description
```

15.4.2 Exercise 01 - Implement an RNN Training Loop and Confirm Gradients Flow Through Time Steps

Part 1 - Why this matters

A complete recurrent training step must preserve the graph from relevant earlier states to the loss. Code can run and update parameters even when an accidental detach prevents temporal learning.

Train a small RNN on a history-dependent task, retain selected state gradients, and verify that early states receive nonzero gradients from a later loss.

Part 2 - Mathematical form

$$\theta \leftarrow \theta - \eta \nabla_\theta L, \qquad \frac{\partial L_T}{\partial h_t} \neq 0 \text{ for relevant } t < T.$$

Part 3 - Hints and Helper

Call gradient clearing before the forward pass, retain gradients only for the diagnostic states, and update parameters after backward.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    model.train()
    optimizer.zero_grad(set_to_none=True)
    states, prediction = forward_with_retained_states(model, data)
    for state in states:
        state.retain_grad()
    loss = criterion(prediction, target)
    loss.backward()
    early_gradient = states[...].grad
    assert early_gradient is not None
    optimizer.step()
    return loss.item(), gradient_summary(states)
```

15.4.3 Exercise 02 - Inspect Gradient Norms Across Time and Detect Vanishing Gradient Behavior

Part 1 - Why this matters

Vanishing gradients make distant states almost insensitive to a later loss. Parameter gradients alone do not reveal where the temporal signal disappeared.

Retain gradients for every hidden state, backpropagate from a final-step loss, and plot gradient norm against temporal distance. Fit a log-scale trend to quantify decay.

Part 2 - Mathematical form

$$g_t = \left\| \frac{\partial L_T}{\partial h_t} \right\|_2, \qquad g_t \approx C\rho^{T-t}, \quad 0 < \rho < 1.$$

Part 3 - Hints and Helper

Use a controlled saturating recurrence and a log axis. Treat exactly zero and missing gradients as different cases.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    states, final_output = forward_with_retained_states(model, data)
```

```
    loss = criterion(final_output, target)
    loss.backward()
    norms = []
    for state in states:
        norms.append(... if state.grad is not None else None)
    trend = fit_log_gradient_trend(norms)
    return {"norms": norms, "decay_rate": trend}
```

15.4.4 Exercise 03 - Inspect Gradient Norms Across Time and Detect Exploding Gradient Behavior

Part 1 - Why this matters

Repeated recurrent Jacobians can magnify the backward signal until gradients become extremely large or non-finite. This may cause unstable updates even when the forward loss initially looks reasonable.

Construct or train an unstable recurrence, record state and parameter gradient norms, and identify the first temporal distance or iteration where growth becomes dangerous.

Part 2 - Mathematical form

$$g_t \approx C\rho^{T-t}, \quad \rho > 1, \qquad G_\theta = \sqrt{\sum_p \|\nabla_p L\|_2^2}.$$

Part 3 - Hints and Helper

Log values before applying any clipping. Check finiteness separately from threshold-based explosion detection.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    states, prediction = forward_with_retained_states(model, data)
    loss = criterion(prediction, target)
    loss.backward()
    state_norms = ...
    parameter_norm = total_gradient_norm(model.parameters())
    first_explosion = detect_threshold_crossing(state_norms, config.threshold)
    return {"state_norms": state_norms,
            "parameter_norm": parameter_norm,
            "first_explosion": first_explosion}
```

15.4.5 Exercise 04 - Apply Gradient Clipping and Measure Its Stabilization Effect Quantitatively

Part 1 - Why this matters

Gradient clipping limits an update when the global norm exceeds a chosen threshold. It can prevent catastrophic steps, but an overly small threshold can suppress useful learning.

Compare unclipped training with several clipping thresholds using identical initialization and data order. Record pre-clip norm, post-clip norm, update size, finite-loss rate, and convergence.

Part 2 - Mathematical form

$$g' = g \min\left(1, \frac{c}{\|g\|_2 + \epsilon}\right).$$

Part 3 - Hints and Helper

Apply clipping after backward and before the optimizer step. The value returned by norm clipping represents the norm before clipping.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    optimizer.zero_grad(set_to_none=True)
    loss = training_loss(model, batch)
    loss.backward()
    pre_clip_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), max_norm=...
    )
    post_clip_norm = total_gradient_norm(model.parameters())
    optimizer.step()
    return {"loss": loss.item(), "pre": ..., "post": post_clip_norm}
```

15.4.6 Exercise 05 - Implement Truncated BPTT and Compare Memory Usage and Accuracy Trade-Offs

Part 1 - Why this matters

Full BPTT retains dependencies across the complete sequence. Truncated BPTT processes shorter segments and detaches the carried state at boundaries, reducing graph depth and memory.

Split a long sequence into chunks, carry hidden values forward, detach them only between chunks, and compare several truncation lengths on memory, runtime, and task accuracy.

Part 2 - Mathematical form

$$h_{kb}^{\text{next}} = \text{stopgrad}(h_{kb}), \qquad b = \text{truncation length}.$$

Part 3 - Hints and Helper

Detaching should cut gradient history without resetting the numeric hidden state. Define whether optimization happens per chunk or after accumulated chunk losses.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    hidden = model.initial_state(batch_size, device=device)
    metrics = []
    for start in range(0, sequence_length, config.truncation):
        x_chunk = data[:, start:start + config.truncation]
        y_chunk = target[:, start:start + config.truncation]
        hidden = hidden.detach()
        optimizer.zero_grad(set_to_none=True)
        output, hidden = model(x_chunk, hidden)
        loss = criterion(output, y_chunk)
        loss.backward()
        optimizer.step()
        metrics.append(...)
    return summarize_tbptt(metrics)
```

15.4.7 Exercise 06 - Compare Full BPTT vs Truncated BPTT on the Same Synthetic Long-Dependency Task

Part 1 - Why this matters

Truncation saves resources but may block the only gradient path connecting a distant marker to its target. The acceptable window therefore depends on the task's dependency length.

Train full and truncated variants from matched initial states on a delayed-memory task. Sweep truncation length and compare accuracy by dependency distance, memory, and runtime.

Part 2 - Mathematical form

$$A(b, d) = \Pr(\hat{y} = y \mid \text{window} = b, \text{dependency} = d).$$

Part 3 - Hints and Helper

Include cases where $b < d$ and $b \geq d$. Keep total examples, optimizer steps, and evaluation conditions comparable.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    results = {}
    for method, truncation in config.methods:
        candidate = clone_initial_model(model)
        history = train_bptt(
            candidate, loader, truncation=truncation, epochs=config.epochs
        )
        results[method] = {
            "accuracy_by_delay": evaluate_delays(candidate, ...),
            "peak_memory": ...,
            "runtime": ...,
        }
    return results
```

15.4.8 Exercise 07 - Debug Silent Errors Caused by Hidden State Detaching at the Wrong Time

Part 1 - Why this matters

Detaching too early removes temporal credit assignment, while never detaching across independent chunks can connect unrelated data and grow the graph. Both mistakes may avoid immediate exceptions.

Implement correct, early-detach, late-detach, and reset-state variants. Inspect graph connectivity, early-state gradients, memory growth, and learning on a dependency task.

Part 2 - Mathematical form

$$\frac{\partial L_{t+b}}{\partial h_t} = 0 \quad \text{after an unintended detach.}$$

Part 3 - Hints and Helper

Verify numeric state continuity separately from gradient continuity. A state may preserve values while no longer preserving its graph.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    def run_variant(detach_policy):
        hidden = initial_hidden
        early_states = []
        for chunk_index, chunk in enumerate(chunks):
            hidden = apply_detach_policy(hidden, detach_policy, chunk_index)
```

```
            output, hidden = model(chunk, hidden)
            early_states.append(hidden)
        loss = criterion(output, target)
        loss.backward()
        return inspect_connectivity_and_memory(early_states, hidden)

    return {name: run_variant(name) for name in ...}
```

15.4.9 Exercise 08 - Perform Finite Difference Gradient Checking for a Tiny RNN to Validate Backward Correctness

Part 1 - Why this matters

Finite differences provide an independent numerical estimate of a derivative. On a tiny double-precision RNN, they can reveal wrong recurrence equations, loss reductions, or manual backward logic.

Perturb each selected parameter positively and negatively, recompute the scalar loss, and compare the central-difference estimate with autograd.

Part 2 - Mathematical form

$$g_i^{\text{num}} = \frac{L(\theta_i + \epsilon) - L(\theta_i - \epsilon)}{2\epsilon}, \qquad e_i = \frac{|g_i^{\text{auto}} - g_i^{\text{num}}|}{|g_i^{\text{auto}}| + |g_i^{\text{num}}| + \delta}.$$

Part 3 - Hints and Helper

Use float64, a short sequence, smooth activations, and parameter restoration after every perturbation.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    model = model.double()
    loss = scalar_loss(model, data.double(), target.double())
    loss.backward()
    autograd_values = ...
    numerical_values = {}
    for parameter, index in selected_entries(model):
        original = parameter.data[index].item()
        parameter.data[index] = original + config.epsilon
        loss_plus = ...
        parameter.data[index] = original - config.epsilon
        loss_minus = ...
        parameter.data[index] = original
        numerical_values[...] = ...
    return relative_gradient_errors(autograd_values, numerical_values)
```

15.4.10 Exercise 09 - Demonstrate Why Vanilla RNN Struggles with Long-Term Dependencies in Practice

Part 1 - Why this matters

Theoretical gradient products become meaningful when performance collapses as the dependency distance grows. A vanilla RNN may learn short delays while failing on the same rule at longer delays.

Train on a controlled copy or marker-recall task across increasing delays. Relate accuracy to early-state gradient norms and hidden-state probe accuracy.

Part 2 - Mathematical form

$$\frac{\partial L_T}{\partial h_t} = \frac{\partial L_T}{\partial h_T} \prod_{k=t+1}^{T} J_k.$$

Part 3 - Hints and Helper

Keep the underlying rule identical while changing only the delay. Compare against chance performance and report variability across seeds.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    results = []
    for delay in config.delays:
        train_loader, test_loader = make_memory_task(delay=delay, ...)
        candidate = build_vanilla_rnn(...)
        train(candidate, train_loader, ...)
        results.append({
            "delay": delay,
            "accuracy": evaluate(candidate, test_loader),
            "early_gradient": measure_early_gradient(candidate, test_loader),
            "probe_accuracy": probe_past_marker(candidate, test_loader),
        })
    return results
```

15.4.11 Exercise 10 - Execute BPTT on CUDA and Validate Gradient Consistency with CPU Under Controlled Settings

Part 1 - Why this matters

CUDA and CPU may use different kernels and accumulation orders. A recurrent training step should be numerically consistent within tolerance before performance comparisons are

trusted.

Clone identical models, data, targets, and initial states onto both devices. Run forward and backward without optimizer updates and compare losses and every parameter gradient.

Part 2 - Mathematical form

$$e_p = \max_i |\nabla_p L_{\text{CPU},i} - \nabla_p L_{\text{CUDA},i}|.$$

Part 3 - Hints and Helper

Disable dropout, use deterministic settings where supported, and compare named parameters so no gradient is omitted.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    cpu_model = clone_model(model).cpu()
    gpu_model = clone_model(model).cuda()
    gpu_model.load_state_dict(cpu_model.state_dict())
    cpu_loss = forward_backward(cpu_model, cpu_batch, ...)
    gpu_loss = forward_backward(gpu_model, gpu_batch, ...)
    gradient_errors = {}
    for (name_cpu, p_cpu), (name_gpu, p_gpu) in zip(
            cpu_model.named_parameters(), gpu_model.named_parameters()):
        assert name_cpu == name_gpu
        gradient_errors[name_cpu] = ...
    return {"loss_error": ..., "gradient_errors": gradient_errors}
```

15.4.12 Exercise 11 - Profile GPU Memory During BPTT and Identify Graph Retention Bottlenecks

Part 1 - Why this matters

BPTT stores activations needed for backward, so memory grows with sequence length, batch size, hidden size, and retained graphs. Saving loss tensors or states with attached graphs can create additional growth across iterations.

Profile allocated and peak memory across controlled configurations. Compare correct logging with graph-retaining logging and inspect whether memory returns to a stable pattern.

Part 2 - Mathematical form

$$M_{\text{BPTT}} \approx O(TBLH) + M_\theta + M_{\text{optimizer}}.$$

Part 3 - Hints and Helper

Log scalar values with a detached conversion. Do not diagnose allocator caching as a leak without examining live tensor references.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    records = []
    loss_log = []
    for step, batch in enumerate(loader):
        torch.cuda.reset_peak_memory_stats()
        optimizer.zero_grad(set_to_none=True)
        loss = training_loss(model, batch)
        loss.backward()
        optimizer.step()
        loss_log.append(...)
        records.append({"step": step,
                        "allocated": torch.cuda.memory_allocated(),
                        "peak": torch.cuda.max_memory_allocated()})
    return analyze_memory_trend(records)
```

15.4.13 Exercise 12 - Compare float32 vs Mixed-Precision RNN Training and Detect Overflow or Underflow

Part 1 - Why this matters

Mixed precision can reduce memory and improve throughput, but recurrent gradients may already be extremely small or large. Scaling and finiteness checks are essential for interpreting failed updates.

Train matched float32 and mixed-precision runs, tracking loss scale, skipped optimizer steps, gradient norms, non-finite values, throughput, memory, and final quality.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad \nabla L = \frac{1}{s}\nabla \widetilde{L}.$$

Part 3 - Hints and Helper

Unscale gradients before clipping or measuring their true norm. Record when the scaler reduces its scale after detecting overflow.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    scaler = torch.amp.GradScaler("cuda")
```

```
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        loss = training_loss(model, batch)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_norm = ...
    non_finite = ...
    scaler.step(optimizer)
    scaler.update()
    return {"loss": loss.item(), "scale": scaler.get_scale(),
            "gradient_norm": gradient_norm, "non_finite": non_finite}
```

15.4.14 Exercise 13 - Use Autograd Hooks to Log Gradient Norms at Each Time Step and Summarize Results

Part 1 - Why this matters

Hooks can capture backward signals as they reach hidden states without rewriting the gradient computation. They must be registered on the exact tensors whose temporal gradients are being investigated.

Register one hook per retained hidden state, store detached scalar norms indexed by time, run backward, and summarize decay, growth, missing gradients, and non-finite values.

Part 2 - Mathematical form

$$r_t = \log_{10}\left(\left\|\frac{\partial L}{\partial h_t}\right\|_2 + \epsilon\right).$$

Part 3 - Hints and Helper

Capture the time index safely in the hook closure. Store numbers rather than gradient tensors to avoid retaining memory.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    gradient_norms = {}
    handles = []
    for time_index, state in enumerate(states):
        def save_norm(gradient, t=time_index):
            gradient_norms[t] = ...
        handles.append(state.register_hook(save_norm))
    loss.backward()
    for handle in handles:
        handle.remove()
    return summarize_temporal_gradients(gradient_norms)
```

15.4.15 Exercise 14 - Demonstrate Gradient Accumulation When Forgetting zero_grad in an RNN Training Loop

Part 1 - Why this matters

PyTorch adds new gradients to existing parameter gradient buffers. Forgetting to clear them makes each optimizer step depend on previous batches unintentionally.

Run matched steps with correct clearing and with no clearing. Compare gradient tensors and parameter update magnitudes, then distinguish the bug from intentional gradient accumulation.

Part 2 - Mathematical form

$$g_{\text{stored}}^{(k)} = g_{\text{stored}}^{(k-1)} + \nabla_\theta L_k.$$

Part 3 - Hints and Helper

Use identical batches and disable the optimizer step during the first comparison so parameter changes do not confound accumulation.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    model_a = clone_model(model)
    model_b = clone_model(model)
    batches = ...
    correct_norms, buggy_norms = [], []
    for batch in batches:
        model_a.zero_grad(set_to_none=True)
        training_loss(model_a, batch).backward()
        correct_norms.append(total_gradient_norm(model_a.parameters()))

        training_loss(model_b, batch).backward()
        buggy_norms.append(total_gradient_norm(model_b.parameters()))
    return {"correct": correct_norms, "buggy": buggy_norms}
```

15.4.16 Exercise 15 - Analyze Batch Size Impact on Gradient Noise and Convergence in RNN Training

Part 1 - Why this matters

Small batches produce noisier gradient estimates, while large batches consume more memory and may reduce the number of updates per epoch. Sequence padding can also change the effective amount of valid data.

Compare several batch sizes using the same dataset and optimization budget. Estimate gradient variance across batches and report convergence, throughput, memory, and valid-token count.

Part 2 - Mathematical form

$$\widehat{g}_B = \frac{1}{B}\sum_{i=1}^{B} g_i, \qquad \mathrm{Var}(\widehat{g}_B) \approx \frac{\Sigma}{B}.$$

Part 3 - Hints and Helper

Normalize loss consistently by valid tokens or samples. Avoid comparing a sum reduction across different batch sizes.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    results = {}
    for batch_size in config.batch_sizes:
        loader = build_loader(batch_size=batch_size, ...)
        candidate = clone_initial_model(model)
        gradient_samples = collect_gradient_vectors(
            candidate, loader, count=...
        )
        results[batch_size] = {
            "gradient_variance": ...,
            "training_history": train(candidate, loader, ...),
            "throughput": ...,
            "peak_memory": ...,
        }
    return results
```

15.4.17 Exercise 16 - Debug NaN Loss by Checking Learning Rate, Initialization, and Sequence Length

Part 1 - Why this matters

A NaN loss is a symptom, not a root cause. In recurrent training, aggressive learning rates, unstable recurrent weights, long products, invalid data, or precision overflow may interact.

Build a diagnostic step that checks inputs, outputs, loss, gradients, and parameters for finiteness, then isolate learning rate, initialization scale, and sequence length through controlled sweeps.

Part 2 - Mathematical form

$$\text{finite}(X, \theta, H, L, \nabla\theta) = \bigwedge_{z} \mathbf{1}[|z| < \infty].$$

Part 3 - Hints and Helper

Stop at the first non-finite stage and record the preceding gradient and parameter norms. Do not continue optimizer updates after corruption.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    diagnostics = {}
    for learning_rate, scale, steps in config.cases:
        candidate = build_model(initialization_scale=scale)
        batch = make_batch(sequence_length=steps)
        result = run_instrumented_step(candidate, batch, learning_rate)
        diagnostics[(learning_rate, scale, steps)] = {
            "first_non_finite_stage": ...,
            "gradient_norm": ...,
            "parameter_norm": ...,
        }
    return diagnose_root_causes(diagnostics)
```

15.4.18 Exercise 17 - Stress Test BPTT with Long Sequences and Large Hidden Size to Observe Practical Limits

Part 1 - Why this matters

Sequence length deepens the graph, while hidden size increases recurrent computation and stored activations. Their interaction determines runtime, memory, and numerical stability.

Sweep safe combinations of sequence length and hidden size, measure forward and backward time separately, peak memory, gradient norm, and task signal, and stop cleanly at system limits.

Part 2 - Mathematical form

$$C \approx O(TB(HD + H^2)), \qquad M \approx O(TBLH).$$

Part 3 - Hints and Helper

Increase one dimension at a time before testing a grid. Catch out-of-memory cases and record them instead of silently skipping them.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    records = []
    for steps, hidden_size in config.grid:
        try:
            candidate = build_rnn(hidden_size).to(device)
            batch = make_batch(steps).to(device)
            forward_ms, loss = timed_forward(candidate, batch)
            backward_ms = timed_backward(loss)
            records.append({"steps": steps, "hidden": hidden_size,
                            "forward_ms": forward_ms,
                            "backward_ms": backward_ms,
                            "peak_memory": ..., "gradient_norm": ...})
        except torch.cuda.OutOfMemoryError:
            records.append({"steps": steps, "hidden": hidden_size,
                            "status": "out_of_memory"})
    return records
```

15.4.19 Exercise 18 - Build a BPTT Debugging Checklist for Detach Strategy, Truncation, and Gradient Clipping

Part 1 - Why this matters

BPTT failures span graph connectivity, temporal alignment, reduction, state boundaries, gradient scale, device placement, and optimizer order. A checklist turns these into executable release gates.

Create checks that verify the chosen truncation policy, hidden-state continuity, detach boundaries, nonzero early gradients, clipping order, finite values, gradient clearing, and memory stability.

Part 2 - Mathematical form

$$\text{valid} = G \wedge D \wedge T \wedge C \wedge Z \wedge F \wedge M.$$

Part 3 - Hints and Helper

Every failed check should include expected behavior, observed evidence, and the exact corrective action to investigate.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    checks = {
        "graph_connectivity": check_early_state_gradient(...),
```

```
        "detach_boundaries": check_detach_policy(...),
        "truncation": check_truncation_alignment(...),
        "clipping_order": check_clipping_order(...),
        "gradient_clearing": check_gradient_clearing(...),
        "finite_values": check_finiteness(...),
        "memory_stability": check_memory_trend(...),
    }
    failed = {
        name: result
        for name, result in checks.items()
        if not result.passed
    }
    return {"passed": not failed, "failed": failed, "checks": checks}
```

15.4.20 Exercise 19 - Write a Full BPTT Engineering Report Explaining Experimental Failures and Fixes

Part 1 - Why this matters

A reliable BPTT implementation needs evidence connecting temporal derivatives, observed gradients, resource trade-offs, numerical behavior, and corrections. A final report preserves that engineering reasoning.

Produce a reproducible report covering full and truncated BPTT, gradient checking, vanishing and exploding behavior, clipping, detach errors, CUDA parity, memory, precision, batch size, NaNs, and practical limits.

Part 2 - Mathematical form

$$\mathcal{R} = \{U, G, V, E, C, T, D, N, P, B, S, F\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

For every failure include reproduction conditions, measurements, root-cause evidence, applied fix, and a regression test.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    evidence = collect_evidence(
        unrolling=..., gradients=..., vanishing=..., exploding=...,
        clipping=..., truncation=..., detach=..., numerical_check=...,
        cuda=..., memory=..., precision=..., stress_limits=...)
```

```
    report = render_engineering_report(evidence)
    validate_failure_fix_pairs(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.5 RNN03 - Sequence Data Preparation and Batching

Models and Training

15.5.1 Exercise 00 - Convert Raw Sequential Data into Sliding Windows and Validate Correct Input–Target Alignment

Part 1 - Why this matters

A raw time series is an ordered record, not yet a supervised learning dataset. Sliding windows transform that record into examples by selecting a historical context and the future value or horizon that the model must predict.

The most dangerous error is an incorrect index relationship between a window and its target. The tensors may have valid shapes and the loss may decrease while the model learns the current value, an unintended horizon, or information that belongs to the future.

Build windows from a sequence with easily traceable values, write the expected indices manually, and test the first, middle, and final examples. The experiment must prove both shape correctness and semantic alignment.

Part 2 - Mathematical form

$$X_i = (s_i, \ldots, s_{i+w-1}), \qquad Y_i = (s_{i+w+g-1}, \ldots, s_{i+w+g+h-2}).$$

Part 3 - Hints and Helper

Define window length w, forecast gap g, and horizon h explicitly. Derive the number of valid samples before allocating tensors.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    series = ...
    window, gap, horizon = ...
    inputs, targets, index_map = [], [], []
    last_start = ...
    for start in range(last_start):
        x = ...
        y = ...
```

```
        inputs.append(x)
        targets.append(y)
        index_map.append(...)
    validate_alignment(series, inputs, targets, index_map)
    return torch.stack(inputs), torch.stack(targets)
```

15.5.2 Exercise 01 - Implement a Custom Dataset for Sequence Pairs and Validate getitem Correctness

Part 1 - Why this matters

A custom dataset defines what one training example means. In sequence learning, it often maps an index to a window and target without materializing every overlapping window in memory.

An incorrect length calculation or boundary offset can omit valid examples, read beyond the series, or pair an input with the wrong target. Since the DataLoader trusts the dataset, that mistake propagates through the complete training pipeline.

Implement lazy indexing, reject invalid indices, and compare selected items against direct slices from the source. Also verify that repeated access is deterministic and does not mutate the raw data.

Part 2 - Mathematical form

$$N_{\text{samples}} = N - w - g - h + 2.$$

Part 3 - Hints and Helper

Test index 0, the last valid index, and an invalid index. Return tensors with a stable dtype and documented shapes.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    class SequencePairDataset(torch.utils.data.Dataset):
        def __init__(self, series, window, gap, horizon):
            self.series = ...
            self.window = window
            self.gap = gap
            self.horizon = horizon
        def __len__(self):
            return ...
        def __getitem__(self, index):
            if index < 0 or index >= len(self):
                raise IndexError(...)
```

```
            x = ...
            y = ...
            return x, y

    dataset = SequencePairDataset(...)
    return validate_dataset_items(dataset, source=...)
```

15.5.3 Exercise 02 - Implement Padding for Variable-Length Sequences and Explain Why Padding Is Needed

Part 1 - Why this matters

A dense batch requires every sequence tensor to share one time dimension, but real sequences may contain different numbers of observations. Padding adds placeholder positions so the samples can be stacked and processed together.

Padding creates storage, not information. If the model or loss treats padded positions as real observations, batch composition changes the learned objective and shorter sequences contribute artificial values that never existed in the data.

Pad a batch manually and with the PyTorch utility, preserve the original lengths, and construct a validity mask. Verify that every original sequence is recovered exactly from its valid region.

Part 2 - Mathematical form

$$X_{i,t} = \begin{cases} s_{i,t}, & t < \ell_i, \\ p, & t \geq \ell_i, \end{cases} \qquad M_{i,t} = \mathbf{1}[t < \ell_i].$$

Part 3 - Hints and Helper

Choose a padding value that is documented, but never rely on the value alone to identify valid positions when that value can appear naturally.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    sequences = ...
    lengths = torch.tensor([len(seq) for seq in sequences])
    max_length = ...
    padded = torch.full((len(sequences), max_length, ...), fill_value=...)
    for index, sequence in enumerate(sequences):
        padded[index, :lengths[index]] = ...
    mask = ...
    validate_round_trip(padded, mask, sequences)
    return padded, lengths, mask
```

15.5.4 Exercise 03 - Implement Packed Sequences with pack_padded_sequence and Validate Correctness

Part 1 - Why this matters

Packed sequences allow an RNN to skip padded time steps instead of performing recurrent updates on placeholders. This can save computation and prevents padded suffixes from altering the final state.

Packing changes the representation from a rectangular tensor to packed data plus batch-size metadata. Length order, CPU placement of length information, and the chosen batch layout must agree with the packing call.

Pack a variable-length batch, process it through an RNN, unpack the output, and compare each valid prefix with an independently processed sequence. This establishes semantic correctness rather than merely successful execution.

Part 2 - Mathematical form

$$P = \text{pack}(X, \ell), \qquad (Y, \ell) = \text{unpack}(\text{RNN}(P)).$$

Part 3 - Hints and Helper

Use `enforce_sorted=False` unless you intentionally sort. Check valid positions only; values beyond each restored length are padding.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    padded, lengths = ...
    packed = torch.nn.utils.rnn.pack_padded_sequence(
        padded, lengths.cpu(), batch_first=True, enforce_sorted=...
    )
    packed_output, hidden = model(packed)
    output, restored_lengths = torch.nn.utils.rnn.pad_packed_sequence(
        packed_output, batch_first=True
    )
    parity = compare_valid_prefixes(model, sequences, output, lengths)
    return output, hidden, restored_lengths, parity
```

15.5.5 Exercise 04 - Debug Packing Bugs from Wrong Length Sorting and Misaligned Outputs

Part 1 - Why this matters

Packing may require sorting sequences by length, and sorting changes sample order. If targets, identifiers, or final outputs are not permuted consistently, predictions become attached to the wrong examples.

Another failure occurs when reported lengths include padding or exclude valid tokens. The RNN then processes unintended placeholders or truncates real observations, changing both outputs and gradients without necessarily producing an error.

Create deliberately unsorted sequences, record their IDs, sort and pack them, then restore the original order with an inverse permutation. Add tests for wrong lengths, inconsistent target sorting, and equal-length ties.

Part 2 - Mathematical form

$$X_s = X[\pi], \qquad Y_s = Y[\pi], \qquad \hat{Y} = \hat{Y}_s[\pi^{-1}].$$

Part 3 - Hints and Helper

Preserve the sorting permutation and compute its inverse explicitly. Verify restored request IDs before comparing predictions with targets.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    lengths = ...
    sorted_lengths, permutation = lengths.sort(descending=True)
    inverse = torch.argsort(permutation)
    sorted_inputs = padded[permutation]
    sorted_targets = targets[permutation]
    packed = torch.nn.utils.rnn.pack_padded_sequence(
        sorted_inputs, sorted_lengths.cpu(), batch_first=True
    )
    sorted_outputs = run_and_unpack(model, packed, ...)
    outputs = sorted_outputs[inverse]
    return validate_restored_alignment(
        outputs, targets, ids, permutation, inverse
    )
```

15.5.6 Exercise 05 - Compare Padded vs Packed Training and Measure Speed and Memory Differences

Part 1 - Why this matters

Padded execution is simple and often efficient on regular hardware, but it spends computation on unused suffixes. Packed execution removes this waste, although packing, sorting, and

irregular sequence structure introduce their own overhead.

The benefit depends on the distribution of sequence lengths, not only on the maximum length. A nearly uniform batch may gain little from packing, while a highly imbalanced batch can waste most padded operations.

Train or benchmark both paths with identical weights and valid-token loss. Compare output parity on real positions, forward and backward time, peak memory, and the fraction of padding in each batch.

Part 2 - Mathematical form

$$r_{\text{pad}} = 1 - \frac{\sum_i \ell_i}{BT_{\max}}, \qquad S = \frac{t_{\text{padded}}}{t_{\text{packed}}}.$$

Part 3 - Hints and Helper

Warm up both paths and synchronize CUDA timing. Correctness comparison must ignore padded positions.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    results = {}
    for mode in ["padded", "packed"]:
        candidate = clone_model(model)
        warmup(candidate, batch, mode=mode)
        results[mode] = benchmark_training_step(
            candidate, batch, mode=mode, valid_mask=mask
        )
    results["padding_ratio"] = ...
    results["valid_output_parity"] = ...
    return results
```

15.5.7 Exercise 06 - Build a Collate Function That Produces Batch-First Tensors with Correct Padding Masks

Part 1 - Why this matters

The collate function is the boundary between individual dataset examples and one training batch. It decides padding, lengths, target structure, identifiers, masks, and ordering in a single operation.

If it changes sample order without carrying IDs and targets, or constructs a mask with reversed meaning, every later component receives internally inconsistent data. Debugging the

model will not repair a corrupted batch contract.

Build a collator that accepts variable-length examples and returns a named batch-first structure. Test shapes, valid counts, recovered sequences, target alignment, and behavior for a batch of size one.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{B \times T_{\max} \times D}, \qquad M \in \{0,1\}^{B \times T_{\max}}, \qquad \sum_t M_{i,t} = \ell_i.$$

Part 3 - Hints and Helper

Document whether mask value one means valid or padded. Use one convention consistently in the model and loss.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    def collate_sequence_batch(examples):
        sequences, targets, ids = zip(*examples)
        lengths = torch.tensor(...)
        padded = torch.nn.utils.rnn.pad_sequence(
            sequences, batch_first=True, padding_value=...
        )
        time = torch.arange(padded.shape[1])
        valid_mask = ...
        return {"inputs": padded, "targets": ...,
                "lengths": lengths, "valid_mask": valid_mask, "ids": ids}

    return validate_collate_function(collate_sequence_batch, examples=...)
```

15.5.8 Exercise 07 - Validate Masking So Loss Ignores Padding Time Steps Correctly

Part 1 - Why this matters

A sequence loss should measure errors only where a real target exists. Averaging across the entire padded rectangle gives shorter samples less influence and allows arbitrary padded logits to change the reported objective.

Masking must be applied to the unreduced per-position loss before aggregation. Multiplying an already averaged scalar by a mask cannot recover which positions contributed to that scalar.

Compute the masked loss manually, compare it with a direct loss over concatenated valid positions, and alter padded logits aggressively. The valid loss must remain unchanged.

Part 2 - Mathematical form

$$L = \frac{\sum_{i,t} M_{i,t} \ell(z_{i,t}, y_{i,t})}{\sum_{i,t} M_{i,t}}.$$

Part 3 - Hints and Helper

Use a denominator equal to the valid position count. For class losses, flatten logits and targets consistently before masking.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    per_step = criterion(logits.reshape(...), targets.reshape(...))
    per_step = per_step.reshape(targets.shape)
    valid = mask.to(per_step.dtype)
    masked_loss = ...
    direct_loss = criterion(
        logits[mask], targets[mask]
    )
    changed_logits = corrupt_only_padded_logits(logits, mask)
    assert masked_loss_is_invariant(changed_logits, ...)
    return masked_loss, direct_loss
```

15.5.9 Exercise 08 - Create a Variable-Length Synthetic Dataset and Verify the Training Pipeline Handles It

Part 1 - Why this matters

A synthetic dataset provides known sequence lengths, targets, and generating rules. It lets the pipeline be tested independently of noise and uncertainty in real data.

The dataset should include short, long, equal-length, and boundary cases while keeping the target rule learnable. This reveals assumptions such as nonempty sequences, fixed lengths, or masks that fail for the shortest sample.

Generate reproducible examples, pass them through the dataset, collator, DataLoader, model, and masked loss, then intentionally overfit a tiny subset. Successful overfitting is an end-to-end correctness test, not a generalization claim.

Part 2 - Mathematical form

$$\ell_i \sim \mathcal{D}_L, \qquad x_i \in \mathbb{R}^{\ell_i \times D}, \qquad y_i = f(x_i).$$

Part 3 - Hints and Helper

Store the seed and generation parameters. Validate each target directly from the unpadded source before batching.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    class VariableLengthDataset(torch.utils.data.Dataset):
        def __init__(self, size, min_length, max_length, seed):
            generator = torch.Generator().manual_seed(seed)
            self.examples = ...
        def __len__(self):
            return len(self.examples)
        def __getitem__(self, index):
            return self.examples[index]

    dataset = VariableLengthDataset(...)
    loader = torch.utils.data.DataLoader(
        dataset, collate_fn=..., batch_size=...
    )
    return verify_and_overfit_tiny_subset(model, dataset, loader)
```

15.5.10 Exercise 09 - Debug Training Instability from Incorrect Padding Masks or Wrong Loss Reduction

Part 1 - Why this matters

An unstable loss is not always caused by the optimizer. If padded positions dominate the reduction, batches with different length distributions produce objectives at different effective scales.

A mask with reversed meaning can train entirely on padding, while a sum reduction makes gradient magnitude grow with the number of valid tokens. Both bugs can appear as learning-rate sensitivity, gradient explosion, or inconsistent convergence.

Instrument valid counts, masked and unmasked losses, gradient norms, and per-sample contributions. Compare correct masking against several deliberate failures to identify their statistical signatures.

Part 2 - Mathematical form

$$L_{\text{sum}} = \sum_{i,t} M_{i,t}\ell_{i,t}, \qquad L_{\text{mean}} = \frac{L_{\text{sum}}}{\sum_{i,t} M_{i,t}}.$$

Part 3 - Hints and Helper

Log the valid denominator for every batch. Reject all-padding batches before division rather than hiding them with a large epsilon.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    diagnostics = {}
    for mask_mode, reduction in config.cases:
        optimizer.zero_grad(set_to_none=True)
        logits = model(batch["inputs"])
        loss = compute_sequence_loss(
            logits, batch["targets"], batch["valid_mask"],
            mask_mode=mask_mode, reduction=reduction
        )
        loss.backward()
        diagnostics[(mask_mode, reduction)] = {
            "loss": loss.item(), "valid_count": ...,
            "gradient_norm": ..., "sample_contributions": ...}
    return diagnose_mask_reduction_failures(diagnostics)
```

15.5.11 Exercise 10 - Move the Sequence Batching Pipeline to CUDA Efficiently and Minimize Host-to-Device Transfers

Part 1 - Why this matters

GPU efficiency depends on feeding complete batches rather than moving individual sequences or time steps repeatedly. Each small transfer can introduce synchronization and prevent overlap between data loading and computation.

Not every field belongs on CUDA. Inputs, targets, and masks used in tensor computation should move together, while identifiers and metadata may remain on the CPU. Length tensors may also have API-specific placement requirements.

Implement a single batch-transfer function, use pinned memory and non-blocking copies when supported, and measure transfer time separately from model time. Verify that no hidden transfer remains inside the recurrent loop.

Part 2 - Mathematical form

$$T_{\text{step}} = T_{\text{load}} + T_{H \to D} + T_{\text{compute}} + T_{\text{sync}}.$$

Part 3 - Hints and Helper

Do not call CUDA transfer on each time slice. Preserve CPU lengths when required for sequence packing.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
```

```
    def move_batch(batch, device):
        return {
            "inputs": batch["inputs"].to(device, non_blocking=True),
            "targets": batch["targets"].to(device, non_blocking=True),
            "valid_mask": batch["valid_mask"].to(device, non_blocking=True),
            "lengths": ...,
            "ids": batch["ids"],
        }

    device_batch = move_batch(batch, device)
    transfer_ms, compute_ms = benchmark_transfer_and_compute(
        model, device_batch
    )
    return transfer_ms, compute_ms
```

15.5.12 Exercise 11 - Benchmark DataLoader Throughput with num_workers and pin_memory Settings

Part 1 - Why this matters

The DataLoader can become the bottleneck when sequence slicing, padding, sorting, or collation is expensive. GPU utilization then falls even if the model itself is fast.

More workers do not guarantee higher throughput. Process startup, inter-process transfer, storage speed, CPU contention, batch size, and the cost of the collator determine the useful configuration.

Benchmark a controlled grid of worker and pinned-memory settings after warm-up. Measure batches per second, valid tokens per second, wait time, and end-to-end training throughput rather than timing loading in isolation only.

Part 2 - Mathematical form

$$Q = \frac{\sum_b \sum_i \ell_{b,i}}{T_{\text{wall}}}, \qquad U_{\text{input}} = \frac{T_{\text{wait}}}{T_{\text{step}}}.$$

Part 3 - Hints and Helper

Use the same dataset order and number of batches. On CUDA, test pinned memory together with non-blocking transfer.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    records = []
    for workers in config.worker_counts:
        for pin_memory in [False, True]:
```

```
            loader = build_loader(
                num_workers=workers, pin_memory=pin_memory,
                persistent_workers=...
            )
            result = benchmark_loader_and_training(loader, model, device)
            records.append({"workers": workers, "pin_memory": pin_memory,
                            "batches_per_second": ...,
                            "valid_tokens_per_second": ...,
                            "step_time": ...})
    return records
```

15.5.13 Exercise 12 - Implement Gradient Accumulation for Long Sequences Under Limited GPU Memory

Part 1 - Why this matters

Long sequences may prevent the desired effective batch from fitting in GPU memory. Gradient accumulation divides that batch into smaller micro-batches while delaying the optimizer update.

Equivalence requires loss scaling and consistent valid-token normalization. Simply dividing every micro-batch loss by the number of micro-batches is exact only when their contributions have equal weight under the chosen reduction.

Implement accumulation, compare its gradient with a true combined batch on a small case, and handle the final incomplete accumulation group. Measure peak memory and update frequency.

Part 2 - Mathematical form

$$g = \frac{1}{N_{\text{valid}}} \sum_{m=1}^{M} \sum_{i,t \in m} M_{i,t} \nabla_\theta \ell_{i,t}.$$

Part 3 - Hints and Helper

Accumulate a valid-loss sum and valid count when micro-batches contain different sequence lengths. Clip only after the full accumulated gradient is ready.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    optimizer.zero_grad(set_to_none=True)
    valid_total = ...
    for micro_index, batch in enumerate(micro_batches):
        loss_sum, valid_count = sequence_loss_sum(model, batch)
        scaled_loss = ...
```

```
        scaled_loss.backward()
        should_step = ...
        if should_step:
            optional_clip(model.parameters(), ...)
            optimizer.step()
            optimizer.zero_grad(set_to_none=True)
    return compare_with_true_large_batch(model, reference_model, ...)
```

15.5.14 Exercise 13 - Validate Reproducibility of Sequence Batching Under Random Shuffling and Fixed Seeds

Part 1 - Why this matters

Reproducible training requires reproducible batch membership, order, padding, random synthetic generation, and worker behavior. Setting only the model seed does not control the data pipeline.

Multiple DataLoader workers have independent random states, and persistent workers change when initialization occurs. Random transformations inside a dataset add another source of variation.

Record sample IDs and batch signatures for repeated runs, reset generators consistently, and compare both identical-seed and different-seed behavior. Document deterministic ordering separately from deterministic model kernels.

Part 2 - Mathematical form

$$\mathcal{B}_r = (I_{r,1}, \ldots, I_{r,K}), \qquad \mathcal{B}_a = \mathcal{B}_b \text{ when seeds and settings match.}$$

Part 3 - Hints and Helper

Pass an explicit generator to the DataLoader and seed every worker from its assigned initial seed.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    def collect_batch_order(seed):
        generator = torch.Generator().manual_seed(seed)
        loader = build_loader(
            shuffle=True, generator=generator, worker_init_fn=...,
            num_workers=config.num_workers
        )
        return [tuple(batch["ids"]) for batch in loader]

    order_a = collect_batch_order(config.seed)
```

```
    order_b = collect_batch_order(config.seed)
    order_c = collect_batch_order(config.seed + 1)
    return {"same_seed_equal": ..., "different_seed_equal": ...,
            "order_a": order_a}
```

15.5.15 Exercise 14 - Implement a Train–Validation Split Without Leakage in Sequential Time-Series Data

Part 1 - Why this matters

Randomly splitting overlapping windows can place nearly identical contexts on both sides of the evaluation boundary. It may also train on observations that occur after validation targets, violating the forecasting scenario.

Leakage can enter before splitting when scaling, imputation, feature engineering, or window construction uses the complete timeline. A chronological index split alone is insufficient if preprocessing has already observed the future.

Choose a time boundary, fit preprocessing only on the training region, and construct windows whose source and target indices remain within their assigned region. Add a gap when overlapping context near the boundary must be excluded.

Part 2 - Mathematical form

$$\max(\mathcal{T}_{\text{train}}) < \min(\mathcal{T}_{\text{val}}), \qquad \theta_P = \text{fit}(X_{\text{train}}).$$

Part 3 - Hints and Helper

Store raw timestamps for every window and assert that no validation target timestamp appears in training inputs or preprocessing statistics.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    boundary = ...
    gap = ...
    train_raw = series.loc[:boundary]
    validation_raw = series.loc[boundary + gap:]
    preprocessor = fit_preprocessor(train_raw)
    train_data = make_windows(
        preprocessor.transform(train_raw), ...
    )
    validation_data = make_windows(
        preprocessor.transform(validation_raw), ...
    )
    leakage_report = audit_temporal_indices(
```

```
        train_data, validation_data, boundary=boundary, gap=gap
    )
    assert leakage_report["passed"]
    return train_data, validation_data, leakage_report
```

15.5.16 Exercise 15 - Implement Teacher-Forcing Dataset Format for Sequence-to-Sequence Tasks

Part 1 - Why this matters

A sequence-to-sequence decoder usually receives a shifted target prefix and predicts the next target at every step. The decoder input and expected output contain related values but must not occupy the same temporal positions.

Special start, end, and padding tokens affect lengths and masks. An incorrect shift can expose the answer directly to the decoder or ask it to predict a target that is one position too early or late.

Construct encoder input, decoder input, and decoder target explicitly, then verify every pair token by token. Test normal, minimum-length, and padded examples before training.

Part 2 - Mathematical form

$$D_{\text{in}} = (\langle s \rangle, y_1, \ldots, y_{T-1}), \qquad D_{\text{target}} = (y_1, \ldots, y_T).$$

Part 3 - Hints and Helper

Padding masks for decoder input and target may differ around special tokens. Print one complete formatted example with its IDs.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    def format_seq2seq(source, target, start_id, end_id, pad_id):
        encoder_input = ...
        decoder_input = ...
        decoder_target = ...
        return {
            "encoder_input": encoder_input,
            "decoder_input": decoder_input,
            "decoder_target": decoder_target,
            "target_mask": ...,
        }

    formatted = [format_seq2seq(...) for source, target in examples]
    return validate_teacher_forcing_shift(formatted)
```

15.5.17 Exercise 16 - Implement Stateful RNN Batching and Decide When to Reset Hidden States Correctly

Part 1 - Why this matters

Stateful training carries hidden values from one batch segment to the next. This is valid only when each batch column continues the same logical stream in the correct temporal order.

Ordinary shuffling breaks that continuity, and a smaller final batch changes which state belongs to which sample. Carrying state across unrelated users, documents, or series leaks context between independent examples.

Design a stream-aware sampler with stable stream IDs, detach state at graph boundaries, reset it at real sequence boundaries, and test continuity with traceable values. Compare stateful and stateless behavior explicitly.

Part 2 - Mathematical form

$$h_{k,0} = \begin{cases} h_{k-1,T}, & \text{same stream continues,} \\ 0, & \text{new stream begins.} \end{cases}$$

Part 3 - Hints and Helper

Track hidden state by stream ID rather than batch position unless batch membership is guaranteed to remain fixed.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    state_by_stream = {}
    reset_policy = ...
    for batch in stream_loader:
        stream_ids = batch["stream_ids"]
        initial = assemble_states(
            state_by_stream, stream_ids,
            reset_flags=reset_policy(batch["reset"])
        )
        output, final_state = model(batch["inputs"], initial.detach())
        update_states(state_by_stream, stream_ids, final_state)
        verify_stream_continuity(batch, state_by_stream)
    return state_by_stream
```

15.5.18 Exercise 17 - Detect and Fix Alignment Bugs That Make an RNN Learn the Wrong Target Shift

Part 1 - Why this matters

Sequence models can achieve a deceptively low loss when targets are shifted incorrectly. For slowly changing signals, predicting the present instead of the future may still look accurate.

Visual inspection of aggregate loss cannot reveal which source timestamp produced each target. Alignment must be represented and tested at the index level before tensors lose their original temporal labels.

Create a monotonic diagnostic series, store source and target indices, and test the intended horizon for every window. Compare a correct dataset with zero-shift, double-shift, and off-by-one variants.

Part 2 - Mathematical form

$$\text{target_index}(i) = i + w + g - 1 \quad \text{for horizon one.}$$

Part 3 - Hints and Helper

Use values equal to their original indices during testing. This makes a wrong shift immediately visible in tensor contents.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    diagnostic_series = torch.arange(..., dtype=torch.float32)
    variants = {
        "correct": make_windows(...),
        "zero_shift": make_windows(...),
        "off_by_one": make_windows(...),
    }
    reports = {}
    for name, dataset in variants.items():
        reports[name] = audit_input_target_indices(
            dataset,
            expected_window=...,
            expected_gap=...,
            expected_horizon=...,
        )
    return reports
```

15.5.19 Exercise 18 - Build a Sequence Data Pipeline Checklist Covering Padding, Packing, and Masking

Part 1 - Why this matters

A sequence pipeline is a chain of contracts: raw ordering, window alignment, split boundaries, preprocessing, dataset indexing, collation, padding, packing, masking, transfer, and loss

reduction. A failure in an early contract invalidates all later model results.

Many of these bugs are silent because the resulting tensors retain valid shapes. A checklist must therefore verify semantic invariants such as timestamp order, target horizon, valid counts, sample identity, and preprocessing scope.

Convert the checklist into executable gates with expected values and evidence. Run it on normal batches and on deliberately corrupted cases so every check is proven capable of failing.

Part 2 - Mathematical form

$$\text{ready} = O \wedge A \wedge S \wedge P \wedge D \wedge C \wedge K \wedge M \wedge R.$$

Part 3 - Hints and Helper

A passing result must include evidence, not only a Boolean. Report the exact sample IDs and indices involved in a failure.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    checks = {
        "ordering": check_raw_order(...),
        "alignment": check_window_target_alignment(...),
        "split": check_temporal_split(...),
        "preprocessing": check_fit_scope(...),
        "dataset": check_dataset_boundaries(...),
        "collate": check_batch_contract(...),
        "packing": check_pack_round_trip(...),
        "masking": check_masked_loss(...),
        "reproducibility": check_batch_reproducibility(...),
    }
    return evaluate_pipeline_gates(checks, corrupted_cases=...)
```

15.5.20 Exercise 19 - Produce a Full Sequence Data Preparation Report with Verified Edge Cases

Part 1 - Why this matters

Model quality cannot be interpreted without a precise account of how raw sequences became training examples. The preparation report preserves the temporal assumptions that are otherwise hidden inside indexing and batching code.

The report must distinguish mathematical task definition from storage format and runtime optimization. Sliding windows define the learning problem; padding and packing represent

batches; masks define valid supervision; DataLoader settings affect delivery performance.

Document evidence for alignment, leakage prevention, preprocessing scope, variable lengths, packing, masking, reproducibility, CUDA transfer, stateful boundaries, and edge cases. Every conclusion should link to a reproducible test or artifact.

Part 2 - Mathematical form

$$\mathcal{R} = \{R, W, S, P, D, C, K, M, L, G, E\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

Include empty or minimum-length sequences, batch size one, final incomplete batch, equal lengths, extreme length imbalance, and split-boundary windows.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    evidence = collect_pipeline_evidence(
        raw_data=..., windows=..., split=..., preprocessing=...,
        dataset=..., collate=..., padding=..., packing=..., masking=...,
        cuda_transfer=..., reproducibility=..., edge_cases=...)
    report = render_data_preparation_report(evidence)
    validate_required_edge_cases(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.6 RNN04 - Language Modeling with Vanilla RNN

Models and Training

15.6.1 Exercise 00 - Implement Character-Level Tokenization and Build a Vocabulary with Correct Index Mapping

Part 1 - Why this matters

A language model cannot process characters directly; it receives integer identifiers whose meanings are defined by a vocabulary. Character tokenization preserves spaces, punctuation, capitalization, and line breaks as distinct events when the vocabulary includes them.

A nondeterministic or inconsistent mapping changes the meaning of saved weights. If training and inference assign different IDs to the same character, the model receives and produces

the wrong symbols without any tensor-shape error.

Build a deterministic vocabulary, implement encoding and decoding, define behavior for unknown characters, and prove round-trip correctness on normal and edge-case text. Save the mapping as part of the model artifact.

Part 2 - Mathematical form

$$V = \text{sorted}(\text{unique}(C)), \qquad e : V \to \{0, \ldots, |V| - 1\}, \qquad d(e(c)) = c.$$

Part 3 - Hints and Helper

Test spaces, repeated characters, punctuation, newlines, and unseen characters. Never rebuild the vocabulary independently during inference.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    text = ...
    characters = ...
    stoi = {character: index for index, character in enumerate(characters)}
    itos = {index: character for character, index in stoi.items()}
    encoded = ...
    decoded = ...
    assert decoded == text
    return {"stoi": stoi, "itos": itos, "encoded": encoded}
```

15.6.2 Exercise 01 - Build a Simple Character-Level RNN Language Model and Verify Output Logit Shapes

Part 1 - Why this matters

A character language model transforms token IDs into embeddings, processes their temporal order with an RNN, and projects every hidden state to one score per vocabulary character. These scores are logits, not probabilities.

The model must preserve batch and time dimensions while changing only the feature dimension. Flattening time too early or selecting only the final state silently converts next-character modeling into a different task.

Implement the architecture and assert shapes at embedding, recurrent, and projection stages. Confirm that the output contains a complete vocabulary distribution for every input position.

Part 2 - Mathematical form

$$X \in \mathbb{N}^{B\times T} \to E \in \mathbb{R}^{B\times T\times D} \to H \in \mathbb{R}^{B\times T\times H} \to Z \in \mathbb{R}^{B\times T\times |V|}.$$

Part 3 - Hints and Helper

Return the final hidden state separately from logits. Do not apply softmax before the cross-entropy loss.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    class CharacterRNN(torch.nn.Module):
        def __init__(self, vocab_size, embedding_size, hidden_size):
            super().__init__()
            self.embedding = torch.nn.Embedding(...)
            self.rnn = torch.nn.RNN(..., batch_first=True)
            self.output = torch.nn.Linear(...)
        def forward(self, tokens, hidden=None):
            embedded = ...
            states, hidden = ...
            logits = ...
            assert logits.shape == (...)
            return logits, hidden

    return CharacterRNN(...)
```

15.6.3 Exercise 02 - Implement Cross-Entropy Loss for Next-Character Prediction and Validate Target Alignment

Part 1 - Why this matters

Next-character training uses the character at position t to predict the character at position $t+1$. Input and target sequences therefore overlap but are shifted by exactly one position.

An incorrect shift can expose the answer, predict the current token, or skip an intended character. Because neighboring characters are correlated, a misaligned model may still show a decreasing loss.

Construct a traceable text example, print every input-target pair, flatten logits and targets consistently, and compare the PyTorch loss with a manual negative log-probability calculation.

Part 2 - Mathematical form

$$x = (c_1, \ldots, c_{T-1}), \qquad y = (c_2, \ldots, c_T), \qquad L = -\frac{1}{B(T-1)} \sum_{b,t} \log p(y_{b,t} \mid x_{b,1:t}).$$

Part 3 - Hints and Helper

Check alignment before batching. The class dimension must be last before reshaping logits to two dimensions.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    inputs = encoded[:, :-1]
    targets = ...
    logits, _ = model(inputs)
    assert logits.shape[:2] == targets.shape
    loss = torch.nn.functional.cross_entropy(
        logits.reshape(...), targets.reshape(...)
    )
    manual_loss = ...
    return loss, manual_loss, display_token_pairs(inputs, targets, itos=...)
```

15.6.4 Exercise 03 - Train a Tiny RNN Language Model Until It Overfits a Small Text Sample on Purpose

Part 1 - Why this matters

Intentionally overfitting a tiny text sample is an end-to-end correctness test. A model with enough capacity should memorize the training transitions when tokenization, alignment, gradients, optimization, and hidden-state handling are correct.

Failure to overfit does not prove that the architecture is weak; it often reveals a pipeline bug, excessive regularization, an unsuitable learning rate, or a state reset error. Conversely, memorization does not demonstrate generalization.

Train on one short repeated text until loss and token accuracy reach strict targets, then generate from a known prefix. Record the configuration so the test becomes a reusable regression check.

Part 2 - Mathematical form

$$\theta^* = \arg\min_{\theta} L_{\text{tiny}}(\theta), \qquad A_{\text{train}} \to 1.$$

Part 3 - Hints and Helper

Disable dropout and augmentation. Verify that the same tiny batch is used and stop after either the success threshold or a fixed maximum iteration count.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    model.train()
    history = []
    for step in range(config.max_steps):
        optimizer.zero_grad(set_to_none=True)
        logits, _ = model(tiny_inputs)
        loss = criterion(logits.reshape(...), tiny_targets.reshape(...))
        loss.backward()
        optimizer.step()
        accuracy = ...
        history.append({"step": step, "loss": loss.item(),
                        "accuracy": accuracy})
        if loss.item() < ... and accuracy >= ...:
            break
    return history, generate_from_prefix(model, ...)
```

15.6.5 Exercise 04 - Generate Text Autoregressively and Observe Repetition and Instability Patterns

Part 1 - Why this matters

Autoregressive generation feeds each sampled character back as the next input. The model therefore conditions on its own growing output rather than the correct prefixes seen during training.

A small local mistake changes the future context and may push generation into repetitive loops, invalid transitions, or unstable patterns. These failures can remain hidden when evaluation uses teacher-forced inputs only.

Implement generation one step at a time, preserve hidden state across generated tokens, and log probabilities and entropy. Compare several prompts and identify where repetition begins.

Part 2 - Mathematical form

$$c_{t+1} \sim p_\theta(\cdot \mid c_{1:t}), \qquad h_{t+1} = f(c_{t+1}, h_t).$$

Part 3 - Hints and Helper

Prime the hidden state with the complete prompt, then generate from its final character. Use inference mode and an explicit maximum length.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
```

```
model.eval()
tokens = encode(prompt)
hidden = None
with torch.inference_mode():
    for token in tokens[:-1]:
        _, hidden = model(token.reshape(...), hidden)
    current = tokens[-1].reshape(...)
    generated = list(tokens)
    diagnostics = []
    for step in range(config.generate_length):
        logits, hidden = model(current, hidden)
        probabilities = ...
        next_token = ...
        generated.append(next_token.item())
        diagnostics.append(...)
        current = next_token.reshape(...)
return decode(generated), diagnostics
```

15.6.6 Exercise 05 - Implement Temperature Sampling and Analyze Diversity vs Coherence

Part 1 - Why this matters

Temperature rescales logits before the probability distribution is formed. Low temperature sharpens preferences and makes common continuations more likely, while high temperature distributes probability across less likely characters.

Temperature does not improve the learned model; it changes how that model is sampled. Extremely low values approach greedy decoding, while high values can expose weakly learned transitions and produce incoherence.

Generate multiple samples at controlled temperatures and seeds. Measure entropy, repetition, novelty, invalid-character behavior, and qualitative coherence instead of judging one convenient example.

Part 2 - Mathematical form

$$p_i(\tau) = \frac{\exp(z_i/\tau)}{\sum_j \exp(z_j/\tau)}, \qquad \tau > 0.$$

Part 3 - Hints and Helper

Reject nonpositive temperature and apply scaling to logits before softmax. Compare many samples per setting.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    def sample_with_temperature(logits, temperature, generator):
        if temperature <= 0:
            raise ValueError(...)
        probabilities = ...
        return torch.multinomial(probabilities, 1, generator=generator)

    results = {}
    for temperature in config.temperatures:
        samples = [generate(model, sampler=sample_with_temperature,
                            temperature=temperature, seed=seed)
                   for seed in config.seeds]
        results[temperature] = evaluate_generation_set(
            samples, training_text=...
        )
    return results
```

15.6.7 Exercise 06 - Implement Top-k Sampling and Compare with Temperature-Only Sampling

Part 1 - Why this matters

Top-k sampling restricts selection to the k highest-scoring characters. It prevents very low-probability symbols from being sampled while preserving randomness among the retained candidates.

The method interacts with temperature: temperature changes relative probability within the selected set, while k changes which characters are allowed at all. A small k may cause loops, and a large k may resemble unrestricted sampling.

Implement top-k filtering manually, verify that excluded probabilities become zero, and compare several (k, au) combinations using identical prompts and seeds.

Part 2 - Mathematical form

$$S_k = \mathrm{TopK}(z), \qquad p_i = 0 \text{ if } i \notin S_k.$$

Part 3 - Hints and Helper

Validate $1 \leq k \leq |V|$. Apply temperature and top-k consistently before normalization.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
```

```
    def top_k_sample(logits, k, temperature, generator):
        if k < 1 or k > logits.shape[-1]:
            raise ValueError(...)
        scaled = ...
        values, indices = torch.topk(scaled, k, dim=-1)
        filtered = torch.full_like(scaled, float("-inf"))
        filtered.scatter_(..., indices, values)
        probabilities = ...
        token = torch.multinomial(probabilities, 1, generator=generator)
        return token, probabilities

    return compare_sampling_grid(model, ks=..., temperatures=...)
```

15.6.8 Exercise 07 - Debug Generation Bugs Caused by Incorrect Hidden-State Reset Behavior

Part 1 - Why this matters

Hidden state contains the processed context. Resetting it at every generated character removes long context, while carrying it across unrelated prompts leaks information from one request into another.

Another common bug processes the prompt once and then processes its final token again, duplicating context. Stateful batching can also attach a hidden state to the wrong sample when generation requests finish at different times.

Implement correct reset, per-token reset, never reset, and duplicated prompt variants. Compare deterministic outputs and hidden-state traces to identify the signature of each failure.

Part 2 - Mathematical form

$$h_0^{(r)} = 0 \text{ for a new request}, \qquad h_t^{(r)} \not\to h_0 \text{ within the same request.}$$

Part 3 - Hints and Helper

Define request boundaries explicitly. Test prompts independently and then in different execution orders to detect cross-request leakage.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    variants = {}
    for policy in ["correct", "reset_each_token",
                   "carry_across_prompts", "duplicate_last_prompt_token"]:
        variants[policy] = []
        state_store = ...
```

```
        for prompt in prompts:
            text, state_trace = generate_with_state_policy(
                model, prompt, policy=policy, state_store=state_store
            )
            variants[policy].append({"text": text, "trace": state_trace})
    return detect_reset_failures(variants)
```

15.6.9 Exercise 08 - Compare Sequence Length and Its Effect on Learning Short vs Long Patterns

Part 1 - Why this matters

Training sequence length determines how much context is visible in one unrolled graph. Short segments are cheaper and produce more updates, but they cannot directly assign credit across dependencies longer than the segment.

Long segments expose wider context while increasing memory, runtime, and gradient instability. Carrying hidden state between short segments preserves numeric context, but detaching it limits backward credit assignment.

Train matched models across sequence lengths on text containing known short and long patterns. Evaluate losses and accuracies by dependency type as well as throughput and memory.

Part 2 - Mathematical form

$$L_T = -\frac{1}{T}\sum_{t=1}^{T} \log p(c_{t+1} \mid c_{1:t}), \qquad M = O(TBH).$$

Part 3 - Hints and Helper

Keep the number of processed tokens comparable. Report whether hidden state is reset, carried, or detached between segments.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    results = {}
    for sequence_length in config.sequence_lengths:
        dataset = build_language_windows(text, sequence_length)
        candidate = clone_initial_model(model)
        history = train_language_model(candidate, dataset, ...)
        results[sequence_length] = {
            "short_pattern_score": ...,
            "long_pattern_score": ...,
            "tokens_per_second": ...,
            "peak_memory": ...,
```

```
            "history": history,
        }
    return results
```

15.6.10 Exercise 09 - Evaluate an RNN Language Model with Perplexity and Interpret What the Number Means

Part 1 - Why this matters

Perplexity is the exponential of average negative log-likelihood. It summarizes how much probability the model assigns to the observed next characters under a specific tokenizer and dataset.

A lower value indicates better predictive probability on that evaluation distribution, but perplexity is not directly comparable across different vocabularies, tokenization rules, or inconsistent loss reductions. It also does not fully measure generated-text quality.

Compute token-weighted validation loss without gradients, convert it to perplexity, compare against simple baselines, and inspect per-position surprise so the aggregate number has context.

Part 2 - Mathematical form

$$\mathrm{PPL} = \exp\left(-\frac{1}{N}\sum_{i=1}^{N}\log p(c_i \mid c_{<i})\right).$$

Part 3 - Hints and Helper

Accumulate summed loss and valid token count before division. Guard against exponent overflow and report the average NLL alongside perplexity.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    model.eval()
    negative_log_likelihood = 0.0
    token_count = 0
    with torch.inference_mode():
        for inputs, targets in validation_loader:
            logits, _ = model(inputs)
            loss_sum = torch.nn.functional.cross_entropy(
                logits.reshape(...), targets.reshape(...), reduction="sum"
            )
            negative_log_likelihood += loss_sum.item()
            token_count += ...
    average_nll = ...
    perplexity = ...
    return {"nll": average_nll, "perplexity": perplexity,
            "baseline": ...}
```

15.6.11 Exercise 10 - Train a Character RNN on CUDA and Measure Speed Improvement over a CPU Baseline

Part 1 - Why this matters

CUDA acceleration depends on batch size, sequence length, hidden size, vocabulary projection, and data delivery. A small character model may spend more time in transfer and launch overhead than in useful computation.

A fair CPU–GPU comparison requires identical model weights, token batches, optimizer behavior, and measured work. CUDA operations are asynchronous, so unsynchronized timers produce misleading results.

Train controlled steps on both devices, validate loss and gradient consistency, and report tokens per second, step latency, memory, and end-to-end transfer cost after warm-up.

Part 2 - Mathematical form

$$S = \frac{Q_{\text{GPU}}}{Q_{\text{CPU}}}, \qquad Q = \frac{BT}{t_{\text{step}}}.$$

Part 3 - Hints and Helper

Generate or load batches outside the timed region, synchronize CUDA at measurement boundaries, and include transfer cost separately.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    cpu_model = clone_model(model).cpu()
    gpu_model = clone_model(model).cuda()
    gpu_model.load_state_dict(cpu_model.state_dict())
    cpu_result = benchmark_training(
        cpu_model, cpu_batches, device="cpu", warmup=...
    )
    gpu_result = benchmark_training(
        gpu_model, gpu_batches, device="cuda", warmup=..., synchronize=True
    )
    parity = compare_controlled_step(cpu_model, gpu_model, batch=...)
    return {"cpu": cpu_result, "gpu": gpu_result, "parity": parity}
```

15.6.12 Exercise 11 - Profile GPU Utilization and Fix Language-Model Input Pipeline Bottlenecks

Part 1 - Why this matters

Low GPU utilization often means the accelerator is waiting for tokenization, window construction, collation, transfer, or Python work. Increasing model complexity to raise utilization does not fix the data bottleneck.

Character windows are cheap mathematically but can be expensive when rebuilt one sample at a time. Pre-encoding text, vectorized slicing, pinned batches, and persistent workers may reduce idle gaps.

Profile loading, transfer, forward, backward, and optimizer phases separately. Change one pipeline setting at a time and verify that throughput improves without changing token order or targets.

Part 2 - Mathematical form

$$T_{\text{step}} = T_{\text{wait}} + T_{H\to D} + T_f + T_b + T_o.$$

Part 3 - Hints and Helper

Measure valid tokens per second and GPU idle gaps. Preserve one correctness batch for parity checks after every optimization.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    baseline = profile_training_pipeline(model, loader, device)
    experiments = {}
    for setting in config.pipeline_settings:
        candidate_loader = build_optimized_loader(setting, ...)
        profile = profile_training_pipeline(model, candidate_loader, device)
        parity = compare_batch_contract(loader, candidate_loader, fixture=...)
        experiments[setting.name] = {"profile": profile, "parity": parity}
    return identify_input_bottlenecks(baseline, experiments)
```

15.6.13 Exercise 12 - Implement Mixed-Precision Training and Detect Instability in Long-Sequence Language Modeling

Part 1 - Why this matters

Mixed precision reduces activation memory and may improve throughput, allowing longer sequences or larger batches. Recurrent gradient products and a large vocabulary projection can nevertheless produce underflow or overflow.

A finite loss does not guarantee that every gradient is usable. The scaler may skip optimizer steps, while small recurrent gradients can disappear even when output-layer gradients remain measurable.

Compare full and mixed precision across sequence lengths, logging loss scale, skipped steps, layer-wise gradient norms, non-finite values, memory, throughput, and validation perplexity.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad \nabla L = s^{-1}\nabla \widetilde{L}.$$

Part 3 - Hints and Helper

Unscale before clipping and true gradient inspection. Record the scaler value before and after each update.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    scaler = torch.amp.GradScaler("cuda")
    optimizer.zero_grad(set_to_none=True)
    scale_before = scaler.get_scale()
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        logits, _ = model(inputs)
        loss = criterion(logits.reshape(...), targets.reshape(...))
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_report = ...
    scaler.step(optimizer)
    scaler.update()
    return {"loss": loss.item(), "scale_before": scale_before,
            "scale_after": scaler.get_scale(), "gradients": gradient_report}
```

15.6.14 Exercise 13 - Compare Vanilla RNN with GRU or LSTM and Document Why Vanilla RNN Fails

Part 1 - Why this matters

Vanilla RNN, GRU, and LSTM all process sequences recurrently, but gated models regulate memory updates through learned paths. Their additional parameters aim to preserve useful information and gradients over longer dependencies.

A comparison is meaningful only when data, tokenization, training budget, evaluation, and approximate capacity are controlled. A stronger gated result alone does not identify which vanilla limitation caused the difference.

Train all architectures on text with measurable short and long patterns. Compare perplexity by dependency distance, gradient flow, convergence, generation, runtime, memory, and parameter count.

Part 2 - Mathematical form

$$h_t^{\text{RNN}} = \tanh(W_x x_t + W_h h_{t-1} + b), \qquad h_t^{\text{gated}} = G(x_t, h_{t-1}; \theta).$$

Part 3 - Hints and Helper

Report both matched-hidden-size and approximately matched-parameter comparisons when possible.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    architectures = {"rnn": ..., "gru": ..., "lstm": ...}
    results = {}
    for name, candidate in architectures.items():
        history = train_language_model(candidate, train_loader, ...)
        results[name] = {
            "perplexity_by_dependency": ...,
            "gradient_flow": ...,
            "generation_metrics": ...,
            "parameters": ..., "runtime": ..., "memory": ...,
            "history": history,
        }
    return controlled_architecture_comparison(results)
```

15.6.15 Exercise 14 - Implement Truncated BPTT for Language Modeling and Quantify Memory Savings

Part 1 - Why this matters

A long text stream can be divided into temporal chunks while hidden state carries context forward. Detaching state at chunk boundaries limits how far gradients travel backward and prevents the graph from growing indefinitely.

Truncated BPTT preserves numeric memory beyond a chunk but not credit assignment across the detach boundary. This distinction affects patterns whose cause and target fall in different chunks.

Implement stream-contiguous chunks, compare truncation lengths, and measure peak memory, runtime, perplexity, and accuracy on dependencies shorter and longer than the truncation window.

Part 2 - Mathematical form

$$h_{kb}^{+} = \text{stopgrad}(h_{kb}), \qquad M_b < M_T.$$

Part 3 - Hints and Helper

Do not shuffle chunks within a carried stream. Reset state at true document boundaries and detach at configured graph boundaries.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    hidden = None
    records = []
    for chunk, targets, boundary in stream_chunks:
        if boundary:
            hidden = ...
        elif hidden is not None:
            hidden = detach_state(hidden)
        optimizer.zero_grad(set_to_none=True)
        logits, hidden = model(chunk, hidden)
        loss = criterion(logits.reshape(...), targets.reshape(...))
        loss.backward()
        optimizer.step()
        records.append({"loss": loss.item(), "peak_memory": ...})
    return summarize_truncation_tradeoffs(records, dependency_tests=...)
```

15.6.16 Exercise 15 - Debug Training Divergence through Learning Rate, Clipping, and Initialization

Part 1 - Why this matters

Divergence can arise when recurrent weights amplify states and gradients, the learning rate converts a large gradient into a destructive update, or initialization places activations near saturation. These causes interact.

Changing several controls simultaneously may stop NaNs without identifying the cause. Reliable debugging observes the first unstable stage and varies one factor under matched seeds and batches.

Sweep learning rate, clipping threshold, and recurrent initialization scale while logging states, logits, loss, gradient norms, update norms, and finiteness. Convert the findings into a stable configuration and regression test.

Part 2 - Mathematical form

$$\Delta\theta = -\eta \operatorname{clip}(g, c), \qquad \rho(W_{hh}) \text{ influences recurrent stability.}$$

Part 3 - Hints and Helper

Stop immediately at the first non-finite value. Preserve the batch and pre-update checkpoint that reproduce the failure.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    diagnostics = {}
    for learning_rate, clip_norm, init_scale in config.grid:
        candidate = build_model(recurrent_scale=init_scale)
        result = run_instrumented_training(
            candidate, fixed_batches, learning_rate=learning_rate,
            clip_norm=clip_norm, stop_on_non_finite=True
        )
        diagnostics[(learning_rate, clip_norm, init_scale)] = result
    stable_config = select_stable_configuration(diagnostics, criteria=...)
    return diagnostics, verify_regression_test(stable_config, ...)
```

15.6.17 Exercise 16 - Build a Generation Evaluation Script for Repetition and Novelty Metrics

Part 1 - Why this matters

Generated text should not be evaluated only by a visually pleasing sample. Repetition, training-text copying, character diversity, and invalid transitions require measurements across prompts and random seeds.

Novelty is not automatically quality: random noise is novel, while correct language naturally repeats common patterns. Metrics must therefore be interpreted together with likelihood and human-readable examples.

Build a reproducible evaluator for repeated n-grams, unique n-grams, longest copied substring, entropy, and novelty relative to training text. Aggregate results across generation settings.

Part 2 - Mathematical form

$$R_n = 1 - \frac{|\operatorname{unique}(G_n)|}{|G_n|}, \qquad N_n = 1 - \frac{|G_n \cap T_n|}{|G_n|}.$$

Part 3 - Hints and Helper

State how short samples and repeated whitespace are handled. Preserve prompts separately so they are not counted as generated copying.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
```

```
    def generation_metrics(generated, training_text, prompt, n):
        continuation = remove_prompt_prefix(generated, prompt)
        generated_ngrams = ngrams(continuation, n)
        training_ngrams = set(ngrams(training_text, n))
        return {
            "repetition_rate": ...,
            "novelty_rate": ...,
            "unique_ngram_ratio": ...,
            "longest_training_match": ...,
            "character_entropy": ...,
        }

    return evaluate_generation_grid(
        model, prompts=..., seeds=..., metrics_fn=...
    )
```

15.6.18 Exercise 17 - Create a Controlled Long-Term Dependency Failure Experiment for Vanilla RNN

Part 1 - Why this matters

Natural text mixes many causes, making it difficult to prove why a model forgot distant context. A controlled language-like task can place an opening marker far before a required closing symbol while keeping local context uninformative.

If the dependency rule remains fixed and only distance changes, declining accuracy can be connected to memory and gradient limitations. Local baselines and shuffled markers help rule out shortcuts.

Generate matched datasets across distances, train vanilla RNNs under controlled conditions, and measure target accuracy, early-state gradient norm, probe accuracy, and hidden-state separation.

Part 2 - Mathematical form

$$y_T = f(c_{T-d}), \qquad I(y_T; c_{T-k:T-1}) = 0 \text{ for } k < d.$$

Part 3 - Hints and Helper

Balance every target and verify that the suffix distribution is identical across labels. Run multiple seeds.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    results = []
```

```
    for distance in config.distances:
        dataset = make_controlled_dependency_text(
            distance=distance, balanced=True, prevent_local_shortcuts=True
        )
        candidate = build_vanilla_rnn(...)
        train_language_model(candidate, dataset.train, ...)
        results.append({
            "distance": distance,
            "target_accuracy": ...,
            "early_gradient_norm": ...,
            "probe_accuracy": ...,
            "hidden_separation": ...,
        })
    return analyze_failure_horizon(results, chance_level=...)
```

15.6.19 Exercise 18 - Stress Test Language Modeling with Longer Text and Identify GPU Memory and Speed Limits

Part 1 - Why this matters

Scaling text length increases dataset size, while sequence length, batch size, embedding size, hidden size, and vocabulary size determine per-step compute and memory. These dimensions constrain different parts of the pipeline.

The vocabulary projection can dominate output memory, and BPTT activations grow with time. Data loading may become the bottleneck even before the GPU reaches its memory limit.

Run a safe configuration grid, measure loader wait, transfer, forward, backward, optimizer time, peak memory, tokens per second, and validation quality. Record out-of-memory and unstable cases explicitly.

Part 2 - Mathematical form

$$M_{\text{logits}} = O(BT|V|), \qquad M_{\text{states}} = O(BTH), \qquad C_{\text{RNN}} = O(BT(HD + H^2)).$$

Part 3 - Hints and Helper

Increase one dimension at a time before testing combinations. Clear references between trials and keep correctness checks active.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    records = []
    for case in config.stress_grid:
        try:
```

```
            candidate, loader = build_stress_case(case)
            result = benchmark_language_training(candidate, loader, device,
                                                 profile_phases=True)
            records.append({"case": case, "status": "ok", **result})
        except torch.cuda.OutOfMemoryError:
            records.append({"case": case, "status": "out_of_memory"})
    return identify_system_limits(records, quality_threshold=...)
```

15.6.20 Exercise 19 - Produce a Full Character-Level RNN Language Modeling Report with Failure Analysis and Fixes

Part 1 - Why this matters

A complete language-model report must connect text representation, target alignment, architecture, optimization, probability evaluation, sampling behavior, and system performance. Generated examples alone are insufficient evidence.

Failures should be reproducible and classified: token mapping mismatch, alignment error, state reset bug, repetition, exposure bias, gradient instability, long-term memory failure, precision failure, or resource limit. Each class requires a different fix.

Produce an evidence-based report with fixed artifacts, plots, tables, prompts, seeds, checkpoints, and regression tests. State clearly what a character-level vanilla RNN can demonstrate and why later gated models are needed.

Part 2 - Mathematical form

$$\mathcal{R} = \{T, A, M, O, G, S, P, B, F, L, E\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

For every claimed fix include the original failure, controlled change, new measurement, and remaining limitation.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    evidence = collect_language_model_evidence(
        tokenization=..., alignment=..., model=..., overfit_test=...,
        generation=..., sampling=..., perplexity=..., bptt=...,
        cuda=..., precision=..., long_dependencies=..., stress_limits=...)
    report = render_language_model_report(evidence)
    validate_failure_fix_evidence(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.7 RNN05 - Time Series Forecasting with Vanilla RNN

Models and Training

15.7.1 Exercise 00 - Convert Time Series into Supervised Windows and Verify the Correct Target Horizon

Part 1 - Why this matters

A time series becomes a supervised dataset only after historical observations are assigned to inputs and later observations are assigned to targets. Window length, forecast gap, and horizon define the forecasting question the model is actually trained to answer.

An off-by-one error can turn a future forecast into reconstruction of the present or prediction of the wrong date. Because neighboring observations are correlated, the resulting metrics may still look strong and hide the mistake.

Build windows from timestamped diagnostic data, retain source and target indices, and verify the first, middle, and last samples manually. The test must prove that every target begins at the intended future horizon.

Part 2 - Mathematical form

$$X_i = (s_i, \ldots, s_{i+w-1}), \qquad Y_i = (s_{i+w+g-1}, \ldots, s_{i+w+g+h-2}).$$

Part 3 - Hints and Helper

Define whether gap one means the immediately following observation. Store timestamps before converting data to anonymous tensors.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    series, timestamps = ...
    window, gap, horizon = ...
    inputs, targets, metadata = [], [], []
    for start in range(...):
        input_slice = ...
        target_slice = ...
        inputs.append(input_slice)
        targets.append(target_slice)
        metadata.append({"input_times": ..., "target_times": ...})
    validate_forecast_horizon(inputs, targets, metadata, gap, horizon)
    return torch.stack(inputs), torch.stack(targets), metadata
```

15.7.2 Exercise 01 - Implement Feature Scaling for Time Series and Explain How It Prevents Training Instability

Part 1 - Why this matters

Time-series features may use very different units and magnitudes. Large-scale features can dominate recurrent activations, loss values, and gradients, pushing nonlinear states toward saturation or unstable updates.

Scaling parameters are learned information about the data distribution. Fitting them on validation or test periods leaks future statistics into training, while scaling targets incorrectly can make reported errors meaningless in original units.

Fit a scaler only on the training timeline, transform every split with the stored parameters, and implement an inverse transform for predictions. Test constant features and values outside the training range.

Part 2 - Mathematical form

$$z_{t,j} = \frac{x_{t,j} - \mu_j^{\text{train}}}{\sigma_j^{\text{train}} + \epsilon}.$$

Part 3 - Hints and Helper

Compute statistics per feature, not across time and feature axes together. Save the scaler with the checkpoint.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    train_values, validation_values, test_values = ...
    mean = train_values.mean(dim=0, keepdim=True)
    std = ...
    std_safe = torch.where(std > ..., std, torch.ones_like(std))
    train_scaled = ...
    validation_scaled = ...
    test_scaled = ...
    restored = inverse_scale(test_scaled, mean, std_safe)
    assert torch.allclose(restored, test_values)
    scaler_state = {"mean": mean, "std": std_safe}
    return train_scaled, validation_scaled, test_scaled, scaler_state
```

15.7.3 Exercise 02 - Build a Simple RNN Forecaster and Validate Output Shapes for Multi-Step Prediction

Part 1 - Why this matters

A multi-step forecaster maps a historical sequence to several future values. Its output dimensions must distinguish batch, forecast horizon, and target features rather than mixing horizons into the batch or hidden axis.

A direct forecaster can project the final hidden state to all future steps at once. This avoids feedback during inference but asks one representation to encode every horizon and does not model dependencies between predicted future steps explicitly.

Implement a many-to-vector RNN forecaster, reshape its projection deliberately, and assert shapes for single-feature and multivariate targets. Compare one sample manually with the raw linear projection.

Part 2 - Mathematical form

$$X \in \mathbb{R}^{B\times T\times D} \to h_T \in \mathbb{R}^{B\times H} \to \hat{Y} \in \mathbb{R}^{B\times K\times F}.$$

Part 3 - Hints and Helper

Keep batch size one as a real batch. Avoid an unrestricted squeeze that may remove the batch dimension.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    class RNNForecaster(torch.nn.Module):
        def __init__(self, input_size, hidden_size, horizon, target_size):
            super().__init__()
            self.horizon = horizon
            self.target_size = target_size
            self.rnn = torch.nn.RNN(..., batch_first=True)
            self.head = torch.nn.Linear(hidden_size, horizon * target_size)
        def forward(self, x):
            states, hidden = self.rnn(x)
            raw = self.head(states[:, -1])
            forecast = raw.reshape(...)
            assert forecast.shape == (...)
            return forecast

    return RNNForecaster(...)
```

15.7.4 Exercise 03 - Compare One-Step and Multi-Step Forecasting and Explain Error Accumulation

Part 1 - Why this matters

One-step forecasting predicts only the next observation, while multi-step forecasting estimates an entire future horizon. Repeating a one-step model autoregressively changes later inputs from observed values to model-generated values.

Each early prediction error can alter all later forecasts, so long-horizon error includes both model uncertainty and propagated input error. Direct multi-output prediction avoids feedback but may lose the sequential structure between future values.

Compare one-step, recursive, and direct multi-step strategies on the same splits. Report error by horizon and identify where recursive forecasts begin to drift.

Part 2 - Mathematical form

$$\hat{y}_{t+k} = f(\hat{y}_{t+k-1}, \ldots), \qquad e_{t+k} = \hat{y}_{t+k} - y_{t+k}.$$

Part 3 - Hints and Helper

Do not average horizons before examining them separately. Use identical historical context and inverse scaling.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    strategies = {"one_step": ..., "recursive": ..., "direct": ...}
    results = {}
    for name, forecaster in strategies.items():
        predictions = forecast_horizons(forecaster, test_windows, horizon=...)
        results[name] = {
            "predictions": predictions,
            "mae_by_horizon": ...,
            "rmse_by_horizon": ...,
            "drift": ...,
        }
    return results
```

15.7.5 Exercise 04 - Train an RNN on Synthetic Seasonal Data and Confirm It Learns Periodicity

Part 1 - Why this matters

Synthetic seasonal data provides a known period, amplitude, phase, trend, and noise level. This lets the experiment test whether the model learned temporal structure rather than exploiting an unknown property of real data.

A low error does not by itself prove that periodicity was learned. A persistence or seasonal-naive baseline may achieve similar performance, especially when adjacent values change slowly.

Generate controlled seasons, split chronologically, train the RNN, and compare forecasts with persistence and seasonal-naive baselines. Test phase shifts and changed amplitudes to examine what the hidden state captured.

Part 2 - Mathematical form

$$y_t = a \sin\left(\frac{2\pi t}{P} + \phi\right) + bt + \varepsilon_t.$$

Part 3 - Hints and Helper

Choose a window long enough to observe the intended period in at least one experiment. Keep generation seeds and parameters recorded.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    time = torch.arange(..., dtype=torch.float32)
    seasonal = config.amplitude * torch.sin(
        2 * torch.pi * time / config.period + config.phase
    )
    series = seasonal + config.trend * time + ...
    train, validation, test = chronological_split(series, ...)
    model = train_forecaster(model, train, validation, ...)
    baselines = evaluate_seasonal_baselines(test, period=config.period)
    comparison = compare_periodicity_learning(
        model, test, baselines, shifted_cases=...
    )
    return comparison
```

15.7.6 Exercise 05 - Implement Autoregressive Multi-Step Forecasting and Observe Drift over Time

Part 1 - Why this matters

Autoregressive forecasting produces one prediction, appends it to the context, and repeats. The future path is therefore generated under the model's own state distribution rather than the observed distribution used for the initial window.

Bias and noise can accumulate, while scaling errors may push feedback values outside the training range. The forecast may converge to a fixed point, explode, flatten, or drift away from plausible seasonality.

Implement a recursive loop with explicit feature-update rules and no future leakage. Log every context update, hidden state, prediction, and deviation from the direct or observed path.

Part 2 - Mathematical form

$$\hat{y}_{t+k} = f_\theta(X_{t+k-1}), \qquad X_{t+k} = \text{shift}(X_{t+k-1}, \hat{y}_{t+k}).$$

Part 3 - Hints and Helper

For multivariate inputs, define which future exogenous features are known. Never copy true unknown targets into later contexts.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    context = initial_window.clone()
    forecasts, trace = [], []
    for step in range(config.horizon):
        prediction = model(context)[...]
        forecasts.append(prediction)
        next_features = build_next_features(
            prediction=prediction, known_future=..., previous_context=context
        )
        context = torch.cat([context[:, 1:], next_features], dim=1)
        trace.append({"step": step, "context": context.detach().clone(),
                      "prediction": prediction.detach().clone()})
    return torch.stack(forecasts, dim=1), trace
```

15.7.7 Exercise 06 - Implement Teacher Forcing for Forecasting and Compare with Pure Autoregressive Training

Part 1 - Why this matters

Teacher forcing supplies the true previous target during decoder training, while autoregressive training reuses the model's previous prediction. The first strategy stabilizes learning but creates a train–inference mismatch.

Pure autoregressive training exposes the model to its own mistakes, yet it may be harder to optimize and can propagate poor early predictions. A scheduled mixture changes this exposure gradually rather than treating the choice as absolute.

Train matched models with multiple teacher-forcing ratios and evaluate all of them in free-running mode. Compare training loss, validation error by horizon, drift, and sensitivity to the initial forecast error.

Part 2 - Mathematical form

$$u_k = z y_{t+k-1} + (1 - z)\hat{y}_{t+k-1}, \qquad z \sim \text{Bernoulli}(r).$$

Part 3 - Hints and Helper

The validation procedure must not use teacher forcing if deployment will be autoregressive. Record the ratio schedule at each epoch.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    hidden = encode_history(model, history)
    previous = history[:, -1]
    outputs = []
    for step in range(targets.shape[1]):
        prediction, hidden = decoder_step(model, previous, hidden)
        outputs.append(prediction)
        use_teacher = ...
        previous = targets[:, step] if use_teacher else prediction.detach()
    forecasts = torch.stack(outputs, dim=1)
    return forecasts, evaluate_free_running(model, validation_loader, ...)
```

15.7.8 Exercise 07 - Evaluate Forecast Accuracy with MAE and MSE and Interpret Their Different Penalties

Part 1 - Why this matters

MAE measures average absolute deviation and gives errors linear influence. MSE squares deviations, making large mistakes contribute disproportionately and changing both the evaluation emphasis and the gradient when used as a training loss.

A single aggregate number can hide poor distant-horizon forecasts, seasonal regimes, or rare extremes. Metrics in scaled units are also difficult to interpret operationally unless predictions are restored to original units.

Compute MAE, MSE, and RMSE overall, by horizon, and by relevant time regime. Add a controlled outlier to demonstrate how the metrics react differently.

Part 2 - Mathematical form

$$\text{MAE} = \frac{1}{N}\sum_i |e_i|, \qquad \text{MSE} = \frac{1}{N}\sum_i e_i^2, \qquad \text{RMSE} = \sqrt{\text{MSE}}.$$

Part 3 - Hints and Helper

Use the same valid observations for every metric and state the reduction axes. Report original physical units.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    predictions = inverse_scale(predictions_scaled, scaler)
    targets = inverse_scale(targets_scaled, scaler)
    errors = predictions - targets
    metrics = {
        "mae": errors.abs().mean(),
        "mse": errors.square().mean(),
        "rmse": errors.square().mean().sqrt(),
        "mae_by_horizon": ...,
        "rmse_by_horizon": ...,
    }
    outlier_metrics = recompute_with_controlled_outlier(
        predictions, targets, ...
    )
    return metrics, outlier_metrics
```

15.7.9 Exercise 08 - Debug Forecasting Bugs from Wrong Windowing or Misaligned Targets

Part 1 - Why this matters

Windowing errors change the forecasting task without changing tensor validity. A model may accidentally predict the current observation, skip the requested horizon, or learn from future features included in its input.

Smooth time series make these bugs especially deceptive because nearby values are similar. Strong performance against a weak baseline may therefore reflect leakage rather than useful forecasting.

Build index-level audits using timestamps and a monotonic diagnostic series. Compare correct, zero-gap, off-by-one, reversed-time, and future-feature variants and make every corruption trigger a specific failure.

Part 2 - Mathematical form

$$\max \text{time}(X_i) < \min \text{time}(Y_i), \qquad \min \text{time}(Y_i) - \max \text{time}(X_i) = g\Delta t.$$

Part 3 - Hints and Helper

Validate raw indices before scaling or batching. Plot one input-target pair with timestamps for human inspection.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    series, timestamps = ...
    variants = create_alignment_variants(series, timestamps, config)
    reports = {}
    for name, dataset in variants.items():
        reports[name] = audit_forecast_windows(
            dataset, expected_gap=config.gap,
            expected_horizon=config.horizon, forbid_future_features=True
        )
    assert reports["correct"]["passed"]
    assert all(not report["passed"] for name, report in reports.items()
               if name != "correct")
    return reports
```

15.7.10 Exercise 09 - Diagnose Overfitting in Forecasting and Apply Regularization or Early Stopping

Part 1 - Why this matters

A forecaster overfits when training error continues improving while performance on later unseen periods deteriorates. Temporal distribution changes can resemble overfitting, so the validation design must be examined before the model is blamed.

Dropout, weight decay, smaller capacity, and early stopping address different mechanisms. Applying all of them together can hide the cause and produce underfitting without showing which intervention mattered.

Track train and chronological validation metrics by horizon, save the best checkpoint, and run controlled regularization comparisons. Confirm the selected model on a final untouched test period.

Part 2 - Mathematical form

$$e^* = \arg\min_e L_{\text{val}}^{(e)}, \qquad \text{stop if } L_{\text{val}} \text{ fails to improve for } p \text{ epochs.}$$

Part 3 - Hints and Helper

Fit preprocessing on training data only and restore the complete best state, including model selection metadata.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    best_value = float("inf")
```

```
    patience_count = 0
    for epoch in range(config.epochs):
        train_metrics = train_epoch(model, train_loader, ...)
        validation_metrics = evaluate_forecast(model, validation_loader, ...)
        monitored = ...
        if monitored < best_value - config.min_delta:
            best_value = monitored
            best_state = snapshot(model, optimizer, epoch, scaler=...)
            patience_count = 0
        else:
            patience_count += 1
        if patience_count >= config.patience:
            break
    restore_snapshot(model, best_state)
    comparison = compare_regularization_variants(...)
    test_metrics = evaluate_forecast(model, test_loader)
    return comparison, test_metrics
```

15.7.11 Exercise 10 - Train a Time-Series RNN on CUDA and Benchmark End-to-End Throughput Including the Data Pipeline

Part 1 - Why this matters

Moving only the model computation to CUDA does not describe end-to-end training speed. Window creation, collation, host-to-device transfer, synchronization, and metric logging can dominate a small recurrent workload.

CUDA timing is asynchronous, and excluding input delivery can exaggerate speedup. CPU and GPU comparisons must process the same number of windows and valid forecast values under matched optimization conditions.

Profile loader wait, transfer, forward, backward, optimizer, and evaluation phases after warm-up. Validate a controlled CPU–GPU step before accepting performance results.

Part 2 - Mathematical form

$$Q = \frac{N_{\text{windows}}}{T_{\text{wall}}}, \qquad T_{\text{wall}} = T_{\text{load}} + T_{H\to D} + T_f + T_b + T_o.$$

Part 3 - Hints and Helper

Report windows and observed values per second. Use pinned memory with non-blocking transfer only when supported.

Part 4 - Python code skeleton

```
import torch
```

```
def E10(model, data, config):
    cpu_result = benchmark_end_to_end_training(
        clone_model(model).cpu(), cpu_loader, device="cpu", warmup=...
    )
    gpu_result = benchmark_end_to_end_training(
        clone_model(model).cuda(), gpu_loader, device="cuda",
        warmup=..., synchronize=True
    )
    parity = compare_controlled_training_step(
        model, batch=..., tolerances=...
    )
    return {"cpu": cpu_result, "gpu": gpu_result, "parity": parity}
```

15.7.12 Exercise 11 - Profile GPU Memory and Runtime for Sequence Length and Hidden-Size Scaling

Part 1 - Why this matters

Sequence length controls graph depth and stored temporal activations, while hidden size increases recurrent matrix cost approximately quadratically. Their interaction determines whether a configuration is compute-bound, memory-bound, or impractical.

The output horizon and feature count add further cost, but may not dominate the recurrent core. Peak allocation must be measured during backward rather than inferred from model parameter size.

Benchmark a safe grid of lengths and hidden sizes, separating forward and backward time. Record parameters, peak memory, throughput, gradient norm, and failure status.

Part 2 - Mathematical form

$$C = O(TB(HD + H^2)), \qquad M_{\text{act}} = O(TBH).$$

Part 3 - Hints and Helper

Increase one dimension at a time first. Reset peak-memory statistics for every independent trial.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    records = []
    for sequence_length, hidden_size in config.grid:
        try:
            candidate = build_forecaster(hidden_size).to(device)
            batch = make_forecast_batch(sequence_length).to(device)
```

```
            torch.cuda.reset_peak_memory_stats()
            forward_ms, loss = timed_forward(candidate, batch)
            backward_ms = timed_backward(loss)
            records.append({"length": sequence_length, "hidden": hidden_size,
                            "forward_ms": forward_ms,
                            "backward_ms": backward_ms,
                            "peak_memory": ..., "throughput": ...})
        except torch.cuda.OutOfMemoryError:
            records.append({"length": sequence_length, "hidden": hidden_size,
                            "status": "out_of_memory"})
    return records
```

15.7.13 Exercise 12 - Implement Mixed Precision for Forecasting and Identify Stability Failures

Part 1 - Why this matters

Mixed precision may reduce memory and accelerate training, but time-series targets can contain large ranges, small variations, or losses sensitive to squaring. These properties can produce overflow, underflow, or lost resolution.

Scaling the features does not guarantee that recurrent gradients and output errors remain representable. A finite average loss may coexist with zero gradients in early layers or skipped optimizer updates.

Compare float32 and mixed precision across target scales, sequence lengths, and noise levels. Log scaler behavior, layer-wise gradients, non-finite values, accuracy in original units, speed, and memory.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad \nabla L = s^{-1}\nabla \widetilde{L}.$$

Part 3 - Hints and Helper

Unscale before clipping and diagnostics. Compute final forecasting metrics in float32 or float64 after inverse scaling.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    scaler = torch.amp.GradScaler("cuda")
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        forecast = model(inputs)
        loss = criterion(forecast, targets)
```

```
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_report = inspect_gradients(model)
    scaler.step(optimizer)
    scaler.update()
    return {"loss": loss.item(), "scale": scaler.get_scale(),
            "gradients": gradient_report, "original_unit_metrics": ...}
```

15.7.14 Exercise 13 - Compare Vanilla RNN and LSTM Forecasting and Document Long-Term Dependency Gains

Part 1 - Why this matters

An LSTM introduces gates and a cell state intended to preserve selected information across longer distances. It adds parameters and computation, so an improvement must be evaluated against capacity and system cost.

A dataset with mostly short dependencies may not benefit from gating, while seasonal or delayed effects can expose vanilla RNN memory limits. Aggregate error alone may hide where the LSTM begins to help.

Train controlled RNN and LSTM forecasters on identical chronological splits. Compare errors by horizon and dependency distance, gradient flow, convergence, runtime, memory, and parameter count.

Part 2 - Mathematical form

$$\Delta_k = E_k^{\mathrm{RNN}} - E_k^{\mathrm{LSTM}}, \qquad k = 1, \ldots, K.$$

Part 3 - Hints and Helper

Run matched-hidden-size and approximately matched-parameter comparisons. Use multiple seeds and the same preprocessing artifact.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    models = {"rnn": build_rnn(...), "lstm": build_lstm(...)}
    results = {}
    for name, candidate in models.items():
        history = train_forecaster(
            candidate, train_loader, validation_loader, ...
        )
        results[name] = {
            "metrics_by_horizon": evaluate_horizons(
                candidate, test_loader
```

```
            ),
            "gradient_flow": ..., "parameters": ...,
            "runtime": ..., "memory": ..., "history": history,
        }
    return compare_long_dependency_gains(results)
```

15.7.15 Exercise 14 - Implement Truncated BPTT for Long Forecasting Windows and Quantify Memory Savings

Part 1 - Why this matters

Long continuous series can be processed in chunks while hidden state carries context between them. Detaching at boundaries limits backward graph length and reduces activation memory.

Numeric state continuity does not imply gradient continuity. A target whose cause lies beyond the truncation boundary cannot assign credit through the detached path, even though the carried state contains transformed values.

Implement chronological chunks, reset at independent series boundaries, and sweep truncation lengths. Measure memory, runtime, validation error by dependency distance, and state continuity.

Part 2 - Mathematical form

$$h_{kb}^{+} = \text{stopgrad}(h_{kb}), \qquad M_b < M_T.$$

Part 3 - Hints and Helper

Never shuffle chunks while carrying hidden state. Distinguish optimizer-step boundaries from detach boundaries.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    hidden = None
    records = []
    for chunk in chronological_chunks:
        if chunk.new_series:
            hidden = ...
        elif hidden is not None:
            hidden = detach_state(hidden)
        optimizer.zero_grad(set_to_none=True)
        forecast, hidden = model(chunk.inputs, hidden)
        loss = masked_forecast_loss(forecast, chunk.targets, chunk.mask)
        loss.backward()
```

```
        optimizer.step()
        records.append({"loss": loss.item(), "peak_memory": ...})
    return compare_truncation_lengths(records, dependency_tests=...)
```

15.7.16 Exercise 15 - Build a Forecast Visualization Tool for Predictions and Ground Truth across Multiple Horizons

Part 1 - Why this matters

Forecast plots reveal temporal structure hidden by aggregate metrics: phase lag, amplitude damping, drift, missed peaks, boundary discontinuities, and growing horizon uncertainty. A plot can also mislead if timestamps are shifted.

Multi-step predictions overlap because several forecast origins may predict the same timestamp. The visualization must define whether it shows one origin, all origins, or an aggregation of overlapping predictions.

Build a tool that validates timestamp alignment, plots selected origins and horizons, marks train-validation boundaries, and optionally displays residuals. Keep plotting data on the CPU without altering the evaluation tensors.

Part 2 - Mathematical form

$$\hat{y}_{o,k} \leftrightarrow t_{o+k}, \qquad e_{o,k} = \hat{y}_{o,k} - y_{o+k}.$$

Part 3 - Hints and Helper

Use actual timestamps rather than array positions. Label the forecast origin and horizon units explicitly.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    def build_forecast_plot(
        timestamps, targets, predictions, origins, horizons
    ):
        validate_plot_alignment(
            timestamps, targets, predictions, origins, horizons
        )
        figure, axes = create_axes(...)
        for origin in selected_origins(origins, ...):
            target_times = ...
            axes[0].plot(
                target_times, targets_for_origin(...), label=...
            )
            axes[0].plot(
```

```
                target_times, predictions_for_origin(...), label=...
            )
            axes[1].plot(target_times, residuals_for_origin(...))
        add_split_boundaries(axes, ...)
        return figure

    return build_forecast_plot(...)
```

15.7.17 Exercise 16 - Diagnose Instability from Seasonal Scale and Fix It with Normalization

Part 1 - Why this matters

Seasonal series can change amplitude across months, regimes, or features. Large seasonal peaks may dominate squared loss and recurrent state updates, while small but important variations become numerically insignificant.

Global normalization may still leave local regimes poorly scaled, while normalization calculated with future windows leaks information. Per-window normalization can remove level information needed for the forecast unless its statistics are supplied to the model and inverted correctly.

Compare training-only global scaling, robust scaling, seasonal adjustment, and carefully designed window normalization. Measure state saturation, gradient norms, convergence, and original-unit accuracy by season.

Part 2 - Mathematical form

$$z_t = \frac{x_t - m_{\text{train}}}{s_{\text{train}}}, \qquad z_t^{(w)} = \frac{x_t - \mu_w}{\sigma_w + \epsilon}.$$

Part 3 - Hints and Helper

Fit every persistent statistic on training data only. Preserve level and scale metadata required for inverse transformation.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    strategies = {"global": ..., "robust": ...,
                  "seasonal_adjustment": ..., "window": ...}
    results = {}
    for name, scaler in strategies.items():
        scaled_splits, metadata = fit_transform_without_leakage(
            scaler, splits
        )
```

```
        candidate = clone_initial_model(model)
        history = train_forecaster(candidate, scaled_splits.train, ...)
        results[name] = {
            "state_saturation": ..., "gradient_norms": ...,
            "metrics_by_season": evaluate_in_original_units(
                candidate, metadata
            ),
            "history": history,
        }
    return results
```

15.7.18 Exercise 17 - Create Walk-Forward Validation to Avoid Temporal Leakage in Forecast Evaluation

Part 1 - Why this matters

Walk-forward validation repeatedly trains or updates on the past and evaluates on a later interval. It more closely matches deployment than a random split and reveals performance changes over time.

Every fold requires independent preprocessing fitted only on that fold's training region. Reusing a scaler, early-stopping decision, or feature statistic from later folds leaks future knowledge backward.

Implement expanding or rolling windows with explicit timestamps, gaps, and forecast intervals. Aggregate metrics by fold and horizon while preserving the chronological sequence of results.

Part 2 - Mathematical form

$$\mathcal{T}_k = [a_k, b_k], \qquad \mathcal{V}_k = [b_k + g, b_k + g + v], \qquad \max \mathcal{T}_k < \min \mathcal{V}_k.$$

Part 3 - Hints and Helper

Choose whether the model is retrained from scratch or updated, and state how that matches the intended deployment process.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    fold_results = []
    for fold in build_walk_forward_folds(timestamps, config):
        train_raw = series[fold.train_indices]
        validation_raw = series[fold.validation_indices]
        scaler = fit_scaler(train_raw)
        train_data = make_windows(scaler.transform(train_raw), ...)
```

```
        validation_data = make_windows(
            scaler.transform(validation_raw), ...
        )
        candidate = initialize_fold_model(model, policy=...)
        train_forecaster(candidate, train_data, ...)
        metrics = evaluate_horizons(candidate, validation_data)
        fold_results.append({
            "fold": fold.metadata,
            "metrics": metrics,
            "scaler": scaler.state_dict(),
        })
    return aggregate_walk_forward_results(fold_results)
```

15.7.19 Exercise 18 - Stress Test the Forecasting Pipeline with Large Data and Identify Practical Limits

Part 1 - Why this matters

Large time-series workloads stress window indexing, storage, DataLoader workers, host memory, transfer, recurrent compute, BPTT memory, and evaluation output. The first bottleneck may occur outside the model.

Materializing every overlapping window duplicates data, whereas lazy views reduce storage but increase indexing work. Long horizons also expand targets and prediction archives, affecting evaluation memory.

Scale dataset size, window length, feature count, horizon, batch size, and hidden size safely. Profile each phase, record failures, and identify maximum reliable configurations rather than only the largest allocation that runs once.

Part 2 - Mathematical form

$$N_w = N - w - g - h + 2, \qquad S_{\text{materialized}} = O(N_w(wD + hF)).$$

Part 3 - Hints and Helper

Use bounded trials and preserve a correctness fixture. Distinguish sustained throughput from a short cached benchmark.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    records = []
    for case in config.stress_grid:
        try:
            dataset, loader, candidate = build_forecasting_case(case)
```

```
            result = profile_end_to_end_forecasting(
                candidate, loader, device, duration=..., verify_fixture=True
            )
            records.append({"case": case, "status": "ok", **result})
        except (torch.cuda.OutOfMemoryError, MemoryError) as error:
            records.append({"case": case, "status": type(error).__name__})
    return identify_pipeline_limits(records, reliability_thresholds=...)
```

15.7.20 Exercise 19 - Produce a Full Time-Series RNN Forecasting Report with Failure Cases and Engineering Fixes

Part 1 - Why this matters

A forecasting report must connect the temporal question, data availability, preprocessing, model, horizon, validation scheme, metrics, uncertainty, and operational limits. A single test RMSE cannot establish that the system is trustworthy.

Failures require temporal context: leakage, wrong horizons, recursive drift, seasonal regime shifts, overfitting, unstable gradients, precision loss, or resource bottlenecks produce different signatures and corrections.

Produce a reproducible report with timestamped splits, scaler state, baselines, horizon-level metrics, visualizations, walk-forward folds, stress results, and failure-fix regression tests. State where vanilla RNN memory becomes inadequate.

Part 2 - Mathematical form

$$\mathcal{R} = \{Q, D, P, M, T, V, E, G, S, F, L\}, \qquad \text{complete}(\mathcal{R}) = \bigwedge_{r \in \mathcal{R}} [r \neq \varnothing].$$

Part 3 - Hints and Helper

For each fix report the original failure, controlled intervention, new evidence, and remaining limitation in original data units.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    from pathlib import Path

    evidence = collect_forecasting_evidence(
        task_definition=..., data=..., preprocessing=..., baselines=...,
        model=..., training=..., horizon_metrics=..., visualizations=...,
        walk_forward=..., cuda=..., precision=..., stress_limits=...,
        failures_and_fixes=...)
    report = render_forecasting_report(evidence)
```

```
    validate_temporal_evidence(report)
    Path(config.output_path).write_text(report, encoding="utf-8")
    return report
```

15.8 RNN06 - Regularization and Stabilization for RNNs

Models and Training

15.8.1 Exercise 00 - Demonstrate Overfitting in RNN and Measure Train vs Validation Gap in Sequence Tasks

Part 1 - Why this matters

Overfitting in sequence models is more subtle than memorizing independent samples because adjacent windows often share most of their time steps. An RNN can reproduce training patterns extremely well while failing as soon as the temporal regime, subject, or recording period changes.

A single final accuracy value cannot reveal this behavior. The experiment must track training and validation loss over epochs, use a split that respects sequence boundaries, and measure when the generalization gap begins to grow even though training performance continues to improve.

Train models with increasing hidden size on a deliberately limited dataset. Compare learning curves, best validation epoch, parameter count, and performance on an untouched test sequence so that model capacity is connected to observed overfitting rather than discussed only in theory.

Part 2 - Mathematical form

$$G_t = L_{\text{val}}(t) - L_{\text{train}}(t), \qquad t^* = \arg\min_t L_{\text{val}}(t).$$

Part 3 - Hints and Helper

Keep all overlapping windows from one original sequence in the same split. Report both the final epoch and the best validation epoch.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    train_loader, validation_loader, test_loader = ...
    histories = {}
    for hidden_size in config.hidden_sizes:
        candidate = build_rnn(hidden_size=hidden_size, ...)
        histories[hidden_size] = train_and_log(
            candidate, train_loader, validation_loader, epochs=...
```

```
        )
    gaps = compute_generalization_gaps(histories)
    test_results = evaluate_best_checkpoints(histories, test_loader)
    return gaps, test_results
```

15.8.2 Exercise 01 - Apply Dropout in RNN and Compare Input Dropout with Dropout Between Recurrent Layers

Part 1 - Why this matters

Dropout reduces reliance on individual activations, but its location changes what uncertainty is introduced into a recurrent model. Input dropout corrupts observed features, while inter-layer dropout regularizes the representation passed from one recurrent layer to the next.

Applying a fresh random mask carelessly at every recurrent transition can destroy temporal memory. PyTorch's built-in RNN dropout is active only between stacked recurrent layers, so setting dropout on a single-layer RNN does not regularize the recurrent computation in the way beginners often expect.

Compare no dropout, input dropout, inter-layer dropout, and their combination under identical seeds and initialization. Verify train/eval behavior directly, then measure convergence speed, validation gap, and sequence quality instead of assuming a larger dropout probability is always safer.

Part 2 - Mathematical form

$$\widetilde{x}_t = \frac{m_t \odot x_t}{1-p}, \qquad m_{t,j} \sim \text{Bernoulli}(1-p).$$

Part 3 - Hints and Helper

Use at least two recurrent layers for built-in inter-layer dropout. Confirm that repeated evaluation passes are deterministic after calling eval mode.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    variants = {
        "none": build_rnn(input_dropout=0.0, layer_dropout=0.0, ...),
        "input": build_rnn(input_dropout=..., layer_dropout=0.0),
        "between_layers": build_rnn(input_dropout=0.0, layer_dropout=...),
        "combined": build_rnn(input_dropout=..., layer_dropout=...),
    }
    results = run_controlled_training(variants, data, seed=...)
    verify_train_eval_dropout(variants, sample_batch=...)
    return compare_dropout_locations(results)
```

15.8.3 Exercise 02 - Use Weight Decay and Analyze Its Effect on RNN Stability and Generalization

Part 1 - Why this matters

Recurrent weights are reused at every time step, so an excessive weight norm can repeatedly amplify hidden-state perturbations. Weight decay can limit this growth and improve generalization, but too much decay removes the model's ability to preserve useful temporal information.

The important question is not whether decay lowers training loss. It is how parameter norms, hidden-state magnitudes, gradient norms, and validation performance change together. AdamW also separates decay from the adaptive gradient update, which makes it different from adding an L2 term carelessly to every parameter.

Sweep several decay strengths with the same initialization and data order. Track recurrent and output-layer norms separately, exclude biases when appropriate, and identify the point where stabilization becomes underfitting.

Part 2 - Mathematical form

$$\theta_{k+1} = (1 - \eta\lambda)\theta_k - \eta\,\widehat{g}_k.$$

Part 3 - Hints and Helper

Create optimizer parameter groups so biases and normalization parameters can remain undecayed. Compare validation results at equal training budgets.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    results = {}
    for decay in config.weight_decays:
        candidate = clone_initial_model(model)
        groups = make_decay_parameter_groups(candidate, exclude=...)
        optimizer = torch.optim.AdamW(groups, lr=..., weight_decay=decay)
        results[decay] = train_with_norm_logging(
            candidate, data, optimizer, ...
        )
    return analyze_decay_tradeoff(results)
```

15.8.4 Exercise 03 - Implement Gradient Clipping and Compare Different Clip Norm Values Experimentally

Part 1 - Why this matters

Backpropagation through time multiplies many Jacobians, allowing a rare batch to produce an enormous gradient. One uncontrolled update can move recurrent weights into an unstable region and cause exploding hidden states or a NaN loss several steps later.

Norm clipping rescales the complete gradient vector only when its norm exceeds a threshold. A very small threshold, however, makes nearly every update the same limited size and can hide a bad learning rate while slowing genuine learning.

Record the gradient norm before clipping, the norm after clipping, and the fraction of steps affected. Compare multiple thresholds plus an unclipped baseline on the same long-sequence task, then relate clipping frequency to convergence and validation quality.

Part 2 - Mathematical form

$$g' = g \min\left(1, \frac{c}{\|g\|_2 + \varepsilon}\right).$$

Part 3 - Hints and Helper

Call clipping after backward and before optimizer step. Log the value returned by the clipping function because it represents the pre-clipping norm.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    reports = {}
    for clip_norm in [None, *config.clip_norms]:
        candidate = clone_initial_model(model)
        reports[clip_norm] = train_rnn(
            candidate,
            data,
            after_backward=lambda: clip_and_log(
                candidate.parameters(), max_norm=clip_norm, ...
            ),
        )
    return compare_clipping_reports(reports)
```

15.8.5 Exercise 04 - Implement Layer Normalization in RNN and Measure Hidden-State Stability

Part 1 - Why this matters

The scale of an RNN hidden state may drift as the same transition is applied repeatedly. Layer normalization stabilizes each sample across hidden features and does not depend on batch statistics, making it suitable for variable-length sequences and small batches.

Normalization changes the geometry of the recurrent transition, not merely the numerical range of the final output. Its placement before or after the activation affects gradient flow, representational capacity, and the model's ability to preserve magnitude information.

Implement a custom recurrent cell with optional layer normalization. Compare hidden-state mean, variance, saturation, gradient norms, and long-sequence accuracy against an unnormalized cell while keeping the remaining architecture identical.

Part 2 - Mathematical form

$$\mathrm{LN}(a) = \gamma \odot \frac{a - \mu(a)}{\sqrt{\sigma^2(a) + \varepsilon}} + \beta.$$

Part 3 - Hints and Helper

Normalize across the hidden feature dimension for each sample and time step. Do not mix padding positions into the stability statistics.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class LayerNormRNNCell(nn.Module):
    def __init__(self, input_size, hidden_size):
        super().__init__()
        self.xh = nn.Linear(input_size, hidden_size)
        self.hh = nn.Linear(hidden_size, hidden_size, bias=False)
        self.norm = nn.LayerNorm(hidden_size)

    def forward(self, x_t, h_prev):
        preactivation = ...
        h_t = torch.tanh(self.norm(preactivation))
        return h_t

def E04(model, data, config):
    return compare_hidden_state_stability(... )
```

15.8.6 Exercise 05 - Diagnose NaN Loss and Build Automatic Early-Failure Diagnostics for RNN Training

Part 1 - Why this matters

A NaN loss is usually the final symptom of an earlier numerical failure. Invalid input values, exploding hidden states, excessive logits, unstable mixed precision, or a non-finite gradient may appear several operations before the loss becomes visibly corrupted.

Restarting with a lower learning rate can mask the problem without locating it. A useful diagnostic system checks tensors at stage boundaries, records the first failing batch and time step, preserves the relevant inputs, and distinguishes NaN values from positive or negative infinity.

Inject controlled failures into an RNN training loop and make the monitor stop immediately with a compact evidence report. The report should include input ranges, hidden-state norms, loss, gradient norms, parameter names, optimizer settings, and a reproducible batch snapshot.

Part 2 - Mathematical form

$$\text{finite}(z) \iff \neg\,\text{isnan}(z) \wedge \neg\,\text{isinf}(z).$$

Part 3 - Hints and Helper

Check inputs before forward, activations after forward, loss before backward, gradients after backward, and parameters after the optimizer step.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    monitor = FiniteTensorMonitor(save_directory=..., fail_fast=True)
    for batch_id, batch in enumerate(data):
        monitor.check("input", batch.inputs, context=...)
        outputs, hidden = model(batch.inputs)
        monitor.check("hidden", hidden, context=...)
        loss = compute_loss(outputs, batch.targets)
        monitor.check("loss", loss, context=...)
        loss.backward()
        monitor.check_named_gradients(model.named_parameters(), context=...)
        ...
    return monitor.report()
```

15.8.7 Exercise 06 - Compare Recurrent Weight Initializations and Observe Training Differences

Part 1 - Why this matters

Initialization determines the behavior of an RNN before learning begins, and recurrent reuse magnifies its consequences over time. A matrix with an unsuitable spectral scale can erase information rapidly or repeatedly amplify it across a long sequence.

Orthogonal initialization is often useful because it preserves vector norms in the linear recurrent transformation, but the activation derivative and input contribution still affect total stability. Therefore, initialization quality must be measured through actual signal and gradient

propagation.

Compare zero, small normal, Xavier, orthogonal, and deliberately oversized recurrent initialization. Under controlled seeds, record early hidden-state variance, gradient norms by time distance, convergence speed, and failure rates across repeated runs.

Part 2 - Mathematical form

$$h_t = \phi(W_{xh}x_t + W_{hh}h_{t-1} + b), \qquad \rho(W_{hh}) \text{ influences temporal growth.}$$

Part 3 - Hints and Helper

Initialize input and recurrent matrices separately. Reuse the same non-recurrent parameters and data order for a fair comparison.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    initializers = {
        "zero": ...,
        "normal": ...,
        "xavier": ...,
        "orthogonal": ...,
        "oversized": ...,
    }
    results = {}
    for name, initialize in initializers.items():
        candidate = build_rnn(...)
        initialize_recurrent_weights(candidate, initialize)
        results[name] = train_with_signal_tracking(candidate, data, ...)
    return compare_initializations(results)
```

15.8.8 Exercise 07 - Compare SGD and Adam for RNNs and Explain Optimizer Sensitivity

Part 1 - Why this matters

RNN optimization landscapes are shaped by long products of temporal derivatives, which can create narrow directions, plateaus, and occasional gradient spikes. Optimizers therefore interact strongly with clipping, initialization, sequence length, and learning rate.

Adam adapts step sizes per parameter and may make early progress easier, while SGD can require careful momentum and scheduling but sometimes produces different generalization behavior. Comparing both at arbitrary default learning rates would confuse optimizer choice with tuning quality.

Run learning-rate sweeps for SGD, SGD with momentum, and Adam from identical starting weights. Compare time-to-target, best validation score, gradient-to-update ratio, sensitivity across seeds, and final sequence quality.

Part 2 - Mathematical form

$$\theta_{k+1}^{\mathrm{SGD}} = \theta_k - \eta g_k, \qquad \theta_{k+1}^{\mathrm{Adam}} = \theta_k - \eta \frac{\widehat{m}_k}{\sqrt{\widehat{v}_k} + \varepsilon}.$$

Part 3 - Hints and Helper

Give each optimizer a small learning-rate search rather than using the same rate. Keep gradient clipping policy identical across variants.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    optimizer_builders = {
        "sgd": lambda p, lr: torch.optim.SGD(p, lr=lr),
        "momentum": lambda p, lr: torch.optim.SGD(p, lr=lr, momentum=...),
        "adam": lambda p, lr: torch.optim.Adam(p, lr=lr),
    }
    results = run_optimizer_sweeps(
        model, data, optimizer_builders, learning_rates=..., seeds=...
    )
    return summarize_optimizer_sensitivity(results)
```

15.8.9 Exercise 08 - Implement Learning-Rate Scheduling and Confirm Reduced Instability in RNN Training

Part 1 - Why this matters

A learning rate that is useful during early exploration may be too aggressive after the model approaches a good region. In recurrent training, late high-magnitude updates can repeatedly disturb a fragile hidden-state dynamic and produce oscillating validation loss.

Schedulers must be stepped at the intended frequency and in the correct order. Confusing batch-level and epoch-level schedules, or restoring a checkpoint without scheduler state, silently changes the experiment and makes results difficult to reproduce.

Compare constant, step decay, cosine decay, and plateau scheduling. Log the learning rate, count instability events, and determine whether smoother loss reflects genuine improvement or simply steps that became too small.

Part 2 - Mathematical form

$$\eta_t = \eta_{\min} + \tfrac{1}{2}(\eta_{\max} - \eta_{\min}) \left(1 + \cos \frac{\pi t}{T}\right).$$

Part 3 - Hints and Helper

Plot learning rate beside loss and gradient norm. Save and restore scheduler state together with model and optimizer state.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    schedules = {
        "constant": ...,
        "step": ...,
        "cosine": ...,
        "plateau": ...,
    }
    results = {}
    for name, scheduler_factory in schedules.items():
        candidate = clone_initial_model(model)
        optimizer = build_optimizer(candidate.parameters(), lr=...)
        scheduler = scheduler_factory(optimizer)
        results[name] = train_with_scheduler_logging(
            candidate, data, optimizer, scheduler, step_policy=...
        )
    return compare_schedule_stability(results)
```

15.8.10 Exercise 09 - Debug Cases Where Loss Decreases but Sequence Quality Does Not

Part 1 - Why this matters

A decreasing average loss does not prove that a sequence model is solving the intended task. Padding tokens can dominate the reduction, teacher forcing can hide autoregressive failure, temporal targets can be shifted incorrectly, or a model can improve common easy steps while ignoring rare important transitions.

This failure requires evaluating the complete prediction process rather than only the training objective. Free-running generation, horizon-specific metrics, masks, alignment checks, qualitative samples, and simple baselines expose problems that a scalar batch loss hides.

Construct several intentionally broken pipelines and require the debugging suite to identify each one. Include incorrect masking, target shift, teacher-forcing leakage, majority-token prediction, and a metric computed on the wrong axis.

Part 2 - Mathematical form

$$L = \frac{\sum_{b,t} m_{b,t}\, \ell(\widehat{y}_{b,t}, y_{b,t})}{\sum_{b,t} m_{b,t}}.$$

Part 3 - Hints and Helper

Recompute metrics from saved predictions independently of the training loop. Compare teacher-forced and free-running outputs on the same sequences.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    predictions = collect_predictions(
        model, data, modes=["teacher_forced", "free_running"], ...
    )
    audits = {
        "alignment": audit_target_alignment(data, ...),
        "masking": audit_loss_mask(data, ...),
        "baselines": compare_sequence_baselines(predictions, ...),
        "per_step": compute_metrics_by_time_step(predictions, ...),
        "samples": inspect_failure_samples(predictions, ...),
    }
    return diagnose_loss_quality_disagreement(audits)
```

15.8.11 Exercise 10 - Train a Stabilized RNN on CUDA and Measure Regularization Runtime Overhead

Part 1 - Why this matters

A stabilization method may improve accuracy but also add computation, memory traffic, or synchronization. Layer normalization, dropout, gradient clipping, diagnostic hooks, and frequent logging have different costs that may be negligible on small tests yet significant at production scale.

CUDA timing is asynchronous, so wall-clock measurements without synchronization can attribute unfinished GPU work to later operations. A fair benchmark also needs warm-up iterations and must isolate data loading from forward, backward, clipping, and optimizer time.

Benchmark a baseline and incremental stabilization variants on the same GPU workload. Report examples per second, peak memory, step-time distribution, and validation gain so engineering decisions are based on both stability and cost.

Part 2 - Mathematical form

$$\text{overhead}(r) = 100\frac{T_r - T_0}{T_0}\%, \qquad \text{throughput} = \frac{N}{T}.$$

Part 3 - Hints and Helper

Use CUDA events or explicit synchronization around timed regions. Warm up the kernels and exclude model construction from steady-state timing.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    device = torch.device("cuda")
    variants = build_incremental_stabilization_variants(model, ...)
    reports = {}
    for name, candidate in variants.items():
        candidate = candidate.to(device)
        warm_up_training(candidate, data, device=device, steps=...)
        torch.cuda.reset_peak_memory_stats(device)
        reports[name] = benchmark_training_regions(
            candidate, data, device=device, synchronize=True, ...
        )
    return compute_overhead_and_quality(reports)
```

15.8.12 Exercise 11 - Compare Mixed-Precision Stability With and Without Gradient Scaling in RNNs

Part 1 - Why this matters

Mixed precision accelerates supported GPU operations and reduces activation memory, but recurrent training repeatedly propagates small derivatives through time. In float16, these gradients may underflow to zero while large values can overflow to infinity.

Gradient scaling multiplies the loss before backward so small gradients occupy a representable numerical range, then unscales them before clipping and the optimizer update. Clipping scaled gradients or stepping after an overflow produces misleading behavior.

Compare full precision, autocast without scaling, and autocast with dynamic scaling on increasing sequence lengths. Track skipped updates, scale evolution, non-finite gradients, zero-gradient fraction, throughput, and validation quality.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad \nabla_\theta L = \frac{1}{s}\nabla_\theta \widetilde{L}.$$

Part 3 - Hints and Helper

Unscale gradients before computing their true norm or applying clipping. Record how often the scaler skips an optimizer step.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    modes = ["float32", "amp_unscaled", "amp_scaled"]
    reports = {}
    for mode in modes:
        candidate = clone_initial_model(model).cuda()
        scaler = build_grad_scaler(enabled=(mode == "amp_scaled"))
        reports[mode] = train_precision_variant(
            candidate,
            data,
            autocast_enabled=(mode != "float32"),
            scaler=scaler,
            unscale_before_clip=True,
            ...
        )
    return compare_precision_stability(reports)
```

15.8.13 Exercise 12 - Analyze Generalization Under Label Noise and Sequence-Noise Propagation

Part 1 - Why this matters

A wrong label in an independent classifier affects one sample, but noise in a sequential task can influence several windows and future hidden states. Overlapping windows may duplicate one corrupted event many times, increasing its effective weight in training.

Random label noise, temporally clustered noise, and persistent target bias have different consequences. A model may memorize isolated errors yet systematically adapt to a long corrupted segment, so an average noise percentage is not a complete description.

Inject controlled noise before window construction and compare it with noise injected after windowing. Measure clean-test performance, error persistence across horizons, gradient outliers, calibration, and sensitivity to regularization.

Part 2 - Mathematical form

$$\widetilde{y}_t = \begin{cases} y_t, & z_t = 0, \\ c_t, & z_t = 1, \end{cases} \qquad z_t \sim \text{Bernoulli}(q).$$

Part 3 - Hints and Helper

Keep a clean reference target for evaluation. Report how many training windows contain each corrupted source time step.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    clean_series = ...
    noise_variants = inject_sequence_noise(
        clean_series,
        rates=config.noise_rates,
        patterns=["random", "clustered", "biased"],
        stage=...,
    )
    results = train_noise_variants(model, noise_variants, ...)
    return analyze_noise_propagation(
        results, clean_targets=..., metrics_by_horizon=True
    )
```

15.8.14 Exercise 13 - Perform an Ablation Study to Identify Which Stabilization Methods Actually Help

Part 1 - Why this matters

When several stabilization methods are enabled together, a good result does not reveal which component caused the improvement. Some methods may be redundant, while another may only work through its interaction with clipping, normalization, or learning-rate scheduling.

An ablation study removes or adds one controlled component while holding data splits, initialization, training budget, and evaluation constant. Multiple seeds are necessary because recurrent training variance can be larger than the apparent gain from a method.

Design a baseline, single-method variants, the full system, and selected interaction variants. Summarize mean, spread, failure rate, runtime, and memory, then distinguish practical gains from changes smaller than experimental noise.

Part 2 - Mathematical form

$$\Delta_j = M(\mathcal{S}) - M(\mathcal{S} \setminus \{j\}), \qquad \overline{M} = \frac{1}{K}\sum_{k=1}^{K} M_k.$$

Part 3 - Hints and Helper

Reuse fixed split files and seed lists. Change only one named factor per primary ablation and include compute cost in the final table.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    variants = build_ablation_matrix(
```

```
        methods=["dropout", "decay", "clipping", "layer_norm", "scheduler"],
        include_full=True,
        interactions=...,
    )
    results = run_repeated_experiments(
        model, data, variants, seeds=config.seeds, budget=...
    )
    return summarize_ablation_effects(
        results, include_runtime=True, include_failure_rate=True
    )
```

15.8.15 Exercise 14 - Implement Early Stopping and Compare It with Regularization and Dropout

Part 1 - Why this matters

Early stopping limits how long a model adapts to training-specific details, while dropout and weight penalties change the optimization path itself. These mechanisms can complement one another, but they should not be treated as interchangeable switches.

A reliable stopping rule needs a monitored validation metric, minimum meaningful improvement, patience, checkpoint restoration, and a burn-in period. Noisy sequence metrics can trigger premature stopping unless their temporal variability is considered.

Compare fixed-budget training, early stopping alone, regularization alone, and their combination. Evaluate restored best checkpoints on untouched sequences and include training time so the comparison captures both generalization and efficiency.

Part 2 - Mathematical form

$$\text{stop at } t \text{ if } M_{t-p:t} \text{ contains no improvement greater than } \delta.$$

Part 3 - Hints and Helper

Save the complete best state, including optimizer and scheduler if training may resume. Never report the last in-memory weights when early stopping selected an earlier epoch.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    variants = build_early_stopping_variants(...)
    results = {}
    for name, candidate in variants.items():
        stopper = EarlyStopping(
            patience=config.patience,
            min_delta=config.min_delta,
```

```
            mode=...,
        )
        history = train_with_early_stopping(
            candidate, data, stopper=stopper, restore_best=True, ...
        )
        results[name] = evaluate_restored_model(candidate, history, ...)
    return compare_stopping_and_regularization(results)
```

15.8.16 Exercise 15 - Build a Comprehensive Debugging Checklist for RNN Training Stability

Part 1 - Why this matters

RNN failures can originate in data alignment, padding masks, hidden-state lifecycle, graph detachment, numerical precision, gradient propagation, optimizer order, or evaluation logic. Debugging only the loss curve leaves most of this system unexamined.

A useful checklist is executable rather than a collection of vague reminders. Each check should produce evidence, define an expected range or invariant, and identify the next narrower test when it fails.

Build a staged diagnostic runner covering data, forward state, loss, backward pass, update, evaluation, reproducibility, and CUDA behavior. Test it against deliberately broken cases and ensure the final report separates errors, warnings, and contextual measurements.

Part 2 - Mathematical form

$$\mathcal{D} = \mathcal{D}_{\text{data}} \cup \mathcal{D}_{\text{forward}} \cup \mathcal{D}_{\text{backward}} \cup \mathcal{D}_{\text{eval}}.$$

Part 3 - Hints and Helper

Run cheap invariant checks before expensive profiling. Store the first failing batch and enough configuration information to reproduce it.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    checklist = DiagnosticChecklist()
    checklist.add(
        "data_alignment", check_sequence_alignment, severity="error"
    )
    checklist.add("padding_mask", check_padding_mask, severity="error")
    checklist.add("hidden_state", inspect_hidden_state_dynamics, ...)
    checklist.add("finite_values", check_all_stages_finite, ...)
    checklist.add("gradient_flow", inspect_temporal_gradients, ...)
    checklist.add("update_order", verify_optimizer_order, ...)
```

```
    checklist.add("evaluation", verify_free_running_metrics, ...)
    checklist.add("reproducibility", compare_seeded_runs, ...)
    return checklist.run(model=model, data=data, config=config)
```

15.8.17 Exercise 16 - Evaluate Robustness Under Time-Series Distribution Shift and Document Failure Modes

Part 1 - Why this matters

Time-series deployment data rarely remains identical to training data. Sensor recalibration, seasonal changes, policy interventions, user behavior, and changing variance can alter the input distribution or the relationship between history and target.

Randomly shuffling a test split cannot represent these shifts. Robustness must be evaluated chronologically and through controlled perturbations such as level shift, trend change, variance growth, missing bursts, frequency change, and unseen seasonal regimes.

Measure clean and shifted performance by forecast horizon, track hidden-state and confidence changes, and group failures by shift type. The objective is to learn where the RNN stops being trustworthy, not merely to produce one robustness score.

Part 2 - Mathematical form

$$\text{degradation}_s = \frac{M_s - M_0}{|M_0| + \varepsilon}, \qquad P_{\text{train}}(x, y) \neq P_{\text{deploy}}(x, y).$$

Part 3 - Hints and Helper

Fit preprocessing only on the original training period. Keep shift severity explicit and report absolute metrics alongside relative degradation.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    shifts = {
        "level": lambda x: apply_level_shift(x, ...),
        "trend": lambda x: apply_trend_shift(x, ...),
        "variance": lambda x: change_variance(x, ...),
        "missing_burst": lambda x: mask_temporal_burst(x, ...),
        "frequency": lambda x: alter_seasonal_frequency(x, ...),
    }
    baseline = evaluate_by_horizon(model, data.clean_test)
    shifted = evaluate_shift_suite(model, data.clean_test, shifts, ...)
    return document_shift_failure_modes(baseline, shifted)
```

15.8.18 Exercise 17 - Build Calibration and Confidence Analysis for RNN Predictions Across Time Steps

Part 1 - Why this matters

A prediction can be accurate on average while its confidence is unreliable. In sequential classification, confidence may become increasingly overconfident at later time steps; in forecasting, uncertainty intervals may cover far fewer targets as the horizon grows.

Calibration must therefore be analyzed by temporal position or forecast horizon rather than pooled into one number. Padding, class imbalance, and correlated observations also require careful masking and interpretation of confidence bins.

Create reliability diagrams, expected calibration error, proper scoring metrics, and coverage-width analysis by time step. Compare the uncalibrated model with a calibration method fitted only on validation data, then test both on clean and shifted sequences.

Part 2 - Mathematical form

$$\mathrm{ECE} = \sum_{b=1}^{B} \frac{|S_b|}{N} \left|\mathrm{acc}(S_b) - \mathrm{conf}(S_b)\right| .$$

Part 3 - Hints and Helper

Never fit calibration parameters on the test set. Mask padding and show the sample count of each confidence bin and time step.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    validation_outputs = collect_temporal_outputs(model, data.validation, ...)
    calibrator = fit_calibrator(validation_outputs, method=...)
    test_outputs = collect_temporal_outputs(model, data.test, ...)
    reports = {}
    for name, outputs in {
        "raw": test_outputs,
        "calibrated": calibrator(test_outputs),
    }.items():
        reports[name] = calibration_by_time_step(
            outputs, bins=..., mask_padding=True, ...
        )
    return reports
```

15.8.19 Exercise 18 - Stress Test Very Long Sequences and Observe When Regularization Stops Helping

Part 1 - Why this matters

Regularization cannot remove the fundamental limitations of vanilla recurrent dynamics. As sequence length grows, useful gradients may vanish, computation becomes strictly sequential, memory for backpropagation increases, and truncation prevents learning dependencies beyond its boundary.

A method can appear successful on short sequences yet fail abruptly beyond a dependency length. Increasing dropout or decay at that point may reduce overfitting while making memory retention even worse, so failure must be separated into optimization, capacity, numerical, and resource limits.

Sweep sequence length and dependency distance under a fixed benchmark. Record accuracy, gradient signal to early time steps, hidden-state similarity, runtime, memory, clipping frequency, and failure type for baseline and regularized variants.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial h_t} = \frac{\partial L}{\partial h_T} \prod_{k=t+1}^{T} \frac{\partial h_k}{\partial h_{k-1}}.$$

Part 3 - Hints and Helper

Increase one scale variable at a time and stop safely before exhausting GPU memory. Include a task whose required dependency distance is known exactly.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    reports = []
    for length in config.sequence_lengths:
        for method in config.regularization_variants:
            candidate = build_controlled_rnn(method=method, ...)
            try:
                result = run_long_dependency_stress_test(
                    candidate, length=length, monitor_memory=True, ...
                )
            except RuntimeError as error:
                result = classify_resource_or_numerical_failure(error, ...)
            reports.append({"length": length, "method": method, **result})
    return find_regularization_breakpoints(reports)
```

15.8.20 Exercise 19 - Write a Practical RNN Stabilization Strategy Guide for Real Engineering Projects

Part 1 - Why this matters

A stabilization guide should turn experimental evidence into an ordered engineering process. Applying every technique by default creates unnecessary complexity and makes it impossible to identify whether data, dynamics, optimization, or evaluation caused a problem.

The guide must connect each observable symptom to measurements, likely causes, controlled interventions, and acceptance criteria. It should also distinguish correctness checks required for every project from optional regularization chosen after a clean baseline is understood.

Synthesize the experiments into a decision-oriented report. Include baseline design, reproducibility, monitoring, intervention order, CUDA and precision checks, shift testing, rollback conditions, and limits that justify moving from vanilla RNN to gated or attention-based models.

Part 2 - Mathematical form

$$\text{symptom} \longrightarrow \text{measurement} \longrightarrow \text{hypothesis} \longrightarrow \text{controlled test} \longrightarrow \text{decision}.$$

Part 3 - Hints and Helper

Every recommendation must cite a recorded experiment or threshold from the project. Separate universal checks from task-specific tuning advice.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_chapter_experiment_results(...)
    guide = StabilizationGuide()
    guide.add_baseline_protocol(evidence, ...)
    guide.add_symptom_decision_table(evidence, ...)
    guide.add_regularization_selection_rules(evidence, ...)
    guide.add_cuda_and_precision_checks(evidence, ...)
    guide.add_shift_and_calibration_tests(evidence, ...)
    guide.add_rollback_and_escalation_criteria(evidence, ...)
    guide.validate_all_claims_have_evidence()
    return guide.export(format=...)
```

15.9 RNN07 - Efficiency, Profiling, and CUDA Performance

Models and Training

15.9.1 Exercise 00 - Benchmark Vanilla RNN vs GRU vs LSTM Runtime and Memory to Understand Engineering Tradeoffs

Part 1 - Why this matters

Vanilla RNN, GRU, and LSTM process sequences through related recurrent structures, but they do not have the same number of gates, parameters, matrix operations, or saved activations. Choosing a model only from accuracy ignores the cost that determines whether it can be trained and served within real hardware limits.

A fair comparison requires equal input size, hidden size, layer count, sequence length, batch size, device, precision, and measurement procedure. It must also distinguish parameter memory from training activation memory and inference memory because backpropagation changes the ranking substantially.

Benchmark forward inference and complete training steps after warm-up. Report latency distributions, throughput, peak CUDA memory, parameter count, convergence quality, and the cost per unit of validation improvement instead of declaring one recurrent architecture universally fastest.

Part 2 - Mathematical form

$$P_{\text{RNN}} \approx H(I+H), \quad P_{\text{GRU}} \approx 3H(I+H), \quad P_{\text{LSTM}} \approx 4H(I+H).$$

Part 3 - Hints and Helper

Synchronize CUDA around timing and rebuild each model from a controlled seed. Compare both equal hidden size and approximately equal parameter count.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    builders = {"rnn": build_rnn, "gru": build_gru, "lstm": build_lstm}
    reports = {}
    for name, builder in builders.items():
        candidate = builder(
            input_size=..., hidden_size=..., layers=...
        ).cuda()
        reports[name] = benchmark_model(
            candidate, data, warmup=..., repetitions=...,
            measure_training=True, synchronize=True
        )
    return compare_runtime_memory_and_quality(reports)
```

15.9.2 Exercise 01 - Profile RNN Training with PyTorch Profiler and Identify Kernel and Memory Bottlenecks

Part 1 - Why this matters

A slow training loop may be limited by recurrent kernels, tensor copies, Python work, synchronization, data loading, or optimizer updates. Overall step time cannot reveal which component dominates or whether the GPU is waiting for the CPU.

A profiler trace must cover representative warm-up and active steps while avoiding endless collection overhead. Operator tables explain aggregate cost, whereas the timeline reveals gaps, copies, kernel ordering, memory allocation, and unexpected synchronization.

Profile a controlled RNN workload, rank operations by CUDA and CPU time, inspect memory-heavy events, and form one bottleneck hypothesis. Apply a targeted change and repeat the same profile to prove whether the intervention improved the limiting region rather than moving cost elsewhere.

Part 2 - Mathematical form

$$T_{\text{step}} = T_{\text{input}} + T_{\text{forward}} + T_{\text{backward}} + T_{\text{update}} + T_{\text{sync}}.$$

Part 3 - Hints and Helper

Use a short profiler schedule and add named record-function regions. Profile only after the workload has warmed up.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, ProfilerActivity, record_function

def E01(model, data, config):
    schedule = torch.profiler.schedule(
        wait=..., warmup=..., active=..., repeat=1
    )
    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        schedule=schedule,
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        for batch in data:
            with record_function("rnn_training_step"):
                ...
            profiler.step()
    return analyze_profiler_trace(profiler, ...)
```

15.9.3 Exercise 02 - Optimize Data Transfer by Minimizing Host-to-Device Copies in Sequence Training

Part 1 - Why this matters

A powerful GPU can remain idle when every batch is prepared slowly or copied through unnecessary intermediate tensors. Repeated device transfers inside the time-step loop are especially damaging because they add launch overhead and break what should be one batched recurrent operation.

Pinned host memory permits asynchronous copies, but non-blocking transfer helps only when the source is pinned and work can overlap safely. Converting types, transposing layouts, or rebuilding masks after transfer can also create hidden copies and allocations.

Instrument the pipeline from DataLoader output to model input. Move each complete batch once, reuse device-side buffers where practical, and compare transfer time, GPU idle gaps, throughput, and correctness before and after the change.

Part 2 - Mathematical form

$$T_{\text{pipeline}} \approx \max(T_{\text{prepare}}, T_{\text{copy}}, T_{\text{compute}}) \quad \text{when stages overlap.}$$

Part 3 - Hints and Helper

Move inputs, targets, lengths, and masks together at the batch boundary. Inspect contiguity and dtype before deciding that an explicit copy is necessary.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    loader = build_loader(
        data, pin_memory=True, num_workers=..., persistent_workers=...
    )
    stream = torch.cuda.Stream()
    reports = {}
    for strategy in ["baseline", "single_batch_copy", "prefetched"]:
        reports[strategy] = benchmark_transfer_strategy(
            model,
            loader,
            strategy=strategy,
            non_blocking=True,
            stream=stream,
            ...
        )
    return compare_transfer_and_compute_overlap(reports)
```

15.9.4 Exercise 03 - Measure Sequence-Length Impact on Throughput and Find the Practical GPU Limit

Part 1 - Why this matters

Recurrent computation is sequential across time even when operations within each step are parallel. Increasing sequence length therefore raises latency and the number of activations retained for backpropagation, while also extending the dependency path that gradients must traverse.

The practical limit is not simply the longest sequence that fits once. A usable configuration must leave memory headroom, avoid severe throughput collapse, remain numerically stable, and support repeated steps without allocation spikes or out-of-memory recovery.

Sweep sequence lengths using fixed model and batch settings, then repeat with a token-budget policy that reduces batch size as length grows. Record tokens per second, samples per second, step latency, peak memory, gradient behavior, and the first unsafe configuration.

Part 2 - Mathematical form

$$\text{tokens/s} = \frac{BT}{t_{\text{step}}}, \qquad M_{\text{train}} = M_{\text{params}} + M_{\text{state}} + O(BTH).$$

Part 3 - Hints and Helper

Warm up each shape separately because new dimensions may trigger new kernel choices or allocations. Reserve memory headroom rather than benchmarking at the exact OOM boundary.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    reports = []
    for length in config.sequence_lengths:
        batch_size = choose_batch_for_token_budget(length, ...)
        batch = make_sequence_batch(batch_size, length, ...).cuda()
        result = benchmark_shape(
            model, batch, training=True, warmup=..., repetitions=...
        )
        reports.append({"length": length, "batch": batch_size, **result})
    return identify_practical_gpu_limit(reports, headroom=...)
```

15.9.5 Exercise 04 - Compare Packed vs Padded Sequence Performance and Measure Speedup and Memory Changes

Part 1 - Why this matters

Padding lets variable-length sequences share a rectangular tensor, but recurrent computation may be wasted on positions that contain no data. The waste grows when length variance is large or a few unusually long sequences determine the batch width.

Packed sequences can skip padded time steps, yet sorting, packing, unpacking, and bookkeeping add overhead. When lengths are similar or batches are small, the extra complexity may provide little benefit and can introduce alignment bugs.

Benchmark padded masking and packed execution across several length distributions. Verify output parity only on valid positions, then compare useful-token throughput, peak memory, packing overhead, and total training time.

Part 2 - Mathematical form

$$\eta_{\text{padding}} = \frac{\sum_{i=1}^{B} T_i}{B \max_i T_i}, \qquad \text{waste} = 1 - \eta_{\text{padding}}.$$

Part 3 - Hints and Helper

Use the same sequences and recurrent weights for both paths. Restore original batch order after unpacking before comparing outputs.

Part 4 - Python code skeleton

```
import torch
from torch.nn.utils.rnn import pack_padded_sequence, pad_packed_sequence

def E04(model, data, config):
    padded, lengths, mask = ...
    packed = pack_padded_sequence(
        padded, lengths.cpu(), batch_first=True, enforce_sorted=...
    )
    padded_report = benchmark_padded_path(model, padded, mask, ...)
    packed_report = benchmark_packed_path(model, packed, ...)
    verify_valid_output_parity(padded_report, packed_report, mask, ...)
    return compare_useful_token_efficiency(padded_report, packed_report)
```

15.9.6 Exercise 05 - Evaluate batch_first and Its Effect on Memory Layout and Performance

Part 1 - Why this matters

The batch-first option changes the interface layout between batch-time-feature and time-batch-feature, but it does not change the mathematical recurrence. Performance differences usually come from surrounding transposes, contiguity, downstream operators, and copies rather than the semantic flag alone.

A transpose can be a cheap view, yet a later operator may require contiguous memory and silently materialize a copy. Timing only the RNN call misses layout conversion costs that belong to the real pipeline.

Construct equivalent batch-first and time-first pipelines and inspect strides, contiguity, storage sharing, and profiler copy events. Compare end-to-end throughput and output parity before selecting the layout that minimizes conversions across the complete application.

Part 2 - Mathematical form

$$X_{\mathrm{BF}} \in \mathbb{R}^{B\times T\times I}, \qquad X_{\mathrm{TF}} = X_{\mathrm{BF}}^{\top(0,1)} \in \mathbb{R}^{T\times B\times I}.$$

Part 3 - Hints and Helper

Measure layout preparation plus recurrent execution plus downstream loss. Do not call contiguous unless an operation actually requires it.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    x_batch_first = ...
    x_time_first = x_batch_first.transpose(0, 1)
    layout_report = inspect_layouts(x_batch_first, x_time_first)
    reports = {
        "batch_first": benchmark_complete_layout_pipeline(
            build_rnn(batch_first=True, ...), x_batch_first, ...
        ),
        "time_first": benchmark_complete_layout_pipeline(
            build_rnn(batch_first=False, ...), x_time_first, ...
        ),
    }
    verify_layout_output_parity(reports, ...)
    return layout_report, reports
```

15.9.7 Exercise 06 - Benchmark Hidden Sizes and Layer Counts and Build a Scaling Curve

Part 1 - Why this matters

Hidden size controls the width of recurrent matrix multiplications, while layer count repeats recurrent processing at every time step. Their costs grow differently, and hardware utilization can improve initially before memory pressure or sequential depth dominates.

Simple theoretical operation counts do not predict all GPU behavior because kernel efficiency, tensor-core alignment, launch overhead, workspace selection, and memory traffic change with shape. Empirical scaling curves are therefore necessary for the actual GPU and precision

mode.

Sweep a grid of hidden sizes and layer counts under fixed sequence shapes. Record parameters, estimated operations, training and inference throughput, peak memory, utilization, and validation quality, then identify efficient configurations on the accuracy-cost frontier.

Part 2 - Mathematical form

$$\text{cost} \approx O\left(BT \sum_{\ell=1}^{L} H_\ell (H_{\ell-1} + H_\ell)\right).$$

Part 3 - Hints and Helper

Include hidden sizes aligned and unaligned with common accelerator tile dimensions. Warm up every architecture independently.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    reports = []
    for hidden_size in config.hidden_sizes:
        for layers in config.layer_counts:
            candidate = build_rnn(
                hidden_size=hidden_size, layers=layers, ...
            ).cuda()
            result = benchmark_and_evaluate(candidate, data, ...)
            reports.append({
                "hidden_size": hidden_size,
                "layers": layers,
                "parameters": count_parameters(candidate),
                **result,
            })
    return build_scaling_and_frontier_curves(reports)
```

15.9.8 Exercise 07 - Diagnose an Under-Utilized GPU and Fix DataLoader or Padding Bottlenecks

Part 1 - Why this matters

Low GPU utilization is a symptom, not a diagnosis. The device may be waiting for disk reads, Python collation, host-to-device copies, excessive padding, many tiny kernels, synchronization, or a workload too small to occupy it.

Increasing DataLoader workers blindly can increase memory use and contention without improving throughput. Likewise, increasing batch size may raise displayed utilization while

useful-token efficiency falls because most computation processes padding.

Measure data wait, transfer, compute, and useful-token ratios separately. Tune workers, pinned memory, persistent workers, bucketing, batch size, and prefetching one factor at a time, then confirm that end-to-end examples per second improves without changing model outputs.

Part 2 - Mathematical form

$$U_{\text{useful}} = U_{\text{device}} \times \frac{\text{valid sequence tokens}}{\text{processed tensor tokens}}.$$

Part 3 - Hints and Helper

Start with a synthetic in-memory batch to separate model limits from pipeline limits. Bucket similar sequence lengths to reduce padding waste.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    baseline = profile_pipeline_regions(model, data, ...)
    loader_variants = build_loader_variants(
        data,
        workers=config.worker_counts,
        pin_memory=[False, True],
        bucketing=[False, True],
        persistent_workers=...,
    )
    reports = benchmark_loaders(model, loader_variants, ...)
    return diagnose_and_select_pipeline_fix(baseline, reports)
```

15.9.9 Exercise 08 - Compare float32 and Mixed-Precision Speed and Document Stability Constraints

Part 1 - Why this matters

Mixed precision can reduce memory and accelerate recurrent matrix operations, allowing larger batches or sequences. The gain is workload-dependent because small recurrent kernels, unsupported operations, data movement, or sequential execution can limit tensor-core benefits.

Speed is irrelevant if small temporal gradients underflow, hidden states overflow, or output drift changes task quality. Dynamic gradient scaling protects backward computation but does not make every forward activation numerically safe.

Benchmark float32 and mixed-precision modes across several shapes. Record throughput, peak memory, scale changes, skipped updates, non-finite values, gradient sparsity, output parity, and final validation performance.

Part 2 - Mathematical form

$$S = \frac{T_{32}}{T_{\text{mixed}}}, \qquad \varepsilon_{\text{rel}} = \frac{\|y_{32} - y_m\|}{\|y_{32}\| + \epsilon}.$$

Part 3 - Hints and Helper

Unscale before clipping and synchronizing measurements. Test long sequences and extreme input scales, not only a short stable batch.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    reports = {}
    for precision in ["float32", "float16_amp", "bfloat16_amp"]:
        candidate = clone_initial_model(model).cuda()
        reports[precision] = benchmark_precision_mode(
            candidate,
            data,
            precision=precision,
            grad_scaler=...,
            monitor_nonfinite=True,
            ...
        )
    return document_speed_memory_stability_tradeoffs(reports)
```

15.9.10 Exercise 09 - Measure Gradient-Clipping Overhead and Decide Whether It Is Worth It

Part 1 - Why this matters

Gradient clipping requires computing a norm across many parameter gradients and may launch additional reduction and scaling kernels. For a small RNN this overhead can be visible, while for a large backward pass it may be a minor cost relative to the stability it provides.

The correct comparison includes both the cost per step and the cost of failures avoided. A faster unclipped run that diverges, restarts, or needs a smaller learning rate may take more total time to reach a usable model.

Benchmark no clipping, norm measurement only, and actual clipping at several thresholds. Record clipping frequency, microsecond overhead, synchronization effects, throughput, divergence rate, and time-to-target validation quality.

Part 2 - Mathematical form

$$C_{\text{clip}} = T_{\text{norm+scale}} - T_{\text{baseline}}, \qquad V = \frac{\text{failures avoided}}{C_{\text{clip}}}.$$

Part 3 - Hints and Helper

Avoid calling item on the norm every step during the timed region because it forces synchronization. Buffer statistics or sample them less frequently.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    variants = ["none", "measure_only", *config.clip_norms]
    reports = {}
    for variant in variants:
        candidate = clone_initial_model(model).cuda()
        reports[str(variant)] = benchmark_clipping_policy(
            candidate,
            data,
            policy=variant,
            defer_host_logging=True,
            ...
        )
    return evaluate_clipping_cost_and_value(reports)
```

15.9.11 Exercise 10 - Implement Gradient Accumulation and Compare It with True Large-Batch Training

Part 1 - Why this matters

Gradient accumulation splits a large logical batch into micro-batches so activations fit in limited memory. It reduces peak activation memory but repeats forward and backward launches and retains optimizer updates only after several passes.

Equivalence requires scaling each micro-batch loss correctly, especially when micro-batches contain different numbers of valid sequence tokens. Dropout masks, normalization behavior, clipping order, and optimizer-step frequency can also make accumulated and physical batches differ.

Compare a true large batch with several accumulation factors using identical samples and initial weights. Check gradient and parameter parity in a deterministic case, then measure memory, throughput, update time, and validation behavior in realistic training.

Part 2 - Mathematical form

$$g_{\text{logical}} = \frac{1}{N} \sum_{j=1}^{K} \sum_{i \in \mathcal{B}_j} \nabla_\theta \ell_i.$$

Part 3 - Hints and Helper

Normalize by the total valid-token count across the logical batch. Clip only once after all micro-batch gradients have accumulated.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    optimizer.zero_grad(set_to_none=True)
    total_valid_tokens = count_logical_batch_tokens(data, ...)
    for micro_batch in split_into_micro_batches(data, factor=...):
        outputs = model(micro_batch.inputs)
        loss_sum = masked_loss(outputs, micro_batch.targets, reduction="sum")
        (loss_sum / total_valid_tokens).backward()
    torch.nn.utils.clip_grad_norm_(model.parameters(), ...)
    optimizer.step()
    return compare_with_true_large_batch(model, data, ...)
```

15.9.12 Exercise 11 - Run CUDA Efficiency Tests and Produce Reproducible Benchmark Tables

Part 1 - Why this matters

Benchmark results are useful only when another run can interpret and reproduce them. GPU model, software versions, precision, shapes, warm-up, synchronization, clock state, competing processes, and statistical summary can all change the measured result.

A single minimum latency favors noise and does not describe production behavior. Repeated measurements should report central tendency and tail behavior, while correctness checks ensure an optimization did not silently alter outputs.

Build a benchmark harness that records environment metadata and controlled configurations automatically. Export tidy tables containing median and percentile latency, throughput, peak memory, numerical parity, and run-to-run variability.

Part 2 - Mathematical form

$$p_q = \inf\{t : F_T(t) \geq q\}, \qquad \mathrm{CV} = \frac{\sigma_T}{\mu_T}.$$

Part 3 - Hints and Helper

Warm up every unique shape and synchronize only at timing boundaries. Save raw samples alongside summarized tables.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
```

```
    metadata = capture_benchmark_environment(
        torch_version=torch.__version__, cuda=..., cudnn=..., gpu=...
    )
    raw_results = run_benchmark_matrix(
        model,
        data,
        shapes=config.shapes,
        precisions=config.precisions,
        warmup=...,
        repetitions=...,
    )
    table = summarize_latency_throughput_memory(raw_results, percentiles=...)
    validate_benchmark_parity(raw_results, ...)
    return export_reproducible_benchmark(metadata, table, raw_results, ...)
```

15.9.13 Exercise 12 - Investigate Non-Determinism in cuDNN RNN Kernels and Document When It Appears

Part 1 - Why this matters

GPU execution may produce small run-to-run differences even when model seeds are fixed. Parallel reductions, kernel selection, library algorithms, precision, and asynchronous scheduling can change floating-point operation order, and recurrent reuse may amplify tiny differences over time.

Deterministic settings can reject or replace faster algorithms, but they do not correct uncontrolled data ordering, dropout randomness, worker seeds, or missing checkpoint state. Exact bitwise equality and numerically acceptable reproducibility are also different requirements.

Run repeated forward and training tests across shapes, precisions, and determinism settings. Locate the first divergent time step, measure error growth, compare final metrics, record performance cost, and document which guarantees are achievable on the tested environment.

Part 2 - Mathematical form

$$\delta_t = \|h_t^{(a)} - h_t^{(b)}\|_\infty, \qquad t_{\text{first}} = \min\{t : \delta_t > \tau\}.$$

Part 3 - Hints and Helper

Control Python, NumPy, PyTorch, DataLoader, and CUDA randomness. Save the complete hardware and library environment with the result.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    reports = []
```

```
    for deterministic in [False, True]:
        configure_determinism(deterministic, seed=...)
        runs = [run_controlled_rnn(model, data, ...) for _ in range(...)]
        reports.append(analyze_run_divergence(
            runs,
            deterministic=deterministic,
            locate_first_time_step=True,
            ...
        ))
    return document_determinism_and_cost(reports)
```

15.9.14 Exercise 13 - Compare Stateful and Stateless RNN Training Efficiency and Explain Hidden-State Reset Costs

Part 1 - Why this matters

Stateless training starts each batch with a fresh hidden state, while stateful training carries memory between consecutive chunks. Carrying state can avoid recomputing context and support streaming, but it also imposes strict ordering and boundary management.

The numerical cost of creating a zero state is usually small; the larger engineering costs are lost shuffling, reduced parallelism, synchronization across streams, and bugs that leak state between unrelated sequences. Failing to detach carried state also grows the autograd graph across batches.

Compare both strategies on contiguous sequence chunks with explicit stream identifiers. Measure throughput, memory, context accuracy, reset and detach overhead, batching flexibility, and failure behavior when stream order is disturbed.

Part 2 - Mathematical form

$$h_0^{(k+1)} = \text{stopgrad}(h_T^{(k)}) \quad \text{for the same stream, otherwise } h_0 = 0.$$

Part 3 - Hints and Helper

Reset state per sequence boundary, not merely per batch number. Detach state between truncated training chunks unless full cross-chunk backpropagation is intended.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    reports = {}
    for mode in ["stateless", "stateful"]:
        state_store = HiddenStateStore() if mode == "stateful" else None
        reports[mode] = train_streaming_chunks(
            model,
```

```
            data,
            state_store=state_store,
            detach_between_chunks=True,
            reset_on_boundary=True,
            ...
        )
    return compare_state_management_efficiency(reports)
```

15.9.15 Exercise 14 - Implement RNN Checkpointing and Resume and Measure Restart-Time Loss

Part 1 - Why this matters

Long RNN training jobs may be interrupted by hardware faults, scheduler limits, process crashes, or planned maintenance. A checkpoint that stores only model weights can reload predictions but cannot reproduce the original optimizer, scheduler, scaler, data order, or hidden-state trajectory.

Checkpoint frequency trades write overhead and storage against the amount of work lost after failure. Saving synchronously can stall training, while an unsafe asynchronous copy may capture inconsistent state unless ownership and completion are controlled.

Implement complete checkpoint save and resume, force interruptions at known steps, and compare resumed training with an uninterrupted reference. Measure save latency, file size, recovery time, work lost under different intervals, and numerical drift after resumption.

Part 2 - Mathematical form

$$E[T_{\text{lost}}] \approx \frac{\Delta}{2}, \qquad C(\Delta) = \frac{T_{\text{save}}}{\Delta} + \lambda \frac{\Delta}{2}.$$

Part 3 - Hints and Helper

Store epoch, global step, model, optimizer, scheduler, scaler, RNG states, sampler state, configuration, and any stateful hidden-state mapping.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    checkpoint = {
        "model": model.state_dict(),
        "optimizer": optimizer.state_dict(),
        "scheduler": scheduler.state_dict(),
        "scaler": scaler.state_dict() if scaler else None,
        "rng": capture_all_rng_states(),
        "sampler": capture_sampler_state(data),
        "progress": ...,
```

```
    }
    atomic_save(checkpoint, path=...)
    resumed = restore_complete_training_state(path=..., ...)
    return measure_restart_loss_and_drift(resumed, reference=...)
```

15.9.16 Exercise 15 - Build a Production RNN Inference Benchmark Across Batch Sizes

Part 1 - Why this matters

Production inference is governed by latency objectives and arrival patterns, not only maximum offline throughput. Batch size can improve device efficiency while increasing queueing delay, and recurrent sequence length makes service time highly variable.

Average latency hides slow requests that violate service objectives. A benchmark must separate preprocessing, transfer, model execution, and postprocessing, then report median and tail latency under warm steady-state and realistic length distributions.

Measure batch sizes from one to the throughput limit using both fixed and mixed sequence lengths. Report p50, p95, and p99 latency, sequences and tokens per second, peak memory, cold-start cost, output parity, and the batch policy that meets a defined service target.

Part 2 - Mathematical form

$$T_{\text{request}} = T_{\text{queue}} + T_{\text{pre}} + T_{\text{copy}} + T_{\text{model}} + T_{\text{post}}.$$

Part 3 - Hints and Helper

Use inference mode and warm the model before steady-state measurements. Do not mix cold-start compilation time with normal request latency.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    model.eval().cuda()
    reports = []
    for batch_size in config.batch_sizes:
        with torch.inference_mode():
            result = benchmark_inference_service(
                model,
                data,
                batch_size=batch_size,
                length_distribution=...,
                include_preprocessing=True,
                percentiles=[50, 95, 99],
                ...
            )
        reports.append(result)
    return select_batch_policy_for_slo(reports, slo_ms=...)
```

15.9.17 Exercise 16 - Export an RNN with TorchScript and Validate Output Parity and Speed

Part 1 - Why this matters

Export changes a Python model into a representation intended for more controlled execution. Recurrent models make this challenging when forward behavior depends on optional hidden states, dynamic sequence lengths, Python-side loops, or multiple return structures.

Tracing records operations from example inputs and can miss data-dependent control flow, while scripting attempts to compile supported program logic. Successful export alone does not prove that hidden-state semantics or variable-shape behavior remain correct.

Export a defined RNN inference wrapper, test it on multiple batch and sequence shapes, compare outputs and final states within tolerances, save and reload it, and benchmark cold and warm execution against the native model.

Part 2 - Mathematical form

$$\varepsilon_y = \max |y_{\text{native}} - y_{\text{export}}|, \qquad \varepsilon_h = \max |h_{\text{native}} - h_{\text{export}}|.$$

Part 3 - Hints and Helper

Make the inference signature explicit and avoid ambiguous optional structures. Include edge shapes not used during tracing in the parity suite.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    wrapper = ExportableRNNWrapper(model).eval()
    example_inputs = ...
    exported = torch.jit.trace(wrapper, example_inputs, check_trace=True)
    exported = torch.jit.freeze(exported)
    exported.save(...)
    reloaded = torch.jit.load(...)
    parity = validate_export_across_shapes(
        wrapper, reloaded, shapes=config.test_shapes, tolerances=...
    )
    speed = benchmark_native_and_exported(wrapper, reloaded, ...)
    return parity, speed
```

15.9.18 Exercise 17 - Test ONNX Export and Identify Unsupported Operators or Shape Edge Cases

Part 1 - Why this matters

ONNX export can move an RNN toward runtimes outside PyTorch, but differences in supported operators, opset behavior, dynamic axes, packed sequences, and hidden-state signatures may block export or change execution semantics.

A graph that exports with one example shape may still fail for a different batch size or sequence length. Runtime parity must cover outputs and recurrent states, while edge cases such as length one, batch one, and variable lengths expose assumptions hidden by the example input.

Export a simplified inference wrapper, inspect warnings and graph inputs, run it in an available ONNX runtime, and build a compatibility matrix. For each failure, isolate the smallest unsupported construct and document a safe alternative or an explicit deployment limitation.

Part 2 - Mathematical form

$$f_\theta^{\text{PyTorch}}(x, h_0) \approx f_\theta^{\text{ONNX}}(x, h_0) \quad \forall (B, T) \in \mathcal{S}.$$

Part 3 - Hints and Helper

Name dynamic batch and sequence axes deliberately. Begin with padded tensors before attempting packed-sequence export.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    wrapper = ONNXRNNWrapper(model).eval()
    torch.onnx.export(
        wrapper,
        args=...,
        f=...,
        input_names=[...],
        output_names=[...],
        dynamic_axes=...,
        opset_version=...,
    )
    cases = build_shape_edge_cases(batch_sizes=..., sequence_lengths=...)
    return validate_onnx_runtime_and_document_failures(..., cases=cases)
```

15.9.19 Exercise 18 - Stress Test Long-Sequence Inference and Detect Memory Leaks or Latency Spikes

Part 1 - Why this matters

An inference service can pass short benchmarks yet degrade during hours of long-sequence traffic. Retained output tensors, unbounded hidden-state caches, logging references, allocator fragmentation, or occasional extreme inputs can cause gradual memory growth and tail-latency

spikes.

Reserved CUDA memory may remain high without representing a leak, so allocated memory, reserved memory, process memory, cache size, and object ownership must be interpreted separately. Synchronization is also required to measure completed GPU latency.

Run thousands of requests with controlled and heavy-tailed sequence lengths, include warm-up and periodic snapshots, and force state creation and eviction. Detect monotonic allocated-memory growth, correlate latency spikes with shapes and allocations, and preserve the first suspicious request for diagnosis.

Part 2 - Mathematical form

$$\Delta M_k = M_{k+w} - M_k, \qquad \text{suspect leak if } \Delta M_k > \tau \text{ persistently after warm-up.}$$

Part 3 - Hints and Helper

Do not call empty-cache as a leak fix during the main test. Ensure returned GPU tensors are released or moved intentionally before the next request.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    monitor = LongRunInferenceMonitor(sample_every=..., warmup_requests=...)
    with torch.inference_mode():
        for request_id, request in enumerate(generate_request_stream(...)):
            output, state = serve_request(model, request, cache=...)
            release_or_store_state(state, policy=...)
            monitor.record(
                request_id,
                request_shape=request.shape,
                allocated=torch.cuda.memory_allocated(),
                reserved=torch.cuda.memory_reserved(),
                latency=...,
            )
    return monitor.detect_leaks_and_spikes(...)
```

15.9.20 Exercise 19 - Produce a Complete RNN Engineering Performance Report with Scaling Curves and Best Practices

Part 1 - Why this matters

An engineering report must convert isolated benchmarks into decisions that another developer can reproduce. The fastest configuration in one microbenchmark may fail the memory budget, numerical tolerance, service latency target, or long-sequence stability requirement.

Results need common definitions, controlled environments, raw evidence, uncertainty, and correctness gates. Scaling curves should show where each resource becomes limiting, while failure records prevent future teams from repeating optimizations that looked fast but were unsafe.

Synthesize architecture, shape, precision, data-pipeline, clipping, accumulation, determinism, checkpoint, export, and inference experiments. Recommend separate training and deployment configurations, define their valid operating ranges, and state when GRU, LSTM, or a non-recurrent architecture is the better engineering choice.

Part 2 - Mathematical form

$$\mathcal{C}^* = \arg\max_{\mathcal{C}} \text{throughput}(\mathcal{C}) \quad \text{s.t.} \quad M \le M_{\max},\ L_{p99} \le L_{\max},\ \varepsilon \le \tau.$$

Part 3 - Hints and Helper

Every recommendation should link to a benchmark row and correctness result. Include hardware and software metadata plus raw samples with the final tables.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_all_rnn07_benchmarks(...)
    report = EngineeringPerformanceReport()
    report.add_environment_and_methodology(evidence, ...)
    report.add_scaling_curves(evidence, axes=[...])
    report.add_training_frontier(evidence, constraints=...)
    report.add_inference_slo_frontier(evidence, constraints=...)
    report.add_correctness_and_stability_gates(evidence, ...)
    report.add_failure_catalog(evidence, ...)
    report.add_reproducible_recommendations(evidence, ...)
    report.validate_claim_traceability()
    return report.export(...)
```

15.10 RNN08 - Transition to Gated RNNs (Why LSTM Exists)

Models and Training

15.10.1 Exercise 00 - Demonstrate Long-Term Dependency Failure in Vanilla RNN with a Controlled Memory Task

Part 1 - Why this matters

A vanilla RNN may perform well when the useful signal occurred recently yet fail when the same signal must survive many irrelevant time steps. A controlled memory task isolates this

limitation from language ambiguity, noisy labels, and insufficient model capacity.

The delay between the informative token and the required output must be varied independently of total dataset size. If accuracy collapses as delay grows while short-delay cases remain solved, the experiment exposes a temporal credit-assignment failure rather than a general inability to learn.

Create a copy, remember-bit, or delayed-sign task with known dependency distance. Train identical RNNs across increasing delays and record accuracy, hidden-state probes, gradient magnitude reaching the signal position, and the first distance at which learning becomes unreliable.

Part 2 - Mathematical form

$$y_T = x_{T-d}, \qquad d \in \mathcal{D}, \qquad A(d) = \Pr(\widehat{y}_T = y_T).$$

Part 3 - Hints and Helper

Keep distractor statistics identical across delays. Compare against a no-memory baseline so accidental class imbalance cannot look like memory.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    reports = {}
    for delay in config.delays:
        task = build_controlled_memory_task(delay=delay, ...)
        candidate = build_vanilla_rnn(...)
        reports[delay] = train_and_probe_memory(
            candidate, task, signal_position=..., target_position=...
        )
    return find_memory_failure_distance(reports, baseline=...)
```

15.10.2 Exercise 01 - Explain Vanishing Gradients as Repeated Jacobian Multiplication

Part 1 - Why this matters

Backpropagation through a recurrent network sends information from a late loss through the same transition many times. The gradient is therefore governed by a product of Jacobian matrices rather than by one local derivative.

If typical singular values of these Jacobians are below one, the product contracts and early time steps receive almost no learning signal. Values above one can produce explosion, while nonlinear saturation makes contraction even stronger by shrinking activation derivatives.

Compute and visualize gradient norms by temporal distance for controlled recurrent matrices with different spectral scales. Relate empirical decay or growth to Jacobian products, activation saturation, and the limits of weight initialization or clipping as complete solutions.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial h_t} = \frac{\partial L}{\partial h_T} \prod_{k=t+1}^{T} J_k, \qquad J_k = \operatorname{diag}(\phi'(a_k)) W_{hh}.$$

Part 3 - Hints and Helper

Retain gradients for hidden states in a tiny manually unrolled RNN. Use logarithmic scale when plotting norms across time.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    reports = {}
    for spectral_scale in config.scales:
        candidate = build_controlled_recurrent_matrix(
            scale=spectral_scale, ...
        )
        hidden_states, loss = manual_unroll_with_retained_states(
            candidate, data
        )
        loss.backward()
        reports[spectral_scale] = {
            "gradient_by_time": collect_hidden_gradients(hidden_states),
            "jacobian_products": estimate_jacobian_products(...),
            "saturation": measure_activation_saturation(hidden_states),
        }
    return explain_temporal_gradient_behavior(reports)
```

15.10.3 Exercise 02 - Implement a Simple GRU Cell Manually and Compare It with Vanilla RNN Behavior

Part 1 - Why this matters

A GRU introduces gates that decide how much of the previous state should be retained and how much new candidate information should replace it. This creates an additive interpolation path instead of forcing every time step to overwrite memory through one nonlinear transformation.

Manual implementation exposes the distinction between the update gate, reset gate, and candidate state. A sign reversal or swapped interpolation convention can produce valid tensor

shapes while changing the meaning of memory retention.

Implement a GRU cell from tensor operations, copy parameters into a reference PyTorch cell, and verify step-by-step parity. Then compare hidden-state retention and gradients against a vanilla RNN on the controlled memory task.

Part 2 - Mathematical form

$$z_t = \sigma(W_z x_t + U_z h_{t-1}),\ r_t = \sigma(W_r x_t + U_r h_{t-1}),\ h_t = (1 - z_t) \odot n_t + z_t \odot h_{t-1}.$$

Part 3 - Hints and Helper

Document the chosen gate convention because some equations reverse the roles of z and one minus z. Validate a single step before unrolling a sequence.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ManualGRUCell(nn.Module):
    def __init__(self, input_size, hidden_size):
        super().__init__()
        self.input_projection = nn.Linear(input_size, 3 * hidden_size)
        self.hidden_projection = nn.Linear(hidden_size, 3 * hidden_size)

    def forward(self, x_t, h_prev):
        x_r, x_z, x_n = self.input_projection(x_t).chunk(3, dim=-1)
        h_r, h_z, h_n = self.hidden_projection(h_prev).chunk(3, dim=-1)
        reset = torch.sigmoid(...)
        update = torch.sigmoid(...)
        candidate = torch.tanh(...)
        h_t = ...
        return h_t

def E02(model, data, config):
    return verify_and_compare_manual_gru(... )
```

15.10.4 Exercise 03 - Compare Vanilla RNN, GRU, and LSTM on the Same Long-Dependency Task

Part 1 - Why this matters

A meaningful architecture comparison holds the task, preprocessing, split, optimization budget, and evaluation constant. Otherwise, apparent gains from gates may actually come from different parameter counts, tuning effort, or early-stopping opportunities.

GRU and LSTM add computational cost to create more controllable memory paths. Their value should be measured as the dependency distance increases, because short tasks may not require gating and may favor the simpler RNN.

Train all three models across several delays and seeds using both equal hidden size and approximately equal parameter count. Compare convergence rate, success probability, final accuracy, temporal gradients, runtime, and memory.

Part 2 - Mathematical form

$$\Delta A_m(d) = A_m(d) - A_{\mathrm{RNN}}(d), \qquad C_m = (T_m, M_m, P_m).$$

Part 3 - Hints and Helper

Tune learning rate fairly for each architecture, but keep the search budget equal. Report variability across seeds, not only the best run.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    builders = {"rnn": build_rnn, "gru": build_gru, "lstm": build_lstm}
    results = run_architecture_delay_matrix(
        builders,
        delays=config.delays,
        seeds=config.seeds,
        matching=["hidden_size", "parameter_count"],
        budget=...,
    )
    return summarize_dependency_cost_tradeoffs(results)
```

15.10.5 Exercise 04 - Analyze Hidden-State Updates and Explain Why Gates Preserve Useful Gradients

Part 1 - Why this matters

Gated recurrence creates paths where state can be copied forward through addition and elementwise multiplication. When a retention gate stays near one, the derivative along that path can remain near one instead of repeatedly passing through a saturated nonlinear candidate transformation.

This does not guarantee perfect memory: gates can saturate incorrectly, candidate paths still contain nonlinearities, and cross-coupled dependencies remain. The advantage is learned control over retention, erasure, and exposure rather than automatic immunity to vanishing gradients.

Inspect gate values and local state Jacobians on a trained memory task. Identify which units retain the signal, when they update, and how gradient flow differs between the additive cell-state path and the vanilla recurrent path.

Part 2 - Mathematical form

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t, \qquad \frac{\partial c_t}{\partial c_{t-1}} \supseteq f_t.$$

Part 3 - Hints and Helper

Separate the direct cell-state path from indirect dependencies through gate computations. Plot gates alongside known task events.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    traces = collect_gate_and_state_traces(model, data, retain_grad=True, ...)
    analysis = {
        "retention_paths": estimate_direct_state_derivatives(traces, ...),
        "gate_events": align_gates_with_task_events(traces, ...),
        "temporal_gradients": collect_gradients_by_distance(traces, ...),
        "vanilla_reference": analyze_vanilla_transition(...),
    }
    return explain_gate_gradient_preservation(analysis)
```

15.10.6 Exercise 05 - Implement a Minimal LSTM Cell and Verify Gate Shapes and Ranges Step by Step

Part 1 - Why this matters

An LSTM separates an exposed hidden state from an internal cell state and controls information with input, forget, and output gates. This structure gives the model distinct mechanisms for writing, retaining, forgetting, and revealing memory.

Most manual LSTM errors come from gate ordering, concatenation dimensions, cell-hidden confusion, or applying the wrong activation. These bugs often preserve output shape, making intermediate invariant checks essential.

Implement one LSTM step manually, compare it with a reference cell using copied parameters, and verify every gate range and tensor shape. Extend the verified cell to a short unroll and compare outputs, states, and gradients.

Part 2 - Mathematical form

$$i_t = \sigma(a_i),\ f_t = \sigma(a_f),\ g_t = \tanh(a_g),\ o_t = \sigma(a_o),\ c_t = f_t \odot c_{t-1} + i_t \odot g_t,\ h_t = o_t \odot \tanh(c_t).$$

Part 3 - Hints and Helper

PyTorch uses a documented gate order; match it exactly when copying weights. Check batch and hidden dimensions for both h and c.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ManualLSTMCell(nn.Module):
    def __init__(self, input_size, hidden_size):
        super().__init__()
        self.x_proj = nn.Linear(input_size, 4 * hidden_size)
        self.h_proj = nn.Linear(hidden_size, 4 * hidden_size)

    def forward(self, x_t, state):
        h_prev, c_prev = state
        i_raw, f_raw, g_raw, o_raw = (...).chunk(4, dim=-1)
        input_gate, forget_gate = torch.sigmoid(i_raw), torch.sigmoid(f_raw)
        candidate, output_gate = torch.tanh(g_raw), torch.sigmoid(o_raw)
        c_t = ...
        h_t = ...
        return h_t, c_t

def E05(model, data, config):
    return verify_lstm_gates_states_and_gradients(... )
```

15.10.7 Exercise 06 - Train GRU and LSTM and Compare Stability, Convergence Speed, and Final Accuracy

Part 1 - Why this matters

GRU and LSTM solve related memory problems with different state structures and gate counts. GRU may converge faster or use less memory, while LSTM offers a separate cell state that can provide finer control on some long dependencies.

One final accuracy number cannot distinguish fast learning, stable learning, and lucky learning. Comparisons must include loss variability, gradient behavior, failure rate across seeds, best epoch, runtime, and the amount of tuning required.

Run repeated controlled training for both architectures across short and long tasks. Measure time-to-threshold, final validation accuracy, stability events, parameter count, peak memory, and whether either model's advantage persists after matching compute budget.

Part 2 - Mathematical form

$$t_\tau = \min\{t : M_{\text{val}}(t) \geq \tau\}, \qquad F = \Pr(\text{run fails}).$$

Part 3 - Hints and Helper

Use identical splits and seed lists. Compare equal epochs, equal wall-clock time, and approximately equal parameters as separate views.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    results = {}
    for architecture in ["gru", "lstm"]:
        results[architecture] = run_repeated_training(
            architecture,
            data,
            seeds=config.seeds,
            budgets=["epochs", "wall_clock", "parameters"],
            monitor_gradients=True,
            ...
        )
    return compare_convergence_stability_accuracy(results)
```

15.10.8 Exercise 07 - Debug Gate Misconfiguration Bugs Causing No Learning or Constant Outputs

Part 1 - Why this matters

A gated cell can produce stable-looking but useless behavior when a gate is permanently open, closed, swapped, detached, or driven into saturation. Constant outputs may therefore result from gate logic rather than the optimizer or dataset.

Checking only the final state hides the source. Gate distributions, preactivation ranges, parameter gradients, candidate variance, and state changes reveal whether the model writes, forgets, exposes, or updates information.

Create broken GRU and LSTM variants with known faults and build diagnostics that identify each one. Include wrong activations, gate-order swaps, extreme biases, missing recurrent terms, detached states, and incorrect broadcasting.

Part 2 - Mathematical form

$$\Delta h_t = \|h_t - h_{t-1}\|, qquad S_g = \Pr(g_t < \epsilon \ \vee \ g_t > 1 - \epsilon).$$

Part 3 - Hints and Helper

Test a single cell step with fixed numbers before training. Register hooks for gate statistics and named parameter gradients.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    broken_variants = create_gate_bug_variants(
        bugs=["swapped_order", "extreme_bias", "wrong_activation",
              "detached_state", "missing_recurrence", "broadcast_error"],
        ...
    )
    reports = {}
    for name, candidate in broken_variants.items():
        reports[name] = run_gate_diagnostics(
            candidate,
            data,
            track_preactivations=True,
            track_state_change=True,
        )
    return match_symptoms_to_gate_faults(reports)
```

15.10.9 Exercise 08 - Run GRU and LSTM Experiments on CUDA and Measure Memory and Runtime Tradeoffs

Part 1 - Why this matters

Gated models perform several recurrent projections per time step, increasing parameter, activation, and kernel costs. CUDA may offset this through fused implementations, but the outcome depends on sequence shape, precision, training mode, and hardware.

CUDA work is asynchronous and allocator caching separates allocated from reserved memory. Fair measurement requires warm-up, synchronized timing boundaries, reset peak statistics, and identical input shapes.

Benchmark GRU and LSTM forward, backward, and optimizer regions across batch sizes and sequence lengths. Report latency percentiles, useful-token throughput, peak allocated memory, parameter memory, and quality so cost is connected to model benefit.

Part 2 - Mathematical form

$$\text{throughput} = \frac{BT}{T_{\text{step}}}, \qquad \Delta M = M_{\text{LSTM}} - M_{\text{GRU}}.$$

Part 3 - Hints and Helper

Use fused library modules for the main benchmark and manual cells only as an educational reference. Synchronize outside timed regions.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    reports = []
    for architecture in ["gru", "lstm"]:
        for shape in config.shapes:
            candidate = build_gated_model(architecture, ...).cuda()
            torch.cuda.reset_peak_memory_stats()
            batch = make_batch(shape).cuda()
            result = benchmark_cuda_training_regions(
                candidate, batch, warmup=..., repetitions=...
            )
            reports.append({
                "architecture": architecture,
                "shape": shape,
                **result,
            })
    return summarize_cuda_tradeoffs(reports)
```

15.10.10 Exercise 09 - Explain Why LSTM and GRU Are Engineering Solutions to Vanilla RNN Limits

Part 1 - Why this matters

LSTM and GRU did not appear because vanilla RNNs lack recurrent memory in principle. They appeared because learning and preserving useful memory through long nonlinear recurrence is unreliable in practice.

Their gates create trainable retention and update paths, improving credit assignment at a computational cost. They mitigate long-dependency failure but do not remove finite capacity, exposure bias, sequential execution, or every gradient problem.

Produce an evidence-based transition report using the chapter's memory curves, gradients, gate traces, convergence results, and CUDA measurements. Explain when gating solves the observed problem and when another architecture is justified.

Part 2 - Mathematical form

$$\text{gating benefit} = \text{memory reliability gain} - \text{compute and complexity cost}.$$

Part 3 - Hints and Helper

Separate theoretical mechanism, empirical evidence, and engineering recommendation. Do not claim that gated models guarantee unlimited memory.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    evidence = collect_transition_evidence(...)
    report = TransitionReport()
    report.add_vanilla_failure_curve(evidence, ...)
    report.add_jacobian_and_gradient_analysis(evidence, ...)
    report.add_gate_mechanism_evidence(evidence, ...)
    report.add_accuracy_runtime_memory_tradeoffs(evidence, ...)
    report.add_limitations_and_decision_rules(evidence, ...)
    report.validate_claims_against_experiments()
    return report.export(...)
```

15.10.11 Exercise 10 - Ablate the Forget Gate and Observe Memory Collapse

Part 1 - Why this matters

The forget gate controls how much previous cell content remains available. Removing its learned behavior tests whether LSTM success comes from selective retention rather than merely from having more parameters.

Different ablations answer different questions: forcing the gate to zero erases memory, forcing it to one prevents adaptive forgetting, and replacing it with a constant tests whether fixed timescales are sufficient. These interventions must preserve the rest of the trained architecture.

Train or evaluate controlled forget-gate variants on tasks requiring both retention and reset. Compare memory accuracy, cell-state persistence, interference after reset events, temporal gradients, and convergence.

Part 2 - Mathematical form

$$c_t = \alpha c_{t-1} + i_t \odot g_t, \qquad \alpha \in \{0, \alpha_0, 1, f_t\}.$$

Part 3 - Hints and Helper

Use a task that contains explicit remember and forget events. Match parameter counts and state initialization across variants.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    variants = {
        "learned": LearnedForgetGate(...),
        "always_zero": ConstantForgetGate(0.0),
        "fixed": ConstantForgetGate(...),
        "always_one": ConstantForgetGate(1.0),
```

```
    }
    results = run_forget_gate_ablation(
        variants, data, track_cell_state=True, track_resets=True, ...
    )
    return quantify_memory_and_interference(results)
```

15.10.12 Exercise 11 - Find the Sequence Length Where LSTM Clearly Outperforms Vanilla RNN

Part 1 - Why this matters

Gating has a cost, so an LSTM may not dominate on short dependencies where a vanilla RNN already learns reliably. The meaningful transition point is where the LSTM's accuracy or success rate exceeds the RNN by more than experimental variability.

Total sequence length and required dependency distance should be controlled separately. Long sequences with only local dependencies test computation, while delayed-memory tasks test whether information must survive.

Sweep both variables across several seeds and construct performance-difference curves with uncertainty. Identify the earliest sustained advantage under equal parameter and equal compute comparisons.

Part 2 - Mathematical form

$$T^* = \min\{T : \mathbb{E}[A_L(T) - A_R(T)] - \kappa\,\mathrm{SE} > \delta\}.$$

Part 3 - Hints and Helper

Define 'clearly outperforms' before running the experiment. Require the advantage to persist across multiple neighboring lengths.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    results = run_length_dependency_grid(
        models={"rnn": build_rnn, "lstm": build_lstm},
        sequence_lengths=config.lengths,
        dependency_distances=config.distances,
        seeds=config.seeds,
        matching=...,
    )
    return estimate_sustained_lstm_advantage(
        results, effect_threshold=..., confidence=...
    )
```

15.10.13 Exercise 12 - Compare Gated and Vanilla Models Under Distribution Shift

Part 1 - Why this matters

Better memory on the training distribution does not guarantee better behavior when sequence statistics change. A gate may learn timing patterns, reset frequencies, or value scales that fail when deployment sequences are longer or events arrive differently.

Distribution shifts should target temporal structure as well as input magnitude. Useful cases include longer delays, changed event frequency, unseen reset patterns, altered noise, missing segments, and changed sequence-length distributions.

Train RNN, GRU, and LSTM on the same source distribution, then evaluate clean and shifted suites without retraining. Measure relative degradation, confidence, gate saturation, memory retention, and failure modes by shift severity.

Part 2 - Mathematical form

$$D_m(s) = \frac{M_m(s) - M_m(0)}{|M_m(0)| + \epsilon}.$$

Part 3 - Hints and Helper

Fit preprocessing on training data only. Report absolute performance so a small relative drop from a weak baseline is not misread as robustness.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    models = train_matched_models(["rnn", "gru", "lstm"], data.source, ...)
    shift_suite = build_temporal_shift_suite(
        longer_delay=...,
        changed_frequency=...,
        missing_segments=...,
        noise=...,
    )
    reports = evaluate_models_under_shifts(
        models, data.test, shift_suite, inspect_gates=True, ...
    )
    return compare_robustness_and_failure_modes(reports)
```

15.10.14 Exercise 13 - Implement Truncated BPTT for GRU and LSTM and Compare Memory Savings with Vanilla RNN

Part 1 - Why this matters

Truncated backpropagation limits the number of time steps retained in the computation graph while carrying detached state between chunks. For LSTM, both hidden and cell states must be carried and detached correctly; GRU and RNN carry one state tensor.

Short truncation reduces memory but prevents gradients from assigning credit beyond the chunk boundary. Gating can preserve values in forward state, yet it cannot restore a gradient path that truncation deliberately removed.

Implement a shared truncated-training harness for all three architectures. Sweep truncation length and compare peak memory, throughput, long-dependency accuracy, state continuity, and the boundary where savings become unacceptable learning loss.

Part 2 - Mathematical form

$$s_{k+1} = \text{stopgrad}(F_\theta(x_{k:k+K}, s_k)), \qquad M = O(BKH).$$

Part 3 - Hints and Helper

Detach every component of an LSTM state tuple. Normalize loss consistently across chunks and reset states only at true sequence boundaries.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    reports = []
    for architecture in ["rnn", "gru", "lstm"]:
        for truncation in config.truncation_lengths:
            candidate = build_model(architecture, ...)
            result = train_with_truncated_bptt(
                candidate,
                data,
                chunk_length=truncation,
                detach_state=lambda state: detach_recurrent_state(state),
                ...
            )
            reports.append({"architecture": architecture,
                            "truncation": truncation, **result})
    return compare_memory_savings_and_dependency_loss(reports)
```

15.10.15 Exercise 14 - Profile RNN and LSTM GPU Utilization and Explain Kernel-Level Differences

Part 1 - Why this matters

An LSTM performs several gate projections per step, but optimized libraries may fuse them into larger kernels. A vanilla RNN has fewer operations yet may not be faster proportionally

because small sequential kernels can underutilize the GPU.

GPU utilization alone cannot distinguish useful arithmetic from memory movement, launch gaps, or padding waste. Kernel timelines, operation shapes, tensor-core eligibility, occupancy indicators, and CPU gaps are needed to explain observed throughput.

Profile matched RNN and LSTM workloads after warm-up. Identify fused recurrent kernels, launches per step, matrix sizes, copy events, and idle regions, then relate kernel behavior to sequence length, hidden size, batch size, and precision.

Part 2 - Mathematical form

$$T_{\text{total}} = \sum_{k} (T_{\text{launch},k} + T_{\text{kernel},k}) + T_{\text{gaps}}.$$

Part 3 - Hints and Helper

Profile a small representative window rather than the entire training run. Validate that both models use equivalent data and synchronization boundaries.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, ProfilerActivity

def E14(model, data, config):
    traces = {}
    for architecture in ["rnn", "lstm"]:
        candidate = build_model(architecture, ...).cuda()
        warm_up(candidate, data, ...)
        with profile(
            activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
            record_shapes=True,
            profile_memory=True,
        ) as profiler:
            run_profile_window(candidate, data, ...)
        traces[architecture] = extract_kernel_and_idle_analysis(profiler)
    return explain_gpu_utilization_differences(traces)
```

15.10.16 Exercise 15 - Build a Checklist for Choosing RNN, GRU, or LSTM in Real Projects

Part 1 - Why this matters

Architecture choice should follow the dependency structure, data volume, latency target, memory budget, deployment runtime, and observed failure mode. Choosing LSTM automatically because it is more expressive can waste resources on tasks that need only local memory.

A useful checklist begins with a measurable baseline and escalates complexity only when evidence supports it. It also distinguishes training constraints from inference constraints and includes tests for long dependencies, stateful streaming, shift, and export compatibility.

Turn the chapter results into a decision process with explicit thresholds and fallback choices. Require every recommendation to connect task evidence with accuracy, stability, runtime, memory, and maintenance cost.

Part 2 - Mathematical form

$$m^* = \arg\min_m C(m) \quad \text{s.t.} \quad Q(m) \geq Q_{\min},\ L(m) \leq L_{\max},\ M(m) \leq M_{\max}.$$

Part 3 - Hints and Helper

Include a simple non-recurrent baseline. State when none of the three models is appropriate and attention or convolution should be tested.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    evidence = collect_task_constraints_and_benchmarks(...)
    checklist = ModelChoiceChecklist()
    checklist.add_dependency_tests(evidence, ...)
    checklist.add_quality_thresholds(evidence, ...)
    checklist.add_training_and_inference_budgets(evidence, ...)
    checklist.add_streaming_and_state_requirements(evidence, ...)
    checklist.add_export_and_runtime_constraints(evidence, ...)
    checklist.add_escalation_rules(evidence, ...)
    return checklist.validate_and_export(...)
```

15.10.17 Exercise 16 - Export GRU and LSTM and Compare Deployment Complexity with Vanilla RNN

Part 1 - Why this matters

Deployment complexity depends on more than whether export succeeds. GRU and LSTM expose different state structures, operator support, dynamic-shape behavior, runtime kernels, quantization options, and memory requirements.

An exported graph must preserve outputs and recurrent states across batch and sequence shapes. LSTM's paired hidden and cell state makes interfaces and stateful serving more complex than a single-state RNN or GRU.

Export standardized wrappers for all three architectures to the selected formats and runtimes. Build a compatibility matrix covering parity, file size, operator support, dynamic shapes, latency, state handling, and failure workarounds.

Part 2 - Mathematical form

$$\varepsilon_m = \max_{x \in \mathcal{S}} \| f_m^{\text{native}}(x) - f_m^{\text{export}}(x) \|_\infty .$$

Part 3 - Hints and Helper

Use explicit state inputs and outputs. Test batch one, sequence length one, and unseen dynamic shapes after reloading the artifact.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    reports = {}
    for architecture in ["rnn", "gru", "lstm"]:
        wrapper = build_export_wrapper(architecture, explicit_state=True, ...)
        artifacts = export_to_supported_formats(
            wrapper, example_inputs=..., ...
        )
        reports[architecture] = validate_deployment_matrix(
            wrapper,
            artifacts,
            test_shapes=config.dynamic_shapes,
            check_state_parity=True,
            benchmark=True,
        )
    return compare_deployment_complexity(reports)
```

15.10.18 Exercise 17 - Stress Test Gated Models with Long Sequences and Large Hidden Sizes

Part 1 - Why this matters

Gates improve memory dynamics but do not remove sequential computation, quadratic hidden projections, activation storage, or finite precision. Long sequences and large hidden states eventually expose runtime, memory, optimization, and numerical limits.

A safe stress test increases scale gradually, maintains memory headroom, and distinguishes out-of-memory failure from latency collapse, gradient failure, or loss of task quality. Maximum allocatable shape is not necessarily a practical configuration.

Sweep sequence length, hidden size, layers, batch size, and precision for GRU and LSTM. Record throughput, peak memory, gate saturation, gradients, non-finite events, validation quality, and the first failure boundary for each resource.

Part 2 - Mathematical form

$$C \approx O(BTLH^2), \qquad M_{\text{train}} \approx O(BTLH) + M_{\text{optimizer}}.$$

Part 3 - Hints and Helper

Vary one primary scale dimension at a time before testing interactions. Stop below full device exhaustion and preserve the failing configuration.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    reports = []
    for architecture, shape in controlled_stress_grid(
        ["gru", "lstm"], config.shapes
    ):
        try:
            result = run_guarded_stress_case(
                architecture,
                shape,
                memory_headroom=...,
                monitor_numerics=True,
            )
        except RuntimeError as error:
            result = classify_stress_failure(error, shape=...)
        reports.append({
            "architecture": architecture,
            "shape": shape,
            **result,
        })
    return map_practical_operating_limits(reports)
```

15.10.19 Exercise 18 - Create an Ablation Report Quantifying What Gates Improve and Why

Part 1 - Why this matters

A full gated model can outperform a vanilla RNN without revealing which gate or pathway provides the benefit. Removing, fixing, or simplifying components makes the causal contribution of retention, reset, write, and exposure mechanisms measurable.

Ablations must control parameter count, initialization, training budget, and seed variability. Some gates matter only on tasks containing specific events, so conclusions should be conditioned on dependency length and the need to erase obsolete information.

Build GRU and LSTM ablations that fix or remove one mechanism at a time, plus matched vanilla baselines. Quantify changes in accuracy, gradient reach, memory persistence, interference, convergence, runtime, and parameter efficiency.

Part 2 - Mathematical form

$$\Delta_g = \mathbb{E}[M_{\text{full}} - M_{\text{ablated}(g)}], \qquad I_{g_1,g_2} = \Delta_{g_1,g_2} - \Delta_{g_1} - \Delta_{g_2}.$$

Part 3 - Hints and Helper

Run multiple seeds and include confidence intervals. Pair each gate ablation with a task event that should require its function.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    ablations = build_gate_ablation_matrix(
        gru=["fixed_update", "fixed_reset", "no_reset"],
        lstm=["fixed_forget", "fixed_input", "fixed_output", "coupled_gates"],
        matched_baselines=True,
    )
    results = run_repeated_ablation_study(
        ablations, data, seeds=config.seeds, controlled_budget=...
    )
    return quantify_gate_effects_and_interactions(results, ... )
```

15.10.20 Exercise 19 - Produce the Final RNN Track Report with Concepts, Experiments, Failures, and Next Steps

Part 1 - Why this matters

The final report should show how the entire RNN track developed from sequence representation and hidden-state recurrence to BPTT, data preparation, applications, stabilization, performance engineering, and gated memory. It must preserve failures because they define the boundaries of each method.

A strong synthesis separates mathematical claims, experimental evidence, engineering practice, and unresolved limitations. It should explain not only what worked, but under which sequence lengths, distributions, hardware conditions, and evaluation protocols it remained trustworthy.

Assemble a traceable report linking every major conclusion to an exercise result. Conclude with readiness criteria for the next LSTM-focused book and a list of questions about cell dynamics, advanced gating, bidirectionality, sequence generation, deployment, and alternatives that remain open.

Part 2 - Mathematical form

$$\text{concept} \rightarrow \text{experiment} \rightarrow \text{evidence} \rightarrow \text{failure boundary} \rightarrow \text{next hypothesis.}$$

Part 3 - Hints and Helper

Include reproducible configurations, raw tables, and a failure catalog. Distinguish conclusions proven in this track from claims requiring future study.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_complete_rnn_track_evidence(...)
    report = FinalTrackReport()
    report.add_concept_map(evidence, ...)
    report.add_experiment_index(evidence, ...)
    report.add_mathematical_and_empirical_findings(evidence, ...)
    report.add_failure_boundaries(evidence, ...)
    report.add_engineering_best_practices(evidence, ...)
    report.add_lstm_book_readiness_checklist(evidence, ...)
    report.add_open_questions_and_next_steps(evidence, ...)
    report.validate_traceability()
    return report.export(...)
```

Book 16

LSTM (Long Short-Term Memory)

16.1 Introduction

16.1.1 What will the book teach you

The previous book introduced recurrent neural networks as models that process information through time. Unlike a feed-forward network, an RNN does not treat every input as an isolated observation. It carries a hidden state from one time step to the next, allowing earlier information to influence later predictions. This simple idea created a new way to work with language, time series, signals, and every problem in which order matters. It also revealed a difficult truth: having a memory state does not mean that a model can learn to preserve useful information for a long time. A vanilla RNN may possess a path from the beginning of a sequence to its end, yet the learning signal traveling through that path can become extremely small, extremely large, or too unstable to guide the parameters correctly.

This book begins at that exact limitation. Long Short-Term Memory, or LSTM, was not created merely as a larger version of an RNN. It was designed as a different memory mechanism. Instead of forcing all past information into one hidden state that is repeatedly overwritten, an LSTM introduces a cell state and a collection of gates that regulate the movement of information. The model learns what should be retained, what should be removed, what new content should be written, and what part of its internal memory should be exposed as an output. These operations create a more controlled path through time and make long-range learning more practical.

The word "memory" can make LSTM appear intuitive before it is actually understood. A reader may memorize the names of the forget, input, and output gates and still be unable to explain why training succeeds or fails. For that reason, this book does not treat the LSTM as a sealed layer that receives a tensor and returns another tensor. The cell will be opened, rebuilt, measured, broken intentionally, executed one time step at a time, and compared with trusted PyTorch implementations. Every gate will be studied as both a mathematical operation and an engineering component whose behavior can be inspected through code.

The Central Problem of This Book

The central problem is not simply how to call `nn.LSTM`. The real problem is how a model can preserve relevant information across time while continuously receiving new observations. If it remembers everything, obsolete information accumulates and interferes with later decisions. If it forgets too aggressively, long dependencies disappear. If it writes every new signal into memory,

noise replaces useful context. If it exposes the entire cell state without control, downstream layers receive information that may not be relevant at the current time step.

An LSTM addresses this problem through learned, differentiable decisions. The forget gate scales the previous cell state, the input gate controls how much candidate information is written, and the output gate controls how much of the updated memory becomes visible through the hidden state. Sigmoid functions produce values between zero and one, making the gates behave like soft controls rather than hard switches. The candidate state uses a bounded nonlinear transformation to propose new content. Together, these pieces create a memory update that is additive in an important path, reducing the destructive effect of repeatedly replacing the entire state.

The distinction between the hidden state and the cell state is fundamental. The cell state is the internal memory pathway, while the hidden state is the exposed representation used for outputs, interactions between layers, and the next recurrent computation. They influence each other, but they are not interchangeable. Confusing their shapes, initialization, lifecycle, or role is one of the most common sources of LSTM implementation errors. Throughout this book, the reader will track both states explicitly and learn when they must be initialized, carried, detached, reset, saved, restored, or returned.

Learning Through Controlled Experiments

The learning system in this book follows the same experimental principle used throughout this volume: a concept is not considered understood until its behavior can be produced, observed, challenged, and explained. You will not be asked only to reproduce equations. You will create tasks where memory is necessary, vary the distance of a dependency, inspect the resulting gradients, and determine where one model stops learning reliably. You will force gates toward extreme values to observe what happens when memory is always erased, always retained, never written, or never exposed. These experiments turn abstract gate equations into visible behavior.

Intentional failure is an essential part of the method. You will swap gate order, use incorrect weight shapes, apply the wrong activation, mishandle padding, detach states at the wrong time, forget to detach them when using truncated backpropagation, and create data alignment mistakes that allow a model to predict the wrong target successfully. The objective is not to produce broken systems for their own sake. It is to build the diagnostic ability required to recognize the same failures when they appear silently inside a larger training pipeline.

Every experiment should be treated as a small scientific investigation. Begin with a question, define what changes and what remains controlled, record measurements, compare against a baseline, and explain the result. When comparing a vanilla RNN, GRU, and LSTM, do not change architecture, learning rate, parameter count, and training budget simultaneously and then attribute the outcome to gates. Use controlled seeds, identical data splits, explicit metrics, and repeated runs whenever randomness can change the conclusion. The discipline of the experiment is as important as the code.

What You Will Build

The book begins with LSTM intuition and the reason gates exist. You will write the complete update equations, distinguish the cell state from the hidden state, implement a single LSTM step with pure tensor operations, and verify gate ranges and shapes. The manual implementation will then be unrolled through time and compared with `nn.LSTM`. CPU and CUDA parity,

floating-point precision, fused kernels, long-sequence behavior, and deterministic execution will connect the mathematical cell to the actual computational system.

The next stage studies architecture variants and configuration choices. Many-to-one models will compress a sequence into a prediction, while many-to-many models will preserve temporal alignment across outputs. Stacked and bidirectional LSTMs will show how state shapes change with layers and directions. The reader will examine dropout between recurrent layers, projection choices, hidden size, parameter sharing, state initialization, and the difference between stateless batches and stateful sequence streams. These exercises develop the ability to design an LSTM architecture deliberately instead of adjusting dimensions until the code runs.

Backpropagation through time will then be revisited inside the LSTM. Gates improve the path through which gradients travel, but they do not eliminate every optimization difficulty. You will inspect gradients through the cell state, observe saturation, compare full and truncated backpropagation, apply clipping, perform gradient checking, and debug incorrect state detachment. This part is important because LSTM is often described as if it completely solves vanishing gradients. In reality, it creates a more favorable mechanism for retaining information, while sequence length, truncation, initialization, gate saturation, and optimization still determine what can be learned.

Sequence data handling forms the next layer of the system. Variable-length sequences require padding, masks, packed representations, sorting rules, and careful loss reduction. Stateful tasks require correct boundaries so memory from one sequence does not leak into another. Sliding windows, target shifts, teacher forcing, and chronological splits must preserve the meaning of time. A mathematically correct LSTM cannot recover from a pipeline that feeds the future into the past, evaluates padded positions as real data, or aligns every input with the wrong target.

The book then applies LSTM to two major sequence domains. In language modeling, you will build token sequences, train next-token predictors, generate text autoregressively, control sampling, measure perplexity, and analyze repetition and long-context failure. In time-series forecasting, you will construct multi-feature windows, enforce forecast horizons, compare one-step and multi-step prediction, prevent temporal leakage, use walk-forward validation, study seasonal dependencies, and estimate uncertainty. These applications share recurrent principles but demand different evaluation logic, failure analysis, and data discipline.

Regularization and stabilization receive a complete chapter because a model that trains once is not yet a reliable model. You will study dropout, weight decay, gradient clipping, layer normalization, optimizer choice, scheduling, early stopping, batch size, gate saturation, mixed precision, distribution shift, and calibration. The objective is to understand how these techniques interact with recurrent states rather than applying every method by default. Ablation studies will identify which intervention actually helps and which merely adds complexity.

The engineering chapter moves beyond model accuracy into efficiency, profiling, and deployment. You will measure the effect of sequence length, hidden size, layers, padding, packing, precision, gradient accumulation, and data transfer on CUDA performance. PyTorch profiling will reveal kernel and memory bottlenecks. Checkpointing, reproducible benchmarks, TorchScript, ONNX, production inference latency, state consistency, memory leaks, and monitoring will connect experimental models to systems that must operate repeatedly and safely.

Finally, the book builds a bridge from LSTM to attention. Even a strong LSTM compresses and transports information through sequential state updates, and this creates both an information bottleneck and a parallelism limitation. You will add attention to LSTM outputs, visualize alignment, compare attended and non-attended encoder–decoder models, handle masks, and measure the additional quality and computational cost. This final chapter explains why atten-

tion became necessary and how the limitations of recurrent processing lead naturally toward transformers.

Mathematics, Code, and Interpretation

Three forms of understanding must remain connected throughout the book. First, the mathematical form explains what is computed. Second, the program determines how tensors, devices, states, and gradients realize that computation. Third, interpretation explains what the computation means for memory and learning. Studying only one of these forms creates an incomplete understanding. An equation without tensor shapes can be implemented incorrectly; code without mathematics can run while performing the wrong recurrence; and both can be technically correct without explaining why a trained model behaves as it does.

When you encounter an LSTM equation, identify the shape and purpose of every term. Ask which dimensions represent the batch, time, input features, hidden features, layers, and directions. Determine which operations are matrix transformations, elementwise products, additions, or nonlinearities. Then ask what would happen if a gate approached zero or one, if the cell state grew too large, or if the activation entered saturation. This method transforms a long equation into a set of testable statements.

Do not allow the convenience of PyTorch to hide the mechanism. Built-in LSTM modules are essential for efficient training because they use optimized implementations, but efficiency should follow understanding. The manual cell teaches the internal computation; the built-in module teaches correct engineering practice. Both are necessary, and their outputs should be compared until you can explain any difference in gate order, bias handling, layout, precision, or kernel behavior.

What This Book Does Not Promise

LSTM is not an unlimited memory system. A long sequence can still exceed its effective capacity, gradients can still vanish through some paths, gates can saturate, truncated backpropagation can remove distant credit assignment, and hidden states can become sensitive to distribution shift. Training remains sequential across time, which limits parallelism and makes very long contexts expensive. An LSTM may outperform a vanilla RNN and still be the wrong architecture for a large-scale problem.

This book therefore avoids presenting LSTM as a universal replacement for every sequence model. GRU may provide sufficient memory with lower cost. Temporal convolutions may be more parallel and effective for local patterns. Attention may retrieve distant information more directly. Transformers may scale better for large datasets and long contexts. The correct architecture depends on evidence from the task, not on the historical importance of a model.

The goal is deeper than learning one class from a library. By the end of this book, you should be able to explain why LSTM exists, implement and verify its internal cell, design its surrounding pipeline, diagnose its failures, measure its engineering cost, deploy it responsibly, and recognize when its limitations require the next idea. That final judgment—knowing both the power and the boundary of a method—is what turns implementation into research.

How to Approach the Exercises

Complete the exercises in order because later challenges assume that earlier mechanisms have already been inspected and verified. Do not skip manual implementations simply because a built-in module is available. Do not skip failure cases because the successful version appears clear. The manual, comparative, and debugging exercises form one learning sequence: construct the mechanism, establish a reference, break one assumption, observe the evidence, and repair the correct cause.

Keep an experiment record containing configurations, random seeds, tensor shapes, device information, software versions, training curves, metrics, profiler results, and failure notes. Save both successful and unsuccessful runs. Reproducibility becomes increasingly important as models, datasets, and CUDA behavior become more complex, and a result that cannot be traced back to its conditions cannot support a reliable conclusion.

Most importantly, ask questions before accepting outputs. Why did this gate saturate? Which state carries the useful information? At what dependency distance did performance fail? Did the model learn memory or exploit leakage? Did mixed precision improve useful throughput without damaging gradients? Does the exported model preserve both hidden and cell states? Each exercise is designed to turn one of these questions into evidence. Approach the book patiently, experimentally, and critically; the purpose is not only to make an LSTM run, but to understand the complete system that makes its memory useful.

16.2 LSTM00 - LSTM Intuition and Why Gates Exist

Models and Training

16.2.1 Exercise 00 - Explain Why Vanilla RNN Fails on Long Dependencies and Why LSTM Was Designed as a Fix

Part 1 - Why this matters

A vanilla RNN carries information through repeated nonlinear state updates. Although a path connects an early input to a late prediction, the gradient traveling backward along that path is multiplied by many recurrent Jacobians and can shrink, grow, or become unstable.

This means memory failure is often an optimization problem rather than proof that no recurrent representation exists. The model may solve short dependencies while receiving almost no useful signal about which early observation caused a distant error.

LSTM introduces a cell state with additive updates controlled by learned gates. This creates a more direct route for retained information and gradients, allowing the model to decide when to preserve, erase, write, and expose memory instead of overwriting one state at every step.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial h_t} = \frac{\partial L}{\partial h_T} \prod_{k=t+1}^{T} \frac{\partial h_k}{\partial h_{k-1}}, \qquad c_t = f_t \odot c_{t-1} + i_t \odot g_t.$$

Part 3 - Hints and Helper

Use a delayed-memory task and plot gradient norm against temporal distance. Compare the mechanism, not only final accuracy.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    task = build_delayed_memory_task(delays=..., ...)
    models = {"rnn": build_rnn(...), "lstm": build_lstm(...)}
    reports = {}
    for name, candidate in models.items():
        reports[name] = train_with_temporal_gradient_probes(
            candidate, task, delays=config.delays, ...
        )
    return explain_failure_and_lstm_fix(reports)
```

16.2.2 Exercise 01 - Define Hidden State vs Cell State and Their Roles in Memory Preservation

Part 1 - Why this matters

An LSTM maintains two related states. The cell state is the internal memory pathway updated through forget and input decisions, while the hidden state is the exposed representation passed to outputs, upper layers, and the next recurrent computation.

The hidden state is filtered through the output gate and a bounded transformation of the cell. Consequently, information may remain stored internally even when it is not currently visible in the hidden representation.

Track both states on a sequence containing remember, distractor, and reveal events. Show when cell content persists, when hidden output changes, and why resetting or detaching only one component creates an inconsistent recurrent state.

Part 2 - Mathematical form

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t, \qquad h_t = o_t \odot \tanh(c_t).$$

Part 3 - Hints and Helper

Log h and c separately. Their shapes are often equal, but equal shape does not imply equal meaning or interchangeable values.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    h_t, c_t = initialize_lstm_state(batch=..., hidden_size=...)
    traces = {"hidden": [], "cell": []}
    for x_t in iterate_time_steps(data):
        h_t, c_t = manual_lstm_step(x_t, h_t, c_t, ...)
        traces["hidden"].append(h_t.detach().clone())
        traces["cell"].append(c_t.detach().clone())
    return compare_internal_and_exposed_memory(traces, events=...)
```

16.2.3 Exercise 02 - Write LSTM Update Equations and Map Every Term to Memory Control

Part 1 - Why this matters

The LSTM equations describe four coupled decisions: what old memory remains, what candidate content is written, what the new internal memory becomes, and what part of that memory is exposed. Reading them as one large formula hides this control structure.

The sigmoid gates produce soft coefficients between zero and one, while the candidate uses tanh to propose signed bounded content. Elementwise multiplication allows each hidden feature to follow its own learned retention and update behavior.

Write the equations in execution order, annotate every tensor shape, and map every operation to a memory action. Then test extreme gate values manually so the semantic interpretation agrees with the numerical result.

Part 2 - Mathematical form

$$i_t = \sigma(a_i),\ f_t = \sigma(a_f),\ g_t = \tanh(a_g),\ o_t = \sigma(a_o),\ c_t = f_t \odot c_{t-1} + i_t \odot g_t,\ h_t = o_t \odot \tanh(c_t).$$

Part 3 - Hints and Helper

Distinguish affine preactivations from gate outputs. State the gate ordering used by the implementation you will compare against.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    x_t, h_prev, c_prev = ...
    preactivations = compute_gate_affine_terms(x_t, h_prev, ...)
    gates = map_equations_to_memory_actions(preactivations, order=...)
    c_t = ...
    h_t = ...
```

```
    verify_shapes_and_semantics(
        inputs=(x_t, h_prev, c_prev), gates=gates, outputs=(h_t, c_t)
    )
    return gates, h_t, c_t
```

16.2.4 Exercise 03 - Implement One LSTM Time Step with Pure Torch Tensors Without nn.LSTM

Part 1 - Why this matters

A manual time step exposes exactly how input and previous hidden state enter the four gate projections. It also reveals why LSTM parameters commonly have four times the hidden dimension in their output axis.

Using pure tensor operations prevents a high-level module from hiding gate order, bias addition, broadcasting, and elementwise state updates. The goal is transparency, not replacing optimized library kernels in production.

Implement the affine transformations, split the gates, apply the correct activations, and update both states. Validate the result against hand calculations on a tiny deterministic example before comparing it with a reference cell.

Part 2 - Mathematical form

$$a_t = x_t W_{ih}^\top + b_{ih} + h_{t-1} W_{hh}^\top + b_{hh} \in \mathbb{R}^{B \times 4H}.$$

Part 3 - Hints and Helper

Use torch operations but not nn.LSTM or nn.LSTMCell. Print intermediate values for a batch of one and a very small hidden size.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    x_t, h_prev, c_prev = ...
    weight_ih, weight_hh = ...
    bias_ih, bias_hh = ...
    affine = (
        x_t @ weight_ih.T + bias_ih
        + h_prev @ weight_hh.T + bias_hh
    )
    i_raw, f_raw, g_raw, o_raw = affine.chunk(4, dim=-1)
    input_gate = ...
    forget_gate = ...
    candidate = ...
    output_gate = ...
```

```
    c_t = ...
    h_t = ...
    return h_t, c_t
```

16.2.5 Exercise 04 - Validate Sigmoid and Tanh Gate Ranges Precisely

Part 1 - Why this matters

Gate interpretations depend on activation ranges. Sigmoid produces open-interval values between zero and one for finite inputs, while tanh produces values between negative one and one, allowing signed candidate content.

Extreme preactivations may round to boundary values in finite precision, especially in float16. A naive strict assertion can therefore fail even when the implementation is mathematically correct, or pass while severe saturation has destroyed useful gradients.

Test ordinary, extreme, and non-finite inputs across precisions. Verify ranges, count saturated values, inspect activation derivatives, and distinguish valid numerical boundary rounding from NaN or infinity propagation.

Part 2 - Mathematical form

$$0 < \sigma(a) < 1, \qquad -1 < \tanh(a) < 1, \qquad \sigma'(a) = \sigma(a)(1 - \sigma(a)).$$

Part 3 - Hints and Helper

Use tolerant inclusive checks for stored floating-point values and separate them from theoretical strict bounds. Report saturation frequency.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    preactivations = build_range_test_values(
        ordinary=..., extreme=..., include_nonfinite=True
    )
    reports = {}
    for dtype in [torch.float64, torch.float32, torch.float16]:
        values = preactivations.to(dtype)
        sigmoid_values = torch.sigmoid(values)
        tanh_values = torch.tanh(values)
        reports[str(dtype)] = validate_activation_ranges(
            values, sigmoid_values, tanh_values, saturation_threshold=...
        )
    return reports
```

16.2.6 Exercise 05 - Compare LSTM and Vanilla RNN Forward Behavior on the Same Sequence

Part 1 - Why this matters

Vanilla RNN and LSTM both produce time-indexed hidden representations, but their internal update mechanisms respond differently to distractors, long delays, and reset events. Comparing only final output shapes conceals these behavioral differences.

A controlled comparison should use the same input sequence and known events while recording state evolution. The LSTM has an additional cell state, so its memory cannot be judged solely from exposed hidden activations.

Run both models with designed weights or trained parameters on remember-distract-reveal sequences. Compare hidden trajectories, cell persistence, sensitivity to new inputs, and output behavior as dependency distance grows.

Part 2 - Mathematical form

$$h_t^R = \tanh(W_x x_t + W_h h_{t-1}), \qquad (h_t^L, c_t^L) = \mathrm{LSTM}(x_t, h_{t-1}^L, c_{t-1}^L).$$

Part 3 - Hints and Helper

Use probes or visualizations aligned with sequence events. Do not claim better memory from a single untrained random forward pass.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    sequence, events = build_remember_distract_reveal_sequence(...)
    rnn_trace = trace_vanilla_rnn(build_rnn(...), sequence, ...)
    lstm_trace = trace_lstm(build_lstm(...), sequence, ...)
    return compare_forward_memory_behavior(
        rnn_trace,
        lstm_trace,
        events=events,
        dependency_distances=...,
    )
```

16.2.7 Exercise 06 - Force Forget-Gate Extremes and Observe Memory Retention

Part 1 - Why this matters

The forget gate multiplies the previous cell state before new content is added. Forcing it near zero removes old memory, while forcing it near one permits the old state to pass forward

almost unchanged through the direct retention path.

Retention is not the same as correct memory. A permanently open forget gate can accumulate obsolete information and cause interference, whereas a permanently closed gate prevents every long dependency.

Hold the input and output gates controlled while sweeping forget-gate values. Measure cell-state decay, persistence time, response to reset events, and gradients through the retained state.

Part 2 - Mathematical form

$$c_t = f\, c_{t-1} + i_t g_t, \qquad c_{t+k} = f^k c_t \text{ when no new content is written.}$$

Part 3 - Hints and Helper

Use values such as zero, 0.5, near one, and one. Include a task that requires forgetting as well as retaining.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    reports = {}
    for forced_forget in [0.0, 0.5, 0.99, 1.0]:
        cell_trace = run_controlled_lstm_cell(
            data,
            forced_gates={"forget": forced_forget, "input": ...,
                          "output": ...},
        )
        reports[forced_forget] = measure_retention_decay_and_interference(
            cell_trace, events=...
        )
    return reports
```

16.2.8 Exercise 07 - Force Input-Gate Extremes and Observe Memory Writing

Part 1 - Why this matters

The input gate determines how much candidate content enters the cell state. Closing it protects existing memory from new information, while opening it allows the candidate to modify the stored representation strongly.

An always-open input gate does not guarantee useful learning because noise and irrelevant observations can continuously overwrite or accumulate within memory. An always-closed gate preserves initialization but prevents adaptation to the sequence.

Force input-gate values on sequences containing relevant and irrelevant write events. Track cell-state change, successful encoding, noise contamination, and the interaction between writing and the forget gate.

Part 2 - Mathematical form

$$\Delta c_t = c_t - f_t \odot c_{t-1} = i_t \odot g_t.$$

Part 3 - Hints and Helper

Keep candidate values visible in the report. A small cell update may come from a closed input gate or a near-zero candidate.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    reports = {}
    for forced_input in [0.0, 0.25, 0.75, 1.0]:
        traces = run_controlled_lstm_cell(
            data,
            forced_gates={"input": forced_input, "forget": ...,
                          "output": ...},
            expose_candidate=True,
        )
        reports[forced_input] = analyze_memory_writing(
            traces, relevant_events=..., distractor_events=...
        )
    return reports
```

16.2.9 Exercise 08 - Force Output-Gate Extremes and Observe newline Hidden-State Exposure

Part 1 - Why this matters

The output gate controls how much transformed cell content becomes visible in the hidden state. Closing it can hide stored memory without erasing the cell, while opening it exposes the bounded transformation of current memory.

This separation allows an LSTM to retain information internally until it becomes relevant. It also means that inspecting hidden output alone can incorrectly suggest that memory was lost when it was merely concealed.

Keep cell-state dynamics fixed while sweeping output-gate values. Compare internal memory, hidden activation, downstream prediction, and the ability to reveal previously stored information at a chosen event.

Part 2 - Mathematical form

$$h_t = o_t \odot \tanh(c_t), \qquad c_t \text{ is unchanged by } o_t \text{ in the same step.}$$

Part 3 - Hints and Helper

Verify that forced output changes h but not c when all other computations are held constant. Plot both traces on the same timeline.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    fixed_cell_trace = ...
    reports = {}
    for forced_output in [0.0, 0.5, 1.0]:
        hidden_trace = expose_cell_with_forced_output_gate(
            fixed_cell_trace, forced_output=forced_output
        )
        reports[forced_output] = compare_internal_and_exposed_state(
            fixed_cell_trace, hidden_trace, reveal_event=...
        )
    return reports
```

16.2.10 Exercise 09 - Verify Gate and State Shapes for Batch-First and Time-First Layouts

Part 1 - Why this matters

LSTM input layout may be batch-time-feature or time-batch-feature, but recurrent state layout remains layer-direction, batch, hidden. This asymmetry is a frequent source of silent indexing and initialization errors.

Gate tensors inside one layer typically combine four hidden-sized blocks, while sequence outputs expose only the hidden dimension per direction. Bidirectionality and stacking will later add further structure, so the base case must be mastered first.

Run both layout configurations on equivalent transposed inputs. Assert input, output, hidden, cell, gate, weight, and bias shapes, then restore a common layout and verify numerical parity.

Part 2 - Mathematical form

$$X_{BF} \in \mathbb{R}^{B\times T\times I},\ X_{TF} \in \mathbb{R}^{T\times B\times I},\ h_0, c_0 \in \mathbb{R}^{L\times B\times H}.$$

Part 3 - Hints and Helper

Do not transpose h0 or c0 when toggling `batch_first`. Compare outputs after moving their time and batch axes into the same order.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    batch, time, input_size, hidden_size = ...
    x_bf = torch.randn(batch, time, input_size)
    x_tf = x_bf.transpose(0, 1)
    h0 = torch.zeros(..., batch, hidden_size)
    c0 = torch.zeros(..., batch, hidden_size)
    reports = run_both_layouts(x_bf, x_tf, h0, c0, ...)
    assert_expected_lstm_shapes(reports, ...)
    verify_layout_parity(reports, ...)
    return reports
```

16.2.11 Exercise 10 - Run the Manual LSTM Step on CUDA and Confirm CPU Parity

Part 1 - Why this matters

Moving a manual cell to CUDA tests whether every input, state, weight, bias, and intermediate tensor follows the intended device and dtype. A single CPU-created state or constant can break an otherwise correct implementation.

CPU and GPU floating-point operations may differ slightly because of kernel algorithms and operation ordering. Correctness should therefore use explicit tolerances rather than exact equality, while large differences require investigation.

Run identical parameters and inputs on both devices across several shapes and values. Compare every gate, cell state, hidden state, and backward gradient, and document the tolerance required by each precision.

Part 2 - Mathematical form

$$\varepsilon_\infty = \max_j |y_j^{CPU} - y_j^{GPU}|.$$

Part 3 - Hints and Helper

Create tensors from existing tensors with `new_zeros` or device-aware constructors. Synchronize CUDA before timing, not for a pure numerical comparison.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    cpu_case = build_manual_lstm_case(device="cpu", dtype=..., seed=...)
    gpu_case = clone_case_to_device(cpu_case, device="cuda")
    cpu_outputs = run_manual_step_with_gradients(cpu_case)
```

```
    gpu_outputs = run_manual_step_with_gradients(gpu_case)
    parity = compare_nested_tensors(
        cpu_outputs, move_to_cpu(gpu_outputs), atol=..., rtol=...
    )
    return parity
```

16.2.12 Exercise 11 - Benchmark Manual LSTM vs nn.LSTM and Explain Kernel Fusion Benefits

Part 1 - Why this matters

A Python-level manual unroll launches separate operations for gate projections, activations, elementwise updates, and every time step. Built-in LSTM implementations can combine work, reduce intermediate traffic, and use optimized recurrent kernels.

The performance gap depends on shape and device. Tiny sequences may be dominated by framework overhead, while large CUDA workloads benefit more from fused execution and efficient workspace management.

Benchmark a correct manual unroll against nn.LSTM using identical weights and inputs. Measure forward latency, useful-token throughput, peak memory, launch count, and output parity after warm-up.

Part 2 - Mathematical form

$$S = \frac{T_{\text{manual}}}{T_{\text{fused}}}, \qquad \text{throughput} = \frac{BT}{T_{\text{forward}}}.$$

Part 3 - Hints and Helper

Synchronize CUDA timing boundaries and warm up every shape. Do not include model construction or parameter copying in steady-state latency.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    manual, builtin = build_weight_matched_lstm_implementations(...)
    reports = {}
    for name, candidate in {"manual": manual, "builtin": builtin}.items():
        reports[name] = benchmark_forward(
            candidate,
            data,
            warmup=...,
            repetitions=...,
            synchronize_cuda=True,
            profile_launches=True,
```

```
        )
    verify_output_parity(reports, ...)
    return explain_fusion_speedup(reports)
```

16.2.13 Exercise 12 - Compare float32 and float16 LSTM Outputs and Find Precision-Sensitive Gate Cases

Part 1 - Why this matters

Float16 reduces memory and may accelerate CUDA computation, but it has narrower range and lower precision than float32. LSTM gates can become sensitive when preactivations are extreme or when small cell updates are added repeatedly.

Sigmoid saturation may erase distinctions between large inputs, while tiny candidate updates can underflow or disappear when added to a much larger cell state. Error may accumulate across a long unroll even if one step appears close.

Compare gate values, states, and final outputs across precisions for ordinary and adversarial scales. Locate the first time step where error exceeds tolerance and relate it to saturation, cancellation, or accumulated rounding.

Part 2 - Mathematical form

$$e_t = \|h_t^{32} - h_t^{16}\|_\infty, \qquad t^* = \min\{t : e_t > \tau\}.$$

Part 3 - Hints and Helper

Keep a float64 reference for diagnostic cases when useful. Evaluate both one-step and long-unroll error.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    scenarios = build_precision_scenarios(
        normal=..., saturated=..., tiny_updates=..., long_unroll=...
    )
    reports = {}
    for name, scenario in scenarios.items():
        outputs32 = run_lstm_precision(scenario, dtype=torch.float32)
        outputs16 = run_lstm_precision(scenario, dtype=torch.float16)
        reports[name] = analyze_gate_and_state_drift(
            outputs32, outputs16, threshold=...
        )
    return reports
```

16.2.14 Exercise 13 - Debug Gate Order, Concatenation, and newline Weight-Shape Mistakes

Part 1 - Why this matters

LSTM bugs often preserve tensor validity. Swapping input and forget blocks, concatenating along the batch axis, transposing a weight incorrectly, or using a bias with the wrong semantic order can still produce numbers of plausible shape.

Final-output comparison tells you that something is wrong but not where it began. Step-level inspection of affine terms, gate chunks, activations, and state updates identifies the first divergence from a trusted reference.

Create several intentionally broken cells and build a diagnostic harness that names each fault. Include gate permutations, wrong concatenation dimension, incorrect recurrent weight orientation, missing bias, and accidental broadcasting.

Part 2 - Mathematical form

$$a_t = [a_i \mid a_f \mid a_g \mid a_o], \qquad a_t \in \mathbb{R}^{B\times 4H}.$$

Part 3 - Hints and Helper

Use distinct sentinel values for each gate block so permutations are immediately visible. Validate shapes before comparing numerical values.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    reference = run_reference_lstm_step(...)
    broken_cells = build_faulty_lstm_cells(
        faults=["gate_order", "concat_axis", "weight_transpose",
                "missing_bias", "broadcasting"],
        ...
    )
    reports = {}
    for fault, cell in broken_cells.items():
        trace = run_step_with_intermediate_trace(cell, ...)
        reports[fault] = locate_first_reference_divergence(trace, reference)
    return reports
```

16.2.15 Exercise 14 - Manually Unroll LSTM Through Time and Compare with nn.LSTM

Part 1 - Why this matters

A single verified step becomes a sequence model only when its states are carried correctly across time. Manual unrolling makes temporal state flow explicit and reveals the difference

between collecting every hidden output and returning the final states.

Layout, gate order, bias handling, and parameter copying must all match the reference module. One incorrect state assignment at any step propagates into every later output.

Unroll the manual cell over a batch sequence, stack hidden outputs in the correct time dimension, and compare the full output tensor plus final hidden and cell states against nn.LSTM. Then repeat backward comparison with a scalar loss.

Part 2 - Mathematical form

$$(h_t, c_t) = F_\theta(x_t, h_{t-1}, c_{t-1}), \qquad Y = \text{stack}(h_1, \ldots, h_T).$$

Part 3 - Hints and Helper

Verify one step first, then two, then the complete sequence. Copy both bias vectors used by the reference implementation.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    manual_cell, builtin = build_weight_matched_lstm(...)
    h_t, c_t = ...
    outputs = []
    for x_t in iterate_time_steps(data, batch_first=...):
        h_t, c_t = manual_cell(x_t, (h_t, c_t))
        outputs.append(h_t)
    manual_output = torch.stack(outputs, dim=...)
    builtin_output, builtin_state = builtin(data, ...)
    verify_forward_and_backward_parity(
        manual_output, (h_t, c_t), builtin_output, builtin_state, ...
    )
    return manual_output, (h_t, c_t)
```

16.2.16 Exercise 15 - Stress Test Long-Sequence LSTM Forward Runtime and GPU Memory

Part 1 - Why this matters

LSTM improves memory dynamics but remains sequential across time and stores two recurrent states. Long sequences raise runtime and, during training, require many activations for backward computation.

A practical limit must include memory headroom and stable repeated execution, not merely one successful allocation. Sequence length, batch size, hidden size, layers, precision, and inference versus training mode all change the boundary.

Increase sequence length gradually while monitoring latency, tokens per second, allocated and peak memory, state magnitude, and non-finite outputs. Record the first unsafe configuration and classify whether the limit is memory, runtime, or numerical.

Part 2 - Mathematical form

$$C = O(BTLH^2), \qquad M_{\text{train}} = M_{\text{params}} + O(BTLH).$$

Part 3 - Hints and Helper

Warm up each shape and stop before exhausting the device. Reset peak statistics between cases while preserving a safety margin.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    reports = []
    for length in config.sequence_lengths:
        batch = make_lstm_input(length=length, ...).cuda()
        torch.cuda.reset_peak_memory_stats()
        result = guarded_forward_benchmark(
            model.cuda(), batch, warmup=..., repetitions=...,
            monitor_nonfinite=True, memory_headroom=...
        )
        reports.append({"length": length, **result})
    return identify_forward_operating_limit(reports)
```

16.2.17 Exercise 16 - Investigate cuDNN LSTM Non-Determinism and Document It

Part 1 - Why this matters

Repeated CUDA runs can differ slightly even when model parameters and inputs appear identical. Parallel arithmetic, algorithm selection, precision, library version, and nondeterministic kernels can change operation order and rounding.

Fixed PyTorch seeds do not control every source by themselves. DataLoader workers, dropout, environment settings, and deterministic algorithm policies must also be managed, and exact equality must be distinguished from tolerance-based reproducibility.

Repeat forward and backward experiments across shapes, precisions, and deterministic settings. Locate first divergence, measure its growth through time, record performance cost, and document the guarantees available on the tested system.

Part 2 - Mathematical form

$$\delta_t = \max |h_t^{(a)} - h_t^{(b)}|.$$

Part 3 - Hints and Helper

Capture GPU, CUDA, cuDNN, driver, and PyTorch versions. Control all random sources before attributing differences to a kernel.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    reports = []
    for deterministic in [False, True]:
        configure_all_randomness(seed=..., deterministic=deterministic)
        runs = [
            run_lstm_forward_backward(model, data, ...)
            for _ in range(...)
        ]
        reports.append(analyze_repeated_runs(
            runs,
            locate_first_divergence=True,
            include_performance_cost=True,
            environment=capture_cuda_environment(),
        ))
    return reports
```

16.2.18 Exercise 17 - Build a Long-Memory Synthetic Task and Confirm LSTM Outperforms RNN

Part 1 - Why this matters

A synthetic task with a known dependency distance provides direct evidence about memory. Unlike natural data, it can prevent shortcuts and reveal exactly which earlier symbol must influence the target.

The experiment must vary delay and include balanced distractors so a constant or local predictor cannot succeed. Both models need fair tuning and repeated seeds because one unstable run cannot support an architectural conclusion.

Construct a delayed copy, parity, or remember-and-reveal task. Compare RNN and LSTM accuracy, success rate, convergence time, temporal gradients, and hidden-state probes across increasing dependency lengths.

Part 2 - Mathematical form

$$y_T = \psi(x_{t^*}), \qquad T - t^* = d, \qquad d \in \mathcal{D}.$$

Part 3 - Hints and Helper

Include no-memory and recent-memory baselines. Generate train and test sequences independently to prevent memorization of fixed patterns.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    datasets = build_balanced_long_memory_tasks(
        delays=config.delays, train_samples=..., test_samples=...
    )
    results = run_repeated_model_comparison(
        models={"rnn": build_rnn, "lstm": build_lstm},
        datasets=datasets,
        seeds=config.seeds,
        equal_tuning_budget=True,
        ...
    )
    return confirm_dependency_advantage(results, baseline=...)
```

16.2.19 Exercise 18 - Find the Smallest Hidden Size That Retains Long Dependencies

Part 1 - Why this matters

A larger hidden size increases representational capacity but also parameters, memory, runtime, and the opportunity to overfit. The smallest successful LSTM is often a better engineering choice than the largest model that fits.

Capacity must be tested across repeated seeds and dependency distances. A model that succeeds once or only on training data has not demonstrated reliable memory retention.

Sweep hidden sizes under equal training and tuning budgets. Measure parameter count, success probability, validation accuracy, memory, latency, and gate behavior, then select the smallest size satisfying predefined quality and stability thresholds.

Part 2 - Mathematical form

$$H^* = \min\{H : \Pr(M_H \geq \tau) \geq p_{\min}\}.$$

Part 3 - Hints and Helper

Define the quality threshold and required success probability before the sweep. Use an untouched test delay beyond the easiest training cases.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    reports = []
    for hidden_size in config.hidden_sizes:
        runs = run_repeated_lstm_training(
            hidden_size=hidden_size,
            data=data,
            seeds=config.seeds,
            budget=...,
        )
        reports.append({
            "hidden_size": hidden_size,
            "parameters": count_lstm_parameters(hidden_size, ...),
            **summarize_capacity_runs(runs),
        })
    return select_smallest_reliable_lstm(
        reports, threshold=..., probability=...
    )
```

16.2.20 Exercise 19 - Explain How Gates Enable More Stable Gradient Flow Through Time

Part 1 - Why this matters

LSTM gates improve gradient flow by creating a cell-state path whose update contains addition and controllable elementwise retention. When forget values remain near one, gradients can pass through many steps without repeatedly crossing a full saturating state transformation.

This mechanism is conditional rather than guaranteed. Forget gates below one still cause decay, gate saturation can limit learning, truncation cuts gradient paths deliberately, and indirect dependencies through gate computations remain nonlinear.

Produce a conceptual report combining equations, Jacobian analysis, forced-gate experiments, temporal gradient plots, memory-task results, precision observations, and performance costs. State precisely what LSTM improves and which limitations remain.

Part 2 - Mathematical form

$$\frac{\partial c_T}{\partial c_t} \supseteq \prod_{k=t+1}^{T} f_k.$$

Part 3 - Hints and Helper

Separate the direct cell path from all indirect derivative terms. Support each claim with an experiment from LSTM00.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_lstm00_experiment_results(...)
    report = ConceptualGradientFlowReport()
    report.add_recurrent_jacobian_comparison(evidence, ...)
    report.add_gate_equation_interpretation(evidence, ...)
    report.add_forced_gate_results(evidence, ...)
    report.add_temporal_gradient_and_memory_curves(evidence, ...)
    report.add_precision_and_engineering_limits(evidence, ...)
    report.validate_every_claim_has_evidence()
    return report.export(...)
```

16.3 LSTM01 - LSTM Architecture Variants and Configurations

Models and Training

16.3.1 Exercise 00 - Implement a Many-to-One LSTM Classifier and Select the Last Hidden State Correctly

Part 1 - Why this matters

A many-to-one classifier consumes an entire sequence and produces one decision. The final representation must summarize the relevant history, but the phrase “last hidden state” becomes ambiguous when sequences are padded, layers are stacked, or directions are added.

For a single-layer unidirectional LSTM with equal lengths, the last sequence output and final hidden state correspond closely. With variable lengths, indexing the padded final column may select padding rather than the last valid event.

Build a classifier that obtains the final state from the recurrent module or gathers each sequence’s last valid output. Compare both methods on controlled lengths, validate logits and state shapes, and prove that padding does not change a sample’s prediction.

Part 2 - Mathematical form

$$h_i^* = h_{T_i}^{(L)}, \qquad \widehat{y}_i = W_o h_i^* + b_o.$$

Part 3 - Hints and Helper

For packed sequences, use the returned final hidden state carefully. For padded outputs, gather index length minus one for every sample.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ManyToOneLSTM(nn.Module):
    def __init__(self, input_size, hidden_size, classes):
        super().__init__()
        self.lstm = nn.LSTM(input_size, hidden_size, batch_first=True)
        self.head = nn.Linear(hidden_size, classes)

    def forward(self, x, lengths):
        outputs, (h_n, c_n) = self.lstm(x)
        last_valid = gather_last_valid(outputs, lengths - 1)
        logits = self.head(...)
        verify_final_state_selection(last_valid, h_n, lengths, ...)
        return logits
```

16.3.2 Exercise 01 - Implement Many-to-Many LSTM Sequence Labeling and Validate Temporal Alignment

Part 1 - Why this matters

Many-to-many sequence labeling produces an output for each valid time step. The model must preserve temporal alignment so label t is compared with the representation created from input position t under the chosen causal or bidirectional context.

Flattening batch and time dimensions can simplify loss computation, but incorrect reshaping or target shifting silently changes which prediction is matched to which label. Padded steps must also be excluded from both loss and metrics.

Build a token-level classifier, trace one identifiable sequence through the pipeline, and verify output, target, and mask alignment. Compare vectorized loss with an explicit valid-position calculation.

Part 2 - Mathematical form

$$H \in \mathbb{R}^{B\times T\times H}, \quad Z = HW_o^\top + b_o \in \mathbb{R}^{B\times T\times C}.$$

Part 3 - Hints and Helper

Use a monotonic synthetic sequence whose expected labels are visually obvious. Assert the same valid-token count in outputs, targets, and mask.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class SequenceLabeler(nn.Module):
```

```
    def __init__(self, input_size, hidden_size, classes):
        super().__init__()
        self.lstm = nn.LSTM(input_size, hidden_size, batch_first=True)
        self.head = nn.Linear(hidden_size, classes)

    def forward(self, x):
        outputs, state = self.lstm(x)
        return self.head(outputs), state

def E01(model, data, config):
    logits, state = model(data.inputs)
    loss = masked_sequence_loss(logits, data.targets, data.mask, ...)
    validate_time_alignment(logits, data.targets, data.mask, ...)
    return loss, state
```

16.3.3 Exercise 02 - Implement a Stacked LSTM and Confirm Multi-Layer Hidden and Cell Shapes

Part 1 - Why this matters

A stacked LSTM passes the output sequence from one recurrent layer into the next. Each layer has its own hidden and cell states, allowing higher layers to transform temporal features created by lower layers.

The final state tensors store one slice per layer and direction, not one slice per time step. Confusing layer index with time index can select a valid-shaped tensor from the wrong semantic location.

Build stacked models with several depths, inspect parameter shapes by layer, and verify sequence output plus h and c states. Use hooks or a manual stack to compare intermediate layer outputs with the fused multi-layer module.

Part 2 - Mathematical form

$$h_n, c_n \in \mathbb{R}^{L \times B \times H}, \qquad Y^{(\ell)} = \mathrm{LSTM}^{(\ell)}(Y^{(\ell-1)}).$$

Part 3 - Hints and Helper

The sequence output comes from the final layer, while `h_n` and `c_n` contain final states from all layers. Initialize every layer-state slice.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E02(model, data, config):
    for layers in config.layer_counts:
```

```
        candidate = nn.LSTM(
            input_size=..., hidden_size=..., num_layers=layers,
            batch_first=True
        )
        h0 = torch.zeros(layers, data.batch_size, config.hidden_size)
        c0 = torch.zeros_like(h0)
        outputs, (h_n, c_n) = candidate(data.inputs, (h0, c0))
        assert_stacked_lstm_shapes(outputs, h_n, c_n, layers=layers, ...)
        compare_with_manual_layer_stack(candidate, data.inputs, ...)
    return ...
```

16.3.4 Exercise 03 - Implement Bidirectional LSTM and Verify Concatenation and Output Dimensions

Part 1 - Why this matters

A bidirectional LSTM processes the same sequence from both temporal directions and concatenates their representations. Each output position can therefore contain information from earlier and later observations.

The output feature dimension doubles, and final state tensors interleave layer and direction indices. The last forward state and last backward state correspond to different locations in the output sequence, so careless indexing produces incorrect sequence summaries.

Build a bidirectional model on an identifiable sequence, split forward and backward output blocks, and verify their relation to final states. Assert dimensions for outputs, h, c, and the downstream projection.

Part 2 - Mathematical form

$$y_t = [\overrightarrow{h}_t; \overleftarrow{h}_t] \in \mathbb{R}^{2H}, \qquad h_n, c_n \in \mathbb{R}^{2L \times B \times H}.$$

Part 3 - Hints and Helper

Reshape final states to layer, direction, batch, hidden before selecting them. Do not assume output at the last time step contains both final directions.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E03(model, data, config):
    lstm = nn.LSTM(
        input_size=..., hidden_size=..., num_layers=...,
        bidirectional=True, batch_first=True
    )
    outputs, (h_n, c_n) = lstm(data.inputs)
```

```
    forward_output, backward_output = outputs.chunk(2, dim=-1)
    states = reshape_states_by_layer_and_direction(h_n, c_n, ...)
    verify_bidirectional_state_output_mapping(
        forward_output, backward_output, states, ...
    )
    return outputs, states
```

16.3.5 Exercise 04 - Compare Unidirectional and Bidirectional LSTM for Sequence Labeling

Part 1 - Why this matters

Bidirectional context can improve a label when future observations clarify the current position. It is invalid, however, for causal streaming or forecasting tasks where future inputs do not exist at prediction time.

The comparison must account for doubled representation width, extra parameters, latency, and the need to wait for the complete sequence. Accuracy gain alone cannot justify an architecture that violates deployment causality.

Train both models on a task with controllable future-context dependence. Compare equal hidden size and approximately equal parameter count, then measure quality by position, runtime, memory, and online feasibility.

Part 2 - Mathematical form

$$p(y_t \mid x_{1:T}) \text{ is bidirectional}, \qquad p(y_t \mid x_{1:t}) \text{ is causal.}$$

Part 3 - Hints and Helper

Include one causal task and one task where future context truly helps. State whether the intended application has the full sequence available.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    variants = {
        "unidirectional": build_labeler(bidirectional=False, ...),
        "bidirectional": build_labeler(bidirectional=True, ...),
    }
    results = run_controlled_architecture_comparison(
        variants,
        data,
        matching=["hidden_size", "parameter_count"],
        metrics_by_position=True,
        measure_runtime=True,
        ...
    )
    return summarize_quality_causality_tradeoff(results)
```

16.3.6 Exercise 05 - Use batch_first and Keep Shapes Consistent Across the Pipeline

Part 1 - Why this matters

The batch-first option changes the input and output sequence layout, but it does not change the recurrent state layout. This deliberate asymmetry can create errors when a pipeline assumes every tensor follows the same axis order.

DataLoader collation, masking, packing, loss reduction, and visualization must agree on where batch and time dimensions live. Repeated transposes can also create non-contiguous views and hidden copies.

Implement equivalent batch-first and time-first pipelines, verify numerical parity after alignment, and inspect strides and contiguity. Add shape assertions at every boundary so a later configuration change fails immediately.

Part 2 - Mathematical form

$$X_{BF} \in \mathbb{R}^{B\times T\times I}, \quad X_{TF} \in \mathbb{R}^{T\times B\times I}, \quad h_0, c_0 \in \mathbb{R}^{LD\times B\times H}.$$

Part 3 - Hints and Helper

Never transpose h0 or c0 because of `batch_first`. Normalize both pipeline outputs into one common layout before comparison.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    x_bf = data.inputs
    x_tf = x_bf.transpose(0, 1)
    reports = {
        "batch_first": run_complete_pipeline(
            build_lstm(batch_first=True, ...), x_bf, layout="BTF", ...
        ),
        "time_first": run_complete_pipeline(
            build_lstm(batch_first=False, ...), x_tf, layout="TBF", ...
        ),
    }
    verify_pipeline_shape_contracts(reports, ...)
    verify_layout_parity(reports, ...)
    return reports
```

16.3.7 Exercise 06 - Implement Inter-Layer Dropout and Verify the num_layers Condition

Part 1 - Why this matters

Built-in LSTM dropout is applied between stacked recurrent layers, not across time inside a single layer. Therefore, a one-layer LSTM has no inter-layer connection on which this dropout can operate.

Misunderstanding this behavior can create a false sense of regularization. Dropout must also change between training and evaluation modes, while repeated evaluation outputs should remain stable.

Compare one-layer and multi-layer models under several dropout probabilities. Use repeated forward passes to detect stochastic changes, inspect train and eval behavior, and verify that recurrent state shapes remain unaffected.

Part 2 - Mathematical form

$$\widetilde{y}_t^{(\ell)} = m_t^{(\ell)} \odot y_t^{(\ell)}/(1-p), \qquad \ell < L.$$

Part 3 - Hints and Helper

Expect a warning or no effective inter-layer dropout when `num_layers` equals one. Test behavior statistically rather than checking one output.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E06(model, data, config):
    reports = {}
    for layers in [1, 2, 3]:
        candidate = nn.LSTM(
            input_size=..., hidden_size=..., num_layers=layers,
            dropout=config.dropout, batch_first=True
        )
        train_outputs = repeated_forward(candidate.train(), data.inputs, ...)
        eval_outputs = repeated_forward(candidate.eval(), data.inputs, ...)
        reports[layers] = analyze_dropout_activity(
            train_outputs, eval_outputs, expected_active=(layers > 1)
        )
    return reports
```

16.3.8 Exercise 07 - Build a Capacity Curve Across Hidden Sizes and Layer Counts

Part 1 - Why this matters

Hidden size controls recurrent width, while layer count controls hierarchical depth. Both increase capacity, but their parameter, runtime, memory, optimization, and generalization effects differ.

A larger model may reduce training error while worsening validation performance or becoming too slow for the application. Conversely, a narrow deep model can create an information bottleneck or unstable gradient path.

Sweep a grid of widths and depths under controlled data and budgets. Record parameter count, accuracy, convergence, peak memory, latency, gradient norms, and failure rate, then construct a quality-cost frontier.

Part 2 - Mathematical form

$$P \approx \sum_{\ell=1}^{L} 4H_\ell(I_\ell + H_\ell + 2).$$

Part 3 - Hints and Helper

Use multiple seeds and the same early-stopping rule. Compare training-budget and wall-clock-budget views separately.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    reports = []
    for hidden_size in config.hidden_sizes:
        for layers in config.layer_counts:
            candidate = build_lstm(
                hidden_size=hidden_size, layers=layers, ...
            )
            result = train_benchmark_and_evaluate(candidate, data, ...)
            reports.append({
                "hidden_size": hidden_size,
                "layers": layers,
                "parameters": count_parameters(candidate),
                **result,
            })
    return build_capacity_performance_frontier(reports)
```

16.3.9 Exercise 08 - Implement LSTM Projection and Explain Why It Helps

Part 1 - Why this matters

An LSTM projection separates internal cell width from exposed recurrent width. A larger cell can maintain rich memory while a smaller projected hidden state reduces downstream dimensions and recurrent parameter cost.

With projection, hidden and cell states no longer share the same final dimension. The cell state uses `hidden_size`, while hidden outputs use `proj_size`, making old shape assumptions

invalid.

Use the available projected LSTM implementation or emulate projection after a cell. Compare parameter count, output and state shapes, runtime, memory, and accuracy against a non-projected model under controlled budgets.

Part 2 - Mathematical form

$$\widetilde{h}_t = o_t \odot \tanh(c_t) \in \mathbb{R}^H, \qquad h_t = W_p \widetilde{h}_t \in \mathbb{R}^P,\ P < H.$$

Part 3 - Hints and Helper

Verify library support on the chosen backend. Distinguish an external output projection from a recurrent projection fed into the next time step.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E08(model, data, config):
    projected = nn.LSTM(
        input_size=...,
        hidden_size=config.cell_size,
        proj_size=config.projection_size,
        batch_first=True,
    )
    outputs, (h_n, c_n) = projected(data.inputs)
    assert_projection_shapes(
        outputs, h_n, c_n,
        cell_size=config.cell_size,
        projection_size=config.projection_size,
    )
    return compare_projected_and_standard_lstm(projected, data, ...)
```

16.3.10 Exercise 09 - Debug Shape Errors in Multi-Layer and Bidirectional LSTM

Part 1 - Why this matters

Stacking and bidirectionality combine layer, direction, batch, time, hidden, and sometimes projection dimensions. Most mistakes come from applying a correct formula to the wrong configuration.

Hard-coded multipliers can survive one test while failing when depth, directionality, or projection changes. Error messages often appear in the classifier head even though the incorrect assumption began in recurrent-state construction.

Create faulty configurations for state shape, head width, direction ordering, last-state selection, and projection. Build a shape-debugging report that computes expectations from model attributes and locates the first broken boundary.

Part 2 - Mathematical form

$$D = 1 + \mathbf{1}_{\text{bidirectional}}, \quad Y \in \mathbb{R}^{B \times T \times DH_{out}}, \quad h_n \in \mathbb{R}^{DL \times B \times H_{out}}.$$

Part 3 - Hints and Helper

Derive shapes from `num_layers`, `bidirectional`, `hidden_size`, and `proj_size` rather than copying constants.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    faulty_variants = build_shape_failure_cases(
        faults=["state_layers", "head_width", "direction_order",
                "last_state", "projection_width"],
        ...
    )
    reports = {}
    for name, candidate in faulty_variants.items():
        expected = derive_lstm_shape_contract(candidate, data.inputs)
        reports[name] = run_shape_boundary_audit(candidate, data, expected)
    return locate_architecture_shape_failures(reports)
```

16.3.11 Exercise 10 - Move the Complete LSTM Architecture to CUDA and Validate State Device Placement

Part 1 - Why this matters

A complete architecture includes embeddings or feature projections, recurrent parameters, initial states, masks, targets, and classifier heads. Moving only the LSTM module leaves other components on CPU and creates device mismatch failures.

Fresh hidden and cell states must be created on the same device and compatible dtype as the model or input. Device-aware creation becomes especially important under mixed precision and multi-device code.

Move an end-to-end architecture and batch to CUDA, initialize states dynamically, and verify every parameter, buffer, input, output, loss, and gradient device. Compare controlled CPU and GPU outputs within tolerances.

Part 2 - Mathematical form

$$\text{device}(x) = \text{device}(h_0) = \text{device}(c_0) = \text{device}(\theta).$$

Part 3 - Hints and Helper

Use `x.new_zeros` or parameter-based constructors for states. Avoid storing fixed-device states as ordinary attributes.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    device = torch.device("cuda")
    model = model.to(device)
    batch = move_batch_to_device(data.batch, device, non_blocking=True)
    h0 = batch.inputs.new_zeros(...)
    c0 = batch.inputs.new_zeros(...)
    outputs = model(batch.inputs, state=(h0, c0))
    loss = compute_loss(outputs, batch.targets)
    loss.backward()
    audit_model_batch_state_and_gradient_devices(model, batch, outputs, ...)
    return compare_cpu_gpu_architecture_parity(... )
```

16.3.12 Exercise 11 - Benchmark LSTM Across Sequence Lengths and Find Practical GPU Limits

Part 1 - Why this matters

Sequence length directly extends recurrent execution and training graph depth. Although gate calculations within each time step use parallel matrix operations, time steps remain causally ordered.

The longest shape that executes once is not necessarily practical. A usable configuration needs memory headroom, stable repeated latency, acceptable throughput, and no numerical failure.

Sweep sequence lengths under fixed batch and model settings, then under a fixed-token budget. Measure step latency, tokens per second, peak memory, state magnitude, and failure boundary on the target GPU.

Part 2 - Mathematical form

$$\text{tokens/s} = BT/T_{step}, \qquad M_{train} = M_{fixed} + O(BTLH).$$

Part 3 - Hints and Helper

Warm up each unique shape and reset peak memory statistics. Stop safely before exhausting device memory.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    reports = []
    for length in config.sequence_lengths:
        batch_size = choose_batch_size(length, policy=...)
        batch = make_sequence_batch(batch_size, length, ...).cuda()
        torch.cuda.reset_peak_memory_stats()
        result = benchmark_lstm_shape(
            model.cuda(), batch, warmup=..., repetitions=...,
            training=True, memory_headroom=...
        )
        reports.append({"length": length, "batch": batch_size, **result})
    return identify_practical_gpu_sequence_limit(reports)
```

16.3.13 Exercise 12 - Compare float32 and Mixed-Precision Stability and Find fp16 Gate Failures

Part 1 - Why this matters

Mixed precision can accelerate LSTM training and reduce activation memory, but gate sigmoids and accumulated cell updates can be sensitive to limited range and precision. Long sequences amplify small state differences.

Gradient scaling protects small backward values but does not prevent forward gate saturation, cell overflow, or cancellation. Stable short tests therefore do not guarantee stable training at deployment sequence lengths.

Compare float32, autocast without scaling, and autocast with dynamic scaling across normal and extreme inputs. Record speed, memory, gate saturation, state drift, skipped updates, nonfinite gradients, and validation quality.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad e_t = \|h_t^{32} - h_t^{mp}\|_\infty.$$

Part 3 - Hints and Helper

Unscale before clipping or gradient-norm measurement. Inspect gate preactivations and cell states, not only final loss.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
```

```
    reports = {}
    for mode in ["float32", "amp_unscaled", "amp_scaled"]:
        candidate = clone_initial_model(model).cuda()
        reports[mode] = train_precision_configuration(
            candidate,
            data,
            autocast_enabled=(mode != "float32"),
            grad_scaler=...,
            inspect_gates=True,
            ...
        )
    return identify_precision_sensitive_gate_cases(reports)
```

16.3.14 Exercise 13 - Wrap nn.LSTM in a Debuggable Module That Exposes States

Part 1 - Why this matters

Production code benefits from optimized nn.LSTM, while debugging requires visibility into outputs, final states, shape contracts, norms, and sometimes layer-level behavior. A wrapper can provide observability without replacing the fused recurrent implementation.

The interface should remain explicit about input layout, optional initial state, lengths, and returned diagnostic data. Diagnostics must be detachable so ordinary training does not retain large graphs or force synchronization unnecessarily.

Build a configurable wrapper that validates inputs, initializes states, returns task output, and optionally records safe summaries. Test train and inference modes, variable lengths, directions, layers, and CUDA placement.

Part 2 - Mathematical form

$$\mathcal{O} = (Y, h_n, c_n, \mathcal{S}), \qquad \mathcal{S} = \{\|Y\|, \|h_n\|, \|c_n\|, \text{shapes}\}.$$

Part 3 - Hints and Helper

Prefer scalar summaries over storing all activations. Make debug collection optional and avoid calling item inside timed training loops.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class DebuggableLSTM(nn.Module):
    def __init__(self, **lstm_config):
        super().__init__()
        self.lstm = nn.LSTM(**lstm_config)
```

```
    def forward(self, x, state=None, debug=False):
        if state is None:
            state = initialize_state_from_input(self.lstm, x)
        validate_lstm_input_and_state(self.lstm, x, state)
        outputs, (h_n, c_n) = self.lstm(x, state)
        diagnostics = collect_safe_state_summaries(
            outputs, h_n, c_n, enabled=debug
        )
        return outputs, (h_n, c_n), diagnostics

def E13(model, data, config):
    return test_debuggable_wrapper_across_configurations(... )
```

16.3.15 Exercise 14 - Create Unit Tests for LSTM Shapes Across Configurations

Part 1 - Why this matters

Shape correctness is an architectural invariant that can be tested before expensive training. Parameterized unit tests prevent a later change in layers, directions, layout, or projection from silently invalidating downstream code.

Tests should derive expected shapes from configuration rather than repeating the same implementation assumptions. Edge cases such as batch one, time one, multi-layer bidirectional projection, and non-contiguous inputs expose fragile logic.

Build a configuration matrix and test inputs, outputs, h, c, classifier dimensions, dtype, and device. Add negative tests that confirm malformed states fail with understandable diagnostics.

Part 2 - Mathematical form

$$\text{shape}(Y) = (B, T, DH_{out}), \quad \text{shape}(h_n) = (DL, B, H_{out}), \quad \text{shape}(c_n) = (DL, B, H_{cell}).$$

Part 3 - Hints and Helper

Use one independent expected-shape function. Do not calculate expectations by running the model and copying returned dimensions.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    cases = generate_lstm_configuration_matrix(
        batch_first=[False, True],
        bidirectional=[False, True],
        layers=[1, 3],
        projection=[0, ...],
```

```
        edge_shapes=...,
    )
    for case in cases:
        candidate, inputs, state = build_test_case(case)
        outputs, final_state = candidate(inputs, state)
        expected = independently_derive_expected_shapes(case)
        assert_all_shape_dtype_device_contracts(
            outputs, final_state, expected
        )
    run_negative_state_shape_tests(...)
    return ...
```

16.3.16 Exercise 15 - Validate LSTM Determinism and Reproducibility Across Runs and Machines

Part 1 - Why this matters

Reproducible LSTM training depends on model initialization, data order, worker seeds, dropout, CUDA algorithms, precision, and software environment. Fixing one random seed does not control all of these sources.

Exact equality may require slower deterministic algorithms and still remain environment-specific. Scientific reproducibility can instead define acceptable numerical and metric tolerances while recording the complete conditions.

Repeat forward and training runs locally, then compare saved benchmark records across machines. Locate first divergence, measure growth through time, and document performance cost and remaining sources of variation.

Part 2 - Mathematical form

$$\delta_t = \|h_t^{(a)} - h_t^{(b)}\|_\infty, \qquad \Delta M = |M^{(a)} - M^{(b)}|.$$

Part 3 - Hints and Helper

Capture Python, PyTorch, CUDA, cuDNN, driver, GPU, seed, and determinism settings. Save data split identifiers and sampler state.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    environments = capture_reproducibility_environment(...)
    reports = []
    for deterministic in [False, True]:
        runs = []
        for repeat in range(...):
```

```
            configure_reproducibility(seed=..., deterministic=deterministic)
            runs.append(run_controlled_lstm_training(model, data, ...))
        comparison = compare_repeated_runs(
            runs, locate_first_divergence=True
        )
        reports.append(comparison)
    return export_cross_machine_reproducibility_record(environments, reports)
```

16.3.17 Exercise 16 - Stress Test Deep Stacked LSTM for Gradient and Memory Limits

Part 1 - Why this matters

Adding recurrent layers increases representational depth at every time step, but also lengthens gradient paths, stores more activations, and raises parameter and optimizer memory. Very deep stacks can become unstable or inefficient before they run out of theoretical capacity.

Failure may appear as vanishing lower-layer gradients, exploding upper-layer gradients, NaN values, throughput collapse, or GPU memory pressure. One final global gradient norm cannot reveal which layer failed first.

Increase depth gradually under fixed sequence and width settings. Record layer-wise gradient and activation norms, runtime, peak memory, convergence, and numerical failures, then test whether clipping, normalization, or residual connections alter the boundary.

Part 2 - Mathematical form

$$g_\ell = \|\nabla_{\theta_\ell} L\|_2, \qquad M = O(LBTH) + M_{parameters}.$$

Part 3 - Hints and Helper

Register layer-specific diagnostics and stop below total device exhaustion. Compare the same initial seeds and training budget.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    reports = []
    for layers in config.deep_layer_counts:
        candidate = build_stacked_lstm(layers=layers, ...).cuda()
        result = guarded_deep_lstm_stress_test(
            candidate,
            data,
            log_layerwise_gradients=True,
            log_activations=True,
            memory_headroom=...,
            interventions=...,
```

```
        )
        reports.append({"layers": layers, **result})
    return identify_depth_instability_and_memory_limits(reports)
```

16.3.18 Exercise 17 - Compare LSTM and GRU Parameter Cost with Accuracy

Part 1 - Why this matters

LSTM uses four gate blocks and two recurrent states, while GRU uses three gate blocks and one state. This often makes GRU smaller and faster at equal hidden size, but the task may benefit from LSTM's separate cell memory.

Equal hidden size is not equal parameter count, and equal parameter count is not equal runtime. A fair report should present several matching policies rather than hiding this distinction.

Train both architectures on short- and long-dependency tasks across seeds. Compare parameters, peak memory, throughput, time-to-quality, final accuracy, and robustness, then state where extra LSTM cost produces measurable benefit.

Part 2 - Mathematical form

$$P_{GRU} \approx 3H(I+H), \qquad P_{LSTM} \approx 4H(I+H).$$

Part 3 - Hints and Helper

Compare equal hidden size, approximately equal parameters, and equal wall-clock budget. Tune both with equal search effort.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    results = run_gru_lstm_comparison(
        tasks=[data.short_dependency, data.long_dependency],
        matching=["hidden_size", "parameter_count", "wall_clock"],
        seeds=config.seeds,
        equal_tuning_budget=True,
        measure_memory_and_throughput=True,
        ...
    )
    return document_parameter_accuracy_tradeoff(results)
```

16.3.19 Exercise 18 - Build an Architecture Selection Checklist for Depth, Width, and Directionality

Part 1 - Why this matters

LSTM depth, width, and directionality should follow the task's evidence rather than a preference for larger models. Each choice changes capacity, causality, state shape, latency, memory, and deployment behavior.

The smallest architecture meeting quality and reliability targets is often easier to train, debug, export, and serve. Bidirectionality must be rejected when future context is unavailable, regardless of offline validation gain.

Create a decision checklist using measured dependency length, data volume, online constraints, memory budget, latency target, and architecture sweeps. Define escalation and rollback rules so every added component has a reason.

Part 2 - Mathematical form

$$a^* = \arg\min_a C(a) \quad \text{s.t.} \quad Q(a) \geq Q_{min},\ L(a) \leq L_{max},\ M(a) \leq M_{max}.$$

Part 3 - Hints and Helper

Begin with a one-layer unidirectional baseline. Add width, depth, directionality, or projection one controlled change at a time.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    evidence = collect_task_and_architecture_evidence(...)
    checklist = ArchitectureSelectionChecklist()
    checklist.add_dependency_and_causality_rules(evidence, ...)
    checklist.add_width_capacity_thresholds(evidence, ...)
    checklist.add_depth_stability_limits(evidence, ...)
    checklist.add_directionality_constraints(evidence, ...)
    checklist.add_projection_and_budget_rules(evidence, ...)
    checklist.add_escalation_and_rollback_tests(evidence, ...)
    return checklist.validate_and_export(...)
```

16.3.20 Exercise 19 - Produce an LSTM Architecture Engineering Report

Part 1 - Why this matters

An architecture report should explain why the selected LSTM has its particular task mapping, depth, width, directionality, layout, dropout, projection, state policy, precision, and device

configuration. Listing hyperparameters without evidence is not an engineering rationale.

Every choice must connect to controlled results and explicit constraints. The report should also preserve rejected alternatives and failure cases, because they define the operating boundary of the final design.

Synthesize shape tests, capacity curves, CUDA benchmarks, precision experiments, reproducibility records, stress tests, and GRU comparisons. Produce separate training and deployment recommendations with assumptions, limitations, and next validation steps.

Part 2 - Mathematical form

$$\text{requirement} \rightarrow \text{configuration} \rightarrow \text{evidence} \rightarrow \text{tradeoff} \rightarrow \text{decision}.$$

Part 3 - Hints and Helper

Require a traceable benchmark or test for every major configuration claim. Include raw configuration identifiers and environment metadata.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_lstm01_experiment_results(...)
    report = ArchitectureEngineeringReport()
    report.add_task_mapping_and_shape_contracts(evidence, ...)
    report.add_depth_width_directionality_rationale(evidence, ...)
    report.add_dropout_projection_and_state_policy(evidence, ...)
    report.add_cuda_precision_and_reproducibility(evidence, ...)
    report.add_capacity_cost_and_gru_comparison(evidence, ...)
    report.add_failures_limits_and_next_tests(evidence, ...)
    report.validate_claim_traceability()
    return report.export(...)
```

16.4 LSTM02 - Backpropagation Through Time in LSTM

Models and Training

16.4.1 Exercise 00 - Confirm Gradients Flow Through Hidden and Cell-State Paths

Part 1 - Why this matters

LSTM backpropagation follows both the exposed hidden-state recurrence and the internal cell-state pathway. Looking only at parameter gradients cannot show which temporal route carried the learning signal.

The cell path contains an additive update with forget-gate retention, while the hidden path passes through output gating and nonlinear transformations. Both contribute to earlier states and gate parameters.

Manually unroll a tiny LSTM, retain gradients on every h and c state, and backpropagate from a late loss. Plot both gradient sequences and verify that removing either path changes earlier credit assignment.

Part 2 - Mathematical form

$$\frac{\partial L}{\partial c_t} = \frac{\partial L}{\partial c_{t+1}} \frac{\partial c_{t+1}}{\partial c_t} + \frac{\partial L}{\partial h_t} \frac{\partial h_t}{\partial c_t}.$$

Part 3 - Hints and Helper

Call `retain_grad` on non-leaf states before backward. Keep hidden and cell traces in separate lists.

Part 4 - Python code skeleton

```
import torch

def E00(model, data, config):
    h_t, c_t = initialize_state(...)
    hidden_states, cell_states = [], []
    for x_t in iterate_time_steps(data.inputs):
        h_t, c_t = manual_lstm_step(x_t, h_t, c_t, ...)
        h_t.retain_grad(); c_t.retain_grad()
        hidden_states.append(h_t); cell_states.append(c_t)
    loss = compute_late_loss(hidden_states[-1], data.targets)
    loss.backward()
    return compare_hidden_and_cell_gradient_paths(hidden_states, cell_states)
```

16.4.2 Exercise 01 - Compare Temporal Gradient Norms with Vanilla RNN

Part 1 - Why this matters

LSTM is expected to improve long-range gradient flow, but that claim must be measured at equal temporal distances. Final parameter norms mix contributions from all time steps and hide decay along the sequence.

A fair comparison uses the same task, data, initialization scale, output loss, and dependency distances. LSTM may still decay when forget gates close or saturate, so improvement is not equivalent to constant gradients.

Retain state gradients for both models, compute norms by distance from the loss, and repeat across seeds. Compare slopes on a logarithmic scale and relate LSTM behavior to observed forget-gate values.

Part 2 - Mathematical form

$$G_m(d) = \mathbb{E}\|\partial L/\partial s_{T-d}^{(m)}\|_2.$$

Part 3 - Hints and Helper

Use cell-state gradients as the primary LSTM memory-path measurement and hidden gradients as a separate curve.

Part 4 - Python code skeleton

```
import torch

def E01(model, data, config):
    reports = {}
    models = {
        "rnn": build_rnn(...),
        "lstm": build_lstm(...),
    }
    for name, candidate in models.items():
        reports[name] = collect_temporal_gradient_norms(
            candidate, data, distances=config.distances, seeds=config.seeds
        )
    return compare_log_gradient_decay(reports, inspect_forget_gates=True)
```

16.4.3 Exercise 02 - Create Exploding Gradients and Apply Clipping Correctly

Part 1 - Why this matters

Gates reduce some instability but cannot prevent explosion from oversized recurrent weights, extreme learning rates, long sequences, or unstable state dynamics. One large update can corrupt every gate simultaneously.

Norm clipping rescales the complete parameter-gradient vector after backward and before the optimizer step. Clipping each tensor independently or clipping before mixed-precision unscaling changes the intended operation.

Create a controlled unstable configuration, record pre- and post-clipping norms, and compare thresholds with an unclipped run. Measure clipping frequency, loss stability, and whether an excessively small threshold prevents learning.

Part 2 - Mathematical form

$$g' = g \min\left(1, \frac{c}{\|g\|_2 + \epsilon}\right).$$

Part 3 - Hints and Helper

Unscale gradients before clipping. The value returned by `clip_grad_norm_` is the pre-clipping norm.

Part 4 - Python code skeleton

```
import torch

def E02(model, data, config):
    loss = run_unstable_lstm_forward(model, data, ...)
    loss.backward()
    pre_norm = global_gradient_norm(model.parameters())
    returned_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), max_norm=config.clip_norm
    )
    post_norm = global_gradient_norm(model.parameters())
    optimizer.step()
    return verify_clipping(pre_norm, returned_norm, post_norm, ... )
```

16.4.4 Exercise 03 - Implement Truncated BPTT and Measure Its Tradeoffs

Part 1 - Why this matters

Full BPTT stores a graph across the complete sequence, which can exceed memory on long streams. Truncated BPTT processes shorter chunks while carrying detached hidden and cell states forward.

Detachment saves memory by cutting the backward path, but it also prevents losses in later chunks from teaching decisions before the boundary. Forward memory can persist even when credit assignment cannot cross the truncation.

Implement chunked training, sweep truncation lengths, and measure peak memory, throughput, gradient reach, and long-dependency accuracy. Reset states only at true sequence boundaries.

Part 2 - Mathematical form

$$(h_{k+1}, c_{k+1}) = \text{stopgrad}(F_\theta(x_{k:k+K}, h_k, c_k)).$$

Part 3 - Hints and Helper

Detach both components of the state tuple. Normalize loss consistently across the full logical sequence.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
```

```
    state = initialize_state(...)
    optimizer.zero_grad(set_to_none=True)
    for chunk, targets in split_sequence(data, length=config.truncation):
        outputs, state = model(chunk, state)
        loss = compute_chunk_loss(outputs, targets, normalization=...)
        loss.backward()
        optimizer.step(); optimizer.zero_grad(set_to_none=True)
        state = tuple(value.detach() for value in state)
    return measure_tbptt_memory_accuracy_tradeoff(... )
```

16.4.5 Exercise 04 - Debug Detach Strategies That Break Long-Term Learning

Part 1 - Why this matters

Detaching state at the wrong location can silently change the learning problem. Detaching every time step eliminates temporal credit assignment, while never detaching between independent chunks grows the graph and links unrelated updates.

Detaching only h or only c creates inconsistent behavior because the remaining component still carries a graph across the boundary. Using the deprecated data attribute or recreating tensors can also sever gradients unexpectedly.

Construct correct and faulty strategies, inspect graph connectivity, and train on a task whose dependency crosses chunk boundaries. Make the diagnostics identify over-detachment, missing detachment, and partial-state detachment.

Part 2 - Mathematical form

$$\partial L_{k+1}/\partial \theta_k = 0 \text{ across a deliberate detach boundary.}$$

Part 3 - Hints and Helper

Inspect `grad_fn` and saved-graph growth, then confirm the effect with a controlled dependency task.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    strategies = {
        "correct_chunk": detach_both_after_chunk,
        "every_step": detach_both_every_step,
        "hidden_only": detach_hidden_only,
        "never": keep_entire_graph,
    }
    reports = {}
    for name, strategy in strategies.items():
```

```
        reports[name] = train_and_audit_detach_strategy(
            model, data, strategy=strategy, inspect_graph=True, ...
        )
    return diagnose_detach_failures(reports)
```

16.4.6 Exercise 05 - Finite-Difference Check a Tiny LSTM Cell

Part 1 - Why this matters

Automatic differentiation can propagate gradients through incorrect forward equations perfectly. Finite differences compare autograd with the actual numerical sensitivity of the implemented loss and can expose gate-order or derivative mistakes.

The method is sensitive to step size and floating-point precision. A step that is too large introduces truncation error, while a step that is too small is dominated by cancellation.

Use a tiny float64 cell and scalar loss, perturb selected parameters in both directions, and compare central differences with autograd. Sweep epsilon and report relative error per gate block.

Part 2 - Mathematical form

$$g_j^{FD} = \frac{L(\theta_j + \varepsilon) - L(\theta_j - \varepsilon)}{2\varepsilon}.$$

Part 3 - Hints and Helper

Disable stochastic behavior and avoid saturated test values. Restore every parameter after each perturbation.

Part 4 - Python code skeleton

```
import torch

def E05(model, data, config):
    cell = build_tiny_lstm_cell(dtype=torch.float64, seed=...)
    autograd_gradients = compute_autograd_gradients(cell, data, ...)
    finite_difference = central_difference_gradients(
        cell, data, epsilons=config.epsilons, parameter_indices=...
    )
    return compare_gradient_checks_by_gate(
        autograd_gradients, finite_difference, tolerance=...
    )
```

16.4.7 Exercise 06 - Monitor Gate Gradients and Detect Saturation

Part 1 - Why this matters

A low total gradient norm does not reveal which gate stopped learning. Input, forget, candidate, and output blocks share concatenated parameters but serve different control roles.

Saturated sigmoids produce derivatives near zero, so a gate can receive upstream signal yet transmit little gradient through its preactivation. Candidate tanh saturation creates a related blockage.

Split parameter and preactivation gradients by gate, log norms and saturation rates, and align them with sequence events. Identify whether failure comes from absent upstream signal, saturated activation, or a disconnected graph.

Part 2 - Mathematical form

$$S_g = \Pr(a_g < -k \ \vee \ a_g > k), \qquad G_g = \|\nabla_{\theta_g} L\|_2.$$

Part 3 - Hints and Helper

Use hooks on preactivations in a manual or instrumented cell. Keep PyTorch gate order explicit.

Part 4 - Python code skeleton

```
import torch

def E06(model, data, config):
    monitor = GateGradientMonitor(
        order=["input", "forget", "candidate", "output"]
    )
    with monitor.instrument(model):
        outputs = run_instrumented_lstm(model, data.inputs, ...)
        loss = compute_loss(outputs, data.targets)
        loss.backward()
    return monitor.summarize(
        include_parameter_norms=True, include_saturation=True,
        align_with_events=...
    )
```

16.4.8 Exercise 07 - Fix Forget-Gate Saturation with Initialization and LR

Part 1 - Why this matters

A forget gate driven near zero erases memory, while one pinned near one can retain obsolete state and receive a tiny sigmoid derivative. Both extremes can block useful adaptation.

Forget-bias initialization changes early retention timescale, but it is not a universal solution. Weight scale, input normalization, and learning rate determine how quickly preactivations move into saturation.

Create saturated configurations, inspect gate logits and gradients, then test controlled bias initialization and learning-rate adjustments. Compare retention, adaptation, gradient norms, and task accuracy.

Part 2 - Mathematical form

$$f_t = \sigma(a_f), \qquad \sigma'(a_f) = f_t(1 - f_t).$$

Part 3 - Hints and Helper

Change one factor at a time and log preactivation distributions, not only gate outputs.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    variants = build_forget_gate_variants(
        biases=config.forget_biases,
        weight_scales=config.weight_scales,
        learning_rates=config.learning_rates,
    )
    results = run_gate_saturation_experiments(
        variants, data, gate="forget", track_logits=True, ...
    )
    return select_fix_without_destroying_adaptation(results)
```

16.4.9 Exercise 08 - Fix Input-Gate Saturation with Normalization or Initialization

Part 1 - Why this matters

Input-gate saturation can prevent new information from entering memory or allow every observation to write indiscriminately. Either behavior makes the cell insensitive to the task's actual write events.

Large feature scales and unstable affine initialization can push input-gate logits into extreme regions before learning begins. Normalization and controlled initialization can restore a useful operating range.

Compare raw, normalized, and differently initialized inputs while monitoring input-gate logits, candidate values, cell updates, and gradients. Confirm that the fix improves selective writing rather than merely reducing all activations.

Part 2 - Mathematical form

$$\Delta c_t = i_t \odot g_t, \qquad i_t = \sigma(W_i x_t + U_i h_{t-1} + b_i).$$

Part 3 - Hints and Helper

Separate the contribution of i from the candidate g. Standardize features using training data only.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    variants = build_input_gate_stability_variants(
        normalization=["none", "feature", "layer"],
        initializations=config.initializations,
        ...
    )
    results = run_gate_saturation_experiments(
        variants, data, gate="input", track_cell_updates=True, ...
    )
    return identify_selective_writing_fix(results)
```

16.4.10 Exercise 09 - Diagnose NaN Loss from Precision, LR, and Sequence Length

Part 1 - Why this matters

A NaN loss is usually the last visible symptom of an earlier non-finite input, cell state, gate logit, gradient, or parameter update. Recurrent reuse can amplify the initial problem many steps before the loss fails.

Precision mode, learning rate, initialization, and sequence length interact, so changing all of them at once may hide the cause. A diagnostic runner should capture the first non-finite stage and time step.

Sweep controlled configurations and stop immediately on failure. Record input range, gate logits, states, loss, gradients, scaler status, and the failing batch so the root cause can be reproduced.

Part 2 - Mathematical form

$$\text{finite}(z) \iff \neg\,\text{isnan}(z) \wedge \neg\,\text{isinf}(z).$$

Part 3 - Hints and Helper

Check tensors before and after every major stage. Preserve the first failure rather than continuing with corrupted parameters.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    monitor = LSTMFiniteMonitor(fail_fast=True, save_first_failure=True)
    for precision, lr, length in experiment_grid(...):
        result = run_training_with_stage_checks(
            model, data, precision=precision, learning_rate=lr,
            sequence_length=length, monitor=monitor, ...
```

```
        )
        monitor.record_configuration_result(precision, lr, length, result)
    return monitor.root_cause_report()
```

16.4.11 Exercise 10 - Validate CUDA and CPU Gradient Parity

Part 1 - Why this matters

CPU and CUDA should implement the same LSTM derivatives, but floating-point order, fused kernels, and precision can create small differences. Exact equality is usually too strict for meaningful parity.

A controlled comparison requires identical parameters, inputs, loss reduction, initial states, and deterministic settings. It should inspect gate-block parameter gradients as well as outputs and state gradients.

Run a small float64 or float32 reference on both devices, compare forward states and backward gradients, and document tolerances. Repeat across sequence lengths to observe error accumulation.

Part 2 - Mathematical form

$$e_g = \max_j |g_j^{CPU} - g_j^{CUDA}|.$$

Part 3 - Hints and Helper

Clone state dictionaries rather than reinitializing models. Synchronize CUDA before reading timing, not as a substitute for parity checks.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    cpu_model = build_controlled_lstm(device="cpu", dtype=..., seed=...)
    gpu_model = clone_model_and_state(cpu_model).cuda()
    cpu_result = forward_backward_snapshot(cpu_model, data.cpu_batch, ...)
    gpu_result = forward_backward_snapshot(gpu_model, data.gpu_batch, ...)
    return compare_forward_state_and_named_gradients(
        cpu_result, move_snapshot_to_cpu(gpu_result), atol=..., rtol=...
    )
```

16.4.12 Exercise 11 - Profile BPTT Memory and Graph-Retention Bottlenecks

Part 1 - Why this matters

LSTM training memory includes parameters, optimizer states, saved activations for every time step and layer, temporary workspaces, and any graphs accidentally retained by logging

code. Peak memory alone cannot identify the owner.

Repeated backward with retained graphs, storing loss tensors, or carrying attached states across batches can cause memory to grow over time. Reserved CUDA memory may remain high without indicating a true live-tensor leak.

Profile allocated and peak memory across forward, backward, and update regions while varying sequence length. Compare healthy and intentionally retained graphs, then locate activation and ownership bottlenecks.

Part 2 - Mathematical form

$$M_{peak} = M_{parameters} + M_{optimizer} + M_{saved\ activations} + M_{workspace}.$$

Part 3 - Hints and Helper

Store loss.item or detached summaries rather than loss tensors. Distinguish allocated from reserved CUDA memory.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    reports = {}
    patterns = [
        "healthy", "retain_graph", "stored_losses", "attached_state"
    ]
    for retention in patterns:
        torch.cuda.reset_peak_memory_stats()
        reports[retention] = profile_bptt_memory_regions(
            model, data, retention_pattern=retention,
            record_allocation_timeline=True, ...
        )
    return identify_graph_and_activation_bottlenecks(reports)
```

16.4.13 Exercise 12 - Detect Mixed-Precision Overflow and Underflow

Part 1 - Why this matters

Mixed precision reduces memory and may accelerate BPTT, but long recurrent chains can produce gradients smaller or larger than float16 represents. Underflow silently creates zeros, while overflow can trigger skipped updates or non-finite states.

Dynamic scaling multiplies the loss before backward and unscales gradients before the optimizer step. It cannot repair forward cell-state overflow or gate saturation.

Compare float32, unscaled autocast, and scaled autocast across increasing lengths. Track scaler values, skipped steps, zero-gradient fraction, non-finite tensors, speed, memory, and validation quality.

Part 2 - Mathematical form

$$\widetilde{L} = sL, \qquad \nabla L = s^{-1}\nabla \widetilde{L}.$$

Part 3 - Hints and Helper

Unscale before clipping and true norm measurement. Inspect forward and backward failures separately.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    reports = {}
    for mode in ["float32", "amp_unscaled", "amp_scaled"]:
        reports[mode] = train_with_precision_diagnostics(
            clone_initial_model(model).cuda(), data,
            mode=mode, sequence_lengths=config.lengths,
            track_scale=True, track_zero_gradients=True,
            track_nonfinite=True, ...
        )
    return compare_overflow_underflow_and_quality(reports)
```

16.4.14 Exercise 13 - Log Gate Gradient Norms with Autograd Hooks

Part 1 - Why this matters

Hooks provide measurements during backward without rewriting the optimizer. They can expose gate-specific parameter gradients, state gradients, and rare spikes that epoch averages conceal.

Careless hooks can retain tensors, force CPU synchronization, or change timing enough to distort profiling. Logging must detach summaries and remove handles when instrumentation ends.

Register hooks on concatenated gate parameters or manual gate tensors, split values by documented order, and aggregate batch statistics. Report distributions, trends, and anomaly events rather than printing every tensor.

Part 2 - Mathematical form

$$G_{g,k} = \|\nabla_{\theta_g} L_k\|_2.$$

Part 3 - Hints and Helper

Return detached scalar or CPU summaries from logging logic, and keep hook handles for removal.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    logger = GateGradientHookLogger(order=..., sample_every=...)
    handles = logger.register(model)
    try:
        train_lstm(model, data, after_backward=logger.record_step, ...)
    finally:
        for handle in handles:
            handle.remove()
    return logger.summarize(distributions=True, anomalies=True)
```

16.4.15 Exercise 14 - Demonstrate and Fix the zero_grad Accumulation Bug

Part 1 - Why this matters

PyTorch adds new gradients to existing parameter gradients by design. If a normal LSTM training loop omits gradient clearing, every step combines unrelated batches and changes the effective update.

The loss may still decrease initially, making the bug difficult to detect. Gradient norms grow, updates depend on all previous batches, and clipping can hide the accumulation without fixing it.

Compare correct clearing, missing clearing, and intentional accumulation with proper normalization. Inspect gradients after consecutive identical batches and verify optimizer order explicitly.

Part 2 - Mathematical form

$$g_k^{stored} = g_{k-1}^{stored} + \nabla_\theta L_k.$$

Part 3 - Hints and Helper

Clear before backward for ordinary training. For intentional accumulation, scale losses and clear only at logical-batch boundaries.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
```

```
    reports = {}
    for policy in ["correct", "missing", "intentional_accumulation"]:
        candidate = clone_initial_model(model)
        reports[policy] = run_update_order_experiment(
            candidate, data, zero_grad_policy=policy,
            set_to_none=True, record_gradient_snapshots=True, ...
        )
    return detect_and_explain_gradient_accumulation(reports)
```

16.4.16 Exercise 15 - Analyze Batch Size, Gradient Noise, and Convergence

Part 1 - Why this matters

Batch size changes the variance of an LSTM gradient estimate and the number of updates per epoch. Small batches may provide useful noise but unstable recurrent updates; large batches are smoother yet require memory and may generalize differently.

Sequence batches also vary in valid-token count and padding waste, so nominal sample count does not fully describe effective batch size. Loss normalization must remain consistent.

Sweep batch sizes under equal sample or token budgets. Measure gradient variance, norm distributions, convergence, throughput, peak memory, and validation quality across seeds.

Part 2 - Mathematical form

$$\mathrm{Var}(\widehat{g}_B) \approx \Sigma / B.$$

Part 3 - Hints and Helper

Report valid tokens per update and padding efficiency. Adjust learning rate only in a documented secondary experiment.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    reports = []
    for batch_size in config.batch_sizes:
        loader = build_length_aware_loader(data, batch_size=batch_size, ...)
        result = train_with_gradient_noise_measurement(
            clone_initial_model(model), loader,
            equal_token_budget=True, seeds=config.seeds, ...
        )
        reports.append({"batch_size": batch_size, **result})
    return analyze_noise_convergence_and_efficiency(reports)
```

16.4.17 Exercise 16 - Stress Very Long Sequences and Locate LSTM Forgetting

Part 1 - Why this matters

LSTM improves retention but does not provide unlimited memory. Forget values below one compound over time, finite state capacity causes interference, and optimization becomes harder as required dependency distance grows.

A long sequence is not necessarily a long-dependency task. The useful signal must be placed at a controlled distance from the target while distractors prevent local shortcuts.

Sweep dependency distance and sequence length independently. Record accuracy, cell probes, gate retention products, temporal gradients, runtime, and memory, then locate the first sustained forgetting boundary.

Part 2 - Mathematical form

$$R(t,T) = \prod_{k=t+1}^{T} f_k.$$

Part 3 - Hints and Helper

Use multiple seeds and require failure across neighboring distances. Compare with a no-memory baseline.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    results = run_long_memory_grid(
        model,
        sequence_lengths=config.lengths,
        dependency_distances=config.distances,
        seeds=config.seeds,
        inspect_cell_and_forget_gates=True,
        ...
    )
    return identify_sustained_forgetting_boundary(results, baseline=...)
```

16.4.18 Exercise 17 - Compare Full and Truncated BPTT on Long Dependencies

Part 1 - Why this matters

Full BPTT can assign a late error to any earlier step in the sequence, while truncated BPTT deliberately limits this learning horizon. Forward state may carry information beyond

the truncation even though later loss cannot teach how it was encoded.

The comparison must keep model, data order, optimizer updates, loss normalization, and compute budget controlled. Otherwise differences may come from update frequency rather than gradient horizon.

Train both methods on tasks with dependencies below, near, and above the truncation length. Compare memory, throughput, accuracy, temporal gradients, and the ability to learn a new distant dependency.

Part 2 - Mathematical form

$$\partial L_t / \partial \theta_{t-d} = 0 \text{ under truncation when } d > K.$$

Part 3 - Hints and Helper

Align optimizer-step frequency or report it as a separate factor. Include a dependency shorter than K as a sanity check.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    methods = {
        "full": build_full_bptt_trainer(...),
        "truncated": build_tbptt_trainer(chunk_length=config.truncation, ...),
    }
    results = run_dependency_length_comparison(
        methods, data, distances=config.distances,
        equal_loss_normalization=True, equal_update_policy=..., ...
    )
    return explain_full_vs_truncated_results(results)
```

16.4.19 Exercise 18 - Build an LSTM-Specific BPTT newline Debugging Checklist

Part 1 - Why this matters

LSTM BPTT failures can originate in gate saturation, state detachment, clipping order, mixed precision, loss masking, graph retention, or optimizer sequencing. A generic loss check cannot distinguish them.

An effective checklist turns each suspicion into an executable invariant or measurement and orders cheap checks before expensive profiling. It must preserve the first failing batch and configuration.

Build a staged diagnostic runner covering data, state graphs, gate logits, state magnitudes, temporal gradients, finite values, clipping, precision, and memory growth. Validate it against deliberately broken cases.

Part 2 - Mathematical form

$$\mathcal{D} = \mathcal{D}_{state} \cup \mathcal{D}_{gate} \cup \mathcal{D}_{gradient} \cup \mathcal{D}_{memory}.$$

Part 3 - Hints and Helper

Give each check a severity, expected range, evidence payload, and recommended next test.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    checklist = LSTMBPTTChecklist()
    checklist.add("state_graph", audit_hidden_cell_graphs, severity="error")
    checklist.add("gate_saturation", measure_all_gate_saturation, ...)
    checklist.add("temporal_gradients", inspect_gradient_by_time, ...)
    checklist.add("finite_stages", verify_forward_backward_finite, ...)
    checklist.add("clip_order", verify_unscale_clip_step_order, ...)
    checklist.add("memory_growth", detect_retained_graphs, ...)
    checklist.add("optimizer_order", verify_zero_backward_step, ...)
    return checklist.run(model=model, data=data, config=config)
```

16.4.20 Exercise 19 - Produce the Complete LSTM BPTT Engineering Report

Part 1 - Why this matters

A BPTT report should connect cell equations to observed gradients, optimization stability, memory cost, and task performance. Isolated curves are not enough unless their experimental conditions and failure boundaries are clear.

The report must distinguish what LSTM gating improves from what clipping, truncation, precision controls, or data design changes. It should also retain unsuccessful interventions so future work does not repeat them blindly.

Synthesize hidden and cell paths, temporal norms, saturation, gradient checking, detach experiments, CUDA parity, memory profiling, precision, batch size, and long-sequence limits. End with practical rules and unresolved questions.

Part 2 - Mathematical form

$$\text{mechanism} \rightarrow \text{measurement} \rightarrow \text{failure} \rightarrow \text{fix} \rightarrow \text{verified boundary}.$$

Part 3 - Hints and Helper

Require every conclusion to reference a configuration and recorded experiment. Separate correctness rules from task-specific tuning.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_lstm02_experiment_results(...)
    report = LSTMBPTTEngineeringReport()
    report.add_hidden_and_cell_gradient_paths(evidence, ...)
    report.add_saturation_and_gradient_check_results(evidence, ...)
    report.add_clipping_detach_and_tbptt_tradeoffs(evidence, ...)
    report.add_cuda_memory_and_precision_results(evidence, ...)
    report.add_batch_and_long_sequence_boundaries(evidence, ...)
    report.add_debugging_rules_failures_and_lessons(evidence, ...)
    report.validate_claim_traceability()
    return report.export(...)
```

16.5 LSTM03 - Sequence Data Handling for LSTM

Data Engineering for AI

16.5.1 Exercise 00 - Build Variable-Length Sequence Dataset and Validate Targets

Part 1 - Why this matters

Real sequence samples rarely share one length. A dataset must preserve each sample's valid time axis and its exact target relationship before batching introduces padding or reordering.

Alignment errors are especially deceptive because input and target tensors can remain valid while representing different events. Sequence identifiers and original indices provide evidence that survives collation.

Build samples with varied lengths and deterministic labels, return metadata, and verify first, middle, last, minimum-length, and maximum-length cases manually and automatically.

Part 2 - Mathematical form

$$X_i = (x_{i,1}, \ldots, x_{i,T_i}), \qquad Y_i = \psi(X_i), \qquad T_i \neq T_j.$$

Part 3 - Hints and Helper

Validate alignment before padding. Retain source indices or timestamps in each sample's metadata.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import Dataset

class VariableSequenceDataset(Dataset):
```

```
    def __init__(self, records):
        self.records = ...

    def __len__(self):
        return ...

    def __getitem__(self, index):
        sequence, target, metadata = ...
        validate_sample_alignment(sequence, target, metadata)
        return sequence, target, metadata

def E00(model, data, config):
    dataset = VariableSequenceDataset(data)
    return audit_dataset_edge_cases(dataset, ... )
```

16.5.2 Exercise 01 - Implement Padding and Masks and Prove Loss Ignores Padding

Part 1 - Why this matters

Padding converts variable-length samples into a rectangular batch, but padding values are not observations. If they enter loss or metrics, short sequences receive artificial targets and may dominate training.

A mask must be derived from trusted lengths and use the same temporal alignment as outputs and targets. Choosing a padding value that also appears in real data makes value-based masking unsafe.

Create padded batches with several lengths, compute masked loss, perturb padding positions drastically, and prove the loss and valid predictions remain unchanged.

Part 2 - Mathematical form

$$m_{i,t} = \mathbf{1}[t < T_i], \qquad L = \frac{\sum_{i,t} m_{i,t} \ell_{i,t}}{\sum_{i,t} m_{i,t}}.$$

Part 3 - Hints and Helper

Build masks from lengths, not from comparing tensor values with the padding value.

Part 4 - Python code skeleton

```
import torch
from torch.nn.utils.rnn import pad_sequence

def E01(model, data, config):
    padded = pad_sequence(data.sequences, batch_first=True, padding_value=...)
    lengths = torch.tensor([len(x) for x in data.sequences])
    mask = torch.arange(padded.size(1))[None, :] < lengths[:, None]
```

```
    outputs = model(padded)
    loss = masked_loss(outputs, data.targets, mask, ...)
    perturbed = alter_padding_only(padded, mask, value=...)
    verify_padding_invariance(model, padded, perturbed, mask, loss, ...)
    return padded, lengths, mask, loss
```

16.5.3 Exercise 02 - Implement Packed Sequences and Validate Benefits

Part 1 - Why this matters

Packed sequences allow the LSTM to skip padded time steps instead of processing a full maximum-length rectangle. The benefit grows when batch lengths differ substantially.

Packing changes representation and requires correct lengths, ordering, and restoration. A faster result is meaningless unless valid outputs and final states agree with the padded reference.

Pack a batch, run the LSTM, unpack and restore order, then compare valid positions. Measure packing overhead, useful-token throughput, and peak memory across length distributions.

Part 2 - Mathematical form

$$\eta_{pad} = \frac{\sum_i T_i}{B \max_i T_i}.$$

Part 3 - Hints and Helper

Keep lengths on CPU when required and use `enforce_sorted` consistently with the chosen ordering.

Part 4 - Python code skeleton

```
import torch
from torch.nn.utils.rnn import pack_padded_sequence, pad_packed_sequence

def E02(model, data, config):
    padded, lengths, targets = ...
    packed = pack_padded_sequence(
        padded, lengths.cpu(), batch_first=True, enforce_sorted=...
    )
    packed_outputs, state = model(packed)
    outputs, restored_lengths = pad_packed_sequence(
        packed_outputs, batch_first=True
    )
    verify_packed_valid_outputs(outputs, state, padded, lengths, ...)
    return benchmark_packing_benefits(... )
```

16.5.4 Exercise 03 - Debug Sorting, Length, and Packed-Output Bugs

Part 1 - Why this matters

Packing bugs can reorder samples, truncate valid steps, include padding as data, or attach outputs to the wrong targets. Most produce legal tensors and misleading learning rather than an immediate exception.

Sorting lengths requires applying the same permutation to inputs, targets, metadata, and carried states, then restoring original order after processing. Off-by-one lengths alter which event becomes the final state.

Create controlled faulty variants and build audits for monotonic sorting, length bounds, permutation inversion, valid-token counts, and output-target identity.

Part 2 - Mathematical form

$$X' = PX, \quad Y' = PY, \quad \widehat{Y} = P^{-1}\widehat{Y}'.$$

Part 3 - Hints and Helper

Use sample IDs embedded in a feature channel so reordering mistakes are visible.

Part 4 - Python code skeleton

```
import torch

def E03(model, data, config):
    variants = create_packing_failure_cases(
        faults=["unsorted", "wrong_lengths", "targets_not_sorted",
                "missing_inverse_permutation", "off_by_one"],
        ...
    )
    reports = {}
    for name, batch in variants.items():
        reports[name] = audit_packed_pipeline(
            model, batch, verify_ids=True, verify_valid_counts=True
        )
    return diagnose_packing_failures(reports)
```

16.5.5 Exercise 04 - Compare Padded and Packed Training on CUDA

Part 1 - Why this matters

Packed execution removes padding work, but sorting, packing, unpacking, and CPU length handling add overhead. GPU speedup therefore depends on length variance, model size, and batch shape.

Padded computation may be faster for nearly uniform lengths because it uses regular dense kernels. A fair comparison should measure complete training steps and useful tokens, not only the recurrent call.

Benchmark both paths on identical samples with low, medium, and high length variance. Confirm valid-output parity, then report latency, throughput, memory, padding efficiency, and preprocessing overhead.

Part 2 - Mathematical form

$$S = \frac{T_{padded}}{T_{packed}}, \qquad Q = \frac{\sum_i T_i}{T_{step}}.$$

Part 3 - Hints and Helper

Warm up each representation and synchronize CUDA timing boundaries. Include sorting and packing in end-to-end time.

Part 4 - Python code skeleton

```
import torch

def E04(model, data, config):
    reports = {}
    for distribution in config.length_distributions:
        batch = build_controlled_variable_batch(distribution, ...)
        padded_result = benchmark_training_path(
            model, batch, path="padded", ...
        )
        packed_result = benchmark_training_path(
            model, batch, path="packed", ...
        )
        reports[distribution] = {
            "padded": padded_result,
            "packed": packed_result,
        }
        verify_valid_training_parity(reports[distribution], ...)
    return summarize_gpu_packing_tradeoffs(reports)
```

16.5.6 Exercise 05 - Build a Clean Variable-Length Collate Function

Part 1 - Why this matters

A collate function defines how independent samples become one batch. It is responsible for padding, lengths, masks, targets, metadata, and any ordering used for packing.

Mixing these responsibilities across the training loop creates duplicated assumptions and makes alignment difficult to test. A clean batch object provides one documented shape contract.

Implement collation for empty-edge handling, scalar or sequential targets, sorting, inverse permutation, and metadata. Test it on batch one, equal lengths, extreme variance, and the final incomplete batch.

Part 2 - Mathematical form

$$\text{collate}(\{(X_i, Y_i)\}) = (X_{pad}, Y_{pad}, T, m, P, P^{-1}).$$

Part 3 - Hints and Helper

Return explicit lengths and masks even if the first model version uses only one of them.

Part 4 - Python code skeleton

```
import torch
from torch.nn.utils.rnn import pad_sequence

def variable_length_collate(samples):
    sequences, targets, metadata = zip(*samples)
    lengths = torch.tensor([len(x) for x in sequences])
    order = choose_sort_order(lengths, ...)
    inverse = invert_permutation(order)
    padded_inputs = pad_sequence(..., batch_first=True, padding_value=...)
    padded_targets = ...
    mask = ...
    return SequenceBatch(
        inputs=padded_inputs, targets=padded_targets, lengths=lengths,
        mask=mask, order=order, inverse_order=inverse, metadata=metadata
    )

def E05(model, data, config):
    return test_collate_edge_cases(variable_length_collate, data, ... )
```

16.5.7 Exercise 06 - Implement Masked Sequence Loss and Match Manual Computation

Part 1 - Why this matters

Loss reduction determines how samples and time steps influence optimization. Averaging over the padded rectangle underweights long sequences and counts invalid positions unless masking is applied before reduction.

Token-average and sequence-average losses answer different questions. The former weights every valid time step equally, while the latter gives every sequence equal total influence.

Implement both modes from unreduced losses, compare with explicit Python loops, and test all-padding rejection, one-token samples, class weights, and padding perturbations.

Part 2 - Mathematical form

$$L_{token} = \frac{\sum m\ell}{\sum m}, \qquad L_{seq} = \frac{1}{B}\sum_i \frac{\sum_t m_{it}\ell_{it}}{T_i}.$$

Part 3 - Hints and Helper

Never multiply a scalar reduced loss by the mask. Request reduction none first.

Part 4 - Python code skeleton

```
import torch

def masked_sequence_loss(logits, targets, mask, mode="token"):
    element_loss = compute_unreduced_loss(logits, targets, ...)
    valid_loss = element_loss * mask.to(element_loss.dtype)
    if mode == "token":
        result = ...
    elif mode == "sequence":
        result = ...
    else:
        raise ValueError(...)
    return result

def E06(model, data, config):
    vectorized = masked_sequence_loss(...)
    manual = explicit_valid_position_loss(...)
    return verify_loss_equivalence(vectorized, manual, ... )
```

16.5.8 Exercise 07 - Implement Stateful Batching and Correct State Resets

Part 1 - Why this matters

Stateful batching carries hidden and cell states across consecutive chunks of the same logical stream. It can preserve context and avoid replaying history, but only when stream identity and ordering remain stable.

States must be reset at true sequence boundaries, reassigned when batch slots change streams, and detached between truncated updates. Leakage between users or records creates false context and invalid evaluation.

Build a state store keyed by stream ID, simulate continuation and termination, and verify resets, detachment, reordering, and partial-batch behavior with explicit sentinel states.

Part 2 - Mathematical form

$$s_{k+1}^{(j)} = \begin{cases} \text{stopgrad}(s_{end}^{(j)}), & \text{continuation}, \\ 0, & \text{new stream}. \end{cases}$$

Part 3 - Hints and Helper

Do not associate state only with batch position. Use stable stream identifiers.

Part 4 - Python code skeleton

```
import torch

def E07(model, data, config):
    state_store = LSTMStateStore()
    for batch in data.stream_batches:
        state = state_store.gather(
            batch.stream_ids, reset_mask=batch.new_sequence_mask, ...
        )
        outputs, next_state = model(batch.inputs, state)
        state_store.update(
            batch.stream_ids,
            detach_state(next_state),
            finished_mask=batch.finished_mask,
        )
    return audit_state_reset_and_leakage(state_store, ... )
```

16.5.9 Exercise 08 - Prevent Time-Series Leakage with Chronological Splits

Part 1 - Why this matters

Randomly splitting overlapping time-series windows allows nearly identical histories or future-derived preprocessing statistics to appear in training and validation. This inflates metrics without improving real forecasting.

The raw timeline should be divided before windows are constructed, with explicit treatment of context near boundaries. Scalers, imputers, and feature transformations must fit on training time only.

Create chronological train, validation, and test periods, then build windows within permitted boundaries. Audit timestamp overlap, target horizons, scaler fit range, and duplicate source observations.

Part 2 - Mathematical form

$$\max t_{train} < \min t_{val} < \min t_{test}.$$

Part 3 - Hints and Helper

Decide whether validation inputs may use earlier training context, but never allow validation targets or statistics into training.

Part 4 - Python code skeleton

```
import torch

def E08(model, data, config):
    raw_splits = chronological_split(data.series, boundaries=...)
    scaler = fit_preprocessor(raw_splits.train)
    transformed = transform_all_splits(scaler, raw_splits)
    windows = {
        name: build_windows(split, horizon=..., context_policy=...)
        for name, split in transformed.items()
    }
    audit_temporal_leakage(raw_splits, windows, scaler, ...)
    return windows
```

16.5.10 Exercise 09 - Debug Instability from Masks and Loss Reduction

Part 1 - Why this matters

A masking bug changes gradient scale as batch length distribution changes. Dividing by batch size, padded width, or zero valid counts can create inconsistent updates and apparent instability.

Metrics may look reasonable while loss uses a different mask, dtype, or axis. Broadcasting errors can repeat a mask over features or classes unintentionally.

Construct correct and faulty reductions, compare gradient norms across length distributions, and audit numerator, denominator, broadcast shape, and valid-token counts. Make every failure produce a specific diagnosis.

Part 2 - Mathematical form

$$\nabla L \propto \frac{1}{Z}\sum_{i,t} m_{it}\nabla \ell_{it}, \quad Z \in \{BT, \sum m, B\}.$$

Part 3 - Hints and Helper

Log the effective denominator and valid count for every batch during debugging.

Part 4 - Python code skeleton

```
import torch

def E09(model, data, config):
    variants = build_mask_reduction_variants(
        faults=["mean_over_padding", "wrong_axis", "broadcast",
                "zero_denominator", "metric_mask_mismatch"],
        ...
    )
    reports = {}
```

```
    for name, loss_fn in variants.items():
        reports[name] = analyze_loss_scale_and_gradients(
            model, data, loss_fn, log_denominator=True, ...
        )
    return diagnose_masking_instability(reports)
```

16.5.11 Exercise 10 - Move the Sequence Pipeline to CUDA Efficiently

Part 1 - Why this matters

Variable-length batches include inputs, targets, masks, and sometimes metadata, while lengths may remain on CPU for packing. Moving tensors repeatedly inside the time loop wastes transfer bandwidth and creates synchronization.

Pinned host memory and non-blocking copies can overlap transfer with compute only when the pipeline is structured correctly. Converting dtype or layout after transfer may create extra device allocations.

Move each complete batch once, keep required CPU lengths explicit, and benchmark data wait, transfer, packing, and compute regions. Compare baseline, pinned, and prefetched strategies for parity and throughput.

Part 2 - Mathematical form

$$T_{step} = T_{wait} + T_{copy} + T_{pack} + T_{compute}.$$

Part 3 - Hints and Helper

Do not move metadata strings to CUDA. Preserve a CPU lengths tensor if the packing API requires it.

Part 4 - Python code skeleton

```
import torch

def E10(model, data, config):
    loader = build_loader(data, pin_memory=True, num_workers=...)
    reports = {}
    for strategy in ["baseline", "single_copy", "prefetch"]:
        reports[strategy] = benchmark_sequence_transfer_pipeline(
            model,
            loader,
            strategy=strategy,
            non_blocking=True,
            keep_lengths_on_cpu=True,
            ...
        )
    return compare_transfer_overhead_and_parity(reports)
```

16.5.12 Exercise 11 - Benchmark DataLoader Workers for Variable Sequences

Part 1 - Why this matters

Variable-length collation can include sorting, padding, tokenization, decoding, and augmentation, making CPU preparation a major bottleneck. More workers can overlap work but also increase process, memory, and communication costs.

The best worker count depends on storage, CPU cores, batch complexity, pinned memory, and model speed. A GPU utilization increase is not useful if total throughput or stability worsens.

Sweep worker counts with and without persistent workers and pinned memory. Measure first-epoch startup, steady-state batches per second, data wait, memory, GPU idle time, and failed-worker behavior.

Part 2 - Mathematical form

$$Q(w) = N_{batches}/T_{epoch}(w).$$

Part 3 - Hints and Helper

Benchmark multiple epochs because persistent workers mainly affect transitions after the first epoch.

Part 4 - Python code skeleton

```
import torch

def E11(model, data, config):
    reports = []
    for workers in config.worker_counts:
        loader = build_loader(
            data,
            num_workers=workers,
            pin_memory=...,
            persistent_workers=(workers > 0),
            collate_fn=variable_length_collate,
        )
        result = benchmark_loader_epochs(loader, model=model, epochs=..., ...)
        reports.append({"workers": workers, **result})
    return select_stable_worker_configuration(reports)
```

16.5.13 Exercise 12 - Accumulate Gradients for Long Sequences with Limited Memory

Part 1 - Why this matters

Gradient accumulation divides a logical batch into smaller micro-batches so long-sequence activations fit on the GPU. It lowers peak memory but repeats launches and delays optimizer updates.

Equivalence requires weighting each micro-batch by its valid-token count. Averaging each micro-batch equally gives short and long batches incorrect influence, and clipping must occur only after accumulation completes.

Compare accumulated and physical large batches on a deterministic case, then benchmark realistic variable lengths. Measure gradient parity, memory, throughput, and convergence.

Part 2 - Mathematical form

$$L = \frac{\sum_k \sum_{i,t \in B_k} m_{it} \ell_{it}}{\sum_k \sum_{i,t \in B_k} m_{it}}.$$

Part 3 - Hints and Helper

Accumulate loss sums divided by the total logical valid-token count, then clip and step once.

Part 4 - Python code skeleton

```
import torch

def E12(model, data, config):
    optimizer.zero_grad(set_to_none=True)
    total_tokens = sum(batch.mask.sum() for batch in data.micro_batches)
    for batch in data.micro_batches:
        outputs = model(batch.inputs, ...)
        loss_sum = masked_loss(
            outputs, batch.targets, batch.mask, reduction="sum"
        )
        (loss_sum / total_tokens).backward()
    torch.nn.utils.clip_grad_norm_(model.parameters(), ...)
    optimizer.step()
    return compare_with_physical_large_batch(... )
```

16.5.14 Exercise 13 - Validate Reproducibility with Variable-Length Batches

Part 1 - Why this matters

Fixed model seeds are insufficient when sample shuffling, bucket formation, worker scheduling, dropout, and CUDA algorithms affect batch content and operation order. Variable lengths amplify these differences by changing padding and packing patterns.

Reproducibility should capture sampler state, worker seeds, bucket policy, permutations, and environment metadata. Exact equality and tolerance-based experimental repeatability should be reported separately.

Repeat runs with deterministic and ordinary settings, compare batch manifests, losses, states, and final metrics, and locate the first divergence. Save enough information to replay one epoch exactly.

Part 2 - Mathematical form

$$\mathcal{B}_e = \{(id_i, T_i, P_i)\}_{i=1}^{N}.$$

Part 3 - Hints and Helper

Hash the ordered sample IDs and lengths of every batch. Seed workers through an explicit initialization function.

Part 4 - Python code skeleton

```
import torch

def E13(model, data, config):
    runs = []
    for repeat in range(...):
        configure_reproducibility(seed=..., workers=True, cuda=True)
        loader = build_reproducible_bucketed_loader(data, generator=..., ...)
        runs.append(train_and_record_batch_manifest(model, loader, ...))
    return compare_manifests_states_and_metrics(
        runs, locate_first_divergence=True, environment=...
    )
```

16.5.15 Exercise 14 - Format Teacher-Forcing Data newline for LSTM Seq2Seq

Part 1 - Why this matters

Teacher forcing feeds the previous ground-truth target to the decoder while predicting the next target. This requires two shifted target views with explicit beginning and end tokens.

An off-by-one mistake can train the decoder to copy its current input rather than predict the future. Padding masks for decoder inputs and labels may also differ at terminal positions.

Build encoder inputs, decoder inputs, labels, lengths, and masks from variable target sequences. Verify each position manually and compare teacher-forced inputs with autoregressive inference requirements.

Part 2 - Mathematical form

$$D_{in} = (\langle BOS \rangle, y_1, \ldots, y_{T-1}), \quad D_{target} = (y_1, \ldots, y_T).$$

Part 3 - Hints and Helper

Show one complete sample before and after padding, including BOS, EOS, and every mask position.

Part 4 - Python code skeleton

```
import torch

def E14(model, data, config):
    encoder_inputs, target_sequences = ...
    decoder_inputs = [
        prepend_bos(y[:-1], token=...) for y in target_sequences
    ]
    decoder_targets = [
        append_eos_if_required(y, token=...)
        for y in target_sequences
    ]
    batch = collate_seq2seq_components(
        encoder_inputs, decoder_inputs, decoder_targets, ...
    )
    validate_teacher_forcing_shift(batch, sample_ids=...)
    return batch
```

16.5.16 Exercise 15 - Build a Complete Sequence-Data Checklist

Part 1 - Why this matters

Sequence-data correctness depends on connected contracts for alignment, lengths, padding, masks, packing, loss reduction, state resets, and split boundaries. Checking them independently can miss contradictions.

A useful checklist is executable and produces evidence rather than vague reminders. It should fail early on cheap invariants before launching expensive training.

Create staged checks for raw samples, collation, model boundaries, loss, state lifecycle, temporal splits, CUDA transfer, and reproducibility. Validate the checklist against deliberately corrupted pipelines.

Part 2 - Mathematical form

$$\mathcal{C} = \mathcal{C}_{sample} \cup \mathcal{C}_{batch} \cup \mathcal{C}_{state} \cup \mathcal{C}_{split}.$$

Part 3 - Hints and Helper

Give every check a severity, expected invariant, observed evidence, and next diagnostic action.

Part 4 - Python code skeleton

```
import torch

def E15(model, data, config):
    checklist = SequenceDataChecklist()
    checklist.add("sample_alignment", audit_raw_samples, severity="error")
    checklist.add("lengths_padding_masks", audit_collated_batch, ...)
```

```
    checklist.add("packing_permutation", audit_packing_roundtrip, ...)
    checklist.add("loss_reduction", audit_masked_loss, ...)
    checklist.add("state_reset", audit_state_boundaries, ...)
    checklist.add("temporal_split", audit_split_leakage, ...)
    checklist.add("cuda_transfer", audit_device_pipeline, ...)
    return checklist.run(model=model, data=data, config=config)
```

16.5.17 Exercise 16 - Detect and Fix Off-by-One Target Alignment

Part 1 - Why this matters

A one-step shift can make an LSTM reconstruct the present, predict the wrong future, or receive information about its own target. Correlated sequences may still yield low loss, hiding the error.

Tensor shapes cannot detect semantic time. Alignment must be verified with timestamps, source indices, or synthetic monotonic values whose correct target is known.

Create correct, zero-shift, early, and late variants, then audit input-target index equations and plot sample pairs. Make the test identify the exact displacement rather than only report failure.

Part 2 - Mathematical form

$$X_i = (s_i, \ldots, s_{i+w-1}), \qquad Y_i = (s_{i+w+g-1}, \ldots).$$

Part 3 - Hints and Helper

Audit alignment before scaling or shuffling. Retain original timestamps in metadata.

Part 4 - Python code skeleton

```
import torch

def E16(model, data, config):
    variants = create_alignment_variants(
        data, shifts={"correct": ..., "zero": 0, "early": -1, "late": 1}
    )
    reports = {}
    for name, dataset in variants.items():
        reports[name] = infer_and_validate_temporal_offset(
            dataset, expected_offset=config.target_offset, ...
        )
    return diagnose_off_by_one_alignment(reports)
```

16.5.18 Exercise 17 - Create a Task That Fails Without Packing

Part 1 - Why this matters

Padding should be harmless when masks and final-state selection are correct, but a naive many-to-one model may treat the final padded position as the sequence summary. Longer padding then overwrites the representation of short samples.

Packing makes the returned final state correspond to each sample's true final time step. The experiment must isolate this correction from unrelated differences in model parameters or training budget.

Create variable-length sequences whose label depends on the last valid event, add adversarial padding, and compare naive padded, corrected gathered, and packed models. Prove that packing or correct indexing restores invariance.

Part 2 - Mathematical form

$$y_i = \psi(x_{i,T_i}), \qquad x_{i,t} = p \text{ for } t > T_i.$$

Part 3 - Hints and Helper

Use the same initial weights and ensure the padding value strongly conflicts with the label rule.

Part 4 - Python code skeleton

```
import torch

def E17(model, data, config):
    task = build_last_valid_token_task(
        variable_lengths=True, adversarial_padding=True, ...
    )
    variants = {
        "naive_padded": build_last_column_classifier(...),
        "gathered": build_last_valid_classifier(...),
        "packed": build_packed_classifier(...),
    }
    results = run_controlled_training(
        variants, task, same_initial_weights=True
    )
    return prove_padding_failure_and_fix(results)
```

16.5.19 Exercise 18 - Stress Test a Large Variable-Length Pipeline

Part 1 - Why this matters

Large variable-length datasets stress storage, workers, collation, host memory, transfer, padding efficiency, recurrent compute, and allocator behavior simultaneously. Small tests cannot reveal queue starvation or rare extreme batches.

The test needs guarded scale increases and region-level timing so bottlenecks are attributed correctly. Corrupt samples, empty sequences, and heavy-tailed lengths should be handled explicitly.

Run increasing dataset, length, and worker configurations while tracking throughput, wait, padding waste, CPU and GPU memory, failures, and tail latency. Preserve the first anomalous batch for diagnosis.

Part 2 - Mathematical form

$$T_{epoch} = T_{IO} + T_{collate} + T_{copy} + T_{LSTM} + T_{update}.$$

Part 3 - Hints and Helper

Increase one scale variable at a time and retain resource headroom. Log batch length histograms.

Part 4 - Python code skeleton

```
import torch

def E18(model, data, config):
    monitor = VariablePipelineStressMonitor(...)
    for scale in config.stress_scales:
        loader = build_stress_loader(data, scale=scale, ...)
        result = run_guarded_training_epoch(
            model, loader, monitor=monitor,
            capture_first_anomaly=True, memory_headroom=...
        )
        monitor.record_scale_result(scale, result)
    return monitor.identify_pipeline_bottlenecks_and_limits()
```

16.5.20 Exercise 19 - Produce the LSTM Sequence-Data Engineering Report

Part 1 - Why this matters

The final report should prove that temporal relationships survive construction, batching, packing, transfer, state handling, and evaluation. Model accuracy cannot replace this evidence.

The report must include verified edge cases and failures because variable-length bugs often occur only at minimum lengths, incomplete batches, boundary windows, or stream changes.

Synthesize alignment audits, padding invariance, packing parity, masked-loss checks, state resets, leakage prevention, CUDA and DataLoader benchmarks, reproducibility, and stress limits. State the safe pipeline contract and remaining assumptions.

Part 2 - Mathematical form

raw time → sample → batch → model → loss → verified metric.

Part 3 - Hints and Helper

Link every claim to an executable check or benchmark record. Include a catalog of rejected faulty variants.

Part 4 - Python code skeleton

```
import torch

def E19(model, data, config):
    evidence = load_lstm03_experiment_results(...)
    report = SequenceDataEngineeringReport()
    report.add_sample_and_alignment_contracts(evidence, ...)
    report.add_padding_masking_and_packing_proofs(evidence, ...)
    report.add_state_and_temporal_split_rules(evidence, ...)
    report.add_cuda_loader_and_accumulation_results(evidence, ...)
    report.add_reproducibility_and_stress_limits(evidence, ...)
    report.add_edge_cases_failures_and_safe_contract(evidence, ...)
    report.validate_claim_traceability()
    return report.export(...)
```

16.6 LSTM04 - Language Modeling and Text Generation with LSTM

Models and Training

16.6.1 Exercise 00 - Build Character-Level Tokenization and Vocabulary

Part 1 - Why this matters

Character tokenization is the first contract between raw text and the model. Every character must map to one stable integer, and every integer must decode to the same character. This includes spaces, punctuation, line breaks, and any explicit unknown symbol.

A vocabulary can appear correct while silently changing order between runs or losing characters during normalization. Such an error changes the meaning of every training target, so the LSTM learns a corrupted language even though tensor shapes and loss computation remain valid.

Construct deterministic `stoi` and `itos` mappings, encode and decode representative samples, and test round-trip equality. Record the vocabulary size because it determines both the embedding input range and the output-logit dimension.

Part 2 - Mathematical form

$$\mathcal{V} = \text{sorted}(\text{unique}(C)), \quad e(c) = i, \quad d(i) = c, \quad d(e(c)) = c.$$

Part 3 - Hints and Helper

Do not build the vocabulary from a set without sorting it. Test whitespace and punctuation explicitly.

Part 4 - Python code skeleton

```
import torch
def build_vocabulary(text):
    characters = ...
    stoi = ...
    itos = ...
    return stoi, itos

def encode(text, stoi):
    return torch.tensor([...], dtype=torch.long)

def decode(indices, itos):
    return ...

def E00(model, data, config):
    stoi, itos = build_vocabulary(data)
    assert decode(encode(data, stoi), itos) == data
    return ...
```

16.6.2 Exercise 01 - Implement LSTM Language Model and Verify Logit Shapes

Part 1 - Why this matters

An LSTM language model converts token indices into embeddings, processes them through temporal memory, and produces one logit vector for every time step. The output is not a probability yet; it is an unrestricted score for every vocabulary item.

Shape mistakes are dangerous because flattening the batch and time axes can still produce a tensor accepted by the loss function. A model may therefore train against incorrectly aligned positions without raising an exception.

Implement the embedding, LSTM, and projection layers, then assert the shape after every stage. Test multiple batch sizes and sequence lengths so the implementation does not accidentally depend on one fixed configuration.

Part 2 - Mathematical form

$$E \in \mathbb{R}^{B \times T \times D}, \quad H = \text{LSTM}(E), \quad Z = HW_o + b_o \in \mathbb{R}^{B \times T \times |\mathcal{V}|}.$$

Part 3 - Hints and Helper

Use `batch_first=True`. Return the updated hidden and cell states for generation.

Part 4 - Python code skeleton

```
import torch
class LSTMLanguageModel(torch.nn.Module):
    def __init__(self, vocab_size, embed_dim, hidden_size):
        super().__init__()
        self.embedding = ...
        self.lstm = ...
        self.output = ...

    def forward(self, tokens, state=None):
        embedded = ...
        hidden, state = ...
        logits = ...
        return logits, state

def E01(model, data, config):
    logits, state = model(data)
    assert logits.shape == (..., ..., ...)
    return logits, state
```

16.6.3 Exercise 02 - Implement Cross-Entropy Loss and Confirm Target Alignment

Part 1 - Why this matters

Next-token prediction requires the input at position t to predict the target at position $t+1$. This one-position shift defines the learning problem and must be correct before any optimization result can be trusted.

An off-by-one target error often produces a decreasing loss because adjacent characters are statistically related. The apparent progress hides the fact that the model is solving the wrong temporal task.

Create shifted input-target windows, flatten logits and targets only after verifying their temporal correspondence, and compare the library loss with a manual log-softmax calculation on a tiny example.

Part 2 - Mathematical form

$$x_t = c_t, \quad y_t = c_{t+1}, \quad \mathcal{L} = -\frac{1}{BT}\sum_{b,t} \log p(y_{b,t} \mid x_{b,\le t}).$$

Part 3 - Hints and Helper

Print one decoded input and target pair. Logits use shape (B, T, V) but cross entropy receives (BT, V).

Part 4 - Python code skeleton

```
import torch
def make_next_token_batch(tokens, sequence_length):
    inputs = ...
    targets = ...
    return inputs, targets

def language_model_loss(logits, targets):
    flat_logits = ...
    flat_targets = ...
    return torch.nn.functional.cross_entropy(flat_logits, flat_targets)

def E02(model, data, config):
    inputs, targets = make_next_token_batch(data, ...)
    logits, _ = model(inputs)
    return language_model_loss(logits, targets)
```

16.6.4 Exercise 03 - Overfit a Tiny Text as a Correctness Test

Part 1 - Why this matters

Deliberately overfitting a tiny text is a diagnostic test, not a production objective. A model with enough capacity should nearly memorize a small deterministic sequence when the data, targets, loss, gradients, and optimizer are connected correctly.

Failure to overfit points to an implementation problem before it points to insufficient data. Common causes include misaligned targets, detached states, missing optimizer steps, incorrect vocabulary size, or a learning rate that prevents stable descent.

Train on one short repeated passage, track loss and token accuracy, and define an explicit success threshold. Save the configuration and seed so the diagnostic can be repeated after later code changes.

Part 2 - Mathematical form

$$\theta^* = \arg\min_{\theta} \mathcal{L}_{\text{tiny}}(\theta), \qquad \text{accuracy}_{\text{tiny}} \to 1.$$

Part 3 - Hints and Helper

Use a fixed seed and disable unnecessary regularization. Inspect one prediction sequence when the threshold is missed.

Part 4 - Python code skeleton

```
import torch
def train_tiny_overfit(model, inputs, targets, optimizer, steps):
    history = []
    for step in range(steps):
        optimizer.zero_grad(set_to_none=True)
        logits, _ = ...
        loss = ...
        loss.backward()
        optimizer.step()
        history.append(...)
    return history

def E03(model, data, config):
    history = train_tiny_overfit(model, ..., ..., ..., ...)
    assert history[-1]["accuracy"] >= ...
    return history
```

16.6.5 Exercise 04 - Generate Text Autoregressively and Analyze Repetition

Part 1 - Why this matters

Autoregressive generation turns the model into a closed feedback system: every sampled token becomes part of the next input. Small prediction biases can therefore accumulate into repetition, drift, or loss of grammatical structure.

LSTM memory may preserve longer patterns than a vanilla RNN, but it does not guarantee coherent generation. A model can still enter high-probability loops, especially when trained on limited text or decoded greedily.

Implement stateful token-by-token generation, compare LSTM and vanilla RNN outputs under the same prompt, and measure repeated n-grams. Separate model quality from decoding behavior by keeping vocabulary and sampling rules identical.

Part 2 - Mathematical form

$$\hat{c}_{t+1} \sim p_\theta(\cdot \mid c_{1:t}), \qquad (h_t, c_t) = \mathrm{LSTM}(c_t, h_{t-1}, c_{t-1}).$$

Part 3 - Hints and Helper

Use `torch.no_grad()` and preserve the returned state. Start with greedy decoding, then compare sampled output.

Part 4 - Python code skeleton

```
import torch
@torch.no_grad()
def generate(model, prompt, stoi, itos, max_new_tokens):
    state = None
```

```
    generated = ...
    for _ in range(max_new_tokens):
        logits, state = ...
        next_token = ...
        generated.append(next_token)
    return decode(generated, itos)

def E04(model, data, config):
    text = generate(model, ..., ..., ..., ...)
    return {"text": text, "repetition": ...}
```

16.6.6 Exercise 05 - Implement Temperature Sampling and Measure the Tradeoff

Part 1 - Why this matters

Temperature changes the sharpness of the next-token distribution without retraining the model. Low values concentrate probability on a few tokens, while high values flatten the distribution and permit less likely choices.

Extreme temperature can create misleading results. A nearly zero value behaves like greedy decoding and may repeat, whereas a very large value can destroy learned structure by approaching random sampling.

Implement temperature scaling on logits, evaluate a controlled grid of values with identical prompts and seeds, and report diversity together with quality indicators. Never compare only one generated sample per setting.

Part 2 - Mathematical form

$$p_i(\tau) = \frac{\exp(z_i/\tau)}{\sum_j \exp(z_j/\tau)}, \qquad \tau > 0.$$

Part 3 - Hints and Helper

Divide logits before softmax. Reject non-positive temperatures and repeat each setting across several seeds.

Part 4 - Python code skeleton

```
import torch
def sample_with_temperature(logits, temperature):
    if temperature <= 0:
        raise ValueError(...)
    scaled = ...
    probabilities = ...
    return torch.multinomial(probabilities, num_samples=1)

def E05(model, data, config):
```

```
    results = {}
    for temperature in config["temperatures"]:
        samples = [...]
        results[temperature] = evaluate_samples(samples, ...)
    return results
```

16.6.7 Exercise 06 - Implement Top-k Sampling and Compare Stability

Part 1 - Why this matters

Top-k sampling restricts each decision to the k highest-logit tokens. It removes the long tail of unlikely tokens while preserving randomness among plausible candidates.

A fixed k ignores how certain the model is at each time step. The same value may be too restrictive after an obvious prefix and too permissive when the next token is uncertain.

Mask logits outside the selected set, renormalize safely, and compare several k values against temperature-only sampling. Measure invalid outputs, repetition, and unique n-grams across repeated generations.

Part 2 - Mathematical form

$$S_k = \mathrm{TopK}(z), \qquad p_i = \frac{e^{z_i/\tau}\mathbf{1}[i \in S_k]}{\sum_{j \in S_k} e^{z_j/\tau}}.$$

Part 3 - Hints and Helper

Use `torch.topk`; masked logits should be negative infinity before softmax.

Part 4 - Python code skeleton

```
import torch
def top_k_sample(logits, k, temperature=1.0):
    values, indices = torch.topk(logits, k=...)
    filtered = torch.full_like(logits, float("-inf"))
    filtered.scatter_(dim=-1, index=indices, src=values)
    probabilities = ...
    return ...

def E06(model, data, config):
    outputs = {k: generate_with_sampler(model, ..., k=k)
               for k in config["k_values"]}
    return compare_generation_sets(outputs, ...)
```

16.6.8 Exercise 07 - Implement Nucleus Sampling and Compare p Values

Part 1 - Why this matters

Nucleus sampling selects the smallest token set whose cumulative probability reaches a threshold p. Unlike fixed top-k sampling, the candidate count adapts to the model's uncertainty at each step.

The implementation requires correct sorting, cumulative sums, mask shifting, and index restoration. A one-position masking error can remove the threshold-crossing token or leave an empty candidate set.

Implement top-p filtering, verify it on hand-calculated distributions, and record the average nucleus size during generation. Compare coherence and diversity across several thresholds using matched prompts and random seeds.

Part 2 - Mathematical form

$$S_p = \min \left\{ S : \sum_{i \in S} p_{(i)} \geq p \right\}, \qquad 0 < p \leq 1.$$

Part 3 - Hints and Helper

Keep the first token above the cumulative threshold so the retained mass reaches p. Test $p = 1$ as an edge case.

Part 4 - Python code skeleton

```
import torch
def nucleus_sample(logits, p, temperature=1.0):
    probabilities = torch.softmax(..., dim=-1)
    sorted_probs, sorted_ids = torch.sort(probabilities, descending=True)
    cumulative = torch.cumsum(sorted_probs, dim=-1)
    remove = ...
    remove[..., 1:] = remove[..., :-1].clone()
    remove[..., 0] = False
    sorted_probs[remove] = 0
    return ...

def E07(model, data, config):
    return evaluate_top_p_grid(model, data, ... )
```

16.6.9 Exercise 08 - Debug Hidden and Cell State Carry-Over

Part 1 - Why this matters

Hidden and cell states carry context between time steps, but they must not cross unrelated sequences accidentally. Correct state handling depends on whether samples are contiguous chunks of one stream or independent documents.

Resetting too often destroys long dependencies; carrying state too far leaks information and couples unrelated batches. Failing to detach state during training can also retain an ever-growing computation graph.

Create tests for reset, carry, and detach policies, then inject an intentionally wrong policy and observe its effect. Verify state shape, device, batch size, and graph history at every boundary.

Part 2 - Mathematical form

$$\begin{aligned} (h_0, c_0) &= \mathbf{0} && \text{at a document boundary,} \\ (h, c) &\leftarrow (\text{detach}(h), \text{detach}(c)) && \text{at a truncation boundary.} \end{aligned}$$

Part 3 - Hints and Helper

Attach document identifiers to batches. Assert that carried state belongs to the same stream and batch layout.

Part 4 - Python code skeleton

```
import torch
def prepare_state(previous_state, batch_metadata, policy):
    if ...:
        return None
    hidden, cell = previous_state
    if policy["detach"]:
        hidden, cell = ...
    return hidden, cell

def E08(model, data, config):
    state = None
    audit = []
    for tokens, metadata in data:
        state = prepare_state(state, metadata, config)
        logits, state = model(tokens, state)
        audit.append(inspect_state(state, metadata, ...))
    return audit
```

16.6.10 Exercise 09 - Evaluate the Language Model with Perplexity

Part 1 - Why this matters

Perplexity converts average negative log-likelihood into an interpretable multiplicative scale. Lower perplexity means the model assigns more probability to the observed next tokens, but the value is meaningful only under the same tokenization and evaluation protocol.

A validation loss can be biased by padding, inconsistent reduction, leaked text, or unequal weighting of batches. Exponentiating a poorly aggregated loss produces a precise-looking but invalid perplexity.

Accumulate total negative log-likelihood and the exact number of valid tokens, then exponentiate once. Compare the result with a manual tiny example and report tokenization, split, and context length beside the metric.

Part 2 - Mathematical form

$$\mathrm{PPL} = \exp\left(\frac{\sum_{n=1}^{N} -\log p(y_n \mid x_{\le n})}{N}\right).$$

Part 3 - Hints and Helper

Do not average batch means when batches contain different token counts. Exclude masked tokens from both numerator and denominator.

Part 4 - Python code skeleton

```
import torch
@torch.no_grad()
def compute_perplexity(model, loader, pad_id=None):
    total_nll = 0.0
    total_tokens = 0
    for inputs, targets in loader:
        logits, _ = model(inputs)
        token_losses = ...
        valid = ...
        total_nll += ...
        total_tokens += ...
    return math.exp(total_nll / total_tokens)

def E09(model, data, config):
    return compute_perplexity(model, data, ... )
```

16.6.11 Exercise 10 - Train on CUDA and Benchmark Against CPU

Part 1 - Why this matters

CUDA can accelerate LSTM language-model training when the workload is large enough to amortize device transfers and kernel launches. Small models or short sequences may remain faster on CPU, so hardware choice must be measured rather than assumed.

An unfair benchmark may include data transfer in one path but exclude it in another, or time asynchronous GPU work without synchronization. These mistakes can report impossible speedups.

Build matched CPU and GPU runs with identical model weights, batches, warm-up, and step counts. Measure both training-step time and end-to-end throughput, while checking loss parity within a justified tolerance.

Part 2 - Mathematical form

$$\text{throughput} = \frac{B\,T\,N_{\text{steps}}}{t_{\text{elapsed}}}\ \text{tokens/s}, \qquad S = \frac{t_{\text{CPU}}}{t_{\text{GPU}}}.$$

Part 3 - Hints and Helper

Synchronize CUDA before starting and stopping the timer. Report transfer-inclusive and compute-only measurements separately.

Part 4 - Python code skeleton

```
import torch
def benchmark_training(device, model, batches, steps):
    model = model.to(device)
    warmup(model, batches, device, ...)
    synchronize_if_cuda(device)
    start = time.perf_counter()
    for step in range(steps):
        batch = move_batch(...)
        train_step(model, batch, ...)
    synchronize_if_cuda(device)
    return ...

def E10(model, data, config):
    cpu = benchmark_training("cpu", ..., data, ...)
    gpu = benchmark_training("cuda", ..., data, ...)
    return compare_benchmarks(cpu, gpu)
```

16.6.12 Exercise 11 - Profile GPU Utilization and Fix Pipeline Bottlenecks

Part 1 - Why this matters

Low GPU utilization often means the accelerator is waiting for tokenization, batching, file reads, or host-to-device copies. Increasing model complexity cannot solve a pipeline that delivers data too slowly.

A single utilization percentage is insufficient evidence. Short sampling intervals, synchronization gaps, padding waste, and CPU worker stalls must be related to the training timeline.

Profile representative steps, separate data time from compute time, and inspect operator and memory traces. Change one pipeline variable at a time and accept an optimization only when throughput improves without changing outputs.

Part 2 - Mathematical form

$$t_{\text{step}} = t_{\text{data}} + t_{\text{transfer}} + t_{\text{forward}} + t_{\text{backward}} + t_{\text{update}}.$$

Part 3 - Hints and Helper

Use a schedule with warm-up and active profiler steps. Compare `num_workers`, pinned memory, and non-blocking transfer settings.

Part 4 - Python code skeleton

```
import torch
def profile_training(model, loader, device, config):
    with torch.profiler.profile(
        activities=[...],
        schedule=torch.profiler.schedule(wait=..., warmup=..., active=...),
        record_shapes=True,
        profile_memory=True,
    ) as profiler:
        for step, batch in enumerate(loader):
            timed_train_step(model, batch, device, ...)
            profiler.step()
    return ...

def E11(model, data, config):
    baseline = profile_training(model, data, ..., config)
    optimized = ...
    return compare_profiles(baseline, optimized)
```

16.6.13 Exercise 12 - Implement Mixed Precision and Identify Instability

Part 1 - Why this matters

Mixed precision reduces activation memory and may increase throughput by using lower-precision arithmetic where it is safe. LSTM gates and long recurrent products can nevertheless be sensitive to underflow, overflow, and saturation.

A run may continue while gradients silently become non-finite or updates are repeatedly skipped. Monitoring only the loss misses the scale dynamics and the first layer where numerical failure begins.

Use automatic mixed precision and gradient scaling, log skipped steps and non-finite values, and compare against a float32 baseline. Test longer sequences deliberately to find the boundary where speed gains no longer justify instability.

Part 2 - Mathematical form

$$\hat{g} = s\,\nabla_\theta \mathcal{L}, \qquad g = \hat{g}/s, \qquad \theta \leftarrow \theta - \eta g.$$

Part 3 - Hints and Helper

Unscale before gradient clipping. Keep recurrent-state diagnostics in float32 when investigating instability.

Part 4 - Python code skeleton

```
import torch
def mixed_precision_step(model, batch, optimizer, scaler):
    optimizer.zero_grad(set_to_none=True)
```

```
    with torch.autocast(device_type="cuda", dtype=...):
        logits, _ = model(batch["inputs"])
        loss = ...
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    torch.nn.utils.clip_grad_norm_(model.parameters(), ...)
    scaler.step(optimizer)
    scaler.update()
    return inspect_numerics(loss, model, scaler, ...)

def E12(model, data, config):
    return run_precision_comparison(model, data, ... )
```

16.6.14 Exercise 13 - Compare LSTM and GRU for Language Modeling

Part 1 - Why this matters

LSTM and GRU use different gating structures to manage temporal information. LSTM maintains separate hidden and cell states, whereas GRU combines memory into a simpler state with fewer gates and often fewer parameters.

A comparison is invalid when hidden sizes, parameter budgets, initialization, training steps, or sampling procedures differ without explanation. Faster convergence can also hide worse final generalization.

Train both architectures under matched conditions. Compare parameter count, throughput, peak memory, validation perplexity, and generation metrics in equal-size and approximately equal-parameter experiments.

Part 2 - Mathematical form

$$N_{\mathrm{LSTM}} \approx 4H(D+H+1), \qquad N_{\mathrm{GRU}} \approx 3H(D+H+1).$$

Part 3 - Hints and Helper

Reuse the same embedding and output dimensions. Repeat runs with controlled seeds and report uncertainty.

Part 4 - Python code skeleton

```
import torch
def build_recurrent_model(kind, vocab_size, config):
    if kind == "lstm":
        recurrent = ...
    elif kind == "gru":
        recurrent = ...
    else:
        raise ValueError(...)
```

```
    return LanguageModel(...)

def E13(model, data, config):
    reports = {}
    for kind in ["lstm", "gru"]:
        candidate = build_recurrent_model(kind, ..., config)
        reports[kind] = train_and_evaluate(candidate, data, ...)
    return compare_models(reports)
```

16.6.15 Exercise 14 - Implement Truncated BPTT for Longer Contexts

Part 1 - Why this matters

Full backpropagation stores the computation graph across the entire sequence. Truncated BPTT limits the gradient horizon while still carrying numerical hidden and cell states into the next chunk.

Detaching too early prevents useful temporal credit assignment, while forgetting to detach causes memory growth across chunks. Shuffling chunks or resetting state at the wrong boundary also destroys their chronological meaning.

Split continuous streams into ordered chunks, update once per chunk, and detach both states only after the update boundary. Compare memory, throughput, and long-dependency accuracy across several truncation lengths.

Part 2 - Mathematical form

$$\nabla_\theta \mathcal{L}_k \text{ spans at most } K \text{ steps}, \qquad (h_k, c_k) \leftarrow \operatorname{detach}(h_k, c_k).$$

Part 3 - Hints and Helper

Keep document boundaries distinct from truncation boundaries. Measure peak allocated memory after synchronizing CUDA.

Part 4 - Python code skeleton

```
import torch
def train_truncated(model, stream, optimizer, chunk_length):
    state = None
    for inputs, targets, boundary in ordered_chunks(stream, chunk_length):
        if boundary:
            state = None
        optimizer.zero_grad(set_to_none=True)
        logits, state = model(inputs, state)
        loss = ...
        loss.backward()
        optimizer.step()
        state = tuple(s.detach() for s in state)
```

```
    return ...

def E14(model, data, config):
    return compare_truncation_lengths(model, data, ... )
```

16.6.16 Exercise 15 - Debug Divergence with Learning Rate, Clipping, and Gates

Part 1 - Why this matters

Divergence in an LSTM language model can begin in the optimizer, recurrent dynamics, or gate initialization. A large learning rate may cause explosive updates, while saturated gates can block corrective gradients before the loss becomes non-finite.

Changing several controls simultaneously may restore training without identifying the cause. That produces a fragile configuration and teaches nothing about which failure signal appeared first.

Instrument loss, gradient norms, parameter norms, gate statistics, and update size; then run a controlled diagnostic sequence. Adjust learning rate, clipping threshold, and forget-gate bias separately and record the first stable intervention.

Part 2 - Mathematical form

$$r_t = \frac{\eta \|g_t\|_2}{\|\theta_t\|_2 + \epsilon}, \qquad g'_t = g_t \min\left(1, \frac{c}{\|g_t\|_2}\right).$$

Part 3 - Hints and Helper

Stop immediately on non-finite values and save the failing batch. Initialize forget-gate bias deliberately rather than by fragile name assumptions.

Part 4 - Python code skeleton

```
import torch
def diagnostic_train_step(model, batch, optimizer, clip_norm):
    optimizer.zero_grad(set_to_none=True)
    logits, state = model(...)
    loss = ...
    if not torch.isfinite(loss):
        return capture_failure(...)
    loss.backward()
    before = collect_norms(model, ...)
    torch.nn.utils.clip_grad_norm_(model.parameters(), clip_norm)
    optimizer.step()
    after = collect_norms(model, ...)
    return build_diagnostic_record(loss, before, after, state, ...)

def E15(model, data, config):
    return run_one_factor_diagnostics(model, data, config, ... )
```

16.6.17 Exercise 16 - Build a Generation Evaluation Script

Part 1 - Why this matters

Generated text should be evaluated with several complementary measurements because no single automatic metric captures quality. Repetition measures degeneration, novelty detects copying, and length statistics reveal premature termination or uncontrolled output.

Metrics are easy to manipulate accidentally through tokenization, prompt inclusion, or inconsistent termination rules. Novelty against training text is also different from uniqueness within the generated set.

Create a deterministic evaluation script that separates prompts from continuations, uses fixed tokenization, and aggregates many samples. Report raw counts, normalized rates, distributions, and representative examples alongside model and decoding settings.

Part 2 - Mathematical form

$$R_n = 1 - \frac{|\operatorname{unique}(G_n)|}{|G_n|}, \qquad N_n = \frac{|G_n \setminus T_n|}{|G_n|}.$$

Part 3 - Hints and Helper

Define repeated and training n-gram sets explicitly. Store per-sample metrics before calculating aggregate summaries.

Part 4 - Python code skeleton

```
import torch
def repetition_rate(tokens, n):
    ngrams = ...
    return ...

def novelty_rate(tokens, training_ngrams, n):
    generated_ngrams = ...
    return ...

def evaluate_generation(samples, training_text, tokenizer, config):
    records = []
    for sample in samples:
        records.append({
            "repetition": ...,
            "novelty": ...,
            "length": ...,
        })
    return summarize(records, ...)

def E16(model, data, config):
    samples = generate_evaluation_set(model, ...)
    return evaluate_generation(samples, data, ..., config)
```

16.6.18 Exercise 17 - Prove LSTM Captures a Controlled Long Dependency

Part 1 - Why this matters

A controlled synthetic pattern isolates long-term memory from vocabulary complexity and real-text ambiguity. The target should depend on a marker placed many steps earlier while intervening tokens provide no shortcut.

If the dataset contains positional, frequency, or padding clues, either model may solve it without remembering the marker. A convincing experiment must remove these shortcuts and vary the dependency distance at evaluation time.

Generate balanced sequences, train matched vanilla RNN and LSTM models, and plot accuracy against dependency length. Probe hidden states or gates to connect performance differences to retained information rather than parameter count alone.

Part 2 - Mathematical form

$$y = x_{t-d}, \qquad d \in \{d_1, \ldots, d_m\}, \qquad I(y; x_{t-d}) > 0, \quad I(y; x_j) = 0 \text{ for distractors.}$$

Part 3 - Hints and Helper

Randomize marker position and distractors. Evaluate on distances both inside and beyond the training range.

Part 4 - Python code skeleton

```
import torch
def make_memory_dataset(samples, min_gap, max_gap, vocab_size):
    sequences = ...
    targets = ...
    distances = ...
    return sequences, targets, distances

def evaluate_by_distance(model, loader):
    correct = defaultdict(int)
    totals = defaultdict(int)
    for inputs, targets, distances in loader:
        predictions = ...
        update_distance_bins(correct, totals, predictions, targets, distances)
    return ...

def E17(model, data, config):
    rnn_report = train_memory_model("rnn", ...)
    lstm_report = train_memory_model("lstm", ...)
    return compare_distance_curves(rnn_report, lstm_report)
```

16.6.19 Exercise 18 - Stress Test Long-Prompt Text Generation

Part 1 - Why this matters

Long prompts increase recurrent computation, state-processing time, and memory used by token storage and evaluation. Although an LSTM state has fixed shape, processing the prompt remains sequential and latency grows with prompt length.

A stress test that measures only successful runs misses out-of-memory errors, latency spikes, synchronization effects, and degradation in generated quality. Generation time must also be separated into prompt ingestion and new-token decoding.

Sweep prompt length, batch size, hidden size, and precision under explicit resource limits. Capture peak memory, prompt throughput, per-token latency, failure type, and output-quality changes, then identify a safe operating envelope.

Part 2 - Mathematical form

$$t_{\text{total}} = t_{\text{prefill}} + \sum_{j=1}^{M} t_{\text{decode},j}, \qquad \text{tokens/s} = \frac{T + M}{t_{\text{total}}}.$$

Part 3 - Hints and Helper

Warm up before measurement and synchronize CUDA. Catch out-of-memory failures, clear references, and continue only with smaller validated configurations.

Part 4 - Python code skeleton

```
import torch
@torch.no_grad()
def stress_case(model, prompt, new_tokens, device):
    reset_peak_memory(device)
    synchronize_if_cuda(device)
    start = time.perf_counter()
    result = generate(model, prompt, ..., max_new_tokens=new_tokens)
    synchronize_if_cuda(device)
    return {
        "elapsed": ...,
        "peak_memory": ...,
        "output": result,
    }

def E18(model, data, config):
    records = []
    for case in build_stress_grid(config):
        records.append(run_or_capture_failure(model, case, ...))
    return determine_safe_envelope(records, ... )
```

16.6.20 Exercise 19 - Produce the Full LSTM Language Modeling Report

Part 1 - Why this matters

A final engineering report must connect data construction, architecture, optimization, decoding, evaluation, and hardware behavior. Reporting only the best perplexity hides the decisions and failures that determine whether the result can be reproduced.

Claims about sampling quality or LSTM memory require controlled evidence. Each comparison should identify fixed variables, changed variables, seeds, dataset boundaries, uncertainty, and the exact metric implementation.

Assemble verified tables, plots, generated examples, failure traces, and recommended operating settings. Separate observed evidence from interpretation, document unresolved limitations, and provide a reproducible path from raw text to final generation.

Part 2 - Mathematical form

$$\mathcal{R} = \{D, \mathcal{V}, M, \theta, H, S, Q, F\}, \quad Q = \{\mathrm{PPL}, R_n, N_n, L, t, m\}.$$

Part 3 - Hints and Helper

Include configuration hashes and checkpoint identifiers. Every recommendation should point to a recorded experiment.

Part 4 - Python code skeleton

```
import torch
def build_final_report(config, artifacts):
    required = [
        "data_audit", "model_summary", "training_curves",
        "perplexity", "sampling_comparison", "failure_log",
        "performance_benchmarks", "generation_examples",
    ]
    validate_artifacts(artifacts, required)
    report = {
        "scope": ...,
        "evidence": ...,
        "failures_and_fixes": ...,
        "recommendations": ...,
        "limitations": ...,
    }
    return report

def E19(model, data, config):
    artifacts = run_verified_experiment_suite(model, data, config, ...)
    return build_final_report(config, artifacts)
```

16.7 LSTM05 - Time Series Forecasting with LSTM

Models and Training

16.7.1 Exercise 00 - Build Multi-Feature Time Series Windows

Part 1 - Why this matters

A forecasting window converts a continuous multivariate series into supervised samples. Every input must contain only observations available at the forecast origin, and each target must begin at the requested future horizon.

A wrong offset can place the target inside the input or make the model predict a past value. Autocorrelation may then produce excellent metrics even though the deployment problem has been changed silently.

Construct windows with timestamps and source indices, then test the first, middle, and last valid samples manually. Assert feature order, lookback length, horizon distance, forecast length, and strict temporal separation before training.

Part 2 - Mathematical form

$$X_i = [\mathbf{x}_{i-L+1}, \ldots, \mathbf{x}_i], \qquad Y_i = [\mathbf{y}_{i+h}, \ldots, \mathbf{y}_{i+h+H-1}].$$

Part 3 - Hints and Helper

Retain the forecast-origin timestamp and original row indices in every sample.

Part 4 - Python code skeleton

```
import torch
def E00(model, data, config):
    prepared = build_multi_feature_windows(model, data, config, ...)
    result = validate_window_alignment(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.2 Exercise 01 - Implement Feature Scaling Strategy

Part 1 - Why this matters

Multivariate features may use radically different units and numerical ranges. Scaling prevents one large-magnitude variable from dominating the affine transformations that feed LSTM sigmoid and tanh gates.

Extreme inputs can saturate gates near zero or one and suppress useful gradients. Fitting the scaler on validation or test observations creates temporal leakage by using future distribution statistics.

Fit every scaling parameter on the training period only, reuse it for later splits, and preserve an inverse transformation for forecasts. Inspect constant features, outliers, and the distribution seen by the gates.

Part 2 - Mathematical form

$$\widetilde{x}_{t,j} = \frac{x_{t,j} - \mu_j^{\text{train}}}{\sigma_j^{\text{train}} + \epsilon}.$$

Part 3 - Hints and Helper

Store feature names beside scaler statistics and never refit on validation or test data.

Part 4 - Python code skeleton

```
import torch
def E01(model, data, config):
    prepared = fit_train_only_scaler(model, data, config, ...)
    result = audit_scaled_features(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.3 Exercise 02 - Build a One-Step LSTM Forecaster

Part 1 - Why this matters

A one-step forecaster processes the complete lookback window and maps its final recurrent representation to the next target. It is the simplest end-to-end test of model structure, shapes, and regression loss.

Selecting the wrong time step, removing the batch dimension, or broadcasting predictions against targets can produce a valid number for the wrong task. Batch size one often hides these defects.

Implement explicit batch-first dimensions and assert prediction-target shape equality before loss computation. Test single-target and multi-target cases with several batch and sequence sizes.

Part 2 - Mathematical form

$$(H, C) = \text{LSTM}(X), \qquad \widehat{\mathbf{y}}_{t+1} = W_o H_{:,-1,:} + b_o.$$

Part 3 - Hints and Helper

Expected input is (B, L, F) and output is (B, O); avoid unrestricted `squeeze()`.

Part 4 - Python code skeleton

```
import torch
def E02(model, data, config):
    prepared = run_one_step_forecaster(model, data, config, ...)
    result = validate_prediction_and_loss(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.4 Exercise 03 - Extend the Forecaster to Multi-Step Prediction

Part 1 - Why this matters

Multi-step forecasting produces an entire future path. A direct model emits all horizons together, whereas an autoregressive model feeds each prediction back into the next decision.

Autoregressive errors accumulate because training often uses clean observations while inference consumes imperfect model outputs. Direct prediction avoids feedback drift but must learn horizon-specific behavior in one output.

Implement both strategies with the same data and splits, verify that the rolling input advances correctly, and compute error separately at every horizon. Do not hide later-horizon degradation inside one mean score.

Part 2 - Mathematical form

$$\widehat{y}_{t+k} = f_\theta(x_{t-L+1:t}, \widehat{y}_{t+1:t+k-1}), \qquad k = 1, \ldots, H.$$

Part 3 - Hints and Helper

Separate known future covariates from unknown future targets during autoregressive rollout.

Part 4 - Python code skeleton

```
import torch
def E03(model, data, config):
    prepared = generate_multi_step_forecast(model, data, config, ...)
    result = compare_direct_and_autoregressive(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.5 Exercise 04 - Learn Long Seasonality Better Than a Vanilla RNN

Part 1 - Why this matters

Synthetic seasonal data gives a controlled setting where the true periods, trend, noise, and dependency length are known. It can test whether an LSTM retains periodic evidence beyond a vanilla RNN's practical memory.

A model may exploit short autocorrelation, overlapping windows, or an explicit time index instead of remembering a long cycle. An unfair parameter budget can also predetermine the comparison.

Generate several periods and phases, split chronologically, and compare matched RNN, LSTM, and seasonal-naive models. Evaluate accuracy as the required memory distance increases and repeat across seeds.

Part 2 - Mathematical form

$$y_t = \sum_{k=1}^{K} a_k \sin\left(\frac{2\pi t}{P_k} + \phi_k\right) + \beta t + \epsilon_t.$$

Part 3 - Hints and Helper

Include a seasonal-naive baseline and report model parameter counts.

Part 4 - Python code skeleton

```
import torch
def E04(model, data, config):
    prepared = generate_seasonal_series(model, data, config, ...)
    result = compare_rnn_lstm_seasonality(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.6 Exercise 05 - Compare Teacher Forcing and Autoregressive Generation

Part 1 - Why this matters

Teacher forcing supplies the true previous target to the decoder during training, which simplifies optimization. Autoregressive inference instead consumes earlier predictions and exposes the model to its own errors.

This mismatch can produce low training loss but unstable rollouts. Pure autoregressive training may reduce exposure bias, yet it can be difficult before the model has learned a useful local forecast.

Train with fixed and scheduled forcing ratios, then evaluate every version with a fully autoregressive rollout. Measure horizon-wise drift and sensitivity to early prediction errors.

Part 2 - Mathematical form

$$u_{t+1} = m_t y_t + (1 - m_t)\widehat{y}_t, \qquad m_t \sim \text{Bernoulli}(\rho).$$

Part 3 - Hints and Helper

Document whether the forcing decision is sampled per sequence, sample, or time step.

Part 4 - Python code skeleton

```
import torch
def E05(model, data, config):
    prepared = decode_with_teacher_forcing(model, data, config, ...)
    result = measure_rollout_drift(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.7 Exercise 06 - Evaluate Forecast Accuracy with MAE, MSE, and MAPE

Part 1 - Why this matters

Forecast metrics emphasize different failures. MAE weights errors linearly, MSE punishes large misses strongly, and MAPE expresses relative error but becomes unstable near zero targets.

A single aggregate can hide horizon degradation, target-specific failure, or scale differences. A few near-zero observations may dominate MAPE and make model comparisons meaningless.

Implement each metric manually, verify it with small tensors, and report results per horizon and target before aggregation. Apply a documented zero policy and evaluate in original units after inverse scaling.

Part 2 - Mathematical form

$$\mathrm{MAE} = \frac{1}{N}\sum |e_i|, \quad \mathrm{MSE} = \frac{1}{N}\sum e_i^2, \quad \mathrm{MAPE} = \frac{100}{N}\sum \left|\frac{e_i}{y_i}\right|.$$

Part 3 - Hints and Helper

Mask or report near-zero targets separately instead of hiding them with a large epsilon.

Part 4 - Python code skeleton

```
import torch
def E06(model, data, config):
    prepared = compute_forecast_metrics(model, data, config, ...)
    result = validate_metric_sensitivity(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.8 Exercise 07 - Debug Windowing and Alignment Bugs

Part 1 - Why this matters

Every forecast label must occur after the forecast origin by exactly the configured horizon. If the offset is wrong, the network may reconstruct recent observations or predict the past instead of the future.

Time-series autocorrelation can make these incorrect tasks look easier than correct forecasting. Loss reduction alone therefore cannot validate temporal alignment.

Build an audit containing source rows, timestamps, input range, origin, target range, and horizon. Inject off-by-one and overlap defects deliberately and require the audit to reject them.

Part 2 - Mathematical form

$$\max \mathcal{T}(X_i) < \min \mathcal{T}(Y_i), \qquad \min \mathcal{T}(Y_i) - \max \mathcal{T}(X_i) = h\Delta t.$$

Part 3 - Hints and Helper

Use a monotonic counter series so every alignment mistake becomes visible immediately.

Part 4 - Python code skeleton

```
import torch
def E07(model, data, config):
    prepared = inject_alignment_cases(model, data, config, ...)
    result = detect_temporal_alignment_failures(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.9 Exercise 08 - Diagnose and Reduce Forecasting Overfitting

Part 1 - Why this matters

An LSTM can memorize local fluctuations or one historical regime while failing on later periods. Temporal overfitting appears when training improvement continues after chronological validation has stopped improving.

Random splitting can hide the gap by placing neighboring windows in both sets. Excessive capacity, weak regularization, and checkpoint selection from a noisy metric can further distort the diagnosis.

Compare capacity, dropout, weight decay, and early stopping one factor at a time on identical validation periods. Restore the best checkpoint and examine horizon-specific behavior rather than only average loss.

Part 2 - Mathematical form

$$g_e = \mathcal{L}_{\text{val},e} - \mathcal{L}_{\text{train},e}, \qquad e^* = \arg\min_e \mathcal{L}_{\text{val},e}.$$

Part 3 - Hints and Helper

Save and restore the best model state rather than keeping the last epoch.

Part 4 - Python code skeleton

```
import torch
def E08(model, data, config):
    prepared = train_with_regularization(model, data, config, ...)
    result = diagnose_forecast_overfitting(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.10 Exercise 09 - Build Walk-Forward Validation without Leakage

Part 1 - Why this matters

Walk-forward validation respects deployment order by training on past data and evaluating on a later period. Expanding and rolling histories test different assumptions about how long old information remains useful.

Leakage can still enter through scaling, feature engineering, overlapping horizons, or repeated tuning on the final test period. Sorting data before a conventional random workflow is not sufficient.

Generate explicit fold boundaries, fit preprocessing inside each fold, and include a gap whenever targets or rolling features require one. Preserve each fold's time-specific results when aggregating performance.

Part 2 - Mathematical form

$$\mathcal{D}_{\text{train}}^{(k)} = [1, t_k], \qquad \mathcal{D}_{\text{val}}^{(k)} = [t_k + g + 1, t_k + g + V].$$

Part 3 - Hints and Helper

Assert that all training target timestamps precede validation forecast origins.

Part 4 - Python code skeleton

```
import torch
def E09(model, data, config):
    prepared = build_walk_forward_folds(model, data, config, ...)
    result = run_leakage_safe_validation(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.11 Exercise 10 - Train the Full Pipeline on CUDA

Part 1 - Why this matters

End-to-end CUDA performance includes data loading, transfer, forward computation, backpropagation, and optimizer updates. A fast recurrent kernel cannot compensate for a host pipeline that leaves the GPU waiting.

Asynchronous timing can understate runtime, while excluding transfers exaggerates operational speed. Device mismatch among data, model, states, and loss tensors may also fail only on particular batches.

Move the entire training path to CUDA, use pinned memory and non-blocking transfer when justified, and time both compute-only and end-to-end execution. Check output and loss parity against a controlled CPU run.

Part 2 - Mathematical form

$$Q = \frac{N_{\text{windows}} L}{t_{\text{wall}}}, \qquad t_{\text{wall}} = t_{\text{load}} + t_{\text{copy}} + t_{\text{compute}}.$$

Part 3 - Hints and Helper

Synchronize CUDA before and after every timed region.

Part 4 - Python code skeleton

```
import torch
def E10(model, data, config):
    prepared = train_forecaster_on_cuda(model, data, config, ...)
    result = benchmark_end_to_end_throughput(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.12 Exercise 11 - Profile Sequence Length and Hidden Size

Part 1 - Why this matters

Lookback length controls temporal context, while hidden size controls recurrent capacity. Both increase computation and activation storage, but additional context or capacity helps only when the data contains usable information.

Large configurations may reduce throughput, exhaust memory, or overfit without improving validation error. Measuring a single cold batch can confuse startup overhead with steady-state performance.

Sweep a controlled grid of sequence and hidden sizes, recording quality, latency, throughput, and peak memory. Select from the Pareto frontier rather than choosing the largest model that fits.

Part 2 - Mathematical form

$$C = \mathcal{O}(BL\, 4H(F+H)), \qquad M_{\text{act}} = \mathcal{O}(BLH).$$

Part 3 - Hints and Helper

Warm up each configuration and keep the evaluation folds identical.

Part 4 - Python code skeleton

```
import torch
def E11(model, data, config):
    prepared = profile_forecaster_configuration(model, data, config, ...)
    result = find_quality_speed_frontier(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.13 Exercise 12 - Implement Mixed Precision and Detect Gate Saturation

Part 1 - Why this matters

Mixed precision can reduce memory and improve CUDA throughput, but LSTM gate computations repeatedly pass values through sigmoid and tanh. Limited precision may saturate gates or lose small recurrent updates.

A run can continue while gradient scaling skips updates or gate outputs collapse near their limits. Final loss alone does not reveal where numerical divergence began.

Use automatic mixed precision and gradient scaling, log non-finite values and gate distributions, and compare with float32. Increase sequence length deliberately to identify the stability boundary.

Part 2 - Mathematical form

$$i_t = \sigma(a_t), \qquad \sigma'(a_t) = \sigma(a_t)(1 - \sigma(a_t)), \qquad |a_t| \uparrow \Rightarrow \sigma'(a_t) \downarrow .$$

Part 3 - Hints and Helper

Unscale gradients before clipping and compute diagnostic statistics in float32.

Part 4 - Python code skeleton

```
import torch
def E12(model, data, config):
    prepared = run_mixed_precision_forecasting(model, data, config, ...)
    result = detect_gate_saturation(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.14 Exercise 13 - Compare LSTM and GRU Forecasting

Part 1 - Why this matters

LSTM and GRU provide different balances between memory control and computational cost. GRU uses fewer gates, while LSTM's separate cell state may help when dependencies are long or multiple time scales interact.

One seed or unequal training budgets can turn random variation into a false architectural conclusion. Equal hidden size and equal parameter count are also different comparison conditions.

Run equal-width and matched-parameter experiments on datasets with short and long dependencies. Measure quality, convergence, throughput, memory, and robustness across controlled seeds.

Part 2 - Mathematical form

$$N_{\text{LSTM}} \approx 4H(F + H + 1), \qquad N_{\text{GRU}} \approx 3H(F + H + 1).$$

Part 3 - Hints and Helper

Use identical folds, preprocessing, optimizer budgets, and evaluation code.

Part 4 - Python code skeleton

```
import torch
def E13(model, data, config):
    prepared = train_matched_lstm_gru_models(model, data, config, ...)
    result = summarize_architecture_tradeoffs(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.15 Exercise 14 - Implement Truncated BPTT for Long Windows

Part 1 - Why this matters

Long forecast windows make full backpropagation expensive because recurrent activations must remain available across all time steps. Truncated BPTT carries states forward while limiting the gradient horizon.

Detaching only one LSTM state can retain graph history, whereas detaching both too frequently prevents long-dependency learning. Unordered chunks and incorrect resets destroy temporal continuity.

Train on ordered chunks, detach hidden and cell states at explicit truncation boundaries, and reset them at independent-series boundaries. Compare memory, throughput, and horizon accuracy across truncation lengths.

Part 2 - Mathematical form

$$(h_k, c_k) = F_\theta(X_k, h_{k-1}, c_{k-1}), \qquad (h_k, c_k) \leftarrow \text{stopgrad}(h_k, c_k).$$

Part 3 - Hints and Helper

Distinguish truncation boundaries from real sequence boundaries in metadata.

Part 4 - Python code skeleton

```
import torch
def E14(model, data, config):
    prepared = train_with_truncated_bptt(model, data, config, ...)
    result = quantify_truncation_tradeoff(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.16 Exercise 15 - Build a Multi-Horizon Forecast Visualization

Part 1 - Why this matters

Forecast plots reveal lag, phase error, amplitude compression, drift, and horizon-specific failure that aggregate metrics cannot show. Correct temporal coordinates are as important as the plotted values.

Overlapping windows can create unreadable lines, and mismatched timestamps can make an incorrect forecast look aligned. Plotting scaled predictions beside original targets is another silent visual error.

Build a tool that receives forecast origins, target timestamps, predictions, and truth in original units. Provide selected-origin views, horizon panels, residuals, and optional uncertainty bands.

Part 2 - Mathematical form

$$e_{i,h} = y_{t_i+h} - \widehat{y}_{t_i+h}, \qquad h = 1, \ldots, H.$$

Part 3 - Hints and Helper

Assert timestamp and value shapes, and mark the forecast origin explicitly.

Part 4 - Python code skeleton

```
import torch
def E15(model, data, config):
    prepared = collect_timestamped_forecasts(model, data, config, ...)
    result = plot_multi_horizon_forecasts(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.17 Exercise 16 - Measure Robustness under Seasonal Shift

Part 1 - Why this matters

Deployed time series may change in seasonal amplitude, baseline, variance, or phase. A model that interpolates its historical regime can fail sharply when this generating structure shifts.

Adding random noise is not the same as changing seasonality. A useful robustness experiment varies one known property while holding other factors fixed so the cause is identifiable.

Create test regimes with controlled amplitude multipliers, evaluate without retraining, and plot degradation against shift magnitude. Compare LSTM, GRU, and seasonal-naive baselines under identical shifted series.

Part 2 - Mathematical form

$$y_t^{(\alpha)} = \alpha A \sin\left(\frac{2\pi t}{P}\right) + r_t, \qquad \Delta(\alpha) = M(\alpha) - M(1).$$

Part 3 - Hints and Helper

Keep training scaler statistics fixed and reuse the same noise realization for all models.

Part 4 - Python code skeleton

```
import torch
def E16(model, data, config):
    prepared = generate_shifted_seasonality(model, data, config, ...)
    result = build_robustness_curve(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.18 Exercise 17 - Estimate Probabilistic Forecast Uncertainty

Part 1 - Why this matters

A point forecast gives one future path but does not express uncertainty. Probabilistic forecasting estimates a distribution or interval and shows how risk changes across horizons.

Narrow intervals may miss most observations, while very wide intervals achieve coverage without usefulness. A constant-variance assumption can also fail when volatility varies over time.

Modify the output head to predict distribution parameters, enforce a positive scale, and optimize negative log-likelihood. Evaluate empirical coverage and interval width separately at each horizon.

Part 2 - Mathematical form

$$(\mu_{t,h}, s_{t,h}) = f_\theta(X_t), \quad \sigma_{t,h} = \mathrm{softplus}(s_{t,h}) + \epsilon, \quad y_{t+h} \sim \mathcal{N}(\mu_{t,h}, \sigma_{t,h}^2).$$

Part 3 - Hints and Helper

Compare nominal coverage with empirical coverage and report interval sharpness.

Part 4 - Python code skeleton

```
import torch
def E17(model, data, config):
    prepared = predict_distribution_parameters(model, data, config, ...)
    result = evaluate_interval_calibration(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.19 Exercise 18 - Stress Test the Large Forecasting Pipeline

Part 1 - Why this matters

Large datasets expose window-construction cost, storage throughput, worker contention, transfer delays, GPU memory pressure, and checkpoint overhead that small experiments cannot reveal.

A stress test must distinguish slow progress from deadlock, memory leak, or an out-of-memory boundary. Total runtime alone cannot identify the limiting system component.

Scale data length, feature count, sequence length, and batch size systematically while recording component timing and resource peaks. Capture failures safely and define a verified operating envelope.

Part 2 - Mathematical form

$$t_{\text{epoch}} = t_{\text{I/O}} + t_{\text{window}} + t_{\text{copy}} + t_{\text{GPU}}, \qquad Q = \frac{N_{\text{samples}}}{t_{\text{epoch}}}.$$

Part 3 - Hints and Helper

Stream windows when full materialization would exceed host memory.

Part 4 - Python code skeleton

```
import torch
def E18(model, data, config):
    prepared = run_forecasting_stress_grid(model, data, config, ...)
    result = identify_pipeline_limits(prepared, data, config, ...)
    assert result is not None
    return result
```

16.7.20 Exercise 19 - Produce the Full Forecasting Engineering Report

Part 1 - Why this matters

A complete report connects data lineage, temporal validation, preprocessing, model design, optimization, uncertainty, robustness, visualization, and system performance. A best metric alone cannot establish forecast correctness.

Forecasting claims are vulnerable to leakage, alignment defects, selective horizons, and favorable historical periods. Each conclusion must identify its fold, forecast origin, horizon, units, baseline, and uncertainty.

Assemble audits, configurations, curves, failure records, and recommended operating limits. Separate observations from interpretation and provide a reproducible path from raw timestamps to final forecasts.

Part 2 - Mathematical form

$$\mathcal{R} = \{D, W, S, M, T, V, Q, U, F, P\}, \qquad Q = \{\mathrm{MAE}, \mathrm{MSE}, \mathrm{MAPE}, C, W_I, t, m\}.$$

Part 3 - Hints and Helper

Include exact split timestamps, data hashes, configuration hashes, and checkpoint identifiers.

Part 4 - Python code skeleton

```
import torch
def E19(model, data, config):
    prepared = collect_verified_forecasting_artifacts(
        model, data, config, ...
    )
    result = build_final_forecasting_report(prepared, data, config, ...)
    assert result is not None
    return result
```

16.8 LSTM06 - Regularization, Stabilization, and Robustness

Models and Training

16.8.1 Exercise 00 - Demonstrate LSTM Overfitting and Measure the Gap

Part 1 - Why this matters

Overfitting occurs when an LSTM learns training-specific patterns that do not transfer to unseen sequences. A realistic task should contain noise, variable lengths, and enough temporal structure to make memorization and genuine generalization distinguishable.

Randomly splitting overlapping windows can place nearly identical sequences in training and validation sets, making the gap appear smaller than it is. Training loss alone therefore cannot establish whether the model learned reusable temporal rules.

Create a chronological split, train an intentionally oversized LSTM without regularization, and log train and validation metrics every epoch. Identify the epoch where the validation trend separates and inspect failures across sequence lengths.

Part 2 - Mathematical form

$$G_e = M_{\text{val},e} - M_{\text{train},e}, \qquad e^* = \arg\min_e M_{\text{val},e}.$$

Part 3 - Hints and Helper

Preserve the best and final checkpoints so their predictions can be compared directly.

Part 4 - Python code skeleton

```
import torch
def E00(model, data, config):
    experiment = train_overcapacity_lstm(model, data, config, ...)
    report = measure_generalization_gap(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.2 Exercise 01 - Compare Inter-Layer and Input Dropout

Part 1 - Why this matters

Dropout can regularize input embeddings or the connections between stacked LSTM layers. These locations remove different information: input dropout perturbs observations, while inter-layer dropout perturbs learned temporal representations.

Applying ordinary dropout independently at every time step may inject inconsistent temporal noise. PyTorch LSTM dropout also has no effect when only one recurrent layer is configured, which can create a silent experimental mistake.

Implement both placements, verify train and evaluation behavior, and compare them under equal dropout probabilities. Track convergence, validation quality, activation statistics, and failure on long dependencies.

Part 2 - Mathematical form

$$\widetilde{x}_t = m_t^{(x)} \odot x_t, \qquad \widetilde{h}_t^{(\ell)} = m_t^{(\ell)} \odot h_t^{(\ell)}, \quad m \sim \text{Bernoulli}(1-p).$$

Part 3 - Hints and Helper

Confirm that `model.eval()` disables dropout and that stacked-LSTM dropout requires more than one layer.

Part 4 - Python code skeleton

```
import torch
def E01(model, data, config):
    experiment = run_dropout_placement_experiments(model, data, config, ...)
    report = compare_dropout_locations(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.3 Exercise 02 - Implement and Evaluate Weight Decay

Part 1 - Why this matters

Weight decay limits the growth of recurrent and output parameters. Smaller norms may improve validation behavior and reduce sensitivity to noisy observations.

Using the same decay for every parameter can regularize biases or normalization parameters unnecessarily. AdamW's decoupled decay is also not identical to adding an L2 term inside adaptive Adam updates.

Create parameter groups deliberately, sweep decay strengths, and record parameter norms, gradient norms, convergence, and validation metrics. Compare no decay, coupled L2, and AdamW under otherwise matched settings.

Part 2 - Mathematical form

$$\theta_{t+1} = (1 - \eta\lambda)\theta_t - \eta\, u_t, \qquad \lambda \geq 0.$$

Part 3 - Hints and Helper

Exclude parameters only with an explicit rationale and print the final optimizer groups for verification.

Part 4 - Python code skeleton

```
import torch
def E02(model, data, config):
    experiment = train_weight_decay_grid(model, data, config, ...)
    report = evaluate_decay_stability(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.4 Exercise 03 - Compare Gradient Clipping Norms

Part 1 - Why this matters

Backpropagation through long sequences can create very large gradient norms. Clipping limits the update magnitude and may prevent an isolated batch from destabilizing all later training.

A threshold that is too small changes nearly every update and can stop useful learning. Clipping after the optimizer step or before unscaling mixed-precision gradients does not protect the intended update.

Log unclipped norms, apply several thresholds at the correct point, and record the fraction of steps that are clipped. Compare stability, convergence speed, and final sequence quality rather than only whether NaN values disappear.

Part 2 - Mathematical form

$$g' = g \min\left(1, \frac{c}{\|g\|_2 + \epsilon}\right).$$

Part 3 - Hints and Helper

Call clipping after backward and mixed-precision unscaling but before the optimizer step.

Part 4 - Python code skeleton

```
import torch
def E03(model, data, config):
    experiment = train_clip_norm_grid(model, data, config, ...)
    report = analyze_clipping_frequency(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.5 Exercise 04 - Apply Layer Normalization inside LSTM

Part 1 - Why this matters

Layer normalization can stabilize recurrent computation by normalizing features within each sample rather than depending on batch statistics. It may reduce gate-logit drift as hidden states evolve across time.

Normalization placement changes the model equation. Normalizing concatenated gates, individual gates, the cell state, or only the output are different architectures and cannot be treated as one experiment.

Implement a transparent LSTM cell with documented normalization points, then inspect gate distributions and state drift. Compare against the unnormalized cell using identical weights where possible.

Part 2 - Mathematical form

$$\mathrm{LN}(a) = \gamma \odot \frac{a - \mu(a)}{\sqrt{\sigma^2(a) + \epsilon}} + \beta.$$

Part 3 - Hints and Helper

Log gate pre-activations and outputs separately; saturation should not be inferred from hidden states alone.

Part 4 - Python code skeleton

```
import torch
def E04(model, data, config):
    experiment = build_layer_normalized_lstm(model, data, config, ...)
    report = measure_gate_saturation_and_drift(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.6 Exercise 05 - Diagnose NaN Loss and Numerical Failure

Part 1 - Why this matters

A NaN loss is usually the final symptom of an earlier numerical failure. The first non-finite value may appear in an input, gate logit, cell state, gradient, optimizer state, or mixed-precision scale.

Checking only the loss loses the location and timing of the original defect. Continuing after the first invalid step can corrupt optimizer moments and make later diagnostics misleading.

Install staged finite-value checks, capture the failing batch and model state, and stop immediately on the first violation. Build automated reports for gate saturation, state growth, gradient overflow, and update magnitude.

Part 2 - Mathematical form

$$t^* = \min\{t : \neg\,\mathrm{isfinite}(z_t)\}, \qquad z_t \in \{x, a_g, c, h, \nabla\theta, \theta\}.$$

Part 3 - Hints and Helper

Save a reproducible failure bundle containing the seed, configuration, batch indices, and last valid checkpoint.

Part 4 - Python code skeleton

```
import torch
def E05(model, data, config):
    experiment = run_nan_diagnostic_training(model, data, config, ...)
    report = locate_first_nonfinite_tensor(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.7 Exercise 06 - Compare SGD, Adam, and AdamW

Part 1 - Why this matters

Optimizers interact differently with recurrent curvature, noisy gradients, and parameter scales. SGD may require careful momentum and learning rates, while Adam adapts coordinate-wise and AdamW decouples weight decay.

Using one learning rate for all optimizers creates an unfair comparison. Reporting the best single run also hides sensitivity to initialization and hyperparameters.

Perform a controlled learning-rate sweep for each optimizer, preserve equal training budgets, and repeat across seeds. Compare convergence, stability, validation quality, parameter norms, and runtime overhead.

Part 2 - Mathematical form

$$\theta_{t+1} = \theta_t - \eta\, U(g_{1:t}),$$

Part 3 - Hints and Helper

Tune each optimizer independently, then compare its best stable configuration under the same evaluation protocol.

Part 4 - Python code skeleton

```
import torch
def E06(model, data, config):
    experiment = run_optimizer_sweeps(model, data, config, ...)
    report = summarize_optimizer_sensitivity(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.8 Exercise 07 - Schedule Learning Rate and Prevent Late Divergence

Part 1 - Why this matters

A learning-rate schedule can allow rapid early progress and smaller late updates when the model approaches a useful region. This may prevent oscillation or late-epoch divergence in sensitive recurrent training.

Calling the scheduler at the wrong frequency shifts the entire schedule. A validation-based scheduler can also react to noise unless patience and thresholds are defined carefully.

Implement fixed-step, cosine, and plateau-based schedules, log the actual learning rate at every update, and compare late-epoch stability. Verify checkpoint restoration together with scheduler state.

Part 2 - Mathematical form

$$\eta_t = \eta_{\min} + \frac{1}{2}(\eta_{\max} - \eta_{\min}) \left(1 + \cos \frac{\pi t}{T}\right).$$

Part 3 - Hints and Helper

State clearly whether the scheduler steps per batch or per epoch and test its first three values manually.

Part 4 - Python code skeleton

```
import torch
def E07(model, data, config):
    experiment = train_learning_rate_schedules(model, data, config, ...)
    report = detect_late_epoch_divergence(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.9 Exercise 08 - Analyze Batch Size and Gradient Noise

Part 1 - Why this matters

Batch size changes gradient variance, memory use, throughput, and the number of optimizer updates per epoch. Smaller batches may add useful noise, while larger batches provide smoother but potentially less generalizable updates.

Comparing batch sizes with the same epoch count changes the number of optimizer steps. Padding ratios and sequence-length composition can also vary with batching and confound the result.

Compare batches under both equal-epoch and equal-update budgets, record gradient variance and hardware utilization, and control sequence bucketing. Identify the best practical setting rather than the largest possible batch.

Part 2 - Mathematical form

$$\widehat{g}_B = \frac{1}{B} \sum_{i=1}^{B} g_i, \qquad \operatorname{Var}(\widehat{g}_B) \approx \frac{\operatorname{Var}(g)}{B}.$$

Part 3 - Hints and Helper

Report effective batch size when gradient accumulation is used.

Part 4 - Python code skeleton

```
import torch
def E08(model, data, config):
    experiment = benchmark_batch_size_grid(model, data, config, ...)
    report = analyze_gradient_noise_tradeoff(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.10 Exercise 09 - Debug Improving Loss but Poor Predictions

Part 1 - Why this matters

A decreasing scalar loss does not guarantee useful sequence predictions. The pipeline may optimize misaligned targets, padded positions, the wrong reduction, or a dominant easy class while the intended outputs remain poor.

Aggregate loss can hide collapsed predictions and horizon-specific failure. Teacher forcing may also produce strong training loss even though free-running generation fails.

Inspect decoded samples, masks, target shifts, baselines, and per-time-step metrics. Create deliberate bugs and require the debugging routine to distinguish data, loss, decoding, and evaluation failures.

Part 2 - Mathematical form

$$\mathcal{L} = \frac{\sum_{b,t} m_{b,t} \ell(\widehat{y}_{b,t}, y_{b,t})}{\sum_{b,t} m_{b,t}}.$$

Part 3 - Hints and Helper

Always compare against a simple baseline and evaluate using the exact inference procedure intended for deployment.

Part 4 - Python code skeleton

```
import torch
def E09(model, data, config):
    experiment = inject_silent_training_bugs(model, data, config, ...)
    report = diagnose_loss_prediction_mismatch(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.11 Exercise 10 - Measure CUDA Overhead of Stabilization

Part 1 - Why this matters

Dropout, gradient clipping, and normalization improve training behavior but add kernels, reductions, memory traffic, or synchronization. Their value must be judged against both quality and runtime cost.

Timing without CUDA synchronization or comparing different batch contents can produce false overhead estimates. Profiler instrumentation itself can also distort very short measurements.

Benchmark a fixed baseline and add one stabilization method at a time, using warm-up and repeated timed regions. Report step latency, throughput, peak memory, and validation improvement together.

Part 2 - Mathematical form

$$\text{overhead}_s = \frac{t_s - t_0}{t_0} \times 100\%.$$

Part 3 - Hints and Helper

Use matched weights and batches for microbenchmarks, then confirm results in an end-to-end epoch.

Part 4 - Python code skeleton

```
import torch
def E10(model, data, config):
    experiment = benchmark_cuda_stabilizers(model, data, config, ...)
    report = compute_quality_adjusted_overhead(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.12 Exercise 11 - Compare Mixed Precision with and without GradScaler

Part 1 - Why this matters

Mixed precision accelerates supported CUDA operations but lower precision can overflow gradients or underflow small values. Gradient scaling moves the loss into a safer numerical range before backward computation.

Training without a scaler may silently lose recurrent gradients, while an aggressive scale may overflow and force skipped optimizer steps. A stable loss does not prove that gate gradients remain informative.

Run float32, autocast-only, and autocast-with-scaler configurations, logging non-finite gradients, skipped steps, and gate statistics. Increase sequence length to reveal numerical limits.

Part 2 - Mathematical form

$$\widehat{\mathcal{L}} = s\mathcal{L}, \qquad \widehat{g} = s\nabla_\theta \mathcal{L}, \qquad g = \widehat{g}/s.$$

Part 3 - Hints and Helper

Unscale before gradient clipping and record the scale value throughout training.

Part 4 - Python code skeleton

```
import torch
def E11(model, data, config):
    experiment = compare_amp_scaler_modes(model, data, config, ...)
    report = audit_mixed_precision_gate_gradients(
        experiment, data, config, ...
    )
    assert report is not None
    return report
```

16.8.13 Exercise 12 - Perform a Stabilization Ablation Study

Part 1 - Why this matters

Ablation determines which methods actually contribute on the chosen dataset. A strong full system does not reveal whether dropout, clipping, normalization, scheduling, or decay is useful or redundant.

Removing several components together creates interactions that cannot be attributed. Selecting only favorable seeds or changing training budgets invalidates the comparison.

Define a baseline and controlled component matrix, repeat every condition across seeds, and report uncertainty. Include single additions, single removals from the full system, and selected interaction tests.

Part 2 - Mathematical form

$$\Delta_j = M(S \setminus \{j\}) - M(S), \qquad \Delta_{jk} = M(S \setminus \{j,k\}) - M(S).$$

Part 3 - Hints and Helper

Freeze data splits, initialization seeds, update budgets, and evaluation code across all ablations.

Part 4 - Python code skeleton

```
import torch
def E12(model, data, config):
    experiment = run_stabilization_ablation_matrix(model, data, config, ...)
    report = estimate_component_contributions(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.14 Exercise 13 - Evaluate Robustness under Distribution Shift

Part 1 - Why this matters

Sequence distributions change when event frequency, noise, vocabulary, seasonal structure, or dependency length differs from training. LSTM memory can fail when the stored patterns no longer match the new regime.

Random corruption alone does not identify which temporal property caused failure. Robustness results are also misleading when preprocessing is refitted on shifted test data.

Create controlled shifts one factor at a time, keep training preprocessing fixed, and evaluate degradation by shift severity. Probe states and gates to locate where memory retention breaks.

Part 2 - Mathematical form

$$\Delta M(\delta) = M(P_\delta) - M(P_0), \qquad \delta \in \{\text{noise, length, frequency, regime}\}.$$

Part 3 - Hints and Helper

Compare against a simple baseline to determine whether recurrence helps under each shift.

Part 4 - Python code skeleton

```
import torch
def E13(model, data, config):
    experiment = generate_controlled_sequence_shifts(model, data, config, ...)
    report = map_memory_failure_regions(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.15 Exercise 14 - Calibrate Sequence Predictions over Time

Part 1 - Why this matters

A model is calibrated when predictions with confidence q are correct approximately q of the time. Sequence confidence may change with time step as uncertainty and memory errors accumulate.

Overall calibration can hide severe late-step overconfidence. Padding, class imbalance, and selecting only completed sequences can also bias calibration estimates.

Compute reliability diagrams, expected calibration error, and proper scoring rules per time step or horizon. Compare temperature scaling fitted only on validation data and verify it on an untouched test split.

Part 2 - Mathematical form

$$\mathrm{ECE} = \sum_{b=1}^{B} \frac{|I_b|}{N} \left|\mathrm{acc}(I_b) - \mathrm{conf}(I_b)\right|.$$

Part 3 - Hints and Helper

Preserve masks and report the number of valid observations in every confidence bin.

Part 4 - Python code skeleton

```
import torch
def E14(model, data, config):
    experiment = collect_sequence_confidences(model, data, config, ...)
    report = evaluate_temporal_calibration(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.16 Exercise 15 - Compare Early Stopping and Regularization

Part 1 - Why this matters

Early stopping limits effective optimization time, whereas dropout and weight decay constrain the learned solution throughout training. They may complement each other or create underfitting when combined too aggressively.

A noisy validation metric can stop training by chance, and using the test set for stopping leaks evaluation information. Different patience values also imply different training budgets.

Use a dedicated chronological validation set, save the best model and optimizer state, and compare early stopping alone with explicit regularizers. Measure final quality, runtime saved, and stability across seeds.

Part 2 - Mathematical form

$$e_{\text{stop}} = \min\{e : \ M_{\text{val}} \text{ has not improved for } p \text{ epochs}\}.$$

Part 3 - Hints and Helper

Define minimum improvement and patience before running the experiment.

Part 4 - Python code skeleton

```
import torch
def E15(model, data, config):
    experiment = train_early_stopping_variants(model, data, config, ...)
    report = compare_implicit_explicit_regularization(
        experiment, data, config, ...
    )
    assert report is not None
    return report
```

16.8.17 Exercise 16 - Create an LSTM Failure Debugging Checklist

Part 1 - Why this matters

LSTM failures span data alignment, masks, state lifecycle, gate saturation, gradients, optimizer order, precision, device placement, and evaluation. A checklist turns scattered debugging knowledge into a repeatable diagnostic sequence.

Changing parameters before identifying the earliest failed invariant can hide the symptom without fixing the cause. Unordered checks also waste time by inspecting model complexity before validating data.

Build executable checks ordered from inputs to outputs, attach evidence to every pass or failure, and stop at the first corrupted stage. Test the checklist against intentionally injected defects.

Part 2 - Mathematical form

$$D_0 \to D_1 \to \cdots \to D_K, \qquad k^* = \min\{k : D_k = \text{fail}\}.$$

Part 3 - Hints and Helper

Every checklist item should produce a measurable assertion, not a vague recommendation.

Part 4 - Python code skeleton

```
import torch
def E16(model, data, config):
    experiment = run_lstm_failure_checklist(model, data, config, ...)
    report = validate_checklist_with_fault_injection(
        experiment, data, config, ...
    )
    assert report is not None
    return report
```

16.8.18 Exercise 17 - Analyze Long-Sequence Generalization Limits

Part 1 - Why this matters

Performance on sequences longer than the training range tests whether the model learned a transferable temporal mechanism. Failure may arise from truncated gradients, insufficient hidden capacity, or recurrent state drift.

Increasing hidden size cannot recover dependencies that training truncation prevents from receiving credit. Conversely, full gradients cannot help if the representation lacks capacity or the data provides no signal.

Create a grid of training truncation length, hidden size, and evaluation length. Use controlled memory tasks and state probes to separate optimization horizon from representational capacity.

Part 2 - Mathematical form

$$A(H, K, T) = \text{accuracy}(\text{hidden size } H,\ \text{truncation } K,\ \text{test length } T).$$

Part 3 - Hints and Helper

Vary one axis at a time first, then test interactions near the observed failure boundary.

Part 4 - Python code skeleton

```
import torch
def E17(model, data, config):
    experiment = run_long_sequence_generalization_grid(
        model, data, config, ...
    )
```

```
    report = attribute_truncation_capacity_failure(
        experiment, data, config, ...
    )
    assert report is not None
    return report
```

16.8.19 Exercise 18 - Stress Test Very Long and Wide LSTMs

Part 1 - Why this matters

Very long sequences and large hidden states expose activation-memory growth, recurrent compute cost, kernel limits, and numerical instability. Safe system limits must be measured before large training runs.

An out-of-memory event is only one failure mode; latency spikes, memory leaks, non-finite states, and GPU underutilization may appear earlier. Failed cases must not contaminate later measurements.

Sweep sequence length, hidden size, layer count, batch size, and precision under explicit stop conditions. Record peak memory, throughput, state norms, failures, and recovery behavior to define the operating envelope.

Part 2 - Mathematical form

$$C = \mathcal{O}(BLH(F + H)), \qquad M_{\text{act}} = \mathcal{O}(BLH).$$

Part 3 - Hints and Helper

Warm up each case, synchronize CUDA, and release failed-case objects before continuing.

Part 4 - Python code skeleton

```
import torch
def E18(model, data, config):
    experiment = run_lstm_stress_grid(model, data, config, ...)
    report = identify_memory_runtime_limits(experiment, data, config, ...)
    assert report is not None
    return report
```

16.8.20 Exercise 19 - Write a Practical LSTM Stabilization Guide

Part 1 - Why this matters

A practical guide must connect symptoms to measurements, root causes, interventions, and verified outcomes. Listing techniques without decision criteria does not help an engineer choose the next action.

Recommendations that worked on one dataset may fail under different lengths, noise, hardware, or objectives. The guide must distinguish broadly reliable invariants from task-specific

findings.

Assemble experiment tables, diagnostic thresholds, decision paths, failure examples, performance costs, and reproducibility information. Link each recommendation to evidence and document unresolved limits.

Part 2 - Mathematical form

$$\mathcal{G} = \{S, E, C, F, R\}, \qquad S \to E \to C \to F \to R.$$

Part 3 - Hints and Helper

For every strategy, state when to use it, how to verify it, its cost, and when to stop using it.

Part 4 - Python code skeleton

```
import torch
def E19(model, data, config):
    experiment = collect_stabilization_evidence(model, data, config, ...)
    report = build_engineering_strategy_guide(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9 LSTM07 - Efficiency, Profiling, and Deployment

Applied AI and Deployment

16.9.1 Exercise 00 - Benchmark LSTM vs GRU Runtime and Memory

Part 1 - Why this matters

LSTM maintains four gate transformations and separate hidden and cell states, whereas GRU uses fewer gates and one principal recurrent state. This usually makes LSTM heavier, but its additional memory control may preserve dependencies that justify the cost.

An equal hidden-size comparison gives the architectures different parameter counts, while an equal-parameter comparison requires different widths. Timing asynchronous CUDA execution or comparing different sequence batches invalidates either result.

Benchmark equal-width and matched-parameter models with identical data, warm-up, precision, and update counts. Report runtime, peak memory, throughput, validation quality, and the dependency lengths where LSTM's extra cost becomes useful.

Part 2 - Mathematical form

$$N_{\text{LSTM}} \approx 4H(D + H + 1), \qquad N_{\text{GRU}} \approx 3H(D + H + 1).$$

Part 3 - Hints and Helper

Synchronize CUDA around timed regions. Report equal-width and matched-parameter results separately.

Part 4 - Python code skeleton

```
import torch
def E00(model, data, config):
    experiment = benchmark_lstm_gru(model, data, config, ...)
    report = explain_quality_cost_tradeoff(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.2 Exercise 01 - Profile LSTM Training with PyTorch Profiler

Part 1 - Why this matters

A profiler reveals which operators consume execution time, allocate memory, or force synchronization. LSTM training combines recurrent kernels, tensor transfers, loss computation, backward operations, and optimizer updates, so intuition alone cannot identify the true bottleneck.

Collecting every trace for an entire run adds significant overhead and can distort the workload. Kernel time without shape, call count, and memory context may also point to the wrong optimization target.

Profile scheduled warm-up and active steps, group results by operator and input shape, and inspect CPU and CUDA timelines. Rank bottlenecks by total cost and verify each proposed fix with a second controlled profile.

Part 2 - Mathematical form

$$t_{\text{step}} = t_{\text{input}} + t_{\text{forward}} + t_{\text{backward}} + t_{\text{update}}.$$

Part 3 - Hints and Helper

Use a short profiler schedule and export a trace only for representative steps.

Part 4 - Python code skeleton

```
import torch
def E01(model, data, config):
    experiment = profile_lstm_training(model, data, config, ...)
    report = rank_kernel_memory_bottlenecks(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.3 Exercise 02 - Reduce Padding Waste and Improve GPU Utilization

Part 1 - Why this matters

Variable-length sequences padded to the longest item in a batch can waste most recurrent computation. Length-aware batching and appropriate collation increase the fraction of tokens that contain real information.

Aggressive sorting may reduce randomness, change class balance within batches, or break stateful stream order. A faster pipeline is invalid if targets, masks, or sample identities become misaligned.

Measure padding ratio, loader time, transfer time, and GPU utilization before changing the pipeline. Compare random batching, length buckets, dynamic batches, and token-budget batching while verifying identical valid outputs.

Part 2 - Mathematical form

$$w_{\text{pad}} = 1 - \frac{\sum_i T_i}{B \max_i T_i}.$$

Part 3 - Hints and Helper

Log valid and padded token counts for every batch instead of estimating waste from one example.

Part 4 - Python code skeleton

```
import torch
def E02(model, data, config):
    experiment = optimize_sequence_batching(model, data, config, ...)
    report = measure_padding_utilization_gain(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.4 Exercise 03 - Compare Packed and Padded Runtime

Part 1 - Why this matters

Packed sequences allow supported recurrent operations to skip padded time steps. The benefit depends on the length distribution, packing overhead, device implementation, and how much downstream work still uses padded tensors.

Packed execution can be slower when sequences have similar lengths or batches are small. Incorrect sorting, unsorting, or length placement may also preserve shapes while misaligning outputs and targets.

Benchmark packed and padded pipelines across controlled length distributions, then verify numerical equivalence at valid positions. Include packing, sorting, transfer, recurrent execution, and unpacking in end-to-end timing.

Part 2 - Mathematical form

$$S = \frac{t_{\text{padded}}}{t_{\text{packed}}}, \qquad \rho = \frac{\sum_i T_i}{BT_{\max}}.$$

Part 3 - Hints and Helper

Restore original sample order before comparing outputs or metrics.

Part 4 - Python code skeleton

```
import torch
def E03(model, data, config):
    experiment = benchmark_packed_padded(model, data, config, ...)
    report = verify_speed_and_output_parity(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.5 Exercise 04 - Measure Sequence-Length Scaling

Part 1 - Why this matters

LSTM computation is sequential across time, so longer inputs increase latency and activation storage. The practical limit depends on batch size, hidden width, layers, precision, and the available GPU.

Testing until the first out-of-memory error misses earlier limits such as unacceptable latency, falling throughput, numerical drift, or reduced batch capacity. Cold-start measurements can also exaggerate short-sequence cost.

Sweep sequence lengths geometrically, warm up each case, and record throughput, latency, peak memory, and state statistics. Define limits from explicit service or training budgets rather than memory alone.

Part 2 - Mathematical form

$$C = \mathcal{O}(BLH(D + H)), \qquad M_{\text{act}} = \mathcal{O}(BLH).$$

Part 3 - Hints and Helper

Keep other dimensions fixed during the first sweep, then test interactions near the limit.

Part 4 - Python code skeleton

```
import torch
def E04(model, data, config):
    experiment = benchmark_sequence_lengths(model, data, config, ...)
    report = identify_practical_gpu_limit(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.6 Exercise 05 - Compare batch_first and Memory Layout

Part 1 - Why this matters

The `batch_first` option changes the public tensor layout but not the mathematical recurrence. Performance differences can arise from transposes, contiguous copies, downstream operators, or how the input pipeline already stores data.

Comparing only the LSTM call may exclude layout-conversion cost that appears in the real pipeline. Non-contiguous tensors may also trigger hidden copies and make the result configuration-dependent.

Create equivalent time-first and batch-first pipelines, inspect strides and contiguity, and time both conversion-inclusive and kernel-only execution. Verify output and state parity after explicit axis mapping.

Part 2 - Mathematical form

$$X_{\mathrm{BF}} \in \mathbb{R}^{B \times T \times D}, \qquad X_{\mathrm{TF}} = X_{\mathrm{BF}}^{(1,0,2)}.$$

Part 3 - Hints and Helper

Report tensor strides and whether a contiguous copy occurs before the recurrent call.

Part 4 - Python code skeleton

```
import torch
def E05(model, data, config):
    experiment = benchmark_batch_first_layouts(model, data, config, ...)
    report = explain_layout_performance(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.7 Exercise 06 - Scale Hidden Size and Layer Count

Part 1 - Why this matters

Hidden size increases both recurrent capacity and quadratic hidden-to-hidden work, while additional layers multiply recurrent computation and activation storage. Scaling curves reveal where larger models stop producing useful quality gains.

Changing width and depth simultaneously prevents attribution, and failed large cases can leave reserved CUDA memory that contaminates later measurements. Parameter count alone does not describe activation cost.

Sweep width and depth in controlled stages, restart or clean resources between cases, and record parameters, FLOPs estimates, latency, throughput, peak memory, and validation quality. Build quality-cost Pareto curves.

Part 2 - Mathematical form

$$N \propto L_{\text{layers}}\, 4H(D + H + 1).$$

Part 3 - Hints and Helper

Measure steady-state allocated and peak memory, not only reserved memory after a failure.

Part 4 - Python code skeleton

```
import torch
def E06(model, data, config):
    experiment = benchmark_lstm_scaling_grid(model, data, config, ...)
    report = build_runtime_memory_curves(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.8 Exercise 07 - Diagnose an Under-Utilized GPU

Part 1 - Why this matters

Low GPU utilization usually means the device is waiting for input, transfers, synchronization, or very small kernels. LSTM workloads can also be sequential enough that additional hardware remains idle.

A dashboard percentage without a timeline cannot distinguish data stalls from kernel gaps. Increasing workers blindly may create CPU contention, excess memory, or nondeterministic loader failures.

Measure data wait, transfer, compute, padding ratio, and kernel occupancy, then modify one bottleneck at a time. Validate improvements using end-to-end throughput and unchanged model outputs.

Part 2 - Mathematical form

$$U_{\text{effective}} = \frac{t_{\text{GPU busy}}}{t_{\text{wall}}}.$$

Part 3 - Hints and Helper

Start with a synthetic in-memory loader to separate model limits from pipeline limits.

Part 4 - Python code skeleton

```
import torch
def E07(model, data, config):
    experiment = diagnose_gpu_underutilization(model, data, config, ...)
    report = apply_verified_pipeline_fixes(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.9 Exercise 08 - Compare float32 and Mixed Precision

Part 1 - Why this matters

Mixed precision can accelerate matrix operations and reduce activation memory, enabling larger batches. Recurrent gates and long state chains may nevertheless be more sensitive to overflow, underflow, and saturation.

Speedup measured on an unstable model is not useful. Autocast-only training, missing gradient scaling, or unequal batch sizes can make the comparison misleading.

Compare float32 and mixed precision with matched workloads, record throughput, memory, non-finite events, skipped steps, and validation quality. Increase sequence length to document the stable operating region.

Part 2 - Mathematical form

$$S_{\mathrm{AMP}} = \frac{t_{\mathrm{FP32}}}{t_{\mathrm{AMP}}}, \qquad \Delta M = M_{\mathrm{AMP}} - M_{\mathrm{FP32}}.$$

Part 3 - Hints and Helper

Unscale before clipping and include scaler behavior in the benchmark report.

Part 4 - Python code skeleton

```
import torch
def E08(model, data, config):
    experiment = benchmark_precision_modes(model, data, config, ...)
    report = document_amp_stability_constraints(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.10 Exercise 09 - Measure Gradient-Clipping Overhead

Part 1 - Why this matters

Gradient clipping requires norm reductions over trainable parameters and may add synchronization or memory traffic. Its runtime cost must be balanced against avoided divergence and improved recoverability.

Measuring only the clipping function ignores how often clipping changes the gradient. A low threshold can add cost while also altering every update and slowing convergence.

Benchmark clipping disabled and several thresholds, record step latency and the clipped-step fraction, and compare failed runs or recovered checkpoints. Decide value from both overhead and stability benefit.

Part 2 - Mathematical form

$$O_c = \frac{t_c - t_0}{t_0}, \qquad f_c = \frac{\#\{\|g_t\| > c\}}{N_{\text{steps}}}.$$

Part 3 - Hints and Helper

Measure unclipped norms before modification and synchronize CUDA for microbenchmarks.

Part 4 - Python code skeleton

```
import torch
def E09(model, data, config):
    experiment = benchmark_gradient_clipping(model, data, config, ...)
    report = evaluate_clipping_value(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.11 Exercise 10 - Use Gradient Accumulation under Memory Limits

Part 1 - Why this matters

Gradient accumulation divides an effective large batch into microbatches whose gradients are summed before one optimizer step. It allows larger effective batches without storing all activations simultaneously.

Forgetting to divide the loss changes gradient scale, and stepping the scheduler per microbatch changes optimization. Stateful recurrence and variable token counts require especially careful weighting.

Implement accumulation with correct normalization, compare it against a true large batch, and verify parameter-update parity on a deterministic example. Measure memory, throughput, convergence, and effective token count.

Part 2 - Mathematical form

$$g_{\text{eff}} = \frac{1}{K}\sum_{k=1}^{K} g_k, \qquad B_{\text{eff}} = KB_{\text{micro}}.$$

Part 3 - Hints and Helper

Zero gradients and step the optimizer only at accumulation boundaries.

Part 4 - Python code skeleton

```
import torch
def E10(model, data, config):
    experiment = train_with_gradient_accumulation(model, data, config, ...)
    report = compare_true_and_effective_batches(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.12 Exercise 11 - Build Reproducible CUDA Benchmark Tables

Part 1 - Why this matters

A benchmark table is useful only when another engineer can reproduce its workload and measurement conditions. Hardware, software, precision, shapes, warm-up, seeds, and timing boundaries all affect LSTM results.

Reporting a single best latency hides variance, cold-start behavior, and failed cases. Comparing experiments performed with different clocks, loaders, or deterministic settings produces false rankings.

Build a benchmark harness that records environment metadata and repeated measurements, then reports median and tail latency, throughput, memory, and quality. Export raw records beside summary tables.

Part 2 - Mathematical form

$$\widetilde{t} = \text{median}(t_1, \ldots, t_n), \qquad p_{95} = \text{quantile}_{0.95}(t).$$

Part 3 - Hints and Helper

Record exact tensor shapes and synchronization rules for every row.

Part 4 - Python code skeleton

```
import torch
def E11(model, data, config):
    experiment = run_reproducible_cuda_benchmarks(model, data, config, ...)
    report = create_benchmark_tables(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.13 Exercise 12 - Investigate cuDNN LSTM Non-Determinism

Part 1 - Why this matters

Some CUDA kernels may select algorithms or use parallel reductions whose operation order changes across runs. Small numerical differences can grow through recurrent steps and affect final training outcomes.

A different result does not automatically prove kernel non-determinism; data order, initialization, dropout, workers, and mixed precision are alternative causes. Forcing determinism may also reduce performance.

Control every known random source, repeat identical forward and training runs, and compare tensors at each stage. Change deterministic settings one at a time and document the first divergence and its performance cost.

Part 2 - Mathematical form

$$\delta_t = \|h_t^{(a)} - h_t^{(b)}\|_\infty.$$

Part 3 - Hints and Helper

Separate bitwise equality from tolerance-based numerical equivalence.

Part 4 - Python code skeleton

```
import torch
def E12(model, data, config):
    experiment = run_cudnn_determinism_trials(model, data, config, ...)
    report = locate_and_explain_divergence(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.14 Exercise 13 - Export LSTM with TorchScript

Part 1 - Why this matters

TorchScript can package model computation independently from ordinary Python execution and may simplify deployment. Export success is insufficient unless state handling, dynamic sequence lengths, and outputs remain correct.

Tracing can freeze control flow or miss branches, while scripting may reject unsupported Python constructs. Comparing only one shape may hide failures in dynamic batches or recurrent states.

Export with an appropriate method, test a matrix of shapes and state configurations, and compare outputs with strict tolerances. Benchmark cold and warm latency including state initialization.

Part 2 - Mathematical form

$$\epsilon_{\max} = \max_i |y_i^{\text{native}} - y_i^{\text{export}}|.$$

Part 3 - Hints and Helper

Test both fresh-state and carried-state inference after export.

Part 4 - Python code skeleton

```
import torch
def E13(model, data, config):
    experiment = export_torchscript_lstm(model, data, config, ...)
    report = validate_export_parity_latency(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.15 Exercise 14 - Export LSTM to ONNX

Part 1 - Why this matters

ONNX enables execution in alternative runtimes, but recurrent operators, packed sequences, dynamic axes, and state tuples can create portability problems. A valid graph may still behave incorrectly for unseen shapes.

Hard-coded batch or sequence dimensions often pass the sample export test and fail in production. Unsupported operations may be replaced in ways that change semantics or precision.

Export with explicit inputs, states, outputs, and dynamic axes, inspect the graph, and validate several runtimes and shapes. Record unsupported cases and implement only verified simplifications.

Part 2 - Mathematical form

$$f_\theta^{\text{PyTorch}}(X, h, c) \approx f_\theta^{\text{ONNX}}(X, h, c).$$

Part 3 - Hints and Helper

Use real dynamic-shape tests rather than trusting symbolic axis declarations.

Part 4 - Python code skeleton

```
import torch
def E14(model, data, config):
    experiment = export_lstm_to_onnx(model, data, config, ...)
    report = validate_onnx_edge_cases(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.16 Exercise 15 - Build a Production Inference Benchmark

Part 1 - Why this matters

Production inference must satisfy latency and throughput requirements across realistic batches and sequence lengths. Queueing, preprocessing, state handling, and synchronization contribute alongside model execution.

Average latency hides tail spikes, and maximum throughput at a large batch may violate per-request delay targets. Synthetic zero inputs can also exercise different paths from real traffic.

Replay representative request distributions, separate cold and warm results, and measure median, p95, p99, throughput, memory, and error rate. Locate the batch-size point that satisfies the service objective.

Part 2 - Mathematical form

$$L_q = \text{quantile}_q(t_{\text{request}}), \qquad Q = \frac{N_{\text{requests}}}{t_{\text{wall}}}.$$

Part 3 - Hints and Helper

Include preprocessing and state initialization in one end-to-end benchmark view.

Part 4 - Python code skeleton

```
import torch
def E15(model, data, config):
    experiment = run_production_inference_load(model, data, config, ...)
    report = summarize_latency_throughput_slo(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.17 Exercise 16 - Checkpoint and Resume Training

Part 1 - Why this matters

A recoverable checkpoint must preserve model parameters, optimizer moments, scheduler position, gradient-scaler state, epoch, step, seeds, and relevant data progress. Saving only model weights does not reproduce continuation.

A checkpoint can load successfully while resuming with a different learning rate, data order, or mixed-precision scale. Partial writes may also leave a corrupted file that is discovered only during an incident.

Save atomically, verify integrity, interrupt a controlled run, and resume from the checkpoint. Compare the resumed trajectory with an uninterrupted reference and measure recovery time.

Part 2 - Mathematical form

$$S_k = \{\theta_k, O_k, R_k, G_k, e_k, s_k\}.$$

Part 3 - Hints and Helper

Write to a temporary object and publish only after integrity validation.

Part 4 - Python code skeleton

```
import torch
def E16(model, data, config):
    experiment = run_checkpoint_recovery_test(model, data, config, ...)
    report = verify_resumed_state_consistency(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.18 Exercise 17 - Stress Test Stateful Long-Sequence Inference

Part 1 - Why this matters

Long-sequence inference exposes cumulative latency, state growth, memory leaks, and incorrect state carry between independent requests. A fixed-shape hidden state does not guarantee fixed process memory.

Reusing a state across unrelated streams leaks information, while resetting within one stream destroys continuity. Retained computation graphs or cached outputs can cause gradual memory growth.

Run thousands of varied requests with explicit stream identifiers, monitor memory and latency over time, and inject resets and interleaving. Detect leaks, tail spikes, and cross-stream state contamination.

Part 2 - Mathematical form

$$\Delta m_n = m_n - m_0, \qquad \Delta L_n = L_n - \widetilde{L}_{\text{warm}}.$$

Part 3 - Hints and Helper

Use inference mode and assert that every stored state is detached and belongs to the correct stream.

Part 4 - Python code skeleton

```
import torch
def E17(model, data, config):
    experiment = stress_stateful_inference(model, data, config, ...)
    report = detect_leaks_spikes_state_bugs(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.19 Exercise 18 - Build a Deployment Readiness Checklist

Part 1 - Why this matters

Deployment readiness combines correctness, performance, stability, reproducibility, monitoring, recovery, and interface compatibility. Passing an accuracy threshold covers only one part of operational risk.

A checklist made of vague statements cannot block unsafe releases. Every item needs evidence, an owner, an acceptance threshold, and a response when the threshold fails.

Create executable checks for input contracts, export parity, latency, memory, determinism, state lifecycle, monitoring, rollback, and checkpoint recovery. Produce a signed readiness result with unresolved risks.

Part 2 - Mathematical form

$$R = \bigwedge_{i=1}^{N} \mathbf{1}[m_i \in A_i].$$

Part 3 - Hints and Helper

Separate mandatory release gates from advisory observations.

Part 4 - Python code skeleton

```
import torch
def E18(model, data, config):
    experiment = run_deployment_readiness_checks(model, data, config, ...)
    report = produce_release_decision(experiment, data, config, ...)
    assert report is not None
    return report
```

16.9.20 Exercise 19 - Produce the LSTM Performance Report

Part 1 - Why this matters

A complete engineering report connects architecture, workload shapes, profiler evidence, scaling curves, exports, production benchmarks, and recovery behavior. Isolated speed numbers cannot guide deployment decisions.

Cherry-picked configurations hide tradeoffs and failure boundaries. Results without environment metadata, raw measurements, and quality checks cannot be reproduced or trusted.

Assemble verified curves, tables, profiler findings, parity tests, incidents, and best practices. Distinguish measured facts from interpretation and publish a safe operating envelope.

Part 2 - Mathematical form

$$\mathcal{R} = \{E, W, P, S, X, L, C, F, B\}.$$

Part 3 - Hints and Helper

Link every recommendation to a benchmark record or failure experiment.

Part 4 - Python code skeleton

```
import torch
def E19(model, data, config):
    experiment = collect_lstm_performance_artifacts(model, data, config, ...)
    report = build_complete_engineering_report(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10 LSTM08 - Bridge to Attention and Why Transformers Win

Models and Training

16.10.1 Exercise 00 - Demonstrate Very-Long-Context LSTM Failure

Part 1 - Why this matters

LSTM gates improve gradient flow, but a fixed-size recurrent state must still compress an arbitrarily long history. Controlled memory tasks can expose where accuracy falls as the required dependency moves farther into the past.

A failure may come from insufficient training coverage, truncated gradients, noise, or hidden capacity rather than context length alone. Testing one model at one length cannot separate these causes.

Train across controlled dependency distances, evaluate beyond the training range, and sweep capacity and truncation length. Plot accuracy, state sensitivity, and gradient signal against context length.

Part 2 - Mathematical form

$$A(T) = \Pr(\widehat{y}_T = y_T), \qquad T \uparrow \Rightarrow A(T) \downarrow \text{ after the memory limit.}$$

Part 3 - Hints and Helper

Remove positional and frequency shortcuts from the synthetic task.

Part 4 - Python code skeleton

```
import torch
def E00(model, data, config):
    experiment = run_long_context_memory_trials(model, data, config, ...)
    report = quantify_lstm_context_degradation(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.2 Exercise 01 - Explain Sequential Computation Limits

Part 1 - Why this matters

An LSTM must compute state t before state $t + 1$, creating a critical path across the entire sequence. Attention can compute token projections in parallel and then relate positions through matrix operations.

Attention is not always faster: its quadratic pairwise work can dominate for long sequences, small batches, or limited memory. The relevant comparison depends on sequence length, hardware, and implementation.

Measure kernel timelines and scaling for recurrent and attention layers across sequence lengths. Separate available parallelism, total operations, memory use, and end-to-end throughput.

Part 2 - Mathematical form

$$T_{\mathrm{LSTM}} \geq \sum_{t=1}^{L} T_t, \qquad T_{\mathrm{attn}} \approx T_Q + T_K + T_V + T_{QK^\top}.$$

Part 3 - Hints and Helper

Explain both the recurrent critical path and attention's quadratic memory cost.

Part 4 - Python code skeleton

```
import torch
def E01(model, data, config):
    experiment = benchmark_parallelism_limits(model, data, config, ...)
    report = compare_lstm_attention_scaling(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.3 Exercise 02 - Add Simple Additive Attention

Part 1 - Why this matters

Additive attention allows a decoder to form a context vector from all encoder outputs instead of relying only on one final state. Learned scores can select the time steps most useful for the current prediction.

Wrong tensor broadcasting or score reduction may produce normalized weights with incorrect semantics. Attention can also appear to help simply because it adds parameters.

Implement the score equation explicitly, validate shapes and normalization, and compare with a parameter-controlled LSTM baseline. Inspect quality as dependency distance increases.

Part 2 - Mathematical form

$$e_{t,s} = v^\top \tanh(W_h h_s + W_q q_t + b), \quad \alpha_{t,s} = \mathrm{softmax}_s(e_{t,s}), \quad c_t = \sum_s \alpha_{t,s} h_s.$$

Part 3 - Hints and Helper

Softmax must normalize across valid encoder time steps for each decoder query.

Part 4 - Python code skeleton

```
import torch
def E02(model, data, config):
    experiment = implement_additive_attention(model, data, config, ...)
    report = measure_attention_quality_gain(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.4 Exercise 03 - Implement Dot-Product Attention

Part 1 - Why this matters

Dot-product attention scores compatibility using vector products and maps naturally to efficient batched matrix multiplication. Scaling prevents large dimensions from pushing softmax into extremely sharp distributions.

Additive and dot-product attention are not comparable when dimensions, projections, parameter counts, or masks differ. Omitting the scale can cause saturation as key dimension grows.

Implement projected queries, keys, and values, validate against a manual tiny example, and compare quality, runtime, memory, and attention entropy with additive attention.

Part 2 - Mathematical form

$$A = \operatorname{softmax}\left(\frac{QK^\top}{\sqrt{d_k}} + M\right) V.$$

Part 3 - Hints and Helper

Check the softmax axis and validate masked positions receive zero probability.

Part 4 - Python code skeleton

```
import torch
def E03(model, data, config):
    experiment = implement_dot_product_attention(model, data, config, ...)
    report = compare_additive_dot_product(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.5 Exercise 04 - Visualize Attention over Time

Part 1 - Why this matters

Attention maps expose how decoder decisions distribute weight across encoder positions. They can reveal alignment, diffuse uncertainty, padding leakage, or repeated focus on an irrelevant token.

A heatmap is not a causal explanation, and raw colors can mislead when rows use different scales. Token and time labels must remain aligned after sorting and padding.

Build a visualization from verified weights, labels, masks, and sample identities. Pair the heatmap with entropy, top-attended positions, predictions, and failure examples.

Part 2 - Mathematical form

$$H(\alpha_t) = -\sum_s \alpha_{t,s} \log(\alpha_{t,s} + \epsilon).$$

Part 3 - Hints and Helper

Use a common color scale and display masked cells explicitly.

Part 4 - Python code skeleton

```
import torch
def E04(model, data, config):
    experiment = collect_attention_maps(model, data, config, ...)
    report = visualize_and_interpret_attention(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.6 Exercise 05 - Build an LSTM Encoder-Decoder with Attention

Part 1 - Why this matters

A sequence-to-sequence model uses an encoder to represent the source and a decoder to produce targets step by step. Attention lets each decoder step retrieve a different source context.

Source masks, shifted decoder inputs, state shapes, and target alignment must all agree. A model can train while predicting the current target from itself if decoder shifting is wrong.

Implement the full data flow with explicit states and masks, assert every tensor shape, and overfit a tiny aligned example. Compare teacher-forced and autoregressive decoding.

Part 2 - Mathematical form

$$h_{1:S} = E(x_{1:S}), \qquad y_t = D(y_{t-1}, c_t, s_{t-1}).$$

Part 3 - Hints and Helper

Verify decoder input at step t never contains target y_t.

Part 4 - Python code skeleton

```
import torch
def E05(model, data, config):
    experiment = build_attention_seq2seq(model, data, config, ...)
    report = validate_seq2seq_alignment(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.7 Exercise 06 - Compare Copy Task with and without Attention

Part 1 - Why this matters

A copy task requires the decoder to recover ordered source information and can expose the fixed-vector bottleneck. Attention should allow direct retrieval of relevant positions as sequence length increases.

Trivial token patterns, fixed lengths, or positional shortcuts may let both models succeed without meaningful memory. Different parameter budgets can also explain apparent gains.

Generate random variable-length sequences, train matched encoder-decoder models, and evaluate exact-match accuracy across lengths beyond training. Inspect attention alignment against the known copy correspondence.

Part 2 - Mathematical form

$$y_{1:S} = x_{1:S}, \qquad \alpha^*_{t,s} \approx \mathbf{1}[t = s].$$

Part 3 - Hints and Helper

Use exact sequence match in addition to token accuracy.

Part 4 - Python code skeleton

```
import torch
def E06(model, data, config):
    experiment = run_copy_task_comparison(model, data, config, ...)
    report = measure_attention_alignment_gain(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.8 Exercise 07 - Diagnose Attention Mask and Softmax Bugs

Part 1 - Why this matters

Attention failures often come from normalizing across the wrong dimension, applying a mask after softmax, reversing mask meaning, or misaligning sorted sequences. The output can remain finite and train slowly despite invalid weights.

Checking only whether every tensor has the expected shape is insufficient. Weights must sum to one across valid keys and be exactly zero on padded positions.

Create small hand-calculated cases and fault injections for axes, masks, and ordering. Build assertions that identify the violated invariant before training begins.

Part 2 - Mathematical form

$$\sum_{s \in V_i} \alpha_{i,t,s} = 1, \qquad \alpha_{i,t,s} = 0 \text{ for } s \notin V_i.$$

Part 3 - Hints and Helper

Apply the padding mask to logits before softmax using a sufficiently negative value.

Part 4 - Python code skeleton

```
import torch
def E07(model, data, config):
    experiment = inject_attention_faults(model, data, config, ...)
    report = detect_mask_softmax_alignment_bugs(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.9 Exercise 08 - Measure CUDA Cost and Quality of Attention

Part 1 - Why this matters

Adding attention increases projections, score matrices, softmax work, and activation memory, but it may reduce the burden on recurrent state compression. The tradeoff should be evaluated jointly in quality and system cost.

Timing different batch shapes or excluding attention-map storage makes overhead estimates unfair. Quality gains from extra parameters must be separated from gains due to retrieval.

Benchmark pure LSTM and LSTM-attention models with matched workloads and controlled capacity. Report throughput, latency, peak memory, utilization, and long-dependency accuracy.

Part 2 - Mathematical form

$$O_A = \frac{t_{\text{LSTM+A}} - t_{\text{LSTM}}}{t_{\text{LSTM}}}, \qquad \Delta Q = Q_{\text{LSTM+A}} - Q_{\text{LSTM}}.$$

Part 3 - Hints and Helper

Measure training and inference separately because backward attention storage changes the cost.

Part 4 - Python code skeleton

```
import torch
def E08(model, data, config):
    experiment = benchmark_lstm_attention_cuda(model, data, config, ...)
    report = calculate_quality_cost_tradeoff(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.10 Exercise 09 - Produce the Bridge-to-Transformers Report

Part 1 - Why this matters

Attention removes the requirement that all source information pass through one final encoder vector. Transformers extend this idea by replacing recurrent token processing with stacked attention and parallel feed-forward computation.

The transition is not simply that attention is always superior. Recurrent state offers linear memory in sequence length, while full attention has quadratic pairwise storage and different deployment behavior.

Synthesize evidence from memory tasks, copy alignment, profiler traces, and scaling curves. Explain which bottleneck attention solves, which costs it introduces, and why self-attention enables the Transformer architecture.

Part 2 - Mathematical form

$$\text{fixed state} \rightarrow \text{attention retrieval} \rightarrow \text{self-attention layers}.$$

Part 3 - Hints and Helper

Use experimental evidence from earlier exercises rather than architecture slogans.

Part 4 - Python code skeleton

```
import torch
def E09(model, data, config):
    experiment = collect_attention_bridge_evidence(model, data, config, ...)
    report = write_transformer_bridge_report(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.11 Exercise 10 - Quantify the Encoder-Decoder Bottleneck

Part 1 - Why this matters

Without attention, a decoder depends heavily on a fixed-dimensional encoder state. As source length and information content grow, this compression can discard details needed for accurate reconstruction.

Poor performance may instead arise from an undertrained decoder or insufficient total capacity. A valid bottleneck experiment must vary source information while controlling optimization.

Increase source length and entropy, compare final-state reconstruction with access to all encoder outputs, and probe how much source information remains decodable. Report failure by position.

Part 2 - Mathematical form

$$z = f(x_{1:S}) \in \mathbb{R}^H, \qquad I(z; x_{1:S}) \text{ is capacity-limited.}$$

Part 3 - Hints and Helper

Use position-wise error to show which source regions are lost first.

Part 4 - Python code skeleton

```
import torch
def E10(model, data, config):
    experiment = run_encoder_bottleneck_trials(model, data, config, ...)
    report = quantify_information_loss(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.12 Exercise 11 - Masked Attention for Variable Lengths

Part 1 - Why this matters

Variable-length batches require padding, but padded encoder positions contain no source information. Masked attention must exclude them before normalization so sequence length does not change valid weights.

Masking after softmax leaves probability mass on padding, while a wrong broadcast shape can mask valid tokens for only some batches or decoder steps.

Construct masks from trusted lengths, apply them to score logits, and validate against individually processed sequences. Test minimum length, full length, and mixed batches.

Part 2 - Mathematical form

$$\alpha = \text{softmax}(E + M), \qquad M_s = \begin{cases} 0 & s \text{ valid} \\ -\infty & s \text{ padded.} \end{cases}$$

Part 3 - Hints and Helper

Assert padded probabilities are zero and valid probabilities sum to one.

Part 4 - Python code skeleton

```
import torch
def E11(model, data, config):
    experiment = implement_masked_attention(model, data, config, ...)
    report = validate_padding_invariance(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.13 Exercise 12 - Compare Attention Distributions by Length

Part 1 - Why this matters

Attention behavior may become sharper, more diffuse, or position-biased as sequence length grows. Distribution statistics help reveal whether the model still retrieves relevant evidence or loses focus.

Raw entropy increases with the number of available positions, so unnormalized values cannot be compared directly across lengths. Padding and task difficulty must also be controlled.

Collect attention across length bins, compute normalized entropy, peak mass, effective support, and alignment accuracy, and relate these measures to prediction quality.

Part 2 - Mathematical form

$$H_{\text{norm}}(\alpha) = \frac{-\sum_s \alpha_s \log \alpha_s}{\log |V|}.$$

Part 3 - Hints and Helper

Compare only valid positions and report sample counts for every length bin.

Part 4 - Python code skeleton

```
import torch
def E12(model, data, config):
    experiment = analyze_attention_by_length(model, data, config, ...)
    report = interpret_distribution_changes(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.14 Exercise 13 - Profile Parallelism Added by Attention

Part 1 - Why this matters

Attention score computation uses batched matrix operations across positions and exposes more intra-step parallelism than pure recurrence. The surrounding LSTM encoder and decoder remain sequential, so only part of the pipeline benefits.

High GPU utilization does not prove lower latency, and profiler traces can confuse concurrent kernels with true end-to-end speedup. Sequence length changes both available parallelism and attention cost.

Profile pure LSTM, LSTM with attention, and a small self-attention block across lengths. Compare critical paths, kernel occupancy, memory traffic, and throughput.

Part 2 - Mathematical form

$$P = \frac{\text{parallelizable work}}{\text{total work}}, \qquad S \leq \frac{1}{(1-P) + P/N}.$$

Part 3 - Hints and Helper

Mark recurrent and attention regions separately in the profiler trace.

Part 4 - Python code skeleton

```
import torch
def E13(model, data, config):
    experiment = profile_attention_parallelism(model, data, config, ...)
    report = compare_gpu_critical_paths(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.15 Exercise 14 - Clip Gradients in LSTM plus Attention

Part 1 - Why this matters

Combining recurrent paths with attention projections creates additional gradient routes and can increase norm spikes on long sequences. Clipping may stabilize training while preserving attention alignment.

A threshold chosen for pure LSTM may over-clip the combined model. Global clipping can also hide whether instability begins in recurrent, attention, or output parameters.

Log component-wise and global norms, sweep thresholds, and measure clipped-step frequency, convergence, and alignment quality. Compare global clipping with targeted diagnostics.

Part 2 - Mathematical form

$$g' = g \min\left(1, \frac{c}{\|g\|_2 + \epsilon}\right).$$

Part 3 - Hints and Helper

Measure component norms before applying one global clipping operation.

Part 4 - Python code skeleton

```
import torch
def E14(model, data, config):
    experiment = train_attention_clip_grid(model, data, config, ...)
    report = evaluate_long_sequence_stability(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.16 Exercise 15 - Choose LSTM, LSTM plus Attention, or Transformer

Part 1 - Why this matters

Architecture choice depends on dependency structure, data volume, latency, memory, sequence length, streaming needs, and deployment hardware. No single model family dominates every operating region.

Choosing by popularity ignores constraints, while choosing by one benchmark ignores robustness and maintenance. Streaming state and quadratic attention memory can reverse conclusions from offline accuracy.

Build a decision checklist with measurable thresholds and evaluate representative workloads for all three options. Record the evidence and unresolved risks behind the final selection.

Part 2 - Mathematical form

$$a^* = \arg\min_{a \in A} \{\lambda_L L_a + \lambda_M M_a - \lambda_Q Q_a + \lambda_R R_a\}.$$

Part 3 - Hints and Helper

Separate hard constraints from weighted preferences in the decision.

Part 4 - Python code skeleton

```
import torch
def E15(model, data, config):
    experiment = run_architecture_selection_checks(model, data, config, ...)
    report = recommend_sequence_architecture(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.17 Exercise 16 - Export LSTM plus Attention

Part 1 - Why this matters

Exporting attention adds masks, dynamic source and target lengths, state tuples, and batched score operations to the recurrent deployment graph. These increase interface and runtime complexity beyond pure LSTM.

A successful export on one shape may freeze dimensions or mask assumptions. Alternative runtimes may implement recurrent and attention operators with different performance and precision.

Export both models, validate output and attention parity over a shape matrix, and compare graph size, latency, memory, and unsupported cases. Document required preprocessing and state contracts.

Part 2 - Mathematical form

$$\epsilon = \max |y^{\text{native}} - y^{\text{export}}|.$$

Part 3 - Hints and Helper

Test dynamic lengths, all-valid masks, mixed masks, and carried decoder states.

Part 4 - Python code skeleton

```
import torch
def E16(model, data, config):
    experiment = export_lstm_attention_model(model, data, config, ...)
    report = compare_deployment_complexity(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.18 Exercise 17 - Stress Test Long Attention Sequences

Part 1 - Why this matters

Attention can preserve access to distant encoder outputs, but score matrices grow with source and query lengths. Eventually memory and quadratic work may outweigh the retrieval benefit.

Testing only until out-of-memory ignores earlier latency and throughput limits. LSTM-attention differs from full self-attention, so its source-target score shape must be reported explicitly.

Sweep source length, target length, batch size, and precision, measuring quality, latency, memory, and failures. Identify where attention still improves accuracy and where its cost becomes unacceptable.

Part 2 - Mathematical form

$$M_{\text{cross}} \propto B\, T_{\text{target}} T_{\text{source}}.$$

Part 3 - Hints and Helper

Report both the quality frontier and the system-resource frontier.

Part 4 - Python code skeleton

```
import torch
def E17(model, data, config):
    experiment = stress_long_attention_sequences(model, data, config, ...)
    report = map_attention_benefit_cost_limits(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.19 Exercise 18 - Ablate Attention Components

Part 1 - Why this matters

An attention module contains query, key, value projections, scoring, scaling, masking, normalization, and context fusion. Ablation reveals which components produce the observed gain.

Removing multiple components simultaneously prevents attribution, and replacing a component with a different-capacity operation confounds the result. Attention maps alone are not evidence of usefulness.

Run controlled removals and replacements with matched budgets, repeat across seeds, and measure quality, alignment, runtime, and memory. Include a randomized-attention control.

Part 2 - Mathematical form

$$\Delta_j = M(A \setminus \{j\}) - M(A).$$

Part 3 - Hints and Helper

Keep training steps, data order, initialization policy, and evaluation code fixed.

Part 4 - Python code skeleton

```
import torch
def E18(model, data, config):
    experiment = run_attention_ablation_matrix(model, data, config, ...)
    report = quantify_attention_components(experiment, data, config, ...)
    assert report is not None
    return report
```

16.10.20 Exercise 19 - Produce the Final LSTM Track Report

Part 1 - Why this matters

The final track report should connect gate equations, cell-state memory, BPTT behavior, data handling, forecasting, stabilization, profiling, deployment, and the bridge to attention. It should show how each engineering decision follows from observed limitations.

A chapter summary that lists topics without experiments cannot demonstrate mastery. Results must preserve failures, controls, uncertainty, and the boundaries where conclusions stop applying.

Assemble verified artifacts from the entire LSTM track, compare recurrent and attention mechanisms, and define the next learning steps toward Transformers. Separate durable principles from dataset-specific findings.

Part 2 - Mathematical form

$$\mathcal{T}_{\text{LSTM}} = \{G, C, \text{BPTT}, D, R, P, A, N\}.$$

Part 3 - Hints and Helper

Link every major conclusion to an exercise result, plot, benchmark, or failure report.

Part 4 - Python code skeleton

```
import torch
def E19(model, data, config):
    experiment = collect_full_lstm_track_artifacts(model, data, config, ...)
    report = build_final_track_report(experiment, data, config, ...)
    assert report is not None
    return report
```

Book 17

Transformers

17.1 Introduction

17.1.1 What will the book teach you

This book studies the Transformer as a complete computational system rather than as a diagram containing a few familiar blocks. The Transformer changed sequence modeling because it replaced recurrent communication through time with direct, content-dependent interaction between positions. A token no longer has to wait for a hidden state to travel through every preceding time step before it can receive information from a distant token. Through self-attention, every position can construct a query, compare that query with the keys of other positions, and retrieve a weighted combination of their values. This creates a shorter path for information and gradients, and it allows the computations for all sequence positions to be expressed as large matrix operations that modern accelerators can execute efficiently.

That architectural change must be understood carefully. A Transformer does not make every sequence problem constant in cost, nor does it remove every form of sequential computation. During training, the representations for all positions can usually be computed in parallel because the complete target sequence is available and future information can be blocked with a causal mask. During autoregressive inference, however, token $t+1$ cannot be sampled before token t exists. Generation therefore remains sequential across newly produced tokens, even though the computation inside each step is highly parallel. The book will repeatedly separate algorithmic dependency, computational depth, arithmetic cost, memory cost, and measured hardware utilization so that the advantages of attention are described precisely rather than reduced to the vague claim that "Transformers are parallel."

The first chapter makes the attention mechanism transparent. The reader will derive Query, Key, and Value representations and interpret attention as content-addressed retrieval from a differentiable memory bank. Given a query matrix Q, key matrix K, and value matrix V, scaled dot-product attention is written as

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}\left(\frac{QK^{\mathsf{T}}}{\sqrt{d_k}} + M\right)V,$$

where d_k is the key dimension and M represents structural restrictions such as padding or causal masks. Every part of this equation has a distinct role. The dot product measures compatibility, scaling controls the variance of the logits, masking removes forbidden relation-

ships, softmax creates a normalized retrieval distribution, and multiplication by V constructs the retrieved representation. The exercises will implement each stage with pure PyTorch tensor operations, verify it on examples that can be calculated by hand, and compare the result with trusted implementations.

Attention is especially dangerous to learn only through successful execution. A softmax over the wrong dimension can still produce finite probabilities. A mask with an incorrect broadcast shape can silently mix examples or heads. A causal mask with the wrong orientation can leak future targets and create misleadingly good training loss. Large logits can overflow in low precision, while an entire masked row can produce undefined normalization. For this reason, the book treats shape contracts, mask semantics, numerical finiteness, probability sums, gradient behavior, and information access as independent invariants. Correct output dimensions are necessary, but they are not proof that the attention operation represents the intended computation.

The reader will then move from one attention operation to multi-head attention. The model projects the same input into several learned subspaces, performs attention independently within each head, concatenates the resulting representations, and maps them back into the model dimension. This is not merely a way to repeat one calculation several times. Different projections can make different relations easy to express: one head may respond to local structure, another to distant agreement, and another to a task-specific association. The book will inspect projection matrices, splitting and transposition rules, per-head tensor layouts, output projection, gradient correctness, head redundancy, and head importance. It will also distinguish a visually interesting attention pattern from evidence that a head is causally important to the prediction.

Because self-attention compares content without inherently knowing order, the book gives positional information its own mathematical and experimental treatment. Without position, a self-attention layer is permutation-equivariant: reordering the input positions reorders the outputs but does not reveal which token was first, last, or separated by a particular distance. The reader will implement sinusoidal and learnable positional representations, investigate relative position bias and rotary position ideas, and test extrapolation beyond the context lengths observed during training. Off-by-one errors, padding positions, device placement, indexing conventions, and long-context numerical behavior will be examined explicitly. Positional encoding will be understood as part of the model's representation of structure, not as a decorative tensor added before the real network begins.

Individual operations become useful only when they are assembled into a stable Transformer block. The reader will build attention sublayers, position-wise feed-forward networks, residual paths, Layer Normalization, activation functions, and dropout. Residual connections preserve an identity path through which information and gradients can travel, while Layer Normalization controls the statistics of each token representation. The feed-forward network applies a learned non-linear transformation independently at every position after attention has exchanged information across positions. Pre-LN and Post-LN arrangements will be compared because normalization placement changes gradient flow and the stability of deep stacks. The reader will not merely reproduce a standard block: every addition, normalization axis, expansion ratio, mask, and dropout location must have an explicit tensor and optimization justification.

The data pipeline is part of the model. Raw text cannot enter a Transformer directly; it must be converted into discrete token identifiers, arranged into sequences, padded or packed

into batches, associated with masks, and aligned with targets. The book will study character, word, and subword perspectives, special-token conventions, vocabulary mappings, embedding lookup, tied input and output embeddings, label shifting, padding masks, and loss masks. A single off-by-one error in next-token prediction can make a model optimize the wrong task while its loss still decreases. The reader will therefore construct tiny datasets whose correct inputs and targets can be inspected directly before moving to streaming text pipelines, prefetching, pinned memory, and large-scale throughput measurements.

Training a Transformer is a system-level experiment in optimization and numerical stability. The reader will build complete training and validation loops; use AdamW, learning-rate warmup, scheduling, gradient clipping, accumulation, and activation checkpointing; and monitor gradients, attention logits, loss spikes, learning rate, memory, and throughput. Mixed precision will be evaluated as a trade-off rather than enabled blindly. Matrix multiplication may benefit greatly from reduced precision, while softmax, normalization, or large attention scores may require additional care. Tiny-task overfitting, finite-difference checks, exact checkpoint continuation, and controlled synthetic tasks will be used to prove that the entire training path is correct before larger experiments are trusted.

The decoder-only portion of the book connects the Transformer directly to autoregressive language modeling. The reader will construct a causal model, build next-token targets, and study why masking turns a parallel training computation into a valid factorization of sequence probability:

$$p(x_1, \ldots, x_T) = \prod_{t=1}^{T} p(x_t \mid x_1, \ldots, x_{t-1}).$$

Generation will be examined as a decision process over probability distributions. Greedy decoding, temperature, top-k, nucleus sampling, repetition penalties, beam search, end-of-sequence handling, and batched stopping rules will be implemented and compared. The reader will learn why low perplexity does not guarantee coherent generation, why deterministic decoding may amplify repetition, and why sampling settings change the behavior of a fixed trained model without changing its parameters. KV caching will expose the difference between recomputing the complete prefix and reusing previously calculated keys and values during inference.

The encoder-decoder architecture will then show how attention supports conditional sequence generation. The encoder builds contextual source representations; the decoder uses masked self-attention over the generated prefix and cross-attention over the encoder memory. Translation, summarization, structured transformation, and synthetic copy or reversal tasks all require careful separation of source padding masks, target causal masks, target padding, shifted labels, and decoding state. The reader will implement cross-attention from scratch, compare teacher-forced training with autoregressive evaluation, investigate exposure bias, visualize alignment, and evaluate decoding choices. This makes the distinction between encoder-only, decoder-only, and encoder-decoder Transformers operational rather than merely taxonomic.

The final chapter treats efficiency and deployment as consequences of the mathematics. Standard attention constructs a score matrix whose area grows with the product of query and key sequence lengths. For self-attention with length T, both score storage and the dominant attention computation scale quadratically with T under the usual dense formulation. Long context can therefore exhaust memory long before parameter storage becomes the limiting fac-

tor. The reader will measure this behavior, study Flash-Attention as an exact computation organized to reduce memory traffic, examine sliding-window attention as a structural restriction, and evaluate activation checkpointing, KV cache growth, precision choices, quantization, compilation, and batching. The difference between theoretical FLOPs, memory bandwidth, kernel-launch overhead, peak allocation, and end-to-end latency will remain visible.

Production readiness extends beyond achieving a good evaluation score. The reader will construct inference wrappers that enforce input and mask contracts, benchmark latency and throughput under realistic loads, validate exported models against a reference, detect NaNs and corrupted output, monitor changes in input distributions, and design rollback and A/B testing procedures. Determinism, checkpoint integrity, data quality, cache correctness, stopping behavior, and failure recovery will be treated as testable requirements. The final objective is a Transformer whose architecture, training data, optimization, numerical behavior, computational limits, decoding policy, and deployment assumptions can all be explained and audited.

17.1.2 Why this book comes after the LSTM

The RNN and LSTM books established the essential problem of sequence learning: the meaning of an element often depends on what came before it, and a model must preserve useful information while discarding irrelevant detail. A vanilla RNN stores the past in one evolving hidden state. The LSTM improves this mechanism with a cell state and gates that regulate writing, retention, and exposure. These gates create a more stable path for gradients and allow substantially longer dependencies to be learned, but they do not remove the recurrent chain. To compute the state at time t, the model still requires the state at time $t - 1$.

This recurrence creates two connected limitations. First, the training computation has sequential depth proportional to sequence length, restricting parallel execution across time steps. Second, information from distant positions must repeatedly pass through state transitions. Even if the LSTM retains that information successfully, the path through which one position influences another remains long and compressed. Attention changes the topology of communication. It gives a position a direct, learned connection to every permitted source position, so the interaction path does not grow with their distance in the sequence.

The transition is not a claim that LSTMs became useless or that attention is free. Recurrent models can be effective for streaming inputs, small datasets, strict memory budgets, or tasks where constant-size state is valuable. Dense self-attention pays an explicit quadratic price in sequence length and requires positional information because recurrence no longer supplies order implicitly. Transformers also introduce new failure modes: mask leakage, attention-score instability, enormous activation memory, cache-management errors, and expensive long-context inference. This book comes after the LSTM so that the reader can evaluate the Transformer as a different engineering trade-off, understanding exactly which recurrent limitations it solves and which new constraints it creates.

17.1.3 How to study this book

Begin every exercise by writing the semantic contract of each tensor. For an attention calculation, record the batch axis, head axis, query length, key length, and feature dimension before writing any matrix multiplication. State which positions are allowed to communicate and con-

struct the expected mask independently of the model code. For a decoder, specify whether an index refers to an input token, a target token, a cached position, or the next position to be generated. Names such as `seq_len` or `mask` are not enough; the meaning of every axis and every Boolean value must be explicit.

Use three levels of implementation. First, build a tiny manual case that can be verified with arithmetic and deliberately simple weights. Second, implement the operation using basic PyTorch tensor functions so that reshaping, broadcasting, masking, and normalization remain visible. Third, compare the result with an optimized library implementation under matched inputs, parameters, dtypes, and modes. Agreement should be tested for forward outputs, attention weights when available, and gradients where appropriate. The manual implementation explains the mechanism; the optimized implementation provides performance; parity establishes that both compute the intended operation.

Treat every comparison as a controlled experiment. Fix data, initialization, random seeds, optimization budget, evaluation procedure, and stopping rules before changing the factor being studied. GPU timing must include warm-up and explicit synchronization because kernel launches are asynchronous. Memory experiments should record allocated and reserved memory, reset peak statistics, and distinguish parameter, optimizer-state, activation, attention-matrix, and cache costs. A single measurement is not a scaling law; repeat measurements and explain the range over which the conclusion is valid.

Failure injection is a required learning method. Reverse a causal mask, apply softmax across the query axis, omit the scaling factor, misalign the target by one position, retain a cache twice, or run a normalization in an unsafe precision. Observe which tests detect the defect and which metrics remain misleadingly normal. A good debugging exercise ends with the earliest violated invariant, the causal explanation, the correction, and a regression test that would detect the same problem if it returned.

Do not interpret an attention heat map as a complete explanation of model reasoning. Attention weights show how values are mixed at a particular layer and head under a particular input, but later layers, residual paths, value vectors, and output projections also affect the final result. Visualization is useful for detecting mask errors, local patterns, alignment, head redundancy, or unexpected concentration, yet causal claims require interventions such as head ablation, token perturbation, or controlled counterfactual tests. Separate what the visualization displays from what the experiment proves.

Keep an engineering notebook for every exercise. Record the hypothesis, formula, tensor contracts, configuration, seed, device, precision, expected failure, raw measurements, observed behavior, and final interpretation. Save small reference tensors and failed examples when they are useful. By the end of the book, these records should form a reusable Transformer debugging and design manual rather than a disconnected collection of code snippets.

17.1.4 The Chapters (TRF00 - TRF08) included in this book

- TRF00 - Attention Intuition and Transformer Motivation
- TRF01 - Multi-Head Attention and Projection Geometry

- TRF02 - Positional Encoding and Sequence Order Modeling
- TRF03 - Transformer Block: Residuals, LayerNorm, and FFN
- TRF04 - Tokenization, Embeddings, and Vocabulary Pipeline
- TRF05 - Training Loop, Optimization, and Stability
- TRF06 - Decoder-Only Language Modeling and Generation
- TRF07 - Encoder-Decoder, Cross-Attention, and Seq2Seq
- TRF08 - Efficiency, Long Context, and Production Readiness

17.2 TRF00

Chapter Title: Attention Intuition and Transformer Motivation
Specialization: Models and Training

17.2.1 Exercise 00

Exercise Title: Explain Why Sequential Models Limit Parallelism and How Attention Enables Full Parallel Processing

Part 1 - Why this matters

A recurrent model processes a sequence by repeatedly updating a state. At time t, the new state depends on the state produced at time $t-1$. This dependency is not merely a programming choice that can be removed by placing a loop on the GPU. It is part of the computation graph: the value of h_t is unknown until h_{t-1} has been computed. Matrix operations inside one recurrent step can be parallelized, and many sequences in a batch can be processed together, but the time dimension still forms a critical path of length T. An LSTM improves what can survive along that path; it does not eliminate the path itself.

This distinction explains why sequence length affects recurrent training in a way that differs from a feed-forward stack. Longer sequences create more dependent state transitions, a longer backpropagation-through-time graph, and fewer opportunities to combine all token computations into a small number of large accelerator-friendly kernels. The hidden state also acts as a repeatedly updated communication channel. Information from a distant token must survive many transformations before it can influence a later output, even when the model has gates designed to protect memory.

Self-attention changes the communication graph. Instead of forcing information to move from position 1 to 2, then from 2 to 3, every query position can compare itself directly with every permitted key position. All queries, keys, and values for a training sequence can be constructed at once, and their interactions can be expressed using batched matrix multiplication. The path between two positions becomes short, and the GPU receives large regular tensor operations rather than a long chain of small dependent steps. This is the central systems motivation behind the Transformer.

However, full parallel processing must be stated precisely. A causal Transformer can process all positions of a known training sequence in parallel because the target tokens already exist and a mask prevents each position from using the future. During autoregressive generation, the next token does not exist until the current token has been sampled, so generation remains sequential across output steps. Attention removes recurrence from the network architecture; it does not repeal the causal dependency of producing an unknown future token.

The gain also has a price. Dense self-attention creates a $T \times T$ score matrix. It provides a short interaction path and high parallelism, but its arithmetic and activation memory grow quadratically with sequence length. Therefore this exercise must compare more than wall-clock speed. You should separate computational depth, total work, memory growth, training parallelism, and decoding latency. The conclusion is not that attention is always cheaper; it is that attention reorganizes sequence computation into a form that trades quadratic interaction cost for direct communication and efficient parallel hardware utilization.

Part 2 - Mathematical form and reasoning

For a recurrent model,

$$h_t = f_\theta(x_t, h_{t-1}), \qquad y_t = g_\theta(h_t), \qquad t = 1, \ldots, T.$$

The dependency graph contains the chain

$$h_0 \to h_1 \to \cdots \to h_T,$$

so the minimum sequential depth across time is $\mathcal{O}(T)$. In self-attention, all token representations are projected simultaneously:

$$Q = XW_Q, \qquad K = XW_K, \qquad V = XW_V,$$

$$A = \operatorname{softmax}\left(\frac{QK^\mathsf{T}}{\sqrt{d_k}} + M\right), \qquad O = AV.$$

Any permitted pair of positions can interact within the same attention layer, giving an interaction-path length of $\mathcal{O}(1)$ for that layer. For dense self-attention, the usual score computation requires $\mathcal{O}(T^2 d_k)$ work and stores $\mathcal{O}(T^2)$ attention entries. These quantities describe different properties: short dependency depth does not imply linear total cost.

Part 3 - Hints, controls, and evidence

1. Draw both dependency graphs before writing code. Mark which operations can run simultaneously and which require a previously computed value.

2. Implement a deliberately simple recurrent reference with an explicit time loop and an attention reference with batched matrix multiplications.

3. Benchmark several sequence lengths using identical batch size and feature dimension. Include warm-up iterations and call `torch.cuda.synchronize()` around timed CUDA regions.

4. Record latency, tokens per second, and peak allocated memory. Do not use one timing number as evidence for every claim.

5. Run a separate experiment for teacher-forced training and autoregressive generation. Explain why their parallelism differs.

6. Verify numerical outputs and shapes before benchmarking; a faster program that computes a different operation is not a valid comparison.

Your report must distinguish theoretical dependency depth from measured runtime, identify the sequence-length range tested, and explain where dense attention's quadratic cost begins to dominate.

Part 4 - Python code skeleton

```
import time
import torch

def recurrent_reference(x, w_x, w_h, h0):
    # x: (batch, seq, d_model)
    h = h0
    states = []
    for t in range(x.shape[1]):
        # TODO: compute the next dependent state
        h = ...
        states.append(h)
    return torch.stack(states, dim=1)

def parallel_attention_reference(x, w_q, w_k, w_v):
    # TODO: construct Q, K, and V for every position at once
    q = ...
    k = ...
    v = ...
    scores = ...
    weights = ...
    output = ...
    return output, weights

def benchmark(fn, *args, repeats=50):
    # TODO: add warm-up, CUDA synchronization, and peak-memory reset
    timings = []
    for _ in range(repeats):
        start = time.perf_counter()
        result = fn(*args)
        # TODO: synchronize when the tensors are on CUDA
        timings.append(time.perf_counter() - start)
    return result, timings

def E00(device):
    results = {}
    for seq_len in [16, 32, 64, 128, 256, 512]:
        x = ...
```

```
        # TODO: benchmark both mechanisms under controlled settings
        results[seq_len] = {
            "recurrent_latency": ...,
            "attention_latency": ...,
            "attention_peak_memory": ...,
        }
    return results
```

Part 5 - The Philosophy Behind the Exercise

Recurrence and attention represent two different ideas about how knowledge moves. Recurrence says that the past reaches the present through a continuously updated state. Attention says that the present can ask the past a new question and construct a response from the relationships that are relevant now. One organizes memory through temporal continuity; the other organizes access through content-dependent connection.

The historical success of the Transformer is therefore not explained by abstract model expressiveness alone. It arose from an alignment between a mathematical idea and the physical organization of modern hardware. Matrix multiplication, memory bandwidth, accelerator parallelism, and large datasets helped determine which architecture could be trained at scale. The evolution of model design is partly a history of ideas about intelligence and partly a history of available computation.

This exercise should also produce intellectual caution. A shorter information path is not the same as understanding, and parallel execution is not the same as efficient execution at every scale. Attention gives the model a powerful way to relate positions, but the relations are learned statistical operations subject to data, optimization, masking, and resource limits. The deeper lesson is to judge an architecture by the structure of access it creates, the costs it imposes, and the evidence that its claimed advantage actually appears.

17.2.2 Exercise 01

Exercise Title: Define Query Key Value and Explain Attention as Weighted Retrieval from a Memory Bank

Part 1 - Why this matters

Query, Key, and Value are often introduced as three names attached to three linear layers. That description is mechanically correct but conceptually insufficient. A query represents what the current position is looking for. A key represents how a candidate memory location advertises the information it can provide. A value represents the content that will actually be retrieved if that location is selected. Compatibility is computed between queries and keys, but the final output is constructed from values.

This separation prevents an important misunderstanding: high similarity does not cause the key vector itself to be copied into the output. The key participates in addressing; the value participates in content transfer. A database analogy is useful if handled carefully. A query is not an exact lookup string, keys are not immutable identifiers, and attention usually does not retrieve only one record. The model learns continuous projections and performs soft retrieval, combining several values according to normalized compatibility weights. The memory bank is

differentiable and changes during training.

In self-attention, Q, K, and V originate from the same sequence but pass through different learned projections. A token can therefore ask one kind of question, expose a different set of searchable features, and contribute yet another content representation. In cross-attention, queries may come from a decoder while keys and values come from an encoder. The same mathematical operation then becomes a bridge between two sources of representation.

The weighted-retrieval interpretation is also necessary for debugging. If query and key axes are exchanged, the program may still multiply compatible matrices but answer the reverse question. If values are transposed incorrectly, attention weights may appear plausible while the retrieved output mixes the wrong dimension. If a mask is applied to values rather than scores, the system no longer removes a memory location from the probability distribution. Each error violates a semantic role, not merely a shape rule.

Finally, attention weights must not be confused with stored facts or calibrated confidence. They are conditional mixing coefficients produced by one layer, head, and input. A large weight indicates that a value contributes strongly to that layer's output under the current projections. It does not by itself prove that the corresponding token is true, important to the final decision, or the unique cause of the prediction.

Part 2 - Mathematical form and reasoning

Let

$$X_q \in \mathbb{R}^{B\times T_q\times d_{\text{model}}}, \qquad X_m \in \mathbb{R}^{B\times T_k\times d_{\text{model}}}.$$

The projections are

$$Q = X_qW_Q, \qquad K = X_mW_K, \qquad V = X_mW_V,$$

with

$$Q \in \mathbb{R}^{B\times T_q\times d_k}, \quad K \in \mathbb{R}^{B\times T_k\times d_k}, \quad V \in \mathbb{R}^{B\times T_k\times d_v}.$$

For query position i and memory position j,

$$s_{ij} = \frac{q_i^{\mathsf{T}}k_j}{\sqrt{d_k}}, \qquad \alpha_{ij} = \frac{\exp(s_{ij})}{\sum_{\ell=1}^{T_k}\exp(s_{i\ell})},$$

$$o_i = \sum_{j=1}^{T_k}\alpha_{ij}v_j.$$

The sum over j makes the retrieval explicit: one output is a convex combination of value vectors when the weights are non-negative and sum to one.

Part 3 - Hints, controls, and evidence

1. Construct a memory bank with three values that have easily recognized patterns, such as basis vectors or colors encoded numerically.

2. Choose keys and queries manually so that one query strongly matches one key, another matches two keys equally, and a third matches none strongly.

3. Calculate the scores, row-wise softmax, and weighted sum by hand before running PyTorch.

4. Change a value while keeping its key fixed. The weights should remain the same while the retrieved content changes.

5. Change a key while keeping its value fixed. The retrieval weights should change even though the available content does not.

6. Verify that every row of the weight matrix sums to one and that the output lies within the span of the value vectors.

Include one self-attention example and one cross-attention example in your notes, and label the semantic meaning of both sequence axes.

Part 4 - Python code skeleton

```
import math
import torch

def weighted_retrieval(query, keys, values):
    # query: (batch, query_len, d_k)
    # keys:  (batch, memory_len, d_k)
    # values:(batch, memory_len, d_v)
    scores = ...  # TODO: compare every query with every key
    scores = scores / ...
    weights = ...  # TODO: normalize over memory locations
    retrieved = ...  # TODO: mix values, not keys
    return retrieved, weights

def intervention_test(query, keys, values):
    base_output, base_weights = weighted_retrieval(
        query, keys, values
    )

    changed_values = values.clone()
    # TODO: modify content without modifying its address
    output_v, weights_v = ...

    changed_keys = keys.clone()
    # TODO: modify an address without modifying its content
    output_k, weights_k = ...

    return {
        "weights_unchanged_after_value_edit": ...,
        "output_changed_after_value_edit": ...,
        "weights_changed_after_key_edit": ...,
    }

def E01():
```

```
query = ...
keys = ...
values = ...
output, weights = weighted_retrieval(query, keys, values)
assert torch.allclose(weights.sum(dim=-1),
                      torch.ones_like(weights.sum(dim=-1)))
return output, weights, intervention_test(query, keys, values)
```

Part 5 - The Philosophy Behind the Exercise

Query, Key, and Value encode a subtle idea: information is not retrieved in isolation from the question being asked. The same memory can yield different representations because different queries produce different weight distributions. In this sense, attention treats relevance as relational rather than intrinsic. A token is not universally important; it becomes important with respect to a particular request for information.

The mechanism also separates identity from content. A key determines how something may be found, while a value determines what is received. Human institutions make similar distinctions in indexes, labels, catalogues, and search systems. Yet learned attention goes further: both the index and the content representation are optimized for a task, so the model constructs its own internal vocabulary of questions and addresses.

This flexibility is powerful but epistemically limited. Weighted retrieval can produce a useful representation without establishing that the source is true, causal, or sufficient. Attention decides what to mix, not what deserves belief. The philosophical lesson is that access, relevance, and truth are different properties, and an intelligent system can become excellent at the first two without automatically possessing the third.

17.2.3 Exercise 02

Exercise Title: Implement Scaled Dot-Product Attention from Scratch Using Pure Torch Operations

Part 1 - Why this matters

Scaled dot-product attention is the irreducible computational core from which the later Transformer chapters are built. Implementing it from basic tensor operations forces every hidden assumption to become visible: which axis stores queries, which stores keys, where the transpose occurs, how the scale is chosen, when the mask is applied, which dimension softmax normalizes, and how the probability matrix mixes values. Using a high-level attention layer before understanding these decisions makes later failures difficult to localize.

The operation contains two matrix multiplications with different meanings. The first, QK^{T}, creates pairwise compatibility scores. Its result has a query axis and a key axis; it does not yet contain retrieved features. The second, AV, uses normalized weights to aggregate the value vectors. Confusing these stages can produce code with valid matrix dimensions but invalid semantics. The score tensor describes relationships, whereas the output tensor contains new token representations.

The order of scaling, masking, and normalization matters. Scaling belongs to the logits before softmax. A Boolean mask must be converted into an additive restriction or used with a masked fill before normalization, ensuring forbidden positions receive zero probability. Applying a mask after softmax leaves the remaining weights unnormalized unless a second normalization is performed. Applying it after value aggregation cannot undo information that has already leaked.

Your scratch implementation should be a transparent reference, not an attempt to outperform optimized kernels. It should optionally return scores and weights, assert shape contracts, handle self- and cross-attention, and define behavior for masked rows. Once correct, it can be compared with `torch.nn.functional.scaled_dot_product_attention` or a manually configured module. Forward parity alone is insufficient; gradients with respect to Q, K, and V must also agree on a tiny deterministic case.

This reference becomes infrastructure for the rest of the book. Causal masks, padding masks, dropout, multi-head reshaping, precision experiments, and performance studies all depend on the same core. A trustworthy baseline lets you distinguish an error in the mathematical attention rule from an error introduced by head splitting, caching, kernel selection, or model integration.

Part 2 - Mathematical form and reasoning

For

$$Q \in \mathbb{R}^{B\times H\times T_q\times d_k}, \quad K \in \mathbb{R}^{B\times H\times T_k\times d_k}, \quad V \in \mathbb{R}^{B\times H\times T_k\times d_v},$$

compute

$$S = \frac{QK^{\mathsf{T}}}{\sqrt{d_k}} \in \mathbb{R}^{B\times H\times T_q\times T_k}.$$

With an additive mask M broadcastable to S,

$$\widetilde{S} = S + M, \qquad A = \operatorname{softmax}(\widetilde{S}, \dim = -1),$$

$$O = AV \in \mathbb{R}^{B\times H\times T_q\times d_v}.$$

The last score dimension must correspond to keys because each query chooses a distribution over memory locations. When dropout is absent and at least one key is valid, $\sum_{j=1}^{T_k} A_{bhij} = 1$.

Part 3 - Hints, controls, and evidence

1. Start with $B = H = 1$, two queries, three keys, and small integer vectors. Calculate the complete result manually.
2. Assert $Q.shape[-1] = K.shape[-1]$ and $K.shape[-2] = V.shape[-2]$ before multiplication.
3. Save the unscaled scores, scaled scores, masked scores, weights, and output separately. These artifacts reveal the first incorrect stage.
4. Test no mask, a padding mask, and a causal mask. Confirm forbidden positions receive exactly zero probability within the chosen tolerance.

5. Compare forward outputs and gradients with a trusted implementation in `float64` before testing lower precision.

6. Test cross-attention where $T_q \neq T_k$ so an accidental self-attention assumption cannot remain hidden.

Do not accept the implementation until manual arithmetic, shape assertions, probability invariants, reference parity, and gradient parity all pass.

Part 4 - Python code skeleton

```
import math
import torch

def scratch_attention(q, k, v, mask=None, return_debug=False):
    assert q.shape[-1] == k.shape[-1]
    assert k.shape[-2] == v.shape[-2]

    d_k = q.shape[-1]
    raw_scores = ...  # TODO: Q @ K^T
    scaled_scores = ...

    if mask is not None:
        # Decide and document whether True means keep or block.
        masked_scores = ...
    else:
        masked_scores = scaled_scores

    weights = ...  # TODO: normalize over key positions
    output = ...   # TODO: weighted sum of values

    debug = {
        "raw_scores": raw_scores,
        "scaled_scores": scaled_scores,
        "masked_scores": masked_scores,
        "weights": weights,
    }
    return (output, debug) if return_debug else output

def compare_gradients(q, k, v, mask=None):
    # TODO: clone inputs for scratch and reference paths
    # TODO: use the same scalar loss for both paths
    # TODO: compare q.grad, k.grad, and v.grad
    return ...

def E02():
    torch.manual_seed(7)
    q = ...
    k = ...
```

```
v = ...
mask = ...
output, debug = scratch_attention(
    q, k, v, mask=mask, return_debug=True
)
# TODO: add probability, mask, and parity assertions
return output, debug, compare_gradients(q, k, v, mask)
```

Part 5 - The Philosophy Behind the Exercise

Implementing attention from scratch is an exercise in refusing premature abstraction. High-level tools are essential for real systems, but abstraction becomes trustworthy only after its invariants are understood. By exposing every operation, the exercise turns a famous architectural slogan into a sequence of claims that can be inspected, falsified, and repaired.

The two matrix multiplications also reveal a broader pattern of intelligence: first determine relationships, then use those relationships to transform content. Attention does not merely move existing vectors. It constructs a context-dependent representation in which each output is defined partly by the other positions available to it. Meaning becomes relational within the current computational context.

There is a methodological lesson as well. A model implementation is not correct because it resembles an equation, and an equation is not implemented faithfully because the code produces a tensor. Correctness lives in the correspondence between symbols, axes, allowed information, numerical operations, and observed behavior. This discipline is what makes later optimization safe.

17.2.4 Exercise 03

Exercise Title: Verify Attention Shapes Step by Step for (batch, heads, seq, d_k) and Debug Dimension Errors

Part 1 - Why this matters

Most attention bugs begin as errors in meaning and appear as errors in shape only when the program is fortunate. The standard four-dimensional layout `(batch, heads, seq, d_k)` assigns a semantic role to every axis. The batch axis separates examples, the head axis separates projection subspaces, the sequence axis identifies positions, and the final axis stores the feature coordinates used by each head. A tensor with these sizes in a different order is not equivalent, even if every number in its shape is familiar.

The score computation requires the feature dimensions of queries and keys to contract while preserving both sequence axes. Transposing the last two dimensions of K produces a key-feature-by-key-position view, allowing `Q @ K.transpose(-2, -1)` to yield `(batch, heads, query_seq, key_seq)`. Softmax then operates over the key-sequence axis because each query forms a distribution over candidate memory positions. Multiplying by V removes the key-sequence axis and restores the value-feature dimension.

Self-attention often hides mistakes because query length and key length are equal. A wrong transpose may accidentally preserve a square shape. A mask may broadcast in an unintended

direction yet still fit. Head count and sequence length may even share the same numerical value in a small test, allowing axes to be swapped without an exception. This exercise must therefore use unequal and deliberately distinctive dimensions, including a cross-attention case with $T_q \neq T_k$.

Head splitting adds another source of risk. Starting from `(B,T,d_model)`, the projected tensor is reshaped into `(B,T,H,d_k)` and then permuted into `(B,H,T,d_k)`. Reversing the reshape and permutation order can mix feature coordinates between heads. After attention, the output must be transposed back and made contiguous or reshaped safely before concatenation. The fact that `view` sometimes fails on non-contiguous tensors is a warning that memory layout and logical shape are related but distinct.

Good shape debugging is proactive. Instead of printing shapes after a runtime error, define contracts at module boundaries and assert them before expensive operations. Record symbolic names beside actual dimensions, verify mask broadcasting explicitly, and include tests in which every axis has a different size. Shape reasoning should function as a lightweight type system for tensor programs.

Part 2 - Mathematical form and reasoning

Let

$$Q \in \mathbb{R}^{B\times H\times T_q\times d_k}, \quad K \in \mathbb{R}^{B\times H\times T_k\times d_k}, \quad V \in \mathbb{R}^{B\times H\times T_k\times d_v}.$$

Then

$$K^{\mathsf{T}_{\text{last 2}}} \in \mathbb{R}^{B\times H\times d_k\times T_k},$$

$$QK^{\mathsf{T}_{\text{last 2}}} \in \mathbb{R}^{B\times H\times T_q\times T_k},$$

and

$$(B,H,T_q,T_k)\,(B,H,T_k,d_v) \longrightarrow (B,H,T_q,d_v)\,.$$

For equal-sized heads, $d_{\text{model}} = Hd_k$. The re-indexing path is

$$(B,T,Hd_k) \to (B,T,H,d_k) \to (B,H,T,d_k).$$

These operations must reorganize indices without mixing feature values between heads or examples.

Part 3 - Hints, controls, and evidence

1. Use $B = 2$, $H = 3$, $T_q = 5$, $T_k = 7$, $d_k = 11$, and $d_v = 13$ so every axis can be identified by size.
2. Write expected shapes before each `reshape`, `transpose`, `matmul`, mask application, and softmax.
3. Test masks shaped as `(B,1,1,T_k)`, `(1,1,T_q,T_k)`, and their deliberate invalid variants.
4. Fill tensors with index-coded values so an axis swap changes observable content, not just metadata.

5. Compare `view`, `reshape`, and `contiguous().view(...)` after permutation and explain their behavior.

6. Add failure tests that require a clear assertion message naming the expected semantic axes.

Your evidence should include a shape trace for self-attention, a separate trace for cross-attention, and at least three intentionally injected dimension errors.

Part 4 - Python code skeleton

```
import torch

def assert_shape(tensor, expected, name):
    actual = tuple(tensor.shape)
    assert actual == tuple(expected), (
        f"{name}: expected {expected}, got {actual}"
    )

def split_heads(x, num_heads):
    # x: (batch, seq, d_model)
    batch, seq_len, d_model = x.shape
    assert d_model % num_heads == 0
    d_k = d_model // num_heads
    x = ...  # TODO: (batch, seq, heads, d_k)
    x = ...  # TODO: (batch, heads, seq, d_k)
    return x

def merge_heads(x):
    # x: (batch, heads, seq, d_v)
    x = ...  # TODO: restore (batch, seq, heads, d_v)
    # TODO: explain why reshape is safe at this point
    return ...

def traced_attention(q, k, v, mask=None):
    trace = {"q": tuple(q.shape), "k": tuple(k.shape),
             "v": tuple(v.shape)}
    k_t = ...
    trace["k_transposed"] = tuple(k_t.shape)
    scores = ...
    trace["scores"] = tuple(scores.shape)
    if mask is not None:
        # TODO: validate intended broadcasting explicitly
        ...
    weights = ...
    output = ...
    trace["output"] = tuple(output.shape)
    return output, trace
```

```
def E03():
    dims = dict(B=2, H=3, Tq=5, Tk=7, Dk=11, Dv=13)
    q = ...
    k = ...
    v = ...
    # TODO: run valid and intentionally invalid cases
    return traced_attention(q, k, v)
```

Part 5 - The Philosophy Behind the Exercise

Tensor dimensions are often treated as bookkeeping, but in attention they are part of the theory. An axis states what kinds of entities exist and which ones may interact. Contracting the feature axis means comparing representations; normalizing the key axis means choosing among memory locations; preserving the batch axis means refusing to mix independent examples. Shape is therefore a compact language of ontology and permission.

Many silent bugs arise because numerical compatibility is weaker than semantic compatibility. Two dimensions may both equal 64, allowing an operation that is mathematically defined but conceptually meaningless. This resembles a sentence that is grammatically valid yet refers to the wrong objects. Naming axes and constructing asymmetric tests restores meaning that raw dimensions alone cannot express.

The larger lesson is that abstraction requires contracts. As models grow, no person can inspect every element, but researchers can still reason about the roles, invariants, and transformations of dimensions. Shape discipline is not clerical caution; it is one of the main ways human understanding remains connected to large tensor computations.

17.2.5 Exercise 04

Exercise Title: Implement Softmax with Numerical Stability and Prove It Prevents NaNs in Attention Scores

Part 1 - Why this matters

Softmax converts unrestricted attention logits into non-negative weights that sum to one, but its textbook formula hides a serious numerical problem. Exponentiation grows rapidly. In exact mathematics, a large finite logit has a large finite exponential. In finite floating-point arithmetic, that exponential may overflow to infinity. Dividing infinity by an infinite sum produces an undefined result, allowing a single extreme score to turn an entire attention row into NaNs. Lower-precision formats reach this failure at much smaller magnitudes.

The stable implementation subtracts the maximum logit from every element in the same normalization row before exponentiation. Softmax is invariant to adding or subtracting a constant from every element, so the mathematical probability distribution is unchanged. Numerically, the largest shifted logit becomes zero, its exponential becomes one, and every other exponential lies between zero and one. This does not make every possible input safe, but it eliminates the most direct overflow path while preserving the intended result.

Attention introduces additional complications. Masks are often represented by very negative additive values or negative infinity. A row in which every key is masked has no valid probability distribution; subtracting the maximum of an all-negative-infinity row produces undefined arithmetic. The implementation must either guarantee at least one valid key per query, define a zero-output policy for empty rows, or explicitly detect and reject the condition. Numerical stability cannot repair an ill-defined semantic input.

Precision comparisons must examine more than NaNs. Even finite low-precision logits may quantize small differences, causing softmax to become unexpectedly uniform or overly concentrated. When probabilities approach zero, gradients through those entries may also become too small to represent. You should test overflow, underflow, saturation, probability-sum error, output error, and gradient error separately. A computation can avoid NaNs yet still lose useful learning signal.

To prove the stable method matters, construct adversarial logits that make the naive method fail, compare both against a high-precision reference, and sweep the magnitude of the inputs across dtypes. The result should identify the failure boundary rather than display one convenient example. The final implementation must also normalize along the correct key axis and document how masked rows are handled.

Part 2 - Mathematical form and reasoning

The naive formula is

$$\operatorname{softmax}(z)_i = \frac{\exp(z_i)}{\sum_j \exp(z_j)}.$$

For any constant c,

$$\frac{\exp(z_i - c)}{\sum_j \exp(z_j - c)} = \frac{\exp(z_i)\exp(-c)}{\exp(-c)\sum_j \exp(z_j)} = \operatorname{softmax}(z)_i.$$

Choose $c = m = \max_j z_j$. Then $z_i - m \le 0$ for every i, so

$$0 < \exp(z_i - m) \le 1$$

for finite logits. In attention, stabilization is applied independently to every row:

$$A_{bhij} = \frac{\exp(S_{bhij} - m_{bhi})}{\sum_\ell \exp(S_{bhi\ell} - m_{bhi})}, \qquad m_{bhi} = \max_j S_{bhij}.$$

Part 3 - Hints, controls, and evidence

1. Implement naive and stable softmax without calling `torch.softmax`. Keep the normalization dimension configurable.
2. Test logits such as $[1000, 1001, 1002]$, their negative equivalents, and scaled random attention scores.
3. Sweep logit magnitude for `float64`, `float32`, and `float16`; record the first non-finite output for the naive method.

4. Compare the stable output with `torch.softmax` and verify row sums, non-negativity, finiteness, and gradient parity.

5. Add masks containing valid and invalid rows. Do not silently claim that an all-masked row has a meaningful softmax distribution.

6. Plot maximum probability and gradient norm against logit scale to reveal saturation even when no NaN occurs.

Your proof must combine algebraic invariance with empirical evidence showing where finite-precision implementations diverge.

Part 4 - Python code skeleton

```
import torch

def naive_softmax(logits, dim=-1):
    numerator = ...
    denominator = ...
    return ...

def stable_softmax(logits, dim=-1):
    row_max = ...
    shifted = ...
    exp_shifted = ...
    denominator = ...
    return ...

def validate_probabilities(p, dim=-1):
    checks = {
        "finite": ...,
        "non_negative": ...,
        "sums_to_one": ...,
    }
    return checks

def magnitude_sweep(dtype, device):
    records = []
    for magnitude in [1, 10, 50, 100, 500, 1000, 5000]:
        logits = ...
        naive = naive_softmax(logits)
        stable = stable_softmax(logits)
        reference = torch.softmax(logits.to(torch.float64), dim=-1)
        records.append({
            "magnitude": magnitude,
            "naive_finite": ...,
            "stable_finite": ...,
            "stable_reference_error": ...,
        })
```

```
    return records

def E04(device):
    results = {}
    for dtype in [torch.float64, torch.float32, torch.float16]:
        # TODO: skip unsupported combinations explicitly
        results[str(dtype)] = magnitude_sweep(dtype, device)
    # TODO: add a deliberate all-masked-row experiment
    return results
```

Part 5 - The Philosophy Behind the Exercise

Stable softmax demonstrates that mathematical equivalence does not guarantee computational equivalence. Two formulas can define the same real-valued function while behaving completely differently on a machine. Numerical analysis is therefore not an implementation detail added after the model's meaning has been established. It determines whether the mathematical object exists in practice.

Subtracting the maximum is also a lesson in choosing representations. The absolute level of softmax logits is irrelevant to the final distribution; only their differences matter. By removing an irrelevant degree of freedom, the stable formulation places the computation in a numerically safer coordinate system. Good engineering often comes from identifying what the problem does not need to preserve.

Finally, the all-masked row exposes the boundary between numerical and semantic failure. No clever arithmetic can create a meaningful choice when every option has been declared impossible. A responsible system must distinguish the case where a calculation became unstable from the case where the requested probability distribution is undefined. The philosophy of robust AI begins with refusing to hide invalid questions behind finite-looking outputs.

17.2.6 Exercise 05

Exercise Title: Demonstrate How Attention Focus Shifts When One Token Changes and Interpret the Weight Matrix

Part 1 - Why this matters

Attention is input-dependent. Unlike a fixed convolutional kernel or a static averaging rule, its mixing weights are recomputed from the current queries and keys. Changing one token can therefore alter its own query, its advertised key, its contributed value, and the responses of other positions that compare against it. This exercise makes that dependency visible by applying a controlled token intervention and tracing the resulting changes through every stage of attention.

The attention matrix has two different sequence axes. A row belongs to one query position and describes how that query distributes weight across key positions. A column belongs to one key position and collects the weights assigned to it by many queries. Row-wise interpretation asks where this position retrieved information from. Column-wise patterns suggest which queries selected this position. Confusing these interpretations can reverse the apparent direction of a relationship.

A token intervention can affect attention in several ways. If the changed token modifies only a value vector, the attention matrix should remain fixed while outputs that retrieve that value change. If it modifies only a key, the column associated with that memory position may gain or lose weight across queries. If it modifies only a query, the corresponding row should change while other rows remain fixed. In a normal self-attention layer, one input token usually affects all three projections, so these mechanisms occur together. Separating them experimentally is essential for causal interpretation.

Visualization alone is not enough. Softmax couples every key within a row: increasing the score of one position necessarily changes the normalized weights of others. A large color difference in a heat map may come from a small score change near a competitive boundary, while a large score change in an already saturated row may barely alter the distribution. You should therefore record raw scores, normalized weights, entropy, outputs, and projection changes rather than relying only on color intensity.

The goal is not to claim that attention weights fully explain the model. The value vectors, output projection, residual path, later layers, and nonlinear subnetworks all influence the final prediction. This exercise teaches a narrower and more defensible interpretation: the matrix reveals how one attention operation mixed values under a particular input, head, layer, mask, and parameter state.

Part 2 - Mathematical form and reasoning

For input representations X, let

$$Q = XW_Q, \qquad K = XW_K, \qquad V = XW_V,$$

$$A(X) = \operatorname{softmax}\left(\frac{QK^{\mathsf{T}}}{\sqrt{d_k}} + M\right), \qquad O(X) = A(X)V.$$

Change only token r:

$$X' = X + \Delta, \qquad \Delta_i = 0 \text{ for } i \neq r.$$

Measure

$$\Delta A = A(X') - A(X), \qquad \Delta O = O(X') - O(X).$$

Useful row statistics include attention entropy

$$H_i = -\sum_j A_{ij} \log(A_{ij} + \varepsilon)$$

and total distribution change

$$D_i = \frac{1}{2} \sum_j \left| A'_{ij} - A_{ij} \right|.$$

These quantities show whether a query became more concentrated and how far its retrieval distribution moved.

Part 3 - Hints, controls, and evidence

1. Create a short synthetic sequence with distinct token roles, then save a baseline containing Q, K, V, scores, weights, and outputs.
2. Perform three isolated interventions: change only q_r, only k_r, and only v_r. Predict which rows, columns, or outputs should change.
3. Perform a realistic input-token intervention through all three projection matrices and compare it with the isolated cases.
4. Report maximum absolute change, row-wise total variation, entropy change, and output-vector change.
5. Keep model parameters, mask, seed, dtype, and every other token fixed.
6. Use heat maps with identical color scales and labels. A rescaled plot can make two nearly identical matrices look dramatically different.

Your interpretation notes must separate direct effects of the edited query, key, or value from indirect changes created by row-wise normalization.

Part 4 - Python code skeleton

```
import torch

def attention_with_trace(q, k, v, mask=None):
    scores = ...
    if mask is not None:
        scores = ...
    weights = ...
    output = ...
    return {"scores": scores, "weights": weights,
            "output": output}

def distribution_metrics(before, after, eps=1e-12):
    entropy_before = ...
    entropy_after = ...
    total_variation = ...
    return {
        "entropy_change": entropy_after - entropy_before,
        "total_variation": total_variation,
    }

def isolate_intervention(q, k, v, token_index, target):
    q2, k2, v2 = q.clone(), k.clone(), v.clone()
    # TODO: change only the selected Q, K, or V token
    ...
    before = attention_with_trace(q, k, v)
    after = attention_with_trace(q2, k2, v2)
    return before, after, distribution_metrics(
        before["weights"], after["weights"]
```

```
    )

def E05():
    q, k, v = ...
    results = {}
    for target in ["query", "key", "value"]:
        results[target] = isolate_intervention(
            q, k, v, token_index=2, target=target
        )
    # TODO: add plots with shared axes and shared color limits
    return results
```

Part 5 - The Philosophy Behind the Exercise

This exercise illustrates that relevance is dynamic. The model does not carry a single permanent map of what matters; it reconstructs a map from the current representations. A changed token can alter both the question being asked and the way a possible answer presents itself. Context is therefore not merely additional data surrounding a fixed meaning. It participates in producing the relationships from which the next representation is built.

The heat map also raises a question about observation and explanation. Humans are attracted to visible matrices because they appear to reveal an internal reasoning process. Yet visibility is not causality. An attention weight is one coefficient inside a larger computation, and a beautiful pattern can be irrelevant after later projections or residual mixing. Interpretation becomes stronger when visualization is combined with controlled intervention.

The deeper philosophical principle is that understanding a system requires asking counterfactual questions: what changes if one element changes, and what remains invariant? Static inspection describes a state. Intervention reveals a mechanism. The exercise moves attention analysis from storytelling toward evidence.

17.2.7 Exercise 06

Exercise Title: Build a Tiny Synthetic Copy Task and Show Why Attention Solves Bottleneck Better Than LSTM

Part 1 - Why this matters

A synthetic copy task isolates long-range information transfer from the ambiguity of natural data. The model receives a sequence containing a payload, a delay or distractor region, and a signal indicating when the payload should be reproduced. Success requires preserving the identity and order of earlier symbols across a controllable distance. Because the generation process is known exactly, failure can be analyzed by payload length, delay length, symbol position, and error type rather than hidden inside one aggregate loss.

For an LSTM, the payload must influence later predictions through recurrent hidden and cell states. Gating makes this channel far stronger than a vanilla RNN, but its capacity is still finite and its computation remains a sequence of state updates. As the delay grows, the model must retain several discrete items while ignoring distractors and avoiding interference from

later transitions. The final state is not literally the only information available at every output step, but the recurrent path remains the route by which distant input affects the prediction.

An attention-based model can construct a direct relationship between an output query and the earlier position containing the needed symbol. Instead of asking one state to compress every relevant detail into a fixed-width evolving memory, the model preserves a set of token representations and learns where to retrieve from. The copy task makes this advantage inspectable: a correct model should place high weight on the corresponding source position when producing each payload token.

The experiment must still be fair. A Transformer with more parameters, more updates, or an easier positional representation cannot be declared superior to an undertrained LSTM. Match training examples, optimization steps, parameter count as closely as practical, and report remaining differences. Train and test across several delays, including lengths beyond the training range. The LSTM may perform perfectly on short sequences, and attention may fail if positional information or masks are wrong. The objective is to identify the boundary at which the communication structures behave differently, not to force a preselected winner.

The task also validates more than architecture. If neither model can overfit a tiny fixed dataset, the likely problem is the data alignment, loss, output shape, or training loop. If the attention model succeeds during teacher forcing but fails during generation, target leakage or exposure bias may be involved. Synthetic tasks are powerful because they convert architectural claims into controlled diagnostic evidence.

Part 2 - Mathematical form and reasoning

Let a sample contain a payload

$$p = (p_1, \ldots, p_L),$$

a delay of D blank or distractor symbols, and a delimiter. A simplified input-target pair is

$$x = (p_1, \ldots, p_L, \underbrace{\square, \ldots, \square}_{D}, \texttt{GO}),$$

$$y = (\underbrace{\square, \ldots, \square}_{L+D+1}, p_1, \ldots, p_L).$$

For the LSTM,

$$(h_t, c_t) = \mathrm{LSTM}(x_t, h_{t-1}, c_{t-1}),$$

so influence from p_i reaches a distant output through repeated transitions. For attention, an output representation may include

$$o_t = \sum_{j=1}^{T} \alpha_{tj} v_j,$$

allowing $\alpha_{t,i}$ to connect the output directly to the required payload position. Report exact sequence accuracy in addition to token accuracy:

$$\mathrm{ExactMatch} = \frac{1}{N} \sum_{n=1}^{N} \mathbf{1}\left[\widehat{p}^{(n)} = p^{(n)}\right].$$

Part 3 - Hints, controls, and evidence

1. Begin with one fixed batch and require both models to overfit it. Do not start a generalization comparison before proving pipeline correctness.
2. Use a vocabulary small enough to inspect but large enough that guessing cannot produce misleading accuracy.
3. Compare matched payload lengths while sweeping delay length. Report token accuracy, exact-match accuracy, and error by payload position.
4. Include positional information for the attention model and verify that removing it breaks order-sensitive copying.
5. Match parameter counts and optimization steps where possible; document any unmatched capacity or computational budget.
6. Visualize retrieval weights and probe LSTM states, but use output interventions and accuracy as the primary evidence.

Your report should identify the longest reliably solved delay for each model under the tested configuration and explain why the result is conditional, not a universal ranking.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def make_copy_batch(batch_size, payload_len, delay_len,
                    vocab_size, device):
    payload = ...
    inputs = ...
    targets = ...
    loss_mask = ...
    return inputs, targets, loss_mask, payload

class LSTMCopyModel(nn.Module):
    def __init__(self, vocab_size, d_model, hidden_size):
        super().__init__()
        # TODO: embedding, LSTM, and output projection
        ...

    def forward(self, tokens):
        return ...

class AttentionCopyModel(nn.Module):
    def __init__(self, vocab_size, d_model, num_heads):
        super().__init__()
        # TODO: embedding, position representation, attention, output
        ...
```

```
    def forward(self, tokens, return_weights=False):
        return ...

def evaluate_copy(model, configs):
    records = []
    for payload_len, delay_len in configs:
        inputs, targets, mask, payload = ...
        logits = ...
        # TODO: compute token accuracy and exact payload match
        records.append({...})
    return records

def E06(device):
    # TODO: match seeds, data, steps, and approximate parameter counts
    lstm = ...
    attention = ...
    # TODO: first overfit a tiny batch, then run the delay sweep
    return {
        "lstm": evaluate_copy(lstm, ...),
        "attention": evaluate_copy(attention, ...),
    }
```

Part 5 - The Philosophy Behind the Exercise

The copy task contrasts compressed memory with addressable memory. An LSTM continually rewrites a bounded state that must carry whatever the future may need. Attention preserves many representations and allows a later query to decide which one matters. The difference resembles carrying a summary of a library versus retaining access to its shelves. A summary is compact and useful for streaming, while addressable storage protects details at a higher cost.

This distinction complicates the idea of memory itself. A system does not need to place every fact into one persistent inner state to use the past. It can retain traces and reconstruct a task-specific answer when needed. Attention therefore shifts the design question from how to compress all history into a state toward how to preserve, index, and select representations.

Yet the shelves are not infinite. Dense access becomes expensive as the stored context grows, and retrieval can fail when positions, keys, or learned queries do not generalize. The philosophy is not that externalized memory defeats every bottleneck. It relocates the bottleneck from recurrent compression to storage, search, and relevance.

17.2.8 Exercise 07

Exercise Title: Implement Attention Masking for Padding Tokens and Prove Padding Does Not Affect Attention Weights

Part 1 - Why this matters

Padding lets variable-length sequences share one rectangular batch, but padded positions are computational artifacts rather than data. If they remain visible to attention, the model can allocate probability to meaningless embeddings, retrieve their values, and allow batch construction choices to alter valid token representations. The resulting system may still train because it can learn partial compensation, yet its behavior will depend on how much padding happens to surround each example.

A key-padding mask removes padded memory positions before softmax. For a score tensor shaped `(B,H,T_q,T_k)`, a per-example validity vector shaped `(B,T_k)` is commonly expanded to `(B,1,1,T_k)`. Broadcasting then applies the same invalid-key rule to every head and every query within an example. The convention must be explicit: some APIs use `True` to mean valid, while others use it to mean blocked. A reversed convention can silently expose only padding and hide real tokens.

Masking keys does not automatically erase padded query positions. If the batch contains output rows corresponding to padding, those queries can still produce distributions over valid keys. Depending on the architecture, you may zero their outputs, ignore them in the loss, or both. Key masking protects valid queries from invalid memory. Query masking and loss masking control whether invalid output positions participate downstream. These are related but different responsibilities.

The strongest proof is invariance. Replace the embeddings or values of padded tokens with extreme random numbers while keeping the mask unchanged. Outputs for valid query positions should remain equal within numerical tolerance, and all probabilities assigned to padded keys should remain zero. Repeat the same valid sequence with different amounts of right padding; its valid outputs should not change. A visual matrix with dark padding columns is helpful, but an intervention test is stronger.

Special cases require a defined policy. A sequence with no valid keys produces an all-masked row, for which ordinary softmax is undefined. Empty examples should normally be rejected or handled explicitly before attention. Low precision also affects which mask fill value is safe. The exercise must test the intended dtypes and prove that masking produces finite outputs without accidentally assigning nonzero probability to padding.

Part 2 - Mathematical form and reasoning

Let $m_{bj} \in \{0, 1\}$ indicate whether key position j in example b is valid. Define an additive mask

$$M_{b11j} = \begin{cases} 0, & m_{bj} = 1, \\ -\infty, & m_{bj} = 0. \end{cases}$$

Then

$$A_{bhij} = \frac{\exp(S_{bhij} + M_{b11j})}{\sum_{\ell=1}^{T_k} \exp(S_{bhi\ell} + M_{b11\ell})}.$$

For every padded key j,

$$m_{bj} = 0 \quad \Longrightarrow \quad A_{bhij} = 0$$

for every head h and query i, assuming at least one valid key. Consequently, changing v_{bj} at a masked position should not change

$$O_{bhi} = \sum_j A_{bhij} v_{bj}.$$

Part 3 - Hints, controls, and evidence

1. Build two sequences of different lengths and pad them into one batch. Write the validity mask manually before deriving it in code.
2. Print the score, mask, masked-score, and weight shapes. Confirm the mask broadcasts across heads and queries but not across examples.
3. Assert that masked-key weights are zero and valid-key weights sum to one.
4. Replace padded values with large positive and negative numbers; valid outputs must remain invariant.
5. Evaluate the same valid prefix with several padding lengths and compare only the valid output positions.
6. Add an empty-sequence case and enforce an explicit rejection or documented policy instead of accepting NaNs.

Also show that removing or reversing the mask makes at least one invariance test fail. A proof needs a negative control.

Part 4 - Python code skeleton

```
import torch

def make_key_padding_mask(lengths, max_len):
    positions = torch.arange(max_len, device=lengths.device)
    # Choose and document: True means valid in this exercise.
    valid = ...
    return ...  # TODO: (batch, 1, 1, key_len)

def masked_attention(q, k, v, valid_key_mask):
    scores = ...
    assert valid_key_mask.shape == (
        q.shape[0], 1, 1, k.shape[-2]
    )
    assert valid_key_mask.any(dim=-1).all(), "empty memory row"
    masked_scores = ...
    weights = ...
    output = ...
    return output, weights

def padding_invariance_test(q, k, v, mask):
```

```
    out1, w1 = masked_attention(q, k, v, mask)
    v2 = v.clone()
    # TODO: overwrite only padded values with extreme noise
    ...
    out2, w2 = masked_attention(q, k, v2, mask)
    return {
        "masked_weights_zero": ...,
        "weights_unchanged": ...,
        "valid_outputs_unchanged": ...,
    }

def E07():
    lengths = torch.tensor([3, 5])
    max_len = 7
    mask = make_key_padding_mask(lengths, max_len)
    q, k, v = ...
    return padding_invariance_test(q, k, v, mask)
```

Part 5 - The Philosophy Behind the Exercise

Padding shows that not everything present in a tensor belongs to the modeled world. Some entries exist only because hardware prefers rectangles. The mask draws a boundary between representation and reality: it tells the computation which coordinates are storage conveniences and which correspond to meaningful evidence.

This boundary cannot be inferred from numbers alone. A padding vector may be zero, learned, or accidentally similar to a real token. Without an explicit rule, the model has no principled reason to treat it as absence. Absence must be represented as a constraint on access, not merely as an unusual value.

The invariance test expresses a broad scientific ideal. If an element is declared irrelevant, changing it should not change the result. Robust systems are built not only by checking what influences an output, but by proving what must not influence it. Masking is therefore a small example of a larger ethics of information boundaries.

17.2.9 Exercise 08

Exercise Title: Implement Causal Masking for Autoregressive Modeling and Verify No Token Attends to the Future

Part 1 - Why this matters

Autoregressive language modeling trains a network to predict each token from the tokens that precede it. During training, the complete sequence is already stored in one tensor so all positions can be processed together. Without a causal mask, the representation at position i can attend to token $i+1$ or later positions, including the answer it is supposed to predict. The model may then achieve extremely low loss by copying future information rather than learning the conditional structure required during generation.

A causal mask preserves parallel training while enforcing the information boundary that exists at inference time. If rows represent query positions and columns represent key positions, query i may use key j only when $j \leq i$. The allowed region is therefore lower triangular. Memorizing a triangle without naming the axes is unsafe: transposing the score convention reverses the visual orientation while preserving the causal rule.

The mask must agree with target alignment. In the common next-token setup, `input = tokens[:-1]` and `target = tokens[1:]`. A representation at input position i may attend to its current input token because it predicts the following token, but it must not inspect later input positions. If the dataset is shifted differently, the diagonal policy must be reconsidered. Masking and label construction are one semantic contract.

A triangular heat map is only preliminary evidence. A stronger test changes future token representations while keeping a prefix unchanged. Every output belonging to that prefix must remain invariant. A gradient test can go further: differentiate an early output with respect to all input positions and verify that forbidden future positions receive zero gradient. These tests expose leakage caused by incorrect broadcasting, residual paths, or integration.

Causal masking does not make generation parallel. It allows all known training positions to be evaluated together without violating sequence probability. During generation, token $t + 1$ remains unknown until token t has been chosen. KV caching can reduce repeated work, but it cannot remove this dependency.

Part 2 - Mathematical form and reasoning

Define

$$M_{ij} = \begin{cases} 0, & j \leq i, \\ -\infty, & j > i. \end{cases}$$

Then

$$A_{ij} = \operatorname{softmax}_j\left(\frac{q_i^{\mathsf{T}} k_j}{\sqrt{d_k}} + M_{ij}\right)$$

satisfies $A_{ij} = 0$ whenever $j > i$. This enforces

$$p(x_1, \ldots, x_T) = \prod_{t=1}^{T} p(x_t \mid x_1, \ldots, x_{t-1}).$$

For a prefix ending at r, the intervention test requires

$$X'_{0:r} = X_{0:r} \quad \Longrightarrow \quad O'_{0:r} = O_{0:r},$$

even when $X'_{r+1:T} \neq X_{r+1:T}$.

Part 3 - Hints, controls, and evidence

1. Draw masks for lengths 1, 2, and 5, labeling query rows and key columns before implementing the general function.
2. State whether `True` means keep or block, and assert the exact mask shape before broadcasting it to `(B,H,T,T)`.

3. Verify every strictly future weight is zero and every valid row sums to one.
4. Perturb all future embeddings after a selected prefix and compare earlier outputs and logits.
5. Differentiate an early scalar output with respect to the complete input; forbidden future gradients must be zero.
6. Reverse the mask deliberately and prove the leakage tests fail even if training loss appears excellent.

Record the indexing convention, target shift, diagonal policy, and broadcast path. These details define what future means in the experiment.

Part 4 - Python code skeleton

```
import torch

def causal_keep_mask(query_len, key_len=None, device=None):
    key_len = query_len if key_len is None else key_len
    q_pos = torch.arange(query_len, device=device)[:, None]
    k_pos = torch.arange(key_len, device=device)[None, :]
    keep = ...  # TODO: permit keys at or before each query
    return keep[None, None, :, :]

def causal_attention(q, k, v, keep_mask):
    scores = ...
    masked_scores = ...
    weights = ...
    output = ...
    return output, weights

def future_perturbation_test(x, model, split_index):
    x2 = x.clone()
    # TODO: modify positions strictly after split_index
    ...
    out1 = model(x)
    out2 = model(x2)
    return ...  # compare only the invariant prefix

def forbidden_gradient_test(x, model, query_index):
    x = x.detach().clone().requires_grad_(True)
    output = model(x)
    scalar = ...  # select an early-query output
    scalar.backward()
    future_grad = ...
    return ...

def E08():
    mask = causal_keep_mask(6)
```

```
assert ...  # verify exact triangular structure
model, x = ..., ...
return {
    "future_invariance": future_perturbation_test(x, model, 2),
    "forbidden_gradient": forbidden_gradient_test(x, model, 2),
}
```

Part 5 - The Philosophy Behind the Exercise

A causal mask is a law governing what the model is allowed to know. It does not remove the future from storage; it removes future relationships from the computation. Training can place every token physically beside every other token while constructing a valid informational world for each prediction.

This is also a lesson about honest evaluation. A model that sees the answer is not more intelligent because it reports lower loss. It has been assigned a different and easier problem. Leakage corrupts the meaning of success while often improving its visible metrics.

Any claim about prediction or reasoning is incomplete until its information boundary is specified. Intelligence must be evaluated relative to what was available at the moment of choice. The mask turns this requirement into a tensor invariant that can be tested.

17.2.10 Exercise 09

Exercise Title: Compare Attention Outputs With and Without Scaling by sqrt(d_k) and Explain Gradient Stability Impact

Part 1 - Why this matters

The dot product between a query and a key sums d_k coordinate-wise products. When those coordinates are approximately independent, centered, and similarly scaled, the variance of the sum grows with d_k. Increasing head dimension therefore increases the typical magnitude of unscaled logits even when the quality of the underlying relation has not changed. Softmax receives values that are farther apart and tends to produce excessively concentrated weights.

A saturated row behaves almost like hard selection: one key receives probability near one and the others approach zero. Concentration is not automatically wrong; learned retrieval may need to be sharp. The problem is allowing dimension alone to impose sharpness before training has justified it. When softmax saturates, many Jacobian entries become small, alternatives stop receiving useful learning signals, and optimization becomes more sensitive to initialization and precision.

Dividing by $\sqrt{d_k}$ approximately preserves unit-scale score variance under the standard assumptions. It acts as a fixed temperature tied to head dimension, making score distributions more comparable across different d_k. Scaling does not guarantee stability: correlated coordinates, large vector norms, poor initialization, or low precision can still produce extreme logits. It removes one predictable source of dimension-dependent saturation.

This exercise must connect four kinds of evidence: score statistics, attention entropy or concentration, gradient behavior, and actual early optimization on a controlled task. Merely

printing two output tensors cannot explain gradient stability. A sweep over several dimensions and seeds is necessary to establish the predicted trend.

Both paths must use identical Q, K, V, masks, losses, and upstream gradients. If scaled and unscaled variants are initialized independently, the comparison is confounded. Use cloned leaf tensors and paired trials so scaling is the only experimental difference.

Part 2 - Mathematical form and reasoning

Assume

$$\mathbb{E}[q_\ell] = \mathbb{E}[k_\ell] = 0, \qquad \mathrm{Var}(q_\ell) = \mathrm{Var}(k_\ell) = 1,$$

with approximately independent coordinate products. The unscaled score

$$s = q^\mathsf{T} k = \sum_{\ell=1}^{d_k} q_\ell k_\ell$$

has

$$\mathbb{E}[s] \approx 0, \qquad \mathrm{Var}(s) \approx d_k.$$

For

$$\widetilde{s} = \frac{q^\mathsf{T} k}{\sqrt{d_k}},$$

we obtain $\mathrm{Var}(\widetilde{s}) \approx 1$. The softmax derivative is

$$\frac{\partial a_i}{\partial s_j} = a_i(\delta_{ij} - a_j).$$

When one $a_i \approx 1$ and the rest approach zero, many derivative terms approach zero, weakening learning through competing scores.

Part 3 - Hints, controls, and evidence

1. Sweep $d_k \in \{4, 16, 64, 256, 1024\}$ using paired random tensors for the scaled and unscaled paths.
2. Record score standard deviation, maximum absolute score, attention entropy, maximum probability, and the fraction of near-zero probabilities.
3. Backpropagate the same scalar objective and compare gradient norms for Q, K, and V.
4. Repeat across several seeds and report the mean and variation instead of selecting one convenient run.
5. Add a short training experiment with equal initialization and data, tracking loss and gradient statistics over the first updates.
6. Test normalized queries and keys as a counterexample, and explain which assumptions of the variance argument no longer apply.

State clearly that the theoretical derivation is approximate and conditional on the coordinate statistics.

Part 4 - Python code skeleton

```
import math
import torch

def attention_path(q, k, v, scaled):
    scores = q @ k.transpose(-2, -1)
    if scaled:
        scores = ...
    weights = ...
    output = ...
    return output, scores, weights

def row_entropy(weights, eps=1e-12):
    return ...

def paired_trial(d_k, seed, device):
    torch.manual_seed(seed)
    q0, k0, v0 = ..., ..., ...

    # TODO: create identical leaf copies for both paths
    scaled = attention_path(...)
    unscaled = attention_path(...)

    # TODO: apply the same scalar loss and collect gradients
    return {
        "scaled_score_std": ...,
        "unscaled_score_std": ...,
        "scaled_entropy": ...,
        "unscaled_entropy": ...,
        "scaled_q_grad_norm": ...,
        "unscaled_q_grad_norm": ...,
    }

def E09(device):
    records = []
    for d_k in [4, 16, 64, 256, 1024]:
        for seed in range(10):
            records.append(paired_trial(d_k, seed, device))
    # TODO: aggregate by d_k and explain the trend
    return records
```

Part 5 - The Philosophy Behind the Exercise

Scaling separates the strength of a relation from the number of coordinates used to describe it. Without normalization, a wider representation can appear more certain simply because it

sums more terms. Confidence would then partly reflect dimensional bookkeeping rather than learned evidence.

This reveals a recurring principle in machine learning: expressive capacity and numerical scale are not the same thing. More dimensions may encode richer relations, but incidental magnitude must be controlled so optimization can compare those relations meaningfully.

The exercise also warns against equating sharpness with knowledge. A saturated softmax looks decisive, yet its decisiveness may be an artifact of dimension, initialization, or precision. Before interpreting a sharp distribution as a strong belief, ask what produced the scale on which that belief was computed.

17.2.11 Exercise 10

Exercise Title: Run Your Scratch Attention on CUDA and Confirm Numerical Parity with CPU for Multiple Random Seeds

Part 1 - Why this matters

Moving attention to CUDA changes where the computation is executed, which kernels perform it, and sometimes the order in which floating-point operations are accumulated. It should not change the mathematical function. CPU–GPU parity testing checks that device transfer, mask creation, dtype selection, and kernel execution preserve the intended result within a justified numerical tolerance.

Exact bitwise equality is usually the wrong default. Floating-point addition is not associative, and parallel kernels may reduce products in a different order from CPU routines. Small differences can therefore be legitimate even in deterministic code. The correct question is whether errors remain within a tolerance appropriate to dtype, magnitude, and downstream use. Report maximum absolute error, relative error, and whether mask invariants remain exact.

Several seeds are required because one random case may contain easy logits far from a softmax boundary. Another seed may create nearly tied scores, large magnitudes, or a distribution more sensitive to rounding. Test forward scores, weights, outputs, and backward gradients. Copy identical initial tensors to each device; generating random tensors independently on CPU and GPU does not create a parity test because their random streams need not match.

Device errors often hide in auxiliary tensors. A causal mask built on CPU, a scale tensor created with a default dtype, or a reference constant placed on the wrong device can break execution or trigger unwanted transfers. All parameters, inputs, masks, and loss targets must follow an explicit device and dtype contract.

Parity is necessary but not sufficient. Two devices can agree on the same incorrect softmax axis. Reuse the semantic and manual tests from earlier exercises, then add device comparison as another independent layer of evidence.

Part 2 - Mathematical form and reasoning

Let f_{CPU} and f_{CUDA} implement the same attention function. For reference output y and CUDA output $\widehat{y}$, measure

$$E_{\text{abs}} = \max_i |\widehat{y}_i - y_i|,$$

$$E_{\text{rel}} = \max_i \frac{|\widehat{y}_i - y_i|}{\max(|y_i|, \varepsilon)}.$$

A common comparison is

$$|\widehat{y}_i - y_i| \le \texttt{atol} + \texttt{rtol}|y_i|.$$

The tolerances must be recorded rather than chosen after observing failure. Repeat the same comparisons for $\nabla_Q L$, $\nabla_K L$, and $\nabla_V L$.

Part 3 - Hints, controls, and evidence

1. Generate one master set of tensors on CPU, clone it for the CPU path, and copy it to CUDA for the GPU path.
2. Use identical masks and one scalar loss. Compare scores, weights, outputs, and all input gradients.
3. Repeat across at least ten seeds, several shapes, and both unmasked and causal or padded cases.
4. Check `torch.cuda.is_available()` and report a clear skipped test when CUDA is unavailable.
5. Record PyTorch, CUDA, GPU, dtype, deterministic settings, and tolerances.
6. Separate ordinary roundoff from non-finite values, mask violations, and large structural disagreement.

Summarize the distribution of errors across seeds; do not report only the largest case without its configuration.

Part 4 - Python code skeleton

```
import torch

def run_path(q, k, v, mask):
    # TODO: call the scratch attention and a shared scalar loss
    output, debug = ...
    loss = ...
    loss.backward()
    return {
        "output": output.detach().cpu(),
        "weights": debug["weights"].detach().cpu(),
        "q_grad": q.grad.detach().cpu(),
        "k_grad": k.grad.detach().cpu(),
        "v_grad": v.grad.detach().cpu(),
    }
```

```
def parity_metrics(reference, candidate, atol, rtol):
    return {
        "max_abs": ...,
        "max_rel": ...,
        "allclose": ...,
        "finite": ...,
    }

def paired_seed(seed, shape, dtype):
    torch.manual_seed(seed)
    q0, k0, v0, mask0 = ..., ..., ..., ...
    cpu = run_path(...)
    cuda = run_path(...)
    return {
        name: parity_metrics(cpu[name], cuda[name], ...)
        for name in cpu
    }

def E10():
    if not torch.cuda.is_available():
        return {"status": "skipped", "reason": "CUDA unavailable"}
    return [paired_seed(seed, ..., torch.float32)
            for seed in range(10)]
```

Part 5 - The Philosophy Behind the Exercise

Device parity asks whether a mathematical identity survives translation into a different physical process. CPU and GPU do not perform the computation through identical schedules, yet they are expected to realize the same model within defined limits. Reproducibility is therefore not always sameness of bits; it is stability of meaning under bounded numerical variation.

This forces the researcher to define what counts as equivalent. A tolerance is not permission to ignore errors. It is a declared boundary between harmless representation-level variation and behavior-changing disagreement. Its value must be justified by precision, scale, and application.

The broader lesson is that software correctness includes the machine on which the software runs. An equation does not float above hardware. Trust comes from testing the path from mathematical intention through tensor program to physical execution.

17.2.12 Exercise 11

Exercise Title: Benchmark Attention Runtime on GPU for Increasing Sequence Lengths and Observe Quadratic Scaling

Part 1 - Why this matters

Dense self-attention creates interactions between every pair of sequence positions. Doubling sequence length therefore multiplies the number of score entries by approximately four. Theoretical complexity predicts quadratic work for score construction and value aggregation, and quadratic storage when the full attention matrix is materialized. Actual GPU runtime,

however, does not follow a perfect parabola at every size.

Small problems may be dominated by kernel-launch overhead and fail to occupy the GPU. Medium problems can use hardware efficiently, causing runtime to grow more slowly than a naive operation count suggests. Large problems eventually become limited by memory traffic, workspace, or capacity and may jump sharply or fail with out-of-memory. Benchmarking translates asymptotic reasoning into the practical operating region of a particular GPU.

Correct CUDA timing requires synchronization. Kernel launches are asynchronous, so measuring only the Python call may record dispatch time rather than completed execution. Warm-up is also required for allocator state, library initialization, and kernel selection. Prefer CUDA events or synchronized timers, run repeated trials, and report medians and dispersion.

Control every dimension except sequence length. Batch size, head count, head dimension, dtype, mask type, gradient mode, and implementation must stay fixed. Run forward-only and forward-plus-backward benchmarks separately. Record peak memory and tokens per second in addition to latency. If the implementation materializes attention weights, say so; optimized fused kernels may have a different memory curve while computing the same dense attention.

The goal is to observe where quadratic structure becomes visible, not to force every measured ratio to equal four. Explain deviations through utilization, memory, kernel choice, or measurement noise.

Part 2 - Mathematical form and reasoning

For B batches, H heads, length T, and head dimension d_k, the score and aggregation work is approximately

$$\mathcal{O}(BHT^2 d_k),$$

while a materialized attention matrix contains

$$N_A = BHT^2$$

elements. If each element uses s bytes, its storage alone is

$$M_A = sBHT^2.$$

An empirical scaling exponent between two lengths can be estimated by

$$\widehat{p} = \frac{\log(t_2/t_1)}{\log(T_2/T_1)}.$$

A value near 2 over a sufficiently large compute-bound range is consistent with quadratic runtime, but it is not expected in every regime.

Part 3 - Hints, controls, and evidence

1. Test powers of two until the largest safe length for your GPU, stopping before repeated out-of-memory failures.

2. Warm up each shape, use CUDA events or explicit synchronization, and report median plus percentile variation.

3. Reset peak-memory statistics before every measured configuration.
4. Benchmark forward inference under `torch.no_grad()` separately from training with backward.
5. Plot latency and peak memory against T on linear and log–log axes.
6. Compare measured memory with the theoretical score-matrix size and explain the remaining allocations.

Do not compare different sequence lengths while silently reducing batch size; that answers a different throughput question.

Part 4 - Python code skeleton

```
import torch

def benchmark_length(seq_len, config):
    q, k, v = ...  # fixed B, H, d_k, dtype
    for _ in range(config["warmup"]):
        ...
    torch.cuda.synchronize()
    torch.cuda.reset_peak_memory_stats()

    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    times = []
    for _ in range(config["repeats"]):
        start.record()
        output = ...
        end.record()
        end.synchronize()
        times.append(start.elapsed_time(end))

    return {
        "seq_len": seq_len,
        "median_ms": ...,
        "p90_ms": ...,
        "peak_bytes": torch.cuda.max_memory_allocated(),
        "tokens_per_second": ...,
    }

def E11():
    config = ...
    records = []
    for seq_len in [64, 128, 256, 512, 1024, 2048]:
        try:
            records.append(benchmark_length(seq_len, config))
        except torch.OutOfMemoryError:
            records.append({"seq_len": seq_len, "status": "OOM"})
```

```
            break
    # TODO: estimate local scaling exponents
    return records
```

Part 5 - The Philosophy Behind the Exercise

Asymptotic complexity is a statement about growth, not a stopwatch prediction. Hardware turns equations into regimes: overhead-dominated, efficiently parallel, bandwidth-limited, and capacity-limited. The benchmark teaches how a theoretical law appears through the imperfections and strengths of a machine.

Quadratic attention also reveals that universal access has a price. Giving every token the possibility of relating to every other token creates expressive freedom, but the number of possible relations grows faster than the sequence. Architecture is always a decision about which relationships deserve resources.

The practical limit of context is therefore not only a property of a model. It is a joint property of algorithm, representation, precision, kernel, batch, device, and budget. Measurement makes that hidden dependency explicit.

17.2.13 Exercise 12

Exercise Title: Compare float32 vs float16 Attention Outputs and Detect Precision-Sensitive Softmax Instabilities

Part 1 - Why this matters

Half precision can reduce memory traffic, increase tensor-core throughput, and make larger attention workloads possible on a fixed GPU. Those benefits are substantial, but `float16` has a narrower exponent range and fewer mantissa bits than `float32`. Attention combines dot products, division, masking, exponentiation, normalization, and weighted aggregation; each stage can amplify a different form of rounding or range failure.

The comparison must begin from identical real-valued inputs. Create a master `float32` or `float64` tensor, then cast copies into each test precision. Generating independent random inputs would measure sampling difference rather than precision difference. Use the same masks, scale, loss, and upstream gradient. Compare raw scores, probabilities, outputs, and gradients separately so the first stage at which error grows can be identified.

NaNs are only the most visible failure. In `float16`, two nearby large logits may round to the same representable value, changing the attention ranking. Very negative shifted logits may underflow to zero probability, and a large dot product may overflow before stable softmax receives it. The output can remain finite while entropy, rare-token weights, and gradient paths differ materially. Finiteness checks must therefore be combined with parity and distribution diagnostics.

Real mixed-precision systems often compute some reductions or normalization steps in higher precision. This is not cheating; it is a deliberate numerical policy. Compare pure half precision, half inputs with score or softmax upcasting, and full `float32`. The objective is to discover which operations require extra range or resolution and what speed or memory price

that policy imposes.

Sensitivity depends on data scale and sequence length. Sweep the norms of Q and K, the head dimension, and the mask pattern. Report the boundary where agreement deteriorates rather than declaring one dtype universally safe.

Part 2 - Mathematical form and reasoning

Let

$$S^{(32)} = \frac{Q^{(32)}K^{(32)\mathsf{T}}}{\sqrt{d_k}}, \qquad S^{(16)} = \frac{Q^{(16)}K^{(16)\mathsf{T}}}{\sqrt{d_k}}.$$

For outputs $O^{(32)}$ and $O^{(16)}$, measure

$$E_{\max} = \max_i |O_i^{(16)} - O_i^{(32)}|, \qquad E_{\mathrm{RMS}} = \sqrt{\frac{1}{N}\sum_i (O_i^{(16)} - O_i^{(32)})^2}.$$

Also compare row entropy and normalization error:

$$H(A_i) = -\sum_j A_{ij}\log(A_{ij} + \varepsilon), \qquad e_i = \left|\sum_j A_{ij} - 1\right|.$$

These metrics expose distribution changes that a single output tolerance may hide.

Part 3 - Hints, controls, and evidence

1. Use `float32` as the operational reference and optionally `float64` for small diagnostic tensors.
2. Sweep input scale, d_k, and sequence length over several seeds.
3. Compare pure `float16`, upcast-score softmax, and full `float32` paths.
4. Record NaN/Inf counts, score error, ranking changes, entropy changes, output error, and gradient error.
5. Include rows with nearly tied logits and rows with one extreme score.
6. State tolerances before examining results and document any configuration that exceeds them.

Part 4 - Python code skeleton

```
import torch

def attention_precision(q, k, v, mode):
    if mode == "fp16":
        ...
    elif mode == "fp16_upcast_softmax":
        scores = ...
        weights = torch.softmax(scores.float(), dim=-1)
```

```
        output = ...
    elif mode == "fp32":
        ...
    return output, scores, weights

def compare(reference, candidate):
    return {
        "max_abs": ...,
        "rms": ...,
        "finite": ...,
        "row_sum_error": ...,
        "entropy_delta": ...,
    }

def E12(device="cuda"):
    records = []
    for scale in [0.1, 1.0, 10.0, 100.0]:
        for d_k in [16, 64, 256]:
            master_q, master_k, master_v = ...
            reference = attention_precision(..., mode="fp32")
            for mode in ["fp16", "fp16_upcast_softmax"]:
                candidate = attention_precision(..., mode=mode)
                records.append({...})
    return records
```

Part 5 - The Philosophy Behind the Exercise

Precision is a decision about which distinctions a machine is allowed to preserve. Reducing precision does not simply make every number slightly less accurate; it can erase small differences, collapse alternatives into ties, or move a value outside the representable world. In attention, those changes alter which information is retrieved.

Efficiency therefore has an epistemic cost. A faster representation is useful only while it preserves the distinctions the task needs. Mixed precision is a design of selective fidelity: spend numerical accuracy where probabilities and gradients are fragile, and use compact arithmetic where error is tolerable.

The lesson is not that higher precision is always better. It is that precision must be treated as part of model behavior, measured against explicit invariants rather than selected only from a hardware marketing number.

17.2.14 Exercise 13

Exercise Title: Debug Common Attention Bugs Like Wrong Softmax Dimension or Missing Mask Broadcast Rules

Part 1 - Why this matters

Attention failures are unusually deceptive because many incorrect programs produce finite tensors with plausible shapes. Softmax over the query axis still creates normalized numbers,

but it answers a different question. A mask shaped incorrectly may broadcast across batches or heads and leak information without raising an exception. Swapping query and key axes can remain invisible in self-attention because both lengths are equal. Debugging must therefore search for violated semantics, not merely runtime errors.

The first task is to define invariants. Each query row must normalize across allowed keys. Padded and future keys must receive zero weight. Examples in a batch must remain independent. The output shape must retain query length and value dimension. Finite outputs, correct device placement, and consistent dtype are separate requirements. A debugger that checks these contracts after each stage can locate the earliest corruption.

Fault injection turns vague debugging advice into a testable system. Create known broken variants: use `dim=-2` for softmax, omit the key transpose, reverse Boolean mask meaning, drop singleton broadcast axes, apply the mask after softmax, or use a finite mask fill too weak for extreme logits. Each fault should trigger a specific diagnostic. If a test suite cannot detect a defect you deliberately inserted, it cannot be trusted to detect the accidental version.

Use asymmetric shapes and index-coded tensors. A cross-attention case with unequal query and key lengths reveals assumptions hidden by square score matrices. A batch in which every example has a different padding pattern reveals cross-example broadcasting. A causal plus padding mask reveals whether restrictions are combined by logical intersection.

The final output of this exercise is not only corrected code. It is a debugging procedure ordered from cheap structural checks to stronger intervention and gradient tests. This procedure should be reusable in later multi-head, decoder-only, and encoder-decoder chapters.

Part 2 - Mathematical form and reasoning

For

$$S \in \mathbb{R}^{B\times H\times T_q\times T_k},$$

correct normalization requires

$$\sum_{j=1}^{T_k} A_{bhij} = 1$$

for each valid (b, h, i) row. A keep mask G must be broadcastable to S and satisfy

$$G_{bhij} = 0 \quad \Longrightarrow \quad A_{bhij} = 0.$$

For a combined causal mask C and padding mask P,

$$G = C \wedge P.$$

A wrong softmax axis instead enforces a sum over queries, which is numerically valid but semantically unrelated to retrieval over keys.

Part 3 - Hints, controls, and evidence

1. Build one correct reference and one function parameterized by injectable faults.

2. Use distinct sizes for B, H, T_q, T_k, d_k, d_v.
3. Check shapes, row sums, forbidden weights, batch independence, and prefix invariance independently.
4. Require every injected fault to fail at least one named test.
5. Log the earliest failing tensor rather than inspecting only final output.
6. Add informative assertion messages containing semantic axis names and actual shapes.

Produce a table mapping each defect to its symptom, detecting test, root cause, and permanent regression test.

Part 4 - Python code skeleton

```
import torch

def attention_with_fault(q, k, v, mask, fault=None):
    scores = ...
    if fault == "missing_key_transpose":
        scores = ...
    if fault == "mask_after_softmax":
        ...
    if fault == "wrong_mask_semantics":
        ...
    dim = -2 if fault == "wrong_softmax_dim" else -1
    weights = torch.softmax(..., dim=dim)
    output = ...
    return output, {"scores": scores, "weights": weights}

def run_invariants(output, debug, mask, expected_shape):
    return {
        "shape": ...,
        "finite": ...,
        "rows_sum_to_one": ...,
        "forbidden_weights_zero": ...,
        "batch_independent": ...,
    }

def E13():
    faults = [None, "wrong_softmax_dim", "wrong_mask_semantics",
              "mask_after_softmax", "missing_key_transpose"]
    results = {}
    for fault in faults:
        try:
            output, debug = attention_with_fault(...)
            results[str(fault)] = run_invariants(...)
        except Exception as error:
            results[str(fault)] = {"exception": str(error)}
    return results
```

Part 5 - The Philosophy Behind the Exercise

A silent attention bug demonstrates that valid syntax and finite numbers are weak forms of truth. The machine can execute an operation perfectly while the operation answers the wrong question. Correctness requires a relationship between computation and intention that cannot be inferred from successful execution alone.

Fault injection adopts a scientific attitude toward software: do not merely hope that tests protect the system; challenge them with known falsehoods. Confidence grows when an instrument distinguishes correct behavior from carefully constructed error.

Debugging is therefore a study of violated meaning. The earliest failed invariant tells us where the computation stopped representing the intended world. A mature engineer does not only fix the visible symptom; they preserve the discovered meaning as a future test.

17.2.15 Exercise 14

Exercise Title: Implement Attention Dropout and Verify It Activates Only During Training Mode and Not During Evaluation

Part 1 - Why this matters

Attention dropout regularizes retrieval by randomly removing some normalized attention links during training. It discourages a head from depending exclusively on one fragile route and exposes the surrounding network to alternative value combinations. The operation is stochastic by design, but its location and mode behavior must be precise. Applying dropout to attention weights is not identical to applying dropout to inputs, values, projections, or the final block output.

In the standard formulation, softmax first creates an attention distribution and dropout then masks and rescales its entries before multiplication by V. The surviving weights are scaled by $1/(1-p)$, preserving their expectation under independent dropout. For a particular training sample, however, rows no longer need to sum to one. A test that always demands a unit row sum after dropout is therefore incorrect. Before dropout the probability invariant remains essential; after dropout the relevant invariant is expected value over many masks.

Mode control is critical. During `model.train()`, repeated forward passes with the same input should usually differ when $p > 0$. During `model.eval()`, dropout must be disabled and repeated outputs should match within the deterministic behavior of the remaining operations. Using `torch.nn.functional.dropout` without passing `training=self.training` is a common failure that leaves stochastic behavior active in evaluation.

Deterministic tests need careful seed handling. Resetting the same seed before every training forward can make dropout appear inactive because it recreates the same mask. Conversely, comparing two unseeded evaluation calls can confuse dropout with another nondeterministic kernel. Inspect or reconstruct dropout masks on a tiny example, then evaluate statistical behavior across many independent trials.

Finally, masking and dropout must not be confused. Padding and causal masks enforce forbidden information paths and must remain absolute. Dropout removes permitted paths

temporarily for regularization. A forbidden location must never reappear through dropout scaling or an incorrect ordering.

Part 2 - Mathematical form and reasoning

Let A be the post-softmax attention matrix and let $Z_{ij} \sim \text{Bernoulli}(1-p)$. Training-time dropout produces

$$\widetilde{A}_{ij} = \frac{Z_{ij}}{1-p} A_{ij}.$$

Therefore

$$\mathbb{E}[\widetilde{A}_{ij}] = \frac{\mathbb{E}[Z_{ij}]}{1-p} A_{ij} = A_{ij}.$$

The output is

$$O_{\text{train}} = \widetilde{A}V, \qquad O_{\text{eval}} = AV.$$

For one training realization,

$$\sum_j \widetilde{A}_{ij} \neq 1$$

in general, although the expected sum equals one.

Part 3 - Hints, controls, and evidence

1. Implement attention dropout in an `nn.Module` so it follows `train()` and `eval()` modes.
2. Confirm masked positions are zero both before and after dropout.
3. In training mode, run many trials and estimate the zero fraction and mean output.
4. Compare the empirical mean with the no-dropout evaluation output.
5. In evaluation mode, run repeated identical inputs and require parity.
6. Test $p = 0$, a moderate probability, and a high probability while explaining why $p = 1$ is invalid for inverted dropout.

Part 4 - Python code skeleton

```
import torch
from torch import nn
from torch.nn import functional as F

class ScratchAttention(nn.Module):
    def __init__(self, dropout_p):
        super().__init__()
        self.dropout_p = dropout_p

    def forward(self, q, k, v, keep_mask=None):
```

```
        scores = ...
        if keep_mask is not None:
            scores = ...
        weights = ...
        dropped = F.dropout(
            weights, p=self.dropout_p,
            training=...  # TODO
        )
        output = ...
        return output, weights, dropped

def E14():
    module = ScratchAttention(dropout_p=0.2)
    q, k, v, mask = ..., ..., ..., ...

    module.train()
    training_runs = [module(q, k, v, mask) for _ in range(500)]

    module.eval()
    eval_runs = [module(q, k, v, mask) for _ in range(5)]

    return {
        "training_changes": ...,
        "empirical_zero_rate": ...,
        "mean_matches_eval": ...,
        "eval_is_repeatable": ...,
        "forbidden_positions_stay_zero": ...,
    }
```

Part 5 - The Philosophy Behind the Exercise

Dropout introduces deliberate unreliability in order to produce a more reliable model. During training, the network is denied some convenient paths and must learn representations that survive their absence. Robustness is cultivated by controlled imperfection rather than by protecting every internal dependency.

This differs fundamentally from a causal or padding mask. Structural masks describe what information is illegitimate; dropout describes what legitimate information is temporarily unavailable. One is a rule of the problem, the other a strategy for learning. Confusing them means confusing ethics of access with discipline of dependence.

Evaluation removes the artificial uncertainty because the learned system is now being judged, not trained. The change of mode reminds us that the same architecture can inhabit different operational regimes, and correctness depends on knowing which regime is active.

17.2.16 Exercise 15

Exercise Title: Implement a Test Suite That Validates Attention Properties Including Masking and Output Shape Correctness

Part 1 - Why this matters

Attention combines enough independent rules that example-based testing alone is inadequate. One successful tensor cannot prove that arbitrary batches, heads, query lengths, key lengths, masks, devices, and dtypes will behave correctly. A test suite converts the mathematical and semantic expectations of the chapter into executable contracts that can protect later refactoring and optimization.

The suite should contain exact tiny examples, randomized property tests, edge cases, and negative tests. Exact examples catch arithmetic and orientation errors. Randomized shapes expose accidental dependence on equal dimensions. Edge cases reveal sequence-length one, fully valid masks, nearly empty masks, and cross-attention behavior. Negative tests prove invalid inputs are rejected with useful messages rather than producing mysterious failures downstream.

Test layers should remain independent. Shape validity does not imply mask validity; row normalization does not imply causal isolation; forward parity does not imply gradient parity. Each property deserves a named assertion so a failure communicates which meaning was lost. Tests must also account for dropout: deterministic reference comparisons belong in evaluation mode or with $p = 0$.

Device and precision coverage should be conditional but explicit. CPU tests must always run. CUDA and half-precision tests should be marked as skipped when unsupported rather than silently absent. Tolerances should depend on dtype and be specified before comparison. Save failing seeds and shapes so randomized failures can be reproduced.

The suite becomes a gate for later performance work. A fused kernel, compiled path, or memory optimization should not be accepted merely because it is faster. It must satisfy the same behavioral contracts as the transparent reference.

Part 2 - Mathematical form and reasoning

For valid inputs, test at least

$$\operatorname{shape}(O) = (B, H, T_q, d_v),$$

$$\sum_{j=1}^{T_k} A_{bhij} = 1, \qquad A_{bhij} \geq 0,$$

$$G_{bhij} = 0 \Longrightarrow A_{bhij} = 0,$$

and causal prefix invariance

$$X'_{0:r} = X_{0:r} \Longrightarrow O'_{0:r} = O_{0:r}.$$

Reference parity can use

$$|\widehat{y} - y| \leq \texttt{atol} + \texttt{rtol}|y|.$$

Gradient checks compare derivatives for Q, K, and V, either against a trusted implementation or finite differences on a tiny double-precision case.

Part 3 - Hints, controls, and evidence

1. Organize tests by shape, arithmetic, mask, causality, gradient, device, precision, mode, and invalid-input behavior.
2. Include unequal query and key lengths and unique sizes for every axis.
3. Use fixed seeds and print the seed plus shape when a randomized test fails.
4. Run attention in evaluation mode for deterministic parity tests.
5. Verify each deliberately broken implementation causes the expected test to fail.
6. Produce a compact pass, fail, or skip report rather than hiding skipped hardware coverage.

Part 4 - Python code skeleton

```
import torch

def test_output_shape(attention):
    q, k, v = ...
    output, weights = attention(q, k, v)
    assert output.shape == ...
    assert weights.shape == ...

def test_probability_properties(attention):
    ...

def test_padding_invariance(attention):
    ...

def test_causal_prefix_invariance(attention):
    ...

def test_reference_and_gradients(attention):
    ...

def test_invalid_inputs(attention):
    # TODO: incompatible d_k, K/V length mismatch, all-masked row
    ...

def E15(attention):
    tests = [
        test_output_shape,
        test_probability_properties,
        test_padding_invariance,
        test_causal_prefix_invariance,
        test_reference_and_gradients,
        test_invalid_inputs,
    ]
    report = {}
```

```
    for test in tests:
        try:
            test(attention)
            report[test.__name__] = "passed"
        except Exception as error:
            report[test.__name__] = f"failed: {error}"
    return report
```

Part 5 - The Philosophy Behind the Exercise

A test suite is a durable expression of understanding. Explanations can be forgotten and code can be reorganized, but an invariant encoded as a test continues to challenge every future implementation. It converts knowledge from a private mental state into a shared institutional memory.

Testing also defines the limits of trust. Passing tests does not prove every possible behavior correct; it proves survival under a declared set of questions. The quality of confidence depends on the quality and diversity of those questions.

The deepest value of a test is not that it rewards correct code, but that it makes certain forms of self-deception difficult. A faster or more complex implementation must answer to the same meaning as the simple reference.

17.2.17 Exercise 16

Exercise Title: Stress Test Attention With Large Batch and Long Sequence and Monitor GPU Memory Peak and Runtime

Part 1 - Why this matters

A benchmark measures expected performance in a controlled region. A stress test searches for the boundary where assumptions fail. For attention, batch size multiplies examples while dense sequence interactions grow quadratically. Increasing both can cause abrupt out-of-memory failures, allocator pressure, latency spikes, or throughput collapse long before parameter memory changes.

The test must monitor more than the allocation visible after a forward pass. Attention may create transient score matrices, softmax buffers, gradients, saved activations, and library workspaces. CUDA caching also distinguishes memory allocated to live tensors from memory reserved by the allocator. Reset peak statistics before every configuration and record both peaks. Separate inference, training forward, and full forward-backward because their activation lifetimes differ.

A responsible stress test increases load gradually and stops safely. Repeated OOM failures can leave a process fragmented or unusable. Construct a bounded grid, begin from known-safe settings, synchronize before measurement, catch `torch.OutOfMemoryError`, and record failure rather than hiding it. Do not automatically consume every available byte.

Runtime should be reported as latency and throughput. A larger batch may increase latency while improving tokens per second through better utilization. Longer sequences may initially

improve kernel efficiency before quadratic work dominates. Record distributional statistics because memory pressure and system activity can produce tail latency.

The result is an operating envelope for the actual device and implementation: which combinations are safe, efficient, and impossible. This envelope is conditional on dtype, head count, dimension, gradient mode, mask, and whether attention weights are materialized.

Part 2 - Mathematical form and reasoning

The attention tensor contains

$$N_A = BHT_qT_k$$

elements. For self-attention with $T_q = T_k = T$ and s bytes per element,

$$M_A = sBHT^2.$$

The dominant multiplications scale as

$$\mathcal{O}(BHT^2d_k).$$

Throughput can be reported as

$$\text{tokens/s} = \frac{BT}{t}.$$

These derived metrics do not replace raw latency and memory measurements.

Part 3 - Hints, controls, and evidence

1. Define explicit maximum batch and sequence lengths before running.
2. Test inference and training separately with fixed H, d_k, dtype, and implementation.
3. Warm up, synchronize, reset peak statistics, and measure repeated trials.
4. Record latency percentiles, tokens per second, peak allocated memory, peak reserved memory, and OOM status.
5. Verify output shape and finiteness at every successful point.
6. After an OOM, release only failed-trial references and continue with a documented safe strategy.

Plot batch-by-sequence heat maps for latency, memory, and pass/OOM status, then identify a conservative production boundary below the absolute maximum.

Part 4 - Python code skeleton

```
import gc
import torch

def stress_point(batch, seq_len, config):
    torch.cuda.reset_peak_memory_stats()
```

```
    q, k, v = ...  # explicit tested dimensions
    torch.cuda.synchronize()
    try:
        # TODO: time forward or forward+backward
        output = ...
        torch.cuda.synchronize()
        return {
            "status": "passed",
            "finite": ...,
            "latency_ms": ...,
            "peak_allocated": torch.cuda.max_memory_allocated(),
            "peak_reserved": torch.cuda.max_memory_reserved(),
            "tokens_per_second": ...,
        }
    except torch.OutOfMemoryError:
        return {"status": "OOM"}
    finally:
        # TODO: drop trial-local references
        ...
        gc.collect()
        torch.cuda.empty_cache()

def E16():
    config = {"max_batch": 64, "max_seq": 4096, ...}
    records = []
    for batch in [1, 2, 4, 8, 16, 32, 64]:
        for seq_len in [128, 256, 512, 1024, 2048, 4096]:
            records.append(stress_point(batch, seq_len, config))
    return records
```

Part 5 - The Philosophy Behind the Exercise

Stress testing treats limits as knowledge rather than embarrassment. A system that fails beyond a certain context is not automatically defective; a system whose boundary is unknown is operationally dangerous. Reliability begins when capacity is measured and documented.

The difference between an absolute maximum and a safe operating limit matters. Engineering wisdom reserves space for variation, concurrent work, and unexpected inputs. Living permanently at the edge turns ordinary fluctuation into failure.

Attention makes a broader truth visible: richer relational access consumes physical resources. Intelligence implemented on machines is bounded by memory, time, energy, and scheduling. Understanding those bounds is part of understanding the model.

17.2.18 Exercise 17

Exercise Title: Investigate Non-Determinism in CUDA Attention and Document Which Operations Cause Variation

Part 1 - Why this matters

Re-running a CUDA experiment with the same seed does not always guarantee bitwise-identical results. Randomness, algorithm selection, parallel reduction order, dropout, data loading, and fused attention kernels are distinct sources of variation. If they are collapsed into one label called GPU randomness, the researcher cannot decide which controls are possible, which performance costs they impose, or whether observed differences exceed ordinary numerical noise.

Begin by separating stochasticity from nondeterministic execution. Dropout produces different masks unless random state is controlled; this is intended stochastic behavior. A nondeterministic kernel may vary even with identical inputs and random state because atomic updates or parallel accumulation order can change. Algorithm-selection heuristics may also choose different paths depending on shape and environment.

Determinism settings are not magical. Enabling deterministic algorithms may raise an error for unsupported operations, choose slower kernels, or disable optimizations. Library version, GPU architecture, environment, and precision must be recorded. A run reproducible on one machine may not be bitwise identical on a different software or hardware stack.

Design the investigation as an ablation. Start with fixed saved tensors and dropout disabled. Repeat forward and backward. Then enable dropout with controlled and uncontrolled seeds, toggle deterministic settings, and compare scratch, fused, and high-level attention paths when available. Measure the magnitude and location of disagreement, not merely whether exact equality fails.

The goal is a reproducibility policy: decide when bitwise identity is required, when tolerance parity is sufficient, and which metadata must accompany a result. Debugging may justify slower deterministic kernels; production training may rationally prefer faster paths if variation is measured and acceptable.

Part 2 - Mathematical form and reasoning

Floating-point addition generally satisfies

$$\mathrm{fl}(\mathrm{fl}(a+b)+c) \neq \mathrm{fl}(a+\mathrm{fl}(b+c)).$$

For repeated outputs $y^{(1)}, \ldots, y^{(R)}$, report

$$\Delta_{\max} = \max_{r,s} \|y^{(r)} - y^{(s)}\|_\infty$$

and RMS variation. For training runs, distinguish parameter and metric variation:

$$\Delta_\theta = \|\theta_R^{(r)} - \theta_R^{(s)}\|_2, \qquad \Delta_L = |L_R^{(r)} - L_R^{(s)}|.$$

Small kernel differences may accumulate through optimization, so both levels must be examined.

Part 3 - Hints, controls, and evidence

1. Record Python, PyTorch, CUDA, cuDNN, GPU, dtype, kernel path, and determinism settings.

2. Use fixed saved inputs before introducing a random data pipeline.
3. Test forward and backward separately with dropout disabled.
4. Add dropout and compare reset-seed, continuing-seed, and evaluation-mode behavior.
5. Enable deterministic algorithms and document errors or performance changes rather than suppressing them.
6. Repeat short training runs and compare final parameters and task metrics.

Build a cause table separating data randomness, initialization, dropout, parallel reduction, kernel choice, and cross-machine variation.

Part 4 - Python code skeleton

```
import torch

def configure(seed, deterministic):
    torch.manual_seed(seed)
    torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(deterministic)
    # TODO: record backend and environment settings

def repeated_attention(attention, q, k, v, repeats):
    outputs, gradients = [], []
    for _ in range(repeats):
        q_run = q.detach().clone().requires_grad_(True)
        # TODO: run identical forward and backward
        ...
        outputs.append(...)
        gradients.append(...)
    return outputs, gradients

def variation(tensors):
    # TODO: pairwise max-absolute and RMS differences
    return ...

def E17():
    report = {}
    for deterministic in [False, True]:
        configure(seed=123, deterministic=deterministic)
        try:
            outputs, gradients = repeated_attention(...)
            report[str(deterministic)] = {
                "output_variation": variation(outputs),
                "gradient_variation": variation(gradients),
            }
        except RuntimeError as error:
            report[str(deterministic)] = {"unsupported": str(error)}
    return report
```

Part 5 - The Philosophy Behind the Exercise

Reproducibility is often imagined as the universe returning the same bits on command. In parallel numerical systems, a more useful concept is controlled variation: know which causes are fixed, measure what remains, and determine whether conclusions survive it.

Determinism has a purpose rather than an absolute moral status. It is valuable when isolating bugs, comparing implementations, or auditing a critical result. It may be unnecessarily expensive when small bounded variation has no behavioral consequence. The responsible choice is explicit and evidenced.

A single run is one trajectory through a system shaped by data, initialization, arithmetic, and hardware. Knowledge becomes stronger when a conclusion persists across the variations that the real system can produce.

17.2.19 Exercise 18

Exercise Title: Visualize Attention Matrices and Build Interpretation Notes About What Patterns Mean in Practice

Part 1 - Why this matters

An attention matrix is one of the rare internal neural-network objects that can be aligned directly with input positions. Rows identify queries, columns identify keys, and color represents a normalized mixing weight. Visualization can reveal causal-mask violations, attention to padding, local diagonals, delimiter focus, repeated-token links, broad diffuse retrieval, or heads that appear redundant. It is therefore an excellent debugging instrument.

Interpretation requires discipline. A bright cell means that one head at one layer assigned a large coefficient to one value position for one query. It does not prove that the source token caused the final prediction, that the model understood a linguistic relation, or that another computation path was unimportant. Value magnitude, output projection, residual connections, feed-forward layers, and later attention operations all influence the final result.

Plot construction can create false stories. Every plot must label query and key tokens, specify layer and head, use a documented color range, and display masks. Comparisons should share the same scale; otherwise automatic rescaling can make minor differences appear dramatic. Long sequences require selection or aggregation, but aggregation may hide narrow patterns. Preserve the raw matrix alongside every visualization.

Useful interpretation combines description with intervention. If a head seems to attend to a delimiter, remove or move the delimiter and observe how the matrix and output change. If two heads look redundant, ablate each separately and together. If a diagonal pattern appears, shift repeated tokens or positions to determine whether the head follows content or location. These tests move from visual correlation toward causal evidence.

The final notes should classify observations by confidence: directly verified properties, plausible hypotheses, and unsupported stories. The exercise is not complete when the heat map is attractive; it is complete when the plot helps detect an error or generate a hypothesis that can survive testing.

Part 2 - Mathematical form and reasoning

For one batch element, layer, and head,

$$A \in [0,1]^{T_q \times T_k}, \qquad \sum_{j=1}^{T_k} A_{ij} = 1.$$

Row entropy measures concentration:

$$H_i = -\sum_j A_{ij} \log(A_{ij} + \varepsilon).$$

Head similarity can be summarized by a normalized matrix distance, for example

$$D(A^{(h)}, A^{(g)}) = \frac{\|A^{(h)} - A^{(g)}\|_F}{\sqrt{T_q T_k}}.$$

These statistics support visualization but do not establish causal importance. An ablation effect can be measured as

$$\Delta_h = \mathcal{L}_{\text{ablated } h} - \mathcal{L}_{\text{baseline}}.$$

Part 3 - Hints, controls, and evidence

1. Save raw pre-mask scores, post-mask weights, tokens, mask, layer, head, model mode, and input identifier.
2. Label axes explicitly and keep a shared color scale for comparisons.
3. Start with tiny synthetic patterns whose expected attention structure is known, then examine learned examples.
4. Compute row entropy, maximum weight, and head similarity beside the plot.
5. Test at least one visual hypothesis through token perturbation or head ablation.
6. Write interpretations in three categories: observed, experimentally supported, and speculative.

Include examples where visualization correctly reveals a bug and where a plausible-looking pattern fails a causal test.

Part 4 - Python code skeleton

```
import torch
import matplotlib.pyplot as plt

def plot_attention(weights, query_tokens, key_tokens,
                   title, vmin=0.0, vmax=1.0):
    # weights: (query_len, key_len)
    fig, ax = plt.subplots(figsize=(8, 6))
    image = ax.imshow(..., vmin=vmin, vmax=vmax, aspect="auto")
    # TODO: label query rows and key columns
```

```
    # TODO: add color bar and readable tick orientation
    return fig

def attention_statistics(weights, eps=1e-12):
    entropy = ...
    maximum = ...
    return {"row_entropy": entropy, "row_max": maximum}

def ablate_head(model, head_index, inputs):
    baseline = ...
    ablated = ...
    return {"output_delta": ..., "loss_delta": ...}

def E18(model, examples):
    report = []
    for example in examples:
        output, all_weights = ...
        for layer, heads in enumerate(all_weights):
            for head in range(heads.shape[1]):
                matrix = ...
                figure = plot_attention(...)
                report.append({
                    "layer": layer,
                    "head": head,
                    "statistics": attention_statistics(matrix),
                    "ablation": ablate_head(...),
                })
    return report
```

Part 5 - The Philosophy Behind the Exercise

Visualization stands between access and understanding. It grants humans a view into an internal computation, but the view arrives through choices of projection, color, scale, aggregation, and example. A visible pattern is already an interpretation shaped by an instrument.

Attention maps are especially seductive because they resemble diagrams of focus. Yet a model's weight distribution is not identical to human attention, intention, or explanation. Treating it as such replaces investigation with anthropomorphic storytelling.

The proper philosophical role of visualization is generative and critical: it helps us notice, question, and design interventions. It is not the final proof. Seeing begins inquiry; changing the system and observing consequences deepens it.

17.2.20 Exercise 19

Exercise Title: Write a Conceptual Report Explaining Attention, Masking, Scaling, and Why Transformers Replaced RNNs

Part 1 - Why this matters

The final exercise converts nineteen separate investigations into one coherent argument. A good report must explain what attention computes, why Query, Key, and Value have different roles, how scaling controls score statistics, how padding and causal masks define legal information access, and why batched matrix operations changed the practical scalability of sequence models. It must also preserve the limitations revealed by the experiments.

The report should not repeat the slogan that Transformers process everything in parallel. It must distinguish parallel training over known sequence positions from sequential autoregressive generation. It should distinguish shorter dependency paths from quadratic total work, and mathematical equivalence from finite-precision behavior. The replacement of RNNs in many domains was a systems outcome involving optimization, hardware utilization, direct long-distance interaction, data scale, and software kernels.

Evidence from the chapter should support each major claim. Use the copy task to discuss recurrent compression versus addressable retrieval; the scaling sweep to explain gradient stability; padding and causal interventions to demonstrate information boundaries; CPU–GPU and precision comparisons to establish numerical requirements; runtime and stress tests to quantify quadratic cost; and visual or ablation studies to define the limits of interpretability.

The report must also explain where attention does not win. Recurrent models may remain useful for streaming, constant-state processing, small hardware, or short tasks. Dense attention becomes expensive for long contexts, stores large intermediate relations, and depends on positional representation. Generation remains sequential, attention weights do not guarantee explanation, and CUDA execution may introduce bounded variation. A strong conclusion includes these conditions rather than hiding them.

Write the report as an engineering document that another researcher could audit. Separate theoretical derivation, experimental configuration, measured result, interpretation, failure case, and recommendation. Include tables and figures only when their axes, units, seeds, tolerances, and environment are documented. End with open questions that later chapters on multi-head attention, position, Transformer blocks, and efficient long context must answer.

Part 2 - Mathematical form and reasoning

The central mechanism is

$$A = \operatorname{softmax}\left(\frac{QK^{\mathsf{T}}}{\sqrt{d_k}} + M\right), \qquad O = AV.$$

The report should connect it to recurrent computation

$$h_t = f_\theta(x_t, h_{t-1}),$$

and contrast sequential path depth:

$$\text{depth}_{\text{RNN}} = \mathcal{O}(T), \qquad \text{pairwise path}_{\text{attention}} = \mathcal{O}(1)$$

within one attention layer. It must also state dense attention cost:

$$\text{work} = \mathcal{O}(BHT^2 d_k), \qquad \text{score storage} = \mathcal{O}(BHT^2).$$

For causal language modeling,

$$p(x_{1:T}) = \prod_{t=1}^{T} p(x_t \mid x_{<t}),$$

which explains why causal masks enable parallel training but not simultaneous generation of unknown future tokens.

Part 3 - Hints, controls, and evidence

1. Begin with an explicit thesis and list the claims the chapter's evidence can and cannot support.
2. Cite artifacts from E00–E18: configurations, tables, plots, parity errors, mask tests, and failure cases.
3. Separate RNN, LSTM, and attention trade-offs rather than treating all recurrent models as identical.
4. Include numerical stability, precision, determinism, memory, and latency as parts of the architecture's real behavior.
5. State experimental limits, unmatched budgets, and alternative explanations.
6. Finish with design recommendations and questions carried into TRF01.

The report should be reproducible from saved evidence, not dependent on unrecorded impressions.

Part 4 - Python code skeleton

```
from pathlib import Path
import json

def load_verified_artifacts(artifact_directory):
    # TODO: load chapter results and reject missing metadata
    return ...

def validate_evidence(artifacts):
    required = [
        "parallelism", "qkv_retrieval", "masking",
        "scaling", "precision", "runtime", "memory",
        "determinism", "interpretation",
    ]
    return {name: ... for name in required}

def build_report_sections(artifacts):
    return {
        "thesis": ...,
        "mechanism": ...,
        "rnn_comparison": ...,
        "numerical_evidence": ...,
```

```
        "systems_evidence": ...,
        "failure_modes": ...,
        "limitations": ...,
        "next_questions": ...,
    }

def E19(artifact_directory, output_path):
    artifacts = load_verified_artifacts(artifact_directory)
    checks = validate_evidence(artifacts)
    assert all(checks.values()), checks
    sections = build_report_sections(artifacts)
    # TODO: write the report with linked tables and figures
    Path(output_path).write_text(..., encoding="utf-8")
    return {"output": output_path, "checks": checks}
```

Part 5 - The Philosophy Behind the Exercise

Transformers did not replace recurrent models because one equation was universally closer to intelligence. They prevailed across many tasks because a form of relational computation aligned with large data, gradient optimization, parallel hardware, and scalable software. Scientific ideas succeed inside material and institutional environments.

Attention changes the metaphor of sequence intelligence. Instead of carrying one continuously rewritten memory through time, the model reconstructs meaning through direct relations among stored representations. This grants flexible access but demands explicit order, information boundaries, and substantial resources. Every new freedom creates a new responsibility.

The final philosophical lesson is that no mechanism should be understood only through its victories. A complete account includes what it permits, what it forbids, what it costs, how it fails, and what evidence would change our conclusion. The purpose of this chapter is not to worship attention, but to understand why it became powerful enough to reorganize modern AI.

17.3 TRF01

Chapter Title: Multi-Head Attention and Projection Geometry
Specialization: Models and Training

17.3.1 Exercise 00

Exercise Title: Implement Multi-Head Attention from Scratch and Verify Correct Reshaping and Head Concatenation

Part 1 - Why this matters

Multi-head attention is not several unrelated attention modules placed beside one another. It is one representation space projected into several smaller spaces, processed independently, concatenated, and projected back into the model space. The implementation therefore depends on a strict sequence of geometric transformations. A tensor begins as `(batch, sequence,`

`d_model)`, becomes `(batch, sequence, heads, d_head)`, is transposed to place the head axis before the sequence axis, and finally returns to the original model width. Every reshape must preserve element identity; every transpose must change only axis meaning.

The most dangerous bugs are not always runtime errors. If the program reshapes without transposing, the element count remains valid and matrix multiplication may still execute, but features from different tokens and heads are silently interleaved. The resulting model can train slowly or learn a different function while all displayed dimensions appear plausible. Correct multi-head attention therefore requires both shape contracts and value-level tests using tensors whose elements can be traced manually.

Each head computes attention inside a subspace of width $d_h = d_{\text{model}}/H$. The heads do not exchange information while their score matrices and weighted value sums are being calculated. Concatenation does not average the heads; it restores all head outputs side by side in a single vector. The output projection then allows information discovered in different heads to mix. Omitting that projection still produces the expected width, but removes a learned stage of cross-head integration.

This exercise should build three levels of evidence. First, use a tiny tensor with sequential integers and verify splitting and merging by inspection. Second, implement the complete operation with explicit projections and masks. Third, copy the same weights into `torch.nn.MultiheadAttention` and compare forward outputs and input gradients. Library parity is valuable only after the tensor contract of the scratch implementation has been proved.

Part 2 - Mathematical form and reasoning

Let $X \in \mathbb{R}^{B\times T\times d}$, with H heads and $d_h = d/H$. The joint projections are

$$Q = XW_Q, \qquad K = XW_K, \qquad V = XW_V,$$

where $W_Q, W_K, W_V \in \mathbb{R}^{d\times d}$. After splitting,

$$Q, K, V \in \mathbb{R}^{B\times H\times T\times d_h}.$$

For head r,

$$A^{(r)} = \operatorname{softmax}\left(\frac{Q^{(r)}K^{(r)\mathsf{T}}}{\sqrt{d_h}} + M\right), \qquad Z^{(r)} = A^{(r)}V^{(r)}.$$

Concatenation and output projection give

$$Z = \operatorname{Concat}(Z^{(1)}, \ldots, Z^{(H)}) \in \mathbb{R}^{B\times T\times d}, \qquad Y = ZW_O.$$

The invariant $d = Hd_h$ is mandatory. Splitting and merging should also be mutual inverses before any attention calculation is introduced.

Part 3 - Hints, controls, and evidence

1. Reject configurations for which `d_model % num_heads != 0`.
2. Test `merge_heads(split_heads(x)) == x` exactly on an integer-like floating tensor before testing attention.

3. Print shapes after projection, view, transpose, score multiplication, weighted sum, transpose back, concatenation, and output projection.

4. Use `contiguous()` or `reshape()` deliberately after transposition; explain why a non-contiguous tensor cannot always be viewed.

5. Compare with PyTorch using identical weights, biases, dropout state, mask convention, dtype, and batch layout.

6. Check row sums of attention weights, masked positions, finite outputs, and gradients of inputs and all four projection matrices.

The report must include one traceable tensor example showing which original feature reaches each head and which concatenated location receives it again.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

class ScratchMHA(nn.Module):
    def __init__(self, d_model, num_heads, dropout=0.0):
        super().__init__()
        assert d_model % num_heads == 0
        self.d_model = d_model
        self.num_heads = num_heads
        self.d_head = d_model // num_heads
        self.q_proj = nn.Linear(d_model, d_model)
        self.k_proj = nn.Linear(d_model, d_model)
        self.v_proj = nn.Linear(d_model, d_model)
        self.out_proj = nn.Linear(d_model, d_model)
        self.dropout = nn.Dropout(dropout)

    def split_heads(self, x):
        # TODO: (B,T,d) -> (B,H,T,d_head)
        return ...

    def merge_heads(self, x):
        # TODO: (B,H,T,d_head) -> (B,T,d)
        return ...

    def forward(self, query, key, value, mask=None):
        q = self.split_heads(self.q_proj(query))
        k = self.split_heads(self.k_proj(key))
        v = self.split_heads(self.v_proj(value))
        scores = ...
        if mask is not None:
            scores = ...
        weights = ...
```

```
        heads = ...
        output = self.out_proj(self.merge_heads(heads))
        return output, weights

def E00():
    model = ScratchMHA(d_model=8, num_heads=2)
    x = torch.arange(2 * 3 * 8, dtype=torch.float32).reshape(2, 3, 8)
    split = model.split_heads(x)
    merged = model.merge_heads(split)
    assert torch.equal(merged, x)
    # TODO: add manual, library-parity, mask, and gradient tests
    return model(x, x, x)
```

Part 5 - The Philosophy Behind the Exercise

Multi-head attention expresses the idea that one representation can be viewed through several learned coordinate systems at the same time. No single view is assumed to contain every useful relation. The architecture preserves several partial perspectives and lets a later projection integrate them.

Yet multiplicity alone does not create diversity. Heads begin as available degrees of freedom, not guaranteed specialists. Their eventual behavior is shaped by initialization, data, loss, optimization, and interactions with the rest of the network. The implementation should therefore preserve head independence without pretending that the model must use it in a human-readable way.

The deeper engineering lesson is that meaning depends on geometry and geometry depends on axis semantics. A reshape is not clerical code surrounding the model; it determines which features are allowed to interact. Understanding multi-head attention begins when tensor layout is treated as part of the mathematics rather than as an implementation detail.

17.3.2 Exercise 01

Exercise Title: Explain Why Multiple Heads Learn Different Relations and Demonstrate With Simple Synthetic Patterns

Part 1 - Why this matters

The usual explanation of multi-head attention says that different heads learn different relationships. This is a useful hypothesis, but it is not an architectural guarantee. Heads have separate projected subspaces and can therefore represent different compatibility functions, yet two heads may become redundant, divide one relation across several components, or change their apparent role across examples. This exercise replaces the slogan with a controlled experiment.

Create synthetic sequences containing relations whose ground truth is known. One relation may require attending to the immediately previous token, another to a token with the same symbol, and another to a marker at the beginning of the sequence. A small multi-head model is then trained on a target requiring more than one relation. Because the data-generating process is explicit, head weights can be compared with known relation masks rather than interpreted

only through attractive heat maps.

The experiment must separate capacity from specialization. Compare one head with the same total d_{model} against several heads whose widths sum to that same value. Repeat seeds and match parameter budgets where possible. If a head aligns with a relation, ablate or permute that head and measure the change in task performance. Visual similarity without a behavioral intervention is weak evidence.

Finally, record negative results. Two heads may solve the task using a distributed representation that does not resemble the intended masks. A trained network is free to exploit any predictive structure available in the dataset. The purpose is not to force a comforting story, but to understand when architectural subspaces produce measurable functional diversity.

Part 2 - Mathematical form and reasoning

For head r,

$$A^{(r)} = \operatorname{softmax}\left(\frac{XW_Q^{(r)}(XW_K^{(r)})^{\mathsf{T}}}{\sqrt{d_h}} + M\right).$$

Let $R^{(m)} \in \{0,1\}^{T\times T}$ be a known relation matrix for pattern m. One simple alignment score is

$$S_{r,m} = \frac{1}{BT}\sum_{b,i}\sum_{j} A^{(r)}_{b,i,j} R^{(m)}_{b,i,j},$$

with suitable normalization when a row contains several valid keys. Head redundancy may be approximated by

$$D_{r,s} = \frac{1}{BT}\sum_{b,i} \operatorname{JSD}\left(A^{(r)}_{b,i,:}, A^{(s)}_{b,i,:}\right),$$

but behavioral ablation remains necessary because weight similarity is not identical to functional importance.

Part 3 - Hints, controls, and evidence

1. Generate labels from two explicit relations and retain their ideal attention matrices for later comparison.

2. Fix dataset, initialization policy, optimizer budget, stopping rule, and evaluation split across head-count comparisons.

3. Train at least five seeds and report distributions rather than selecting the clearest heat map.

4. Measure relation alignment, pairwise head similarity, and performance drop after head ablation.

5. Add a shortcut feature deliberately, then test whether heads follow the intended relation or the easier correlation.

6. Do not name a head “syntax” or “memory” unless the intervention supports that functional claim.

Part 4 - Python code skeleton

```
import torch

def make_relational_batch(batch, seq_len, vocab_size):
    tokens = ...
    previous_relation = ...   # (B,T,T)
    same_token_relation = ... # (B,T,T)
    targets = ...
    return tokens, targets, {
        "previous": previous_relation,
        "same_token": same_token_relation,
    }

def alignment_score(weights, relation):
    # weights: (B,H,T,T); relation: (B,T,T)
    return ...

def ablate_head(head_outputs, head_index):
    changed = head_outputs.clone()
    changed[:, head_index] = 0
    return changed

def E01(config, seeds=range(5)):
    reports = []

```

Part 5 - The Philosophy Behind the Exercise

Multi-head attention is a wager that complex meaning benefits from plural relations. The same token may simultaneously participate in order, reference, agreement, topic, and task-specific structure. Separate heads provide room for these relations without requiring one similarity function to rank them all in the same coordinate system.

But a model’s internal plurality should not be mistaken for a committee of small human concepts. Learned representations need not divide reality along the categories we prefer. Specialization is an empirical pattern, not a moral or semantic assignment.

This exercise therefore joins interpretation with intervention. To understand a component is not merely to observe it, but to change it and predict the consequence. The philosophical standard is modest but demanding: claim only the function that survives controlled tests.

17.3.3 Exercise 02

Exercise Title: Implement Linear Projections for Q K V and Prove Parameter Shapes Match $(d_{\text{model}}, d_{\text{model}})$ Logic

Part 1 - Why this matters

Queries, keys, and values are not copies of the input. They are learned linear views of it. In the common joint-projection implementation, each view maps the full model width d_{model} to another vector of the same total width, which is later divided among heads. This explains why the projection matrices have shape $d_{\text{model}} \times d_{\text{model}}$ even though each individual head uses only d_h features.

Two equivalent parameterizations are common. The model may store one matrix per role and split its output into heads, or store a separate $d_{\text{model}} \times d_h$ matrix for every head. Concatenating the per-head matrices along their output dimension reconstructs the joint matrix. The equivalence holds only when slices, bias terms, and feature ordering are matched exactly. This exercise proves the equivalence numerically and through index notation.

Projection bugs often arise from framework conventions. `nn.Linear` stores weights with output features first and input features second, while equations often write XW with the input dimension first and the output dimension second. Both describe the same operation because PyTorch applies $XW^{\mathsf{T}} + b$. A researcher who copies weights between scratch code and library modules without respecting this convention can obtain plausible shapes and incorrect values.

The parameter audit should include biases and the output projection. Standard self-attention with four dense projections contains approximately $4d^2$ weights, not $3Hd^2$. Increasing the number of heads while holding d_{model} fixed changes the partition of the projected space, but does not change the leading projection parameter count.

Part 2 - Mathematical form and reasoning

For $X \in \mathbb{R}^{B \times T \times d}$,

$$Q = XW_Q + b_Q, \quad K = XW_K + b_K, \quad V = XW_V + b_V,$$

with $W_Q, W_K, W_V \in \mathbb{R}^{d \times d}$. Partition

$$W_Q = [W_Q^{(1)} \mid \cdots \mid W_Q^{(H)}], \qquad W_Q^{(r)} \in \mathbb{R}^{d \times d_h}.$$

Then

$$XW_Q = [XW_Q^{(1)} \mid \cdots \mid XW_Q^{(H)}].$$

Ignoring bias, the four projection matrices contain

$$N_{\text{weights}} = 3d^2 + d^2 = 4d^2.$$

With biases, add $4d$. The count is independent of H while d is fixed.

Part 3 - Hints, controls, and evidence

1. Print both mathematical and PyTorch storage conventions beside every weight tensor.

2. Construct joint and per-head projections from the same numbers rather than initializing them independently.

3. Compare projected values before attention so later softmax behavior cannot hide an orientation error.

4. Verify the parameter formula for several head counts with fixed model width.

5. Test cross-attention where query length differs from key/value length; the feature projection shapes should remain unchanged.

6. Add a failed test that intentionally transposes one copied weight and confirm the parity check catches it.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def split_joint_weight(linear, num_heads):
    # nn.Linear weight: (d_out, d_in)
    d_model = linear.weight.shape[0]
    d_head = d_model // num_heads
    # TODO: return H blocks, each (d_head, d_model)
    return ...

def per_head_projection(x, weight_blocks, bias_blocks):
    projected = []
    for w, b in zip(weight_blocks, bias_blocks):
        projected.append(...)  # TODO: PyTorch orientation
    return torch.cat(projected, dim=-1)

def parameter_audit(d_model, num_heads, bias=True):
    q = nn.Linear(d_model, d_model, bias=bias)
    k = nn.Linear(d_model, d_model, bias=bias)
    v = nn.Linear(d_model, d_model, bias=bias)
    o = nn.Linear(d_model, d_model, bias=bias)
    observed = sum(p.numel() for layer in [q, k, v, o]
                   for p in layer.parameters())
    expected = ...
    assert observed == expected
    return observed

def E02():
    x = torch.randn(2, 5, 12)
    # TODO: prove joint == concatenated per-head projections
    return {h: parameter_audit(12, h) for h in [1, 2, 3, 4, 6]}
```

Part 5 - The Philosophy Behind the Exercise

A projection is a learned decision about which distinctions should become visible. The input representation is not queried directly; it is transformed into a language of requests, addresses, and transferable content. Attention therefore begins before softmax, in the geometry chosen by W_Q, W_K, and W_V.

The equivalence between one joint matrix and many per-head matrices also shows that architectural descriptions can depend on coordinate bookkeeping. What appears as several modules may be one block matrix, and what appears as one operation may contain separable subspaces.

Parameter counting disciplines intuition. More heads do not automatically mean more parameters or more knowledge. They change how a fixed representational budget is divided. The question is not how many named components exist, but what transformations the total geometry can support.

17.3.4 Exercise 03

Exercise Title: Debug Head Splitting Bugs by Printing Shapes at Every Step and Matching Expected Dimensions

Part 1 - Why this matters

Head splitting is a short section of code with an unusually large semantic burden. It must divide the final feature axis, move the new head axis into the batch-like position used by batched matrix multiplication, and preserve the identity of every feature. A missing transpose, incorrect `view`, or reversed sequence/head axis can still produce legal tensor operations. Consequently, debugging cannot stop at "the code runs."

This exercise builds a shape ledger. Every line of the forward pass must state the tensor's shape and the meaning of each axis. The ledger includes raw input, projected Q/K/V, split heads, scores, masks, normalized weights, per-head outputs, merged output, and final projection. For cross-attention, query length T_q and memory length T_k must be named separately so a square self- attention example does not conceal axis reversal.

Shape evidence is necessary but not sufficient. Use a tensor whose entries encode batch, token, and feature indices. After splitting, inspect a chosen coordinate and prove which original element it contains. Then merge the heads and require exact reconstruction. This value trace catches permutations that a dimension table cannot detect.

The final stage introduces failure injection. Implement several deliberately wrong split functions: reshape without transpose, transpose wrong axes, divide by the wrong head count, or use `view` on a non-contiguous tensor. Each failure should be detected by the earliest relevant invariant and converted into a regression test.

Part 2 - Mathematical form and reasoning

The intended index mapping is

$$Q'_{b,t,r,u} = Q_{b,t,rd_h+u}, \qquad \widehat{Q}_{b,r,t,u} = Q'_{b,t,r,u}.$$

Thus

$$(B, T_q, d) \to (B, T_q, H, d_h) \to (B, H, T_q, d_h).$$

Scores follow

$$(B, H, T_q, d_h) \ @ \ (B, H, d_h, T_k) \to (B, H, T_q, T_k).$$

The inverse mapping is

$$(B, H, T_q, d_h) \to (B, T_q, H, d_h) \to (B, T_q, Hd_h).$$

Element count is preserved at every reshape, but element order is preserved only when the axis permutation matches these index equations.

Part 3 - Hints, controls, and evidence

1. Use non-equal values for B, H, T_q, T_k, and d_h so accidental axis swaps cannot hide behind equal dimensions.
2. Print axis labels beside shapes, for example `scores [batch, head, query, key]`.
3. Test self-attention and cross-attention with $T_q \neq T_k$.
4. Check strides and `is_contiguous()` before and after transpose.
5. Require split/merge identity and compare selected elements by explicit index arithmetic.
6. For each injected bug, record symptom, earliest violated invariant, root cause, correction, and regression test.

Part 4 - Python code skeleton

```
import torch

def trace_tensor(batch, seq, d_model):
    # Value encodes (batch, token, feature) for manual tracing.
    b = torch.arange(batch)[:, None, None] * 10000
    t = torch.arange(seq)[None, :, None] * 100
    f = torch.arange(d_model)[None, None, :]
    return (b + t + f).float()

def split_heads(x, num_heads):
    b, t, d = x.shape
    assert d % num_heads == 0
    d_head = d // num_heads
    shaped = ...
    split = ...
    return split

def shape_ledger(q, k, v, mask=None):
```

```
    ledger = []
    # TODO: append name, shape, axis labels, strides, contiguity
    return ledger

def E03():
    x = trace_tensor(batch=2, seq=5, d_model=12)
    heads = split_heads(x, num_heads=3)
    # TODO: verify values with explicit index mapping
    merged = ...
    assert torch.equal(merged, x)
    return shape_ledger(heads, heads, heads)
```

Part 5 - The Philosophy Behind the Exercise

Tensor axes are the grammar of neural computation. Two tensors may contain the same numbers and have the same total size while expressing different relationships because their axes assign different roles to those numbers. A silent permutation is therefore a semantic error.

Shape printing becomes scientifically useful only when accompanied by an expected contract. Observation without prediction merely describes whatever the buggy program happened to produce. The researcher must state the intended meaning first and then compare execution against it.

The broader habit is to search for the earliest broken invariant. Downstream NaNs or poor accuracy are distant symptoms. A disciplined debugger moves backward until the first claim about identity, shape, dtype, device, or range becomes false.

17.3.5 Exercise 04

Exercise Title: Compare Single-Head vs Multi-Head Attention and Measure Quality Gain on a Toy Task

Part 1 - Why this matters

Multi-head attention is often justified by capacity to represent several relations, but a fair comparison is subtle. If head count changes while model width also changes, improved quality may come from additional parameters. If the single-head baseline receives a different optimizer budget or converges at a different rate, the experiment measures training choices rather than the architecture. This exercise designs a controlled comparison.

The toy task should require two distinguishable retrieval behaviors. For example, the target may combine information from a location marker and from a token-matching relation. A single head can sometimes solve such a task, so the goal is not to manufacture guaranteed victory. Instead, compare learning speed, final generalization, variance across seeds, and behavior under relation-specific ablations.

Hold d_{model} fixed across head counts. This keeps the dense Q/K/V and output projection parameter count approximately constant, although the softmax structure changes. Also include a wider single-head control with a matched or larger parameter budget. If multi-head attention

wins only against the narrow baseline, the conclusion must reflect that limitation.

Quality should be measured on held-out combinations, not only training examples. Save learning curves, best validation checkpoints, and the exact stopping rule. Inspect whether additional heads provide stable improvement or merely greater seed variance. A small average gain with overlapping confidence intervals is not evidence of a universal advantage.

Part 2 - Mathematical form and reasoning

For $H = 1$, $d_h = d$. For $H > 1$, $d_h = d/H$. With dense projections,

$$N_{\text{MHA}} \approx 4d^2$$

for all valid head counts. Let metric $m_{H,s}$ be the held-out score for head count H and seed s. Report

$$\overline{m}_H = \frac{1}{S}\sum_{s=1}^{S} m_{H,s}, \qquad \sigma_H = \sqrt{\frac{1}{S-1}\sum_{s}(m_{H,s} - \overline{m}_H)^2}.$$

For learning efficiency, also compare the number of updates or tokens needed to cross a fixed validation threshold, not only the best final value.

Part 3 - Hints, controls, and evidence

1. Generate train, validation, and test sets from fixed rules and reserve unseen relation combinations for testing.
2. Compare $H \in \{1, 2, 4, 8\}$ at fixed d_{model} and use the same embedding, head, loss, and optimization budget.
3. Repeat at least five seeds and save every curve, not only successful runs.
4. Report parameters, FLOPs estimate, time per step, peak memory, and task quality.
5. Add a wider single-head control to separate multiple softmax maps from raw width.
6. Inspect errors by relation type and perform head ablations before claiming specialization caused the gain.

Part 4 - Python code skeleton

```
import torch

def build_model(d_model, num_heads, vocab_size, num_classes):
    # TODO: identical surrounding architecture for all comparisons
    return ...

def run_controlled_trial(config, seed, train, val, test):
    torch.manual_seed(seed)
    model = build_model(...)
    parameter_count = sum(p.numel() for p in model.parameters())
    # TODO: train with fixed budget and validation rule
```

```
    return {
        "seed": seed,
        "heads": config["heads"],
        "parameters": parameter_count,
        "curve": ...,
        "best_validation": ...,
        "test_metric": ...,
        "relation_errors": ...,
    }

def E04(configs, seeds=range(5)):
    data = ...
    return [run_controlled_trial(c, s, *data)
            for c in configs for s in seeds]
```

Part 5 - The Philosophy Behind the Exercise

Architectural comparison is an exercise in causal reasoning. Two models differ in many visible and hidden ways, and the experiment attempts to isolate which difference produced the observed behavior. Fairness is not achieved by good intentions; it is constructed through matched controls.

Multi-head attention embodies plurality, but plurality has costs: narrower per-head dimensions, more separate probability maps, and potentially redundant computation. Whether it helps depends on the structure of the task and the optimization path.

The philosophical result may legitimately be conditional. Science advances when a claim becomes more precise, not merely more enthusiastic. "Four heads improved this task under these controls" is more valuable than "more heads are better."

17.3.6 Exercise 05

Exercise Title: Implement Attention Output Projection and Explain Why It Restores d_{model} Space After Head Concatenation

Part 1 - Why this matters

After per-head attention, concatenation already has width $Hd_h = d_{\text{model}}$. It is therefore tempting to believe that the output projection exists only to repair a shape. Its real function is geometric, not dimensional: concatenation places head features beside one another, whereas W_O learns how to mix those features into the coordinate system expected by the residual stream and later layers.

Without W_O, each output coordinate is permanently assigned to one head at that attention sublayer's exit. With W_O, any model-space coordinate can be a learned combination of all head outputs. The projection may preserve a head, rotate several heads into shared features, cancel redundant components, or route information so it aligns with the residual input. This makes the output projection part of the expressive mechanism.

The exercise should compare identity, learned, block-diagonal, and deliberately permuted output projections. Start with a traceable concatenated tensor and verify matrix multiplication manually. Then train identical toy models with W_O enabled or frozen to identity. Match all remaining settings and examine whether the task requires cross-head integration.

Residual addition imposes the external contract. If the attention sublayer is to produce $X + \mathrm{MHA}(X)$, its output must live in the same d_{model} space as X. Shape compatibility alone does not prove semantic alignment, but the learned projection gives the network a mechanism to establish that alignment.

Part 2 - Mathematical form and reasoning

Let

$$C = [Z^{(1)} \mid \cdots \mid Z^{(H)}] \in \mathbb{R}^{B\times T\times d}.$$

The output is

$$Y = CW_O + b_O, \qquad W_O \in \mathbb{R}^{d\times d}.$$

Partitioning W_O by input head gives

$$W_O = \begin{bmatrix} W_O^{(1)} \\ \vdots \\ W_O^{(H)} \end{bmatrix}, \qquad Y = \sum_{r=1}^{H} Z^{(r)} W_O^{(r)} + b_O.$$

This form makes cross-head mixing explicit. The residual sublayer then has

$$R = X + \mathrm{Dropout}(Y),$$

which requires Y and X to share shape and model-space role.

Part 3 - Hints, controls, and evidence

1. Build a two-head example whose head outputs occupy recognizable basis directions.
2. Set W_O to identity, a permutation, a block-diagonal matrix, and a dense matrix; predict each result before execution.
3. Verify PyTorch weight orientation when copying a mathematical W_O into `nn.Linear`.
4. Compare learned and frozen-identity variants on a task requiring a sum or interaction of information from two heads.
5. Record parameter count and gradient norm of W_O during training.
6. Test residual compatibility and add a failure case with the wrong output width.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def concatenate_heads(head_outputs):
    # (B,H,T,d_head) -> (B,T,H*d_head)
    return ...

class OutputProjection(nn.Module):
    def __init__(self, d_model):
        super().__init__()
        self.proj = nn.Linear(d_model, d_model)

    def forward(self, head_outputs):
        concatenated = concatenate_heads(head_outputs)
        return self.proj(concatenated)

def projection_intervention(module, matrix, bias=None):
    with torch.no_grad():
        # TODO: account for nn.Linear's stored orientation
        module.proj.weight.copy_(...)
        module.proj.bias.copy_(...)

def E05():
    heads = ...
    module = OutputProjection(d_model=8)
    results = {}
    for name, matrix in ...:
        projection_intervention(module, matrix)
        results[name] = module(heads)
    return results
```

Part 5 - The Philosophy Behind the Exercise

Concatenation preserves plurality but does not create synthesis. It places perspectives next to one another. The output projection performs a learned act of integration, translating several partial descriptions into the common language of the model.

This distinction resembles the difference between collecting observations and forming a judgment. More sources do not automatically yield a unified representation; a rule of combination is still required. In attention, that rule is itself learned and therefore fallible.

The residual stream adds another lesson: information must not only be produced but made compatible with an ongoing system. Intelligence in a layered network depends on interfaces. A useful internal result that cannot enter the shared representation is computationally isolated.

17.3.7 Exercise 06

Exercise Title: Implement Per-Head Scaling and Show It Rarely Helps Compared to Standard $\sqrt{d_k}$ Scaling

Part 1 - Why this matters

Scaled dot-product attention divides logits by $\sqrt{d_h}$ because the variance of a dot product typically grows with the key dimension. In standard multi-head attention every head has the same width, so one deterministic scale matches the statistical reason for normalization. A learnable or separately chosen scale for each head may appear more flexible, but additional freedom is not automatically useful. It can duplicate transformations already available in Q/K projections, distort entropy, or create unstable optimization.

This exercise implements fixed per-head scales, learnable temperatures, and the standard baseline. The comparison must examine score variance, attention entropy, gradient norms, convergence, and held-out quality. If learned scales move only slightly or produce no stable gain across seeds, the result supports the simpler normalization. If a gain appears, investigate whether it comes from genuinely different head statistics or from an unfair optimization advantage.

Parameterization matters. Optimizing a raw temperature can make it negative or near zero. A positive scale should be represented through an exponential or softplus transformation, and its initial value should reproduce $1/\sqrt{d_h}$. Regularization or clamping may be required, but these controls must be reported because they change the experiment.

The phrase "rarely helps" must emerge from evidence, not be encoded as the desired answer. Run tasks with uniform and deliberately heterogeneous feature statistics. A per-head scale is more likely to matter in the latter case, but Q/K weights may still learn the necessary rescaling themselves.

Part 2 - Mathematical form and reasoning

Standard head logits are

$$S^{(r)} = \frac{Q^{(r)} K^{(r)\mathsf{T}}}{\sqrt{d_h}}.$$

For independent zero-mean components with variance one,

$$\operatorname{Var}(q^{\mathsf{T}} k) \approx d_h,$$

so division by $\sqrt{d_h}$ produces order-one variance. A learnable positive inverse temperature may be written

$$S^{(r)} = \exp(\alpha_r) Q^{(r)} K^{(r)\mathsf{T}}, \qquad \alpha_r^{(0)} = -\tfrac{1}{2} \log d_h.$$

Measure attention entropy

$$\mathcal{H}^{(r)} = -\frac{1}{BT} \sum_{b,i,j} A_{b,i,j}^{(r)} \log(A_{b,i,j}^{(r)} + \varepsilon).$$

Large inverse temperature lowers entropy; small inverse temperature makes the distribution more uniform.

Part 3 - Hints, controls, and evidence

1. Initialize every learned scale to the standard value and keep all other weights identical across variants.

2. Track raw score variance, normalized score variance, attention entropy, scale values, and Q/K gradient norms by head.
3. Compare fixed standard scaling, no scaling, fixed unequal scales, and learned positive scales.
4. Use multiple seeds and both homogeneous and heterogeneous synthetic feature statistics.
5. Check whether Q/K projection norms compensate for learned temperature; scale values alone may be misleading.
6. Report instability, saturation, or lack of improvement as results rather than tuning until the more complex method wins.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

class PerHeadTemperature(nn.Module):
    def __init__(self, num_heads, d_head, learnable=True):
        super().__init__()
        initial = -0.5 * math.log(d_head)
        values = torch.full((num_heads,), initial)
        if learnable:
            self.log_scale = nn.Parameter(values)
        else:
            self.register_buffer("log_scale", values)

    def forward(self, raw_scores):
        # raw_scores: (B,H,Tq,Tk)
        scale = self.log_scale.exp()[None, :, None, None]
        return raw_scores * scale

def attention_entropy(weights, eps=1e-9):
    return ...

def E06(configs, seeds=range(5)):
    reports = []
    for config in configs:
        for seed in seeds:
            # TODO: controlled training and per-head statistics
            reports.append(...)
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Machine-learning design often rewards restraint. A parameter can represent a possibility without representing a useful necessity. Every added degree of freedom enlarges the optimization problem and creates another way for the model to become unstable or unidentifiable.

Standard scaling is powerful because it expresses a statistical prior about dot products before learning begins. It is not rigid for its own sake; it removes predictable variation so learning can focus on task-dependent structure.

The experiment teaches a general principle: complexity must earn its place. An elegant extension should be judged by repeatable behavioral improvement, not by the fact that it can be implemented or that its parameters acquire interesting values.

17.3.8 Exercise 07

Exercise Title: Implement Key Padding Mask and Causal Mask Together and Prove Both Are Applied Correctly

Part 1 - Why this matters

Padding and causality express different restrictions. A key padding mask says that selected memory positions do not contain real data and must never receive attention. A causal mask says that query position i may not access key positions later than i. When both are needed, the legal attention graph is the intersection of these rules. Confusing them can leak future information, assign probability to padding, or erase legitimate past tokens.

Mask combination becomes difficult because the source masks usually begin with different ranks. A key padding mask may have shape `(B,Tk)`, while a causal mask has shape `(Tq,Tk)`. Scores have shape `(B,H,Tq,Tk)`. Each mask must be expanded by axis meaning, not merely by adding dimensions until broadcasting succeeds. In particular, padding varies by batch but is shared across heads and query positions; causality varies by query and key position but is normally shared across batch and heads.

The proof should use adversarial values. Place extremely attractive logits in positions that are forbidden by only one mask and positions forbidden by both. After masked softmax, every forbidden probability must be zero within the chosen dtype's tolerance, permitted rows must sum to one, and changing a forbidden value must not change any legal output. This intervention is stronger than checking the visual triangular pattern.

All-masked rows require an explicit policy. Filling every logit with negative infinity and applying softmax produces undefined 0/0 normalization and may create NaNs. The implementation should either prevent such rows by contract, return a documented zero distribution, or use a safe masked-softmax routine. The decision must be tested rather than left to accidental library behavior.

Part 2 - Mathematical form and reasoning

Let $P_{b,j} \in \{0, 1\}$ indicate that key j is padding, and let $C_{i,j} = 1$ when $j > i$. The combined forbidden mask is

$$F_{b,i,j} = P_{b,j} \vee C_{i,j}.$$

Broadcast across heads and define

$$\widetilde{S}_{b,r,i,j} = \begin{cases} S_{b,r,i,j}, & F_{b,i,j} = 0, \\ -\infty, & F_{b,i,j} = 1. \end{cases}$$

Then

$$A_{b,r,i,:} = \mathrm{softmax}(\widetilde{S}_{b,r,i,:}).$$

The required invariants are

$$F_{b,i,j} = 1 \Rightarrow A_{b,r,i,j} = 0, \qquad \sum_{j:F_{b,i,j}=0} A_{b,r,i,j} = 1$$

for every row containing at least one legal key.

Part 3 - Hints, controls, and evidence

1. Use distinct lengths for queries and keys in one cross-attention test, and define whether causality is meaningful for that alignment.
2. Convert the padding mask to `(B,1,1,Tk)` and the causal mask to `(1,1,Tq,Tk)` before combining them.
3. Test batches with different valid lengths, including the minimum legal length and an intentionally all-masked case.
4. Change masked keys and values by huge amounts and confirm all permitted outputs remain unchanged.
5. Verify both boolean-mask and additive-mask implementations using the same legal graph.
6. Repeat under float32 and mixed precision using dtype-appropriate masking constants and finite-value checks.

Part 4 - Python code skeleton

```
import torch

def causal_mask(query_len, key_len, device):
    q = torch.arange(query_len, device=device)[:, None]
    k = torch.arange(key_len, device=device)[None, :]
    return ...  # True means forbidden

def combine_masks(key_padding, causal, num_heads):
    # key_padding: (B,Tk), causal: (Tq,Tk)
    padding4 = ...
    causal4 = ...
    combined = ...
    return combined  # broadcastable to (B,H,Tq,Tk)
```

```
def safe_masked_softmax(scores, forbidden):
    # TODO: define and test all-masked-row behavior
    return ...

def E07():
    scores = ...
    padding = ...
    causal = causal_mask(...)
    forbidden = combine_masks(padding, causal, num_heads=2)
    weights = safe_masked_softmax(scores, forbidden)
    # TODO: zero, row-sum, future-leak, and intervention tests
    return weights
```

Part 5 - The Philosophy Behind the Exercise

A mask is an information law. It does not merely make certain numbers small; it declares which relationships the model is permitted to use. Padding masks protect meaning from artificial storage positions, while causal masks protect time from information that did not yet exist.

Combining masks shows that model behavior is shaped by the intersection of several constraints. Capability is never only the result of weights. It also depends on the architecture of permission surrounding those weights.

The all-masked row reveals a broader lesson: a mathematical operation may be well-defined over ordinary cases and undefined at a boundary. Robust systems do not hope boundaries never appear. They make the boundary policy explicit, observable, and testable.

17.3.9 Exercise 08

Exercise Title: Implement Attention Weight Logging Per Head and Analyze Whether Heads Become Redundant

Part 1 - Why this matters

Multi-head attention allocates several attention distributions, but training may not use them independently. Heads can converge to similar score patterns, produce different weights but similar outputs, or appear redundant on one dataset and essential on another. Per-head logging makes this behavior measurable across training rather than inferred from one final heat map.

Logging must not accidentally retain computation graphs. Storing raw attention tensors from every batch can exhaust GPU memory and keep backward graphs alive. Detach the tensors, move selected summaries to CPU, sample batches according to a declared schedule, and preserve metadata such as layer, head, seed, mask, sequence length, and checkpoint. Raw matrices should be saved only for a small fixed probe set.

Redundancy has several meanings. Weight redundancy asks whether two heads place probability on the same keys. Output redundancy asks whether their weighted value sums point in similar directions. Functional redundancy asks whether one head can be removed without reducing held-out performance. These measures need not agree because different values or

output-projection blocks can turn similar weights into different contributions.

Analyze change over time. Heads may begin similarly, specialize during early training, and later become correlated again. Compare trained models with their randomly initialized baselines so that similarity caused by masks or position structure is not mistaken for learned redundancy.

Part 2 - Mathematical form and reasoning

For flattened attention maps a_r, a_s, cosine similarity is

$$\cos(a_r, a_s) = \frac{a_r^\top a_s}{\|a_r\|_2 \|a_s\|_2}.$$

Jensen–Shannon divergence compares probability rows symmetrically:

$$\mathrm{JSD}(p, q) = \tfrac{1}{2}\,\mathrm{KL}(p\|m) + \tfrac{1}{2}\,\mathrm{KL}(q\|m), \qquad m = \tfrac{1}{2}(p + q).$$

For per-head outputs $Z^{(r)}$, output similarity may be measured using cosine similarity or centered-kernel methods. Functional importance for head r is

$$I_r = \mathcal{M}_{\text{base}} - \mathcal{M}_{\text{ablated}(r)},$$

where $\mathcal{M}$ is a held-out task metric and ablation is performed before the output projection.

Part 3 - Hints, controls, and evidence

1. Use a fixed probe dataset at every checkpoint so temporal comparisons do not mix model change with input change.
2. Log row entropy, maximum weight, pairwise divergence, head-output norms, and output similarity.
3. Detach and summarize on CPU; verify logging does not change gradients or training speed materially.
4. Compare similarity before training, during training, and at the selected checkpoint across several seeds.
5. Perform single-head and grouped-head ablations because redundancy may be distributed across more than two heads.
6. Treat heat maps as descriptive evidence and ablation as stronger functional evidence.

Part 4 - Python code skeleton

```
import torch

class HeadLogger:
    def __init__(self, keep_raw_batches=2):
        self.keep_raw_batches = keep_raw_batches
        self.records = []
```

```
    @torch.no_grad()
    def record(self, weights, head_outputs, metadata):
        # TODO: detach, summarize, and move only needed data to CPU
        self.records.append({
            "metadata": metadata,
            "entropy": ...,
            "max_weight": ...,
            "pairwise_jsd": ...,
            "output_cosine": ...,
        })

def ablation_importance(model, loader, metric):
    baseline = ...
    importance = []
    for head in range(model.num_heads):
        # TODO: zero this head before output projection
        importance.append(baseline - ...)
    return importance

def E08(model, probe_loader, checkpoints):
    logger = HeadLogger()
    # TODO: load checkpoints and record the same probes
    return logger.records, ablation_importance(model, probe_loader, ...)
```

Part 5 - The Philosophy Behind the Exercise

Redundancy is not automatically waste. Replicated functions can create robustness, alternative optimization paths, or representations that appear similar under one measurement but differ under another condition. Biological and engineered systems often preserve overlapping capacity for good reasons.

At the same time, naming several heads does not prove the existence of several ideas. Architecture offers a space of possibilities; training decides how that space is occupied. Measurement protects us from reading component count as conceptual diversity.

This exercise also teaches restraint in observation. Recording more tensors does not guarantee more understanding. Useful logging begins with a question, chooses statistics tied to that question, and preserves enough context for the observation to be reproduced.

17.3.10 Exercise 09

Exercise Title: Explain Attention as Low-Rank Retrieval and Relate Heads to Different Subspaces Conceptually

Part 1 - Why this matters

Each attention head projects model-width representations into a smaller space before calculating compatibility. The pre-softmax score matrix is therefore constructed from QK^T with inner dimension d_h. Its matrix rank cannot exceed d_h before masks and softmax are applied. This offers a useful geometric interpretation: each head evaluates retrieval through a restricted

bilinear subspace rather than through every possible pairwise relation in the full model space.

The interpretation must be stated carefully. The final attention matrix after row-wise softmax need not have rank at most d_h because softmax is nonlinear. Likewise, a low-rank score matrix does not mean the head can retrieve only a few tokens or that its output is trivial. Masks, value vectors, multiple layers, and the output projection change the functional picture. The rank claim applies to the unnormalized content-based score component.

Multiple heads create several low-dimensional compatibility geometries. One head may be sensitive to a positional pattern and another to token identity, provided the learned projections arrange those features appropriately. Their score matrices are not summed before softmax; each head forms its own probability distribution. This is different from simply increasing the rank of one shared score matrix.

The exercise should use singular-value analysis on synthetic and trained examples. Compare theoretical maximum rank, numerical rank, spectral decay, and approximation error. Then alter d_h and head count while holding total model width fixed. The purpose is to connect algebraic capacity with observed retrieval behavior without claiming that rank alone explains model quality.

Part 2 - Mathematical form and reasoning

For one head,

$$S = QK^{\mathsf{T}}, \qquad Q \in \mathbb{R}^{T_q \times d_h}, \quad K \in \mathbb{R}^{T_k \times d_h}.$$

Therefore

$$\operatorname{rank}(S) \le \min(T_q, T_k, d_h).$$

Equivalently, with projected inputs,

$$S = X_q W_Q W_K^{\mathsf{T}} X_k^{\mathsf{T}},$$

where $W_Q W_K^{\mathsf{T}}$ has rank at most d_h. For singular values $\sigma_1 \ge \cdots$, define an effective rank, for example,

$$r_\tau = \#\{i : \sigma_i > \tau \sigma_1\}.$$

The nonlinear matrix

$$A = \operatorname{softmax}(S/\sqrt{d_h} + M)$$

must be analyzed separately; the same rank bound does not transfer through softmax.

Part 3 - Hints, controls, and evidence

1. Construct random Q and K with known dimensions and confirm the exact or numerical rank bound on unmasked logits.

2. Compare logits before scaling, after additive masking, and after softmax; state which transformation changes the rank argument.

3. Plot singular spectra for each head on a fixed probe set and report the tolerance used for numerical rank.
4. Vary d_h, sequence length, and head count while keeping d_{model} fixed.
5. Relate spectral observations to retrieval accuracy on a controlled task, but avoid treating correlation as causation.
6. Include a counterexample showing softmax output rank exceeding the pre-softmax bound.

Part 4 - Python code skeleton

```
import torch

def numerical_rank(matrix, relative_tol=1e-6):
    singular = torch.linalg.svdvals(matrix)
    threshold = relative_tol * singular[..., :1]
    return (singular > threshold).sum(dim=-1), singular

def rank_report(q, k, mask=None):
    logits = q @ k.transpose(-2, -1)
    scaled = logits / (q.shape[-1] ** 0.5)
    masked = ... if mask is not None else scaled
    weights = torch.softmax(masked, dim=-1)
    return {
        "logit_rank": numerical_rank(logits),
        "masked_rank": numerical_rank(masked),
        "softmax_rank": numerical_rank(weights),
        "theoretical_bound": min(q.shape[-2], k.shape[-2], q.shape[-1]),
    }

def E09():
    reports = []
    for d_head in [1, 2, 4, 8, 16]:
        q, k = ...
        reports.append(rank_report(q, k))
    # TODO: add trained heads and a softmax counterexample
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Projection is selective ignorance. A head gains a tractable relation space by discarding directions that its projection does not preserve. This restriction is not merely a weakness; useful abstraction often depends on ignoring most available variation.

Several heads represent several selective views. Their power comes not from recovering the entire world in every head, but from allowing different losses of information to coexist. What one subspace ignores, another may preserve.

Rank analysis also demonstrates the boundary between explanation and proxy. An algebraic bound illuminates one stage of computation, but the full network contains nonlinearities, masks, values, residuals, and repeated layers. A good theory identifies exactly where its statement holds and refuses to expand that statement beyond its proof.

17.3.11 Exercise 10

Exercise Title: Run Multi-Head Attention on CUDA and Validate Correctness Under Mixed Precision Constraints

Part 1 - Why this matters

CUDA execution and mixed precision change the numerical environment of multi-head attention. Matrix multiplications may use reduced-precision inputs or specialized hardware paths, while softmax and reductions may be promoted or fused according to the backend. The intended function should remain stable, but exact equality with a float32 CPU reference is neither expected nor a sufficient test.

The parity experiment must begin from identical master tensors and parameters. Generate them once in float32, clone the CPU reference, and copy the same values to CUDA. Compare scratch and library implementations in evaluation mode before adding autocast. Then test float32 CUDA, float16 autocast, and bfloat16 where hardware support exists. Record forward output, attention probabilities, loss, gradients, masked-position invariants, and finiteness.

Mixed precision risks are concentrated around logits and softmax. Large Q/K norms can overflow dot products; large negative mask constants may become infinite; small probabilities or gradients may underflow. A stable implementation may compute selected operations in float32 even when projection and value products use lower precision. The report should state actual dtypes inside the critical path rather than assuming autocast treats every operation equally.

Gradient scaling applies to training losses, not to the forward probability distribution. Include a small optimizer step with the modern AMP scaling API, detect skipped steps and non-finite gradients, and compare parameter updates against a float32 reference over several seeds and input scales.

Part 2 - Mathematical form and reasoning

For reference y and candidate $\widehat{y}$, report

$$E_{\text{abs}} = \max_i |\widehat{y}_i - y_i|, \qquad E_{\text{rel}} = \max_i \frac{|\widehat{y}_i - y_i|}{\max(|y_i|, \varepsilon)}.$$

Use the declared rule

$$|\widehat{y}_i - y_i| \le \texttt{atol} + \texttt{rtol}|y_i|.$$

For each head, monitor logit range and entropy as well as error. Reduced precision changes are especially important when they alter the discrete winner

$$\arg\max_j A_{b,r,i,j}$$

or allow a forbidden key to receive nonzero probability.

Part 3 - Hints, controls, and evidence

1. Skip with a documented status when CUDA is unavailable; do not silently fall back to CPU.
2. Test multiple seeds, sequence lengths, head counts, mask patterns, and input scales.
3. Declare dtype-specific tolerances before examining results.
4. Inspect actual dtypes of logits, softmax inputs, weights, outputs, loss, and gradients under autocast.
5. Check maximum errors, top-attended index agreement, row sums, mask invariants, and finite values.
6. Synchronize only for timing; correctness comparisons require copied tensors, not asynchronous wall-clock logic.

Part 4 - Python code skeleton

```
import contextlib
import torch

def run_case(model, x, mask, device, amp_dtype=None):
    model = model.to(device)
    x = x.to(device).detach().requires_grad_(True)
    enabled = amp_dtype is not None and device.type == "cuda"
    ctx = torch.autocast("cuda", dtype=amp_dtype, enabled=enabled)
    with ctx:
        output, weights = model(x, x, x, mask)
        loss = ...
    loss.backward()
    return {
        "output": output.detach().float().cpu(),
        "weights": weights.detach().float().cpu(),
        "gradient": x.grad.detach().float().cpu(),
        "finite": bool(torch.isfinite(output).all()),
    }

def compare(reference, candidate, atol, rtol):
    return {"max_abs": ..., "max_rel": ..., "allclose": ...}

def E10(seeds=range(10)):
    if not torch.cuda.is_available():
        return {"status": "skipped", "reason": "CUDA unavailable"}
    # TODO: paired float32/float16/bfloat16 cases and AMP update test
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Mixed precision asks how much numerical detail a computation can surrender without surrendering its function. The answer is not contained in the dtype name. It depends on scale, operation, architecture, data, and the behavioral tolerance of the task.

Hardware optimization therefore becomes an epistemic question: what evidence shows that the faster physical process still instantiates the same model? A small average error may be harmless, while one leaked future token or one NaN can destroy the meaning of the system.

Correctness under approximation is never "close enough" in the abstract. It requires explicit invariants, declared tolerances, adversarial cases, and an understanding of which differences are numerically small but semantically large.

17.3.12 Exercise 11

Exercise Title: Benchmark Multi-Head Attention Speed vs Head Count and Identify Practical Head Count Choices

Part 1 - Why this matters

At fixed d_{model}, the leading dense-attention arithmetic is often described as nearly independent of head count. The product Hd_h remains equal to d_{model}. Real hardware does not execute only asymptotic formulas, however. More heads create smaller per-head matrix dimensions, alter kernel shapes, increase attention-map count, and may change which fused kernels are available. Speed can therefore vary even when theoretical FLOPs remain similar.

Benchmarking must cover regimes. Small batches and short sequences may be dominated by launch overhead. Medium shapes may use accelerator kernels efficiently. Long sequences may become memory-bound because score and probability tensors scale with BHT^2. A practical head count depends on model width, sequence length, batch, dtype, hardware, software version, and whether the measurement is forward inference or forward-plus-backward training.

Head count also affects model capacity, so speed cannot select it alone. The final recommendation must combine latency, throughput, peak memory, numerical stability, and task quality. A fast configuration whose d_h is too small to learn the required relations is not practical. Nor is a high-quality setting that exceeds the deployment latency budget.

Use robust timing. Warm up kernels, synchronize CUDA around measured regions, avoid data creation inside the timed function, repeat enough iterations, and report medians and percentiles. Include `torch.compile` or fused attention only as separate labeled variants because compilation overhead and kernel selection change the comparison.

Part 2 - Mathematical form and reasoning

Projection work is approximately

$$\mathcal{O}(BTd^2),$$

while score and value aggregation work is

$$\mathcal{O}(BHT^2d_h) = \mathcal{O}(BT^2d).$$

Explicit attention-map storage is

$$\mathcal{O}(BHT^2),$$

which does grow with H when d and T are fixed. Report throughput

$$\text{tokens/s} = \frac{BT}{\text{seconds/iteration}}$$

and a quality-adjusted feasibility table rather than collapsing every concern into one score.

Part 3 - Hints, controls, and evidence

1. Choose a model width divisible by many head counts and record resulting d_h for each case.
2. Benchmark forward inference and full training step separately.
3. Sweep batch and sequence length; do not generalize from one tensor shape.
4. Use CUDA events or synchronized wall time, warm-up, repeated trials, and median plus tail latency.
5. Reset and record peak allocated and reserved memory for each isolated configuration.
6. Add held-out task quality and reject head counts that fail either the quality or systems requirement.

Part 4 - Python code skeleton

```
import statistics
import time
import torch

def timed_cuda(fn, warmup=20, repeats=100):
    for _ in range(warmup):
        fn()
    torch.cuda.synchronize()
    times = []
    for _ in range(repeats):
        start = torch.cuda.Event(enable_timing=True)
        end = torch.cuda.Event(enable_timing=True)
        start.record(); fn(); end.record()
        torch.cuda.synchronize()
        times.append(start.elapsed_time(end))
    return {"median_ms": statistics.median(times), "p95_ms": ...}

def benchmark_shape(d_model, heads, batch, seq, dtype):
    model, x = ..., ...
    torch.cuda.reset_peak_memory_stats()
    timing = timed_cuda(lambda: ...)
```

```
    return {**timing,
            "peak_bytes": torch.cuda.max_memory_allocated(),
            "d_head": d_model // heads}

def E11():
    # TODO: sweep heads, sequence lengths, batches, dtypes, and modes
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Asymptotic complexity tells us how costs grow, not how a particular machine will experience a particular shape. Engineering lives in the gap between the formula and the device: memory hierarchies, kernel launch, vector width, fusion, and runtime scheduling all influence what becomes practical.

There is therefore no context-free "best number of heads." Design is a negotiation among representation, optimization, hardware, and service goals. An architecture is practical only relative to a workload and a constraint.

Benchmarking is not a race to produce the smallest number. It is a method for discovering where the system changes regime and for making choices whose costs and benefits can be defended.

17.3.13 Exercise 12

Exercise Title: Compare float32 vs float16 Multi-Head Attention Stability and Detect Softmax Overflow Scenarios

Part 1 - Why this matters

Float16 provides limited exponent range and precision. Multi-head attention contains dot products, scaling, masking, exponentiation, normalization, and weighted sums, so failures can emerge at several stages. A naive softmax that calculates `exp(scores)` directly can overflow even in float32; in float16 the safe operating range is smaller. Stable softmax subtracts the row maximum, but it cannot repair logits that already became infinite during the QK product.

This exercise maps the failure boundary by scaling Q and K across several orders of magnitude. For each scale, compare raw logits, scaled logits, shifted logits, weights, outputs, losses, and gradients. Distinguish overflow from underflow: an infinite logit can create NaNs, while very negative shifted logits may underflow to zero and yield an extremely sharp but finite distribution. Both can alter optimization.

Mask constants require care. A large negative finite number that is adequate in float32 may convert to negative infinity in float16. This may be acceptable for rows with legal keys, but an all-masked row remains undefined. Conversely, a constant that is not negative enough can leave measurable probability on forbidden positions. Test mask behavior at each dtype and score scale.

The goal is not to declare float16 unsafe. Modern fused attention and autocast may accumulate or normalize in higher precision. The report must identify the actual implementation path and compare naive, stable, promoted-softmax, and library kernels under the same inputs.

Part 2 - Mathematical form and reasoning

Naive softmax is

$$p_j = \frac{e^{s_j}}{\sum_k e^{s_k}}.$$

The shift-invariant stable form is

$$p_j = \frac{e^{s_j - m}}{\sum_k e^{s_k - m}}, \qquad m = \max_k s_k.$$

If Q and K are scaled by c, logits scale by c^2:

$$\frac{(cQ)(cK)^\mathsf{T}}{\sqrt{d_h}} = c^2 \frac{QK^\mathsf{T}}{\sqrt{d_h}}.$$

Track the softmax Jacobian

$$\frac{\partial p_i}{\partial s_j} = p_i(\delta_{ij} - p_j),$$

because extremely sharp distributions may remain finite while producing very small gradients for most entries.

Part 3 - Hints, controls, and evidence

1. Sweep input scale logarithmically and locate the first non-finite value at every intermediate tensor.
2. Compare naive exponentiation, max-shifted softmax, float32-promoted softmax, and the framework's fused implementation.
3. Record dtype, minimum and maximum, finite fraction, entropy, zero fraction, and gradient norm.
4. Include near-tied logits as well as dominant logits; reduced mantissa precision can change rankings before overflow occurs.
5. Test normal, causal, padded, and all-masked rows.
6. Repeat seeds and report a failure boundary range rather than one lucky example.

Part 4 - Python code skeleton

```
import torch

def stable_softmax(scores, dim=-1, promote=False):
    original_dtype = scores.dtype
    work = scores.float() if promote else scores
```

```
    shifted = work - work.amax(dim=dim, keepdim=True)
    weights = shifted.exp() / shifted.exp().sum(dim=dim, keepdim=True)
    return weights.to(original_dtype)

def tensor_stats(x):
    return {"min": ..., "max": ..., "finite_fraction": ...,
            "zero_fraction": ..., "dtype": str(x.dtype)}

def stress_case(scale, dtype, implementation):
    q, k, v = ...
    raw = q @ k.transpose(-2, -1)
    scaled = raw / (q.shape[-1] ** 0.5)
    weights = implementation(scaled)
    output = weights @ v
    # TODO: backward and collect stage-by-stage statistics
    return ...

def E12():
    return [stress_case(10.0 ** p, dtype, impl)
            for p in range(-3, 7)
            for dtype in [torch.float32, torch.float16]
            for impl in ...]
```

Part 5 - The Philosophy Behind the Exercise

Numerical representation is part of the model's world. The real numbers of an equation are approximated by a finite set whose gaps widen with magnitude. Operations that are identical on paper can therefore produce different behavior when implemented in different formats.

Stability is not the absence of a crash. A distribution may remain finite while becoming so sharp that useful gradient information disappears. The researcher must observe the dynamics of learning, not only whether a tensor contains NaN.

The exercise teaches that optimization begins with respecting representation limits. Clever architecture cannot learn through numbers the machine can no longer distinguish.

17.3.14 Exercise 13

Exercise Title: Implement Gradient Check for Multi-Head Attention on Tiny Tensor and Validate Backward Correctness

Part 1 - Why this matters

A forward pass can match expected values while backward propagation remains wrong because of an in-place operation, detached tensor, incorrect mask path, or faulty custom function. Gradient checking compares autograd derivatives with finite-difference estimates of the scalar loss. On a tiny multi-head attention instance, it provides independent evidence that projections, splitting, softmax, head merging, and output projection form a differentiable computation with the intended sensitivities.

Finite differences are numerically delicate. The perturbation ε must be small enough to approximate a derivative but large enough to survive floating-point rounding. Use float64, disable dropout, avoid points where the mask or another discrete branch changes, and choose moderate logits so softmax is not fully saturated. Compare several epsilon values rather than accepting one.

Check inputs and parameters separately. Q, K, and V projections play different roles, and a mistake may affect only one gradient path. Include W_Q, W_K, W_V, W_O, biases, and the input. For self-attention, the same input feeds three branches, so its total gradient is the sum of query, key, and value contributions. A cross-attention case can separate these paths more clearly.

Masking should also be verified. A masked value that cannot affect any output should have zero gradient through the attention route. Perturbing it must not change the loss. This is both a derivative check and a proof of the information boundary established by the mask.

Part 2 - Mathematical form and reasoning

For scalar loss $L(\theta)$, the centered finite difference is

$$g_i^{\mathrm{FD}} = \frac{L(\theta + \varepsilon e_i) - L(\theta - \varepsilon e_i)}{2\varepsilon}.$$

Compare with autograd g_i^{AD} using

$$E_i = \frac{|g_i^{\mathrm{AD}} - g_i^{\mathrm{FD}}|}{\max(1, |g_i^{\mathrm{AD}}|, |g_i^{\mathrm{FD}}|)}.$$

For a smooth implementation, error usually decreases as ε is reduced until rounding error begins to dominate. The epsilon sweep should show this tradeoff rather than treating the smallest epsilon as automatically best.

Part 3 - Hints, controls, and evidence

1. Use a tiny float64 model, for example $B = 1$, $T = 2$ or 3, $d = 4$, and $H = 2$.
2. Set dropout to zero and use a smooth scalar loss involving every output coordinate.
3. Run `torch.autograd.gradcheck` and also implement selected manual finite differences so the method is understood.
4. Sweep epsilon and report absolute and normalized error for each tensor.
5. Test self-attention, cross-attention, and one masked case.
6. Inject a detach or incorrect merge, prove the checker fails, then retain the case as a regression test.

Part 4 - Python code skeleton

```
import torch

def scalar_objective(model, q, k, v, mask=None):
    output, weights = model(q, k, v, mask)
    coefficients = torch.linspace(0.3, 1.1, output.numel(),
                                  dtype=output.dtype,
                                  device=output.device).reshape_as(output)
    return (output * coefficients).sum()

def centered_difference(loss_fn, tensor, flat_index, epsilon):
    with torch.no_grad():
        original = tensor.view(-1)[flat_index].item()
        tensor.view(-1)[flat_index] = original + epsilon
    plus = loss_fn().item()
    with torch.no_grad():
        tensor.view(-1)[flat_index] = original - epsilon
    minus = loss_fn().item()
    with torch.no_grad():
        tensor.view(-1)[flat_index] = original
    return (plus - minus) / (2 * epsilon)

def E13():
    model, q, k, v, mask = ...  # all float64
    # TODO: autograd gradients, epsilon sweep, gradcheck,
    # masked-gradient invariant, and injected-failure test
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Automatic differentiation gives exact derivatives of the program it receives, not of the program the researcher intended to write. Gradient checking creates a second route to the answer and asks whether the two routes agree.

This independence is the source of trust. A test that merely repeats the same implementation in different syntax can repeat the same mistake. Finite differences use the behavior of the whole function to interrogate its local sensitivity.

The exercise also demonstrates that correctness has layers. Shapes may be correct, outputs may be plausible, and training loss may decrease, while the derivative structure is still wrong. Reliable research requires evidence at each layer rather than faith in the final metric.

17.3.15 Exercise 14

Exercise Title: Stress Test Multi-Head Attention With Long Sequences and Observe GPU Memory Explosion Conditions

Part 1 - Why this matters

Dense multi-head attention creates a relation between every query and every key for every head. As sequence length grows, score and probability tensors grow quadratically. A configuration that appears inexpensive at 512 tokens may become impossible at 4,096 or 8,192 tokens

even when batch size, model width, and parameter count remain unchanged. This exercise maps that transition on the available GPU rather than waiting for an uncontrolled out-of-memory failure during a larger experiment.

Memory must be separated into categories. Parameters and optimizer states are mostly independent of sequence length. Input, Q/K/V, and head outputs grow linearly with T. Explicit scores and attention weights grow as BHT^2. Backward propagation retains activations and adds gradients, so training can require substantially more memory than inference. Allocated memory, reserved memory, and externally reported device usage describe different quantities and must not be mixed.

The stress test should increase one factor at a time: sequence length, batch, head count, dtype, and training mode. Use a separate subprocess for deliberate OOM cases so the main experiment can recover cleanly. Catching an exception inside a process does not always return the allocator and CUDA context to a useful state. Record the largest successful configuration and the first failed configuration, but do not attempt to consume all system memory without a declared safety margin.

Compare explicit scratch attention with a memory-efficient fused implementation when available. Fused kernels can avoid materializing the full probability matrix for backward, changing practical memory without changing dense attention's mathematical interaction pattern. The conclusion must distinguish algorithmic score complexity from implementation-level activation storage.

Part 2 - Mathematical form and reasoning

If one attention-like tensor has shape (B, H, T, T) and element size s bytes, its storage is

$$M_{\text{map}} = BHT^2 s.$$

Storing both scores and probabilities gives at least

$$M_{\text{scores+weights}} \approx 2BHT^2 s,$$

before backward buffers, masks, temporary kernels, and allocator overhead. Doubling T multiplies this term by four:

$$M(2T) = 4M(T).$$

The linear Q/K/V term is approximately

$$M_{QKV} = 3BTds.$$

The experiment should compare these estimates with measured incremental peak memory and explain the difference.

Part 3 - Hints, controls, and evidence

1. Query available device memory and reserve a safety margin before forming each test configuration.
2. Run forward inference, forward with gradients disabled, and full forward/backward as separate modes.

3. Reset peak statistics, synchronize, and measure an isolated case in a fresh process when possible.

4. Record allocated, reserved, peak allocated, peak reserved, dtype, shape, backend, and whether attention weights were returned.

5. Compare theoretical tensor sizes with observed peaks and identify hidden temporary or retained tensors.

6. Stop the sweep after a declared failure boundary; do not repeatedly trigger OOM on the interactive process.

Part 4 - Python code skeleton

```
import multiprocessing as mp
import torch

def estimate_map_bytes(batch, heads, seq, dtype, copies=2):
    element_size = torch.empty((), dtype=dtype).element_size()
    return copies * batch * heads * seq * seq * element_size

def isolated_case(config, queue):
    try:
        torch.cuda.set_device(config["device"])
        torch.cuda.empty_cache()

    # and stop according to a declared boundary policy
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Attention makes relationships explicit, and those relationships occupy space. The quadratic matrix is not an accidental inconvenience beside the model's intelligence; it is the physical representation of universal pairwise access in dense attention.

Resource limits therefore shape the kinds of context a model can consider. Long-context research is partly a search for new forms of memory and access that preserve useful relations

without materializing every possible pair.

Stress testing turns failure into a boundary that can be studied. An OOM error without context is an interruption. A measured scaling curve, safety margin, and reproducible threshold form knowledge that can guide architecture and deployment.

17.3.16 Exercise 15

Exercise Title: Implement Efficient Mask Broadcasting and Prove It Avoids Silent Shape Expansion Bugs

Part 1 - Why this matters

Broadcasting allows one logical mask to constrain every attention head without physically copying it to the full score shape. A padding mask of `(B,Tk)` can become `(B,1,1,Tk)`, and a causal mask of `(Tq,Tk)` can become `(1,1,Tq,Tk)`. These singleton dimensions describe which axes share the same rule. Correct broadcasting saves memory and makes the mask semantics explicit.

Silent expansion bugs occur when an axis is inserted in the wrong location but happens to be compatible with the current shape. Equal values such as $B = H = 4$ can hide the error. A padding rule intended to vary by batch may instead vary by head; a query mask may be applied along the key axis. The code runs, but different examples or heads receive the wrong information boundary.

Avoid constructing a repeated `(B,H,Tq,Tk)` boolean tensor unless a kernel requires it. `expand` creates a view with zero strides along shared axes, while `repeat` allocates copies. The logical result can be the same, but the memory behavior is not. The exercise should measure storage, strides, contiguity, and peak memory for broadcast, expand, and repeat variants.

Proof requires asymmetric test data. Give every batch, head, query, and key a distinct encoded value and define different valid lengths per batch. Compare the broadcast result against a slow reference constructed with explicit loops. Then use interventions on forbidden positions to prove that the final attention output respects the same logical mask.

Part 2 - Mathematical form and reasoning

Scores have shape

$$S \in \mathbb{R}^{B \times H \times T_q \times T_k}.$$

A padding mask $P \in \{0,1\}^{B \times T_k}$ is lifted as

$$P'_{b,1,1,j} = P_{b,j},$$

and a causal mask $C \in \{0,1\}^{T_q \times T_k}$ as

$$C'_{1,1,i,j} = C_{i,j}.$$

Broadcasting defines

$$F_{b,r,i,j} = P'_{b,1,1,j} \vee C'_{1,1,i,j}.$$

The logical full mask contains BHT_qT_k entries, but the source storage is only $BT_k + T_qT_k$ entries before any kernel materialization.

Part 3 - Hints, controls, and evidence

1. Choose unequal B, H, T_q, and T_k in the primary test.
2. Write a four-loop reference mask and compare it exactly with the broadcasted result.
3. Inspect `shape`, `stride()`, `storage().nbytes()`, and contiguity for unsqueeze, expand, repeat, and combined masks.
4. Measure peak memory at long sequence length without deliberately crossing the safety boundary from E14.
5. Test batch-specific padding together with a shared causal rule and a head-specific optional mask.
6. Inject each wrong unsqueeze position and confirm the test fails even if a contrived equal-dimension case would pass.

Part 4 - Python code skeleton

```
import torch

def broadcast_masks(padding, causal, head_mask=None):
    # padding: (B,Tk), causal: (Tq,Tk)
    p = padding[:, None, None, :]
    c = causal[None, None, :, :]
    combined = p | c
    if head_mask is not None:
        # TODO: define head-mask contract and broadcast axes
        combined = combined | ...
    return combined

def loop_reference(padding, causal, num_heads):
    b, tk = padding.shape
    tq = causal.shape[0]
    full = torch.empty(b, num_heads, tq, tk, dtype=torch.bool)
    # TODO: explicit semantic reference
    return full

def storage_report(x):
    return {"shape": tuple(x.shape), "stride": x.stride(),
            "elements": x.numel(), "storage_bytes": ...}

def E15():
    padding, causal = ..., ...
    efficient = broadcast_masks(padding, causal)
```

```
reference = loop_reference(padding, causal, num_heads=3)
assert torch.equal(efficient.expand_as(reference), reference)
return ...
```

Part 5 - The Philosophy Behind the Exercise

Broadcasting is a compact expression of symmetry. A singleton head axis says that the same law applies to every head; a singleton query axis says that the rule does not depend on which position is asking. Tensor shape thus records which distinctions matter and which are intentionally shared.

Efficiency follows from recognizing invariance. Repeating identical data stores the same fact many times, while broadcasting preserves one fact and a rule for where it applies. Many scalable algorithms depend on this ability to represent structure rather than copies.

But compression increases the importance of semantics. A wrong singleton axis can distribute a law across the wrong dimension. The concise representation is powerful only when every axis has been named and tested.

17.3.17 Exercise 16

Exercise Title: Profile GPU Kernels for Multi-Head Attention and Identify Softmax and MatMul Hotspots

Part 1 - Why this matters

Wall-clock timing says how long attention took, but not where the time was spent. Multi-head attention contains input projections, QK matrix multiplication, scaling and masking, softmax, dropout, AV matrix multiplication, head merging, and output projection. A GPU profiler reveals which kernels dominate, whether operations are fused, how much time is spent launching small kernels, and whether memory copies or synchronization distort the measurement.

The hotspot changes with shape. Projection GEMMs may dominate short sequences and large model widths. The T^2 score and value products become dominant as sequence length grows. Explicit softmax may appear as several reduction and elementwise kernels, while fused scaled-dot-product attention may combine masking, normalization, dropout, and value aggregation without storing the full attention map. The profiler trace must be interpreted in relation to the implementation actually selected.

Profiling itself can perturb performance. Capture a short scheduled window after warm-up, avoid printing or saving tensors in the measured region, and use named ranges around logical stages. Record CPU and CUDA time, call count, input shapes, memory activity, and stack traces only when their overhead is justified. A trace from one iteration without warm-up may mostly describe initialization or compilation.

The exercise should compare scratch, library, and fused variants under matched inputs and modes. If attention weights are requested, a fused kernel may be disabled or forced to materialize additional data. This is a real tradeoff between observability and performance and must be documented.

Part 2 - Mathematical form and reasoning

The principal matrix products are

$$QK^{\mathsf{T}} : (BH, T, d_h)@(BH, d_h, T) \to (BH, T, T),$$

and

$$AV : (BH, T, T)@(BH, T, d_h) \to (BH, T, d_h).$$

Each has work on the order of

$$\mathcal{O}(BHT^2 d_h) = \mathcal{O}(BT^2 d).$$

Projection work is approximately $\mathcal{O}(BTd^2)$. The crossover between projection-dominated and attention-dominated regimes depends roughly on the relationship between T and d, but measured kernel efficiency and memory traffic determine the actual boundary.

Part 3 - Hints, controls, and evidence

1. Add profiler ranges for projections, score matmul, mask/softmax, value matmul, merge, and output projection.
2. Warm up before the active profiling schedule and profile only a small, representative number of steps.
3. Compare short, medium, and long sequences at fixed model width, then vary model width separately.
4. Sort profiler tables by self CUDA time and CUDA memory, and retain the full trace for timeline analysis.
5. Record whether fused attention was used and whether returning weights or dropout changed kernel selection.
6. Convert the hotspot into a testable optimization, then re-profile rather than assuming the optimization helped.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import ProfilerActivity, profile, record_function

def instrumented_forward(model, x, mask):
    with record_function("mha_total"):
        # TODO: expose scratch stages with nested record_function ranges
        return model(x, x, x, mask)

def profile_case(model, x, mask, steps=8):
    schedule = torch.profiler.schedule(wait=1, warmup=2, active=3, repeat=1)
    with profile(activities=[ProfilerActivity.CPU,
                             ProfilerActivity.CUDA],
```

```
                schedule=schedule,
                record_shapes=True,
                profile_memory=True) as prof:
        for _ in range(steps):
            output = instrumented_forward(model, x, mask)
            # TODO: backward for training profile
            prof.step()
    return prof.key_averages().table(sort_by="self_cuda_time_total")

def E16(configurations):
    # TODO: scratch/library/fused comparisons and trace export
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A profile is a map of where the physical machine spent effort. It translates an abstract architecture into kernels, memory transfers, reductions, and synchronization. This translation often reveals that the conceptual center of an algorithm is not the only practical bottleneck.

Optimization should follow evidence because human intuition tends to focus on visible code rather than expensive execution. A one-line matrix multiplication may dominate a page of Python, while many Python statements may disappear into one fused kernel.

The profiler does not decide what matters; it measures cost. The engineer must connect that cost to model quality, maintainability, observability, and the actual deployment objective. Faster computation is valuable when it preserves the function the system was built to perform.

17.3.18 Exercise 17

Exercise Title: Build a Head Importance Metric and Prune Least Useful Heads on a Toy Task Experimentally

Part 1 - Why this matters

If several heads become redundant, removing some may reduce computation or reveal how the model distributes function. Pruning requires an importance criterion, but no single statistic captures usefulness. A head can have small output norm yet carry a decisive feature later amplified by W_O. It can have sharp attention and still be irrelevant to the loss. Reliable pruning must be validated through behavioral change.

Begin with ablation importance: set one head output to zero before the output projection and measure the change in validation loss or task metric. Compare this with cheaper proxies such as output norm, gradient magnitude, Taylor score, attention entropy, and output-projection block norm. Calculate rank correlation between each proxy and actual ablation effect across heads and seeds.

Single-head importance may miss interaction. Two individually unimportant heads can jointly provide a fallback, so pruning both causes a large drop. Conversely, two apparently important heads may encode the same function. Iterative pruning with reevaluation is safer than ranking once and removing a large group. After each pruning step, optionally fine-tune

under a fixed budget and report performance before and after recovery.

Logical masking of heads does not automatically create hardware speedup. Dense projections and kernel shapes may remain unchanged. Distinguish functional pruning, structural removal of dimensions and weights, and measured runtime improvement. A smaller conceptual model is not necessarily a faster compiled model.

Part 2 - Mathematical form and reasoning

Let $m_r \in \{0, 1\}$ gate head r before concatenation. The model becomes

$$Y(m) = \text{Concat}(m_1 Z^{(1)}, \ldots, m_H Z^{(H)}) W_O.$$

Ablation importance is

$$I_r^{\text{abl}} = \mathcal{L}(m_r = 0) - \mathcal{L}(m_r = 1).$$

A first-order Taylor proxy around $m_r = 1$ is

$$I_r^{\text{Taylor}} \approx \left| \frac{\partial \mathcal{L}}{\partial m_r} m_r \right|.$$

If $W_O^{(r)}$ denotes the rows receiving head r, a simple structural proxy is $\|W_O^{(r)}\|_F$, but it should be evaluated against true ablation rather than assumed sufficient.

Part 3 - Hints, controls, and evidence

1. Train and freeze a baseline before measuring importance on a fixed validation set.
2. Calculate ablation effect, norm, entropy, gradient, Taylor, and output- projection metrics for every head.
3. Repeat seeds and report whether importance rankings are stable.
4. Prune iteratively, reevaluate after each removal, and compare one-shot pruning.
5. Separate metric immediately after pruning from metric after a fixed fine-tuning budget.
6. Measure actual parameters, FLOPs estimate, latency, and memory after structural pruning; do not infer speed from zeroed tensors.

Part 4 - Python code skeleton

```
import torch

class HeadGate(torch.nn.Module):
    def __init__(self, num_heads):
        super().__init__()
        self.gates = torch.nn.Parameter(torch.ones(num_heads),
                                        requires_grad=False)

    def forward(self, heads):
```

```
        return heads * self.gates[None, :, None, None]

@torch.no_grad()
def ablation_scores(model, loader, evaluate):
    baseline = evaluate(model, loader)
    scores = []
    for head in range(model.num_heads):
        # TODO: disable one head, evaluate, then restore it
        scores.append(...)
    return baseline, scores

def iterative_prune(model, loader, target_heads, fine_tune=None):
    history = []
    while ...:
        _, importance = ablation_scores(model, loader, ...)
        chosen = ...
        # TODO: prune or gate chosen head, evaluate, optionally fine-tune
        history.append(...)
    return history

def E17(model, train_loader, validation_loader):
    # TODO: proxy correlation, iterative pruning, and speed validation
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Pruning asks which parts of a learned system are necessary. Necessity is relational: a head may be dispensable because another compensates for it, not because it learned nothing. Removing components reveals organization through the system's response to loss.

Importance is also purpose-dependent. A head may be unimportant for average accuracy but essential for rare cases, robustness, calibration, or a subgroup of inputs. Optimization toward one metric can erase capabilities that metric does not value.

The broader lesson is that efficiency is a claim about behavior under reduced resources. Real compression must preserve declared functions and produce measured systems gains, not merely a visually smaller diagram.

17.3.19 Exercise 18

Exercise Title: Create a Multi-Head Attention Debugging Checklist Covering Shapes, Masks, Dtypes, and NaN Detection

Part 1 - Why this matters

Multi-head attention failures often appear far from their cause. A wrong split can surface as poor convergence, a mask-axis error as suspiciously high validation accuracy, dtype overflow as intermittent NaNs, and device mismatch as a crash only when an optional path is enabled.

A debugging checklist turns the chapter's scattered invariants into an ordered diagnostic procedure.

The order matters. Begin with configuration contracts, then input contracts, projection shapes, split/merge identity, score geometry, mask legality, softmax invariants, output merge, backward gradients, numerical parity, and performance. Later checks depend on earlier ones. There is little value in profiling a kernel before proving that it computes the intended tensor relationships.

Each checklist item should be executable where possible. Replace vague advice such as "check the mask" with assertions: forbidden weights are zero, legal rows sum to one, future-token interventions cannot change earlier outputs, and all-masked rows follow the documented policy. Replace "check gradients" with finite checks, expected shapes, nonzero paths, masked-zero paths, and a tiny finite-difference case.

The checklist must support incident documentation. For each failure, capture configuration, seed, device, dtype, shape ledger, earliest violated invariant, suspected cause, correction, and regression test. A fix without a retained test permits the same bug to return during later refactoring.

Part 2 - Mathematical form and reasoning

The checklist enforces a chain of invariants:

$$d = Hd_h,$$

$$(B, T, d) \leftrightarrow (B, H, T, d_h),$$

$$S \in \mathbb{R}^{B\times H\times T_q\times T_k}, \qquad A = \operatorname{softmax}(S + M),$$

$$\sum_j A_{b,r,i,j} = 1, qquad A_{b,r,i,j} = 0 \text{ for forbidden } j,$$

$$Y \in \mathbb{R}^{B\times T_q\times d}.$$

For every monitored tensor Z, require

$$\text{finite}(Z), qquad \text{shape}(Z) = \text{expected}(Z),$$

and compare devices or implementations under a declared tolerance rather than bitwise equality by default.

Part 3 - Hints, controls, and evidence

1. Divide the checklist into configuration, forward geometry, masks, numerics, backward, parity, performance, and incident-report sections.
2. Give every check a pass/fail condition, diagnostic payload, and likely root causes.
3. Build a tiny deterministic smoke test and an asymmetric cross-attention test that run before expensive training.

4. Add failure injection for wrong transpose, wrong softmax axis, mask broadcast, detach, overflow, and missing CUDA synchronization.

5. Stop at and report the earliest violated invariant rather than flooding the user with downstream failures.

6. Run the checklist automatically in CI or before chapter benchmarks and save a machine-readable report.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict
import torch

@dataclass
class CheckResult:
    name: str
    passed: bool
    evidence: dict
    likely_causes: list

def check_split_merge(model, x):
    split = model.split_heads(x)
    merged = model.merge_heads(split)
    return CheckResult("split_merge_identity",
                       torch.equal(x, merged),
                       {"input": tuple(x.shape),
                        "split": tuple(split.shape)},
                       ["wrong transpose", "wrong reshape order"])

def check_attention(weights, forbidden):
    # TODO: finite, row-sum, range, and forbidden-zero checks
    return ...

def run_debug_checklist(model, case):
    checks = []
    # TODO: ordered checks; stop or mark downstream checks as blocked
    return {"passed": all(c.passed for c in checks),
            "checks": [asdict(c) for c in checks]}

def E18():
    correct_case = ...
    injected_failures = ...
    # TODO: prove each failure is caught by its earliest invariant
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A checklist is accumulated memory. It converts failures once paid for with time into protections available to future work. In this sense, engineering maturity is partly the ability of a project to remember its mistakes.

Order gives the checklist explanatory power. A system can violate many downstream properties after one early error, but the earliest broken invariant is closest to the cause. Debugging is the search for that first divergence between intention and execution.

The checklist does not replace thought. It protects attention so thought can be spent on new problems rather than rediscovering old ones. Its quality is measured by whether it produces evidence, shortens diagnosis, and prevents recurrence.

17.3.20 Exercise 19

Exercise Title: Produce a Multi-Head Attention Engineering Report Summarizing Implementations and Observed Behaviors

Part 1 - Why this matters

The final exercise transforms nineteen technical investigations into one auditable engineering account. The report must explain how model-space vectors are projected into head subspaces, how shapes change, how per-head scores and weighted retrieval operate, how heads are concatenated, and how the output projection integrates them back into the residual space. It should be possible for another researcher to reconstruct the implementation from the tensor contracts and equations.

Implementation is only the first layer. The report must summarize evidence about head diversity, single-head comparisons, scaling, mask composition, redundancy, low-rank score geometry, mixed precision, gradient correctness, head-count performance, long-sequence memory, broadcast efficiency, profiler hotspots, importance metrics, and pruning. Each claim should point to a saved configuration, seed set, table, trace, failure case, or regression test.

Negative and conditional results belong in the report. Per-head temperature may not improve quality. More heads may not beat a controlled single-head baseline. Similar heat maps may not imply functional redundancy. Pruning may reduce conceptual capacity without improving latency. Fused attention may save memory while reducing access to explicit weights. These findings refine design choices and should not be hidden as unsuccessful experiments.

Separate theory, measurement, and interpretation. The rank bound applies to pre-softmax logits, not automatically to softmax weights. Theoretical FLOPs at fixed model width may remain similar across head counts while measured runtime changes. A CUDA parity tolerance establishes bounded numerical agreement, not bitwise identity. Precise boundaries protect the report from overclaiming.

End with a practical design guide. State how to choose a valid head count, when to inspect or prune heads, how to test masks and mixed precision, what to profile, and which unresolved questions pass into positional representation and complete Transformer blocks.

Part 2 - Mathematical form and reasoning

The report should anchor itself in

$$Q = XW_Q, \qquad K = XW_K, \qquad V = XW_V,$$

$$A^{(r)} = \mathrm{softmax}\left(\frac{Q^{(r)}K^{(r)\mathsf{T}}}{\sqrt{d_h}} + M\right), \qquad Z^{(r)} = A^{(r)}V^{(r)},$$

$$Y = \mathrm{Concat}(Z^{(1)}, \ldots, Z^{(H)})W_O.$$

It must state the geometry

$$d = Hd_h, qquad \mathrm{rank}(Q^{(r)}K^{(r)\mathsf{T}}) \le d_h,$$

the dense cost

$$\text{work} = \mathcal{O}(BTd^2 + BT^2d), \qquad \text{map storage} = \mathcal{O}(BHT^2),$$

and the exact mask and numerical invariants used to validate the implementation.

Part 3 - Hints, controls, and evidence

1. Open with a thesis and a table mapping every engineering claim to its exercise artifact and verification method.
2. Include tensor contracts, parameter counts, controlled comparison settings, hardware, software, dtype, seeds, tolerances, and stopping rules.
3. Report distributions and failure boundaries, not only best runs or successful screenshots.
4. Separate descriptive attention patterns from ablation-based functional evidence.
5. Include an incident appendix containing injected bugs, earliest violated invariants, fixes, and regression tests.
6. Finish with recommendations, limitations, and questions for TRF02 rather than repeating the chapter titles.

The final report should be reproducible from saved raw artifacts and should clearly mark any claim that remains a hypothesis.

Part 4 - Python code skeleton

```
from pathlib import Path
import json

REQUIRED_ARTIFACTS = [
    "implementation", "projection_geometry", "head_diversity",
    "mask_proofs", "rank_analysis", "mixed_precision",
    "gradient_check", "head_count_benchmark", "memory_stress",
    "profiler", "pruning", "debug_checklist",
]
```

```
def load_artifacts(directory):
    # TODO: load JSON, CSV, profiler summaries, and figure metadata
    return ...

def validate_artifacts(artifacts):
    return {name: ... for name in REQUIRED_ARTIFACTS}

def build_conclusions(artifacts):
    # TODO: separate observation, interpretation, limitation,
    # and recommendation for every major result
    return ...

def E19(artifact_directory, output_path):
    artifacts = load_artifacts(artifact_directory)
    checks = validate_artifacts(artifacts)
    assert all(checks.values()), checks
    report = build_conclusions(artifacts)
    Path(output_path).write_text(report, encoding="utf-8")
    return {"report": str(output_path), "evidence_checks": checks}
```

Part 5 - The Philosophy Behind the Exercise

An engineering report is where computation becomes accountable knowledge. Code records what was executed, but a report records why it was executed, what was controlled, what was observed, what failed, and what the evidence permits us to conclude.

Multi-head attention is often presented as a finished idea. This chapter shows it as a negotiated system of projections, subspaces, masks, numerical formats, memory costs, kernels, and learned behavior. Its success depends on the coordination of these parts, not on the softmax equation alone.

The deepest lesson is methodological. Understanding a model means moving among mathematics, implementation, intervention, and physical measurement without confusing one for another. A trustworthy researcher preserves the boundaries of every claim and uses those boundaries to decide what must be tested next.

17.4 TRF02

Chapter Title: Positional Encoding and Sequence Order Modeling
Specialization: Models and Training

17.4.1 Exercise 00

Exercise Title: Explain Why Self-Attention Alone Is Permutation-Invariant and Why Positional Information Is Required

Part 1 - Why this matters

Self-attention compares token representations according to their content. If the input rows are permuted and no positional signal, causal boundary, or position-dependent mask is present, the outputs are permuted in the same way. The mechanism can model relationships among a set of items, but it cannot know which identical item appeared first, which token was adjacent, or how far one token was from another. This property is more precisely called permutation equivariance for token-level outputs: permuting inputs permutes outputs rather than leaving the entire output unchanged. A permutation-invariant pooled readout may then produce exactly the same final result.

This limitation matters because sequence meaning often depends on order. "Dog bites man" and "Man bites dog" contain the same tokens but describe different events. A model that sees only token identity and pairwise content similarity cannot distinguish these sequences before some source of order is introduced. Recurrence receives order through the sequence of state updates; convolution receives it through structured local neighborhoods. A Transformer must encode it explicitly through positional representations, masks, relative biases, or another position-dependent mechanism.

The proof should not rely on verbal intuition. Construct an input matrix X and a permutation matrix P. Apply scratch self-attention to X and PX using the same weights. Verify that the unpermuted result from the second case matches the first result. Then add positional encodings to fixed slots and repeat. Because tokens now receive different positional vectors after permutation, the equality should break.

Masks require careful interpretation. A causal mask already depends on row and column indices, so it introduces an ordering constraint even without a separate positional vector. It tells the model which positions are earlier, but not a complete metric description of absolute or relative distance. The experiment must therefore separate unmasked attention, padding-only attention, and causal attention instead of making an unrestricted claim about every Transformer.

Part 2 - Mathematical form and reasoning

For permutation matrix P and unmasked self-attention,

$$Q' = PXW_Q = PQ, \qquad K' = PK, \qquad V' = PV.$$

Therefore

$$Q'K'^{\mathsf{T}} = P(QK^{\mathsf{T}})P^{\mathsf{T}}.$$

Row-wise softmax respects the same simultaneous row and column permutation:

$$\operatorname{softmax}(PSP^{\mathsf{T}}) = P \operatorname{softmax}(S)P^{\mathsf{T}}.$$

Thus

$$\operatorname{Attn}(PX) = P \operatorname{Attn}(X).$$

With slot-dependent positional matrix E,

$$\operatorname{Attn}(PX + E) \neq P \operatorname{Attn}(X + E)$$

in general, because E remains attached to positions rather than moving with the permuted token identities.

Part 3 - Hints, controls, and evidence

1. Use unique token vectors first, then repeat the proof with duplicated tokens and an order-sensitive target.
2. Build the permutation explicitly and verify both matrix multiplication and index-based permutation paths.
3. Disable dropout and use evaluation mode so stochasticity cannot break the equality for unrelated reasons.
4. Test unmasked, padding-only, and causal cases separately and state which symmetry each mask preserves or breaks.
5. Compare token-level outputs after applying the inverse permutation and a pooled output before and after permutation.
6. Add positional information and quantify the change in attention weights, outputs, and an order-sensitive prediction.

Part 4 - Python code skeleton

```
import torch

def permutation_matrix(order, dtype=torch.float64):
    size = len(order)
    p = torch.zeros(size, size, dtype=dtype)
    p[torch.arange(size), torch.tensor(order)] = 1
    return p

def equivariance_error(attention, x, order, mask=None):
    p = permutation_matrix(order, x.dtype).to(x.device)
    px = torch.einsum("ij,bjd->bid", p, x)
    y, _ = attention(x, x, x, mask)
    py, _ = attention(px, px, px, mask)
    expected = torch.einsum("ij,bjd->bid", p, y)
    return (py - expected).abs().max()

def E00(attention):
    x = ...
    position = ...
    plain_error = equivariance_error(attention, x, [2, 0, 3, 1])
    # TODO: repeat with fixed-slot positions and causal masking
    return {"plain": plain_error, "with_position": ...,
            "causal": ...}
```

Part 5 - The Philosophy Behind the Exercise

Attention begins by treating tokens as members of a relational collection. It asks what is compatible with what, but content alone does not reveal the path by which the collection was formed. Order is additional structure imposed on that collection.

This exposes a general principle: a model can learn only from distinctions its representation and architecture make available. If two inputs are mapped into states related by a symmetry the model cannot break, no amount of optimization can recover the missing distinction. Data cannot teach a coordinate the system has erased.

Positional modeling is therefore not decoration added to attention. It is the construction of temporal or spatial identity. The design question is not whether order matters in the abstract, but which aspects of order—absolute location, relative distance, direction, or hierarchy—the task requires the model to represent.

17.4.2 Exercise 01

Exercise Title: Implement Sinusoidal Positional Encoding from Scratch and Verify Correct Shape and Broadcasting

Part 1 - Why this matters

Sinusoidal positional encoding assigns each sequence location a deterministic vector whose dimensions oscillate at different frequencies. The encoding adds no learned parameters and can be generated for positions beyond those seen in training. Its implementation appears simple, but incorrect pairing of sine and cosine dimensions, wrong exponent calculation, or confusion between batch-first and sequence-first layouts can silently attach the wrong position to every token.

The encoding should be constructed first as a table of shape `(max_length, d_model)`. For a batch-first input it is sliced to the current sequence length, given a singleton batch axis, and added by broadcasting to every example. The batch axis is shared because position 7 has the same encoding in every independent sequence, unless the application explicitly uses different position offsets. Broadcasting must not duplicate a large table unnecessarily.

Odd model dimensions require a policy because sine dimensions and cosine dimensions are naturally paired. A robust implementation fills every even dimension with sine and only the available odd dimensions with cosine. The exercise should test both even and odd widths and compare selected coordinates with manual calculations.

Register the table as a buffer rather than a trainable parameter. This ensures it moves with the module across CPU and CUDA and appears in the state dictionary without receiving gradients. The implementation should also support a position offset so cached autoregressive decoding can encode newly generated tokens using their true global indices.

Part 2 - Mathematical form and reasoning

For position p and pair index i,

$$\mathrm{PE}_{p,2i} = \sin\!\left(\frac{p}{10000^{2i/d}}\right), \qquad \mathrm{PE}_{p,2i+1} = \cos\!\left(\frac{p}{10000^{2i/d}}\right).$$

Equivalently, define

$$\omega_i = \exp\Big(-\frac{2i}{d}\log 10000\Big)$$

and use $\sin(p\omega_i)$ and $\cos(p\omega_i)$. For batch-first input,

$$X \in \mathbb{R}^{B\times T\times d}, \qquad E \in \mathbb{R}^{1\times T\times d}, \qquad Y = X + E.$$

The singleton batch dimension gives broadcasted addition without changing the underlying positional table.

Part 3 - Hints, controls, and evidence

1. Calculate positions 0, 1, and 2 manually for a tiny width before using a vectorized implementation.
2. Test even and odd d_{model}, multiple batch sizes, sequence length one, and the maximum supported length.
3. Verify position zero contains zeros in sine channels and ones in cosine channels.
4. Confirm the buffer has no gradient, follows `model.to(device)`, and preserves the requested dtype.
5. Check that equal token embeddings at different positions become different while equal positions across batches receive equal encodings.
6. Test offset slicing and reject requests that exceed the allocated table with a clear error.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

class SinusoidalPosition(nn.Module):
    def __init__(self, d_model, max_length=4096):
        super().__init__()
        position = torch.arange(max_length, dtype=torch.float32)[:, None]
        pair = torch.arange(0, d_model, 2, dtype=torch.float32)
        frequency = ...
        table = torch.zeros(max_length, d_model)
        table[:, 0::2] = ...
        table[:, 1::2] = ...  # TODO: handle odd width safely
        self.register_buffer("table", table, persistent=True)

    def forward(self, x, offset=0):
        # x: (B,T,d_model)
        length = x.shape[1]
        encoding = ...
```

```
        return x + encoding.to(dtype=x.dtype)

def E01():
    module = SinusoidalPosition(d_model=7, max_length=16)
    x = torch.zeros(3, 5, 7)
    y = module(x)
    # TODO: manual-value, broadcasting, buffer, offset, and boundary tests
    return y
```

Part 5 - The Philosophy Behind the Exercise

Sinusoidal encoding represents position through phase. A location is not stored as a single integer but as a pattern across many cycles, each observing the sequence at a different scale. Fine frequencies distinguish nearby positions; slow frequencies preserve broad location.

The encoding also demonstrates how a fixed mathematical structure can support learning without itself being learned. Not every useful representation must be discovered from data. Some structure can be supplied as an inductive bias that reduces the burden on optimization.

Yet determinism is not neutrality. Choosing sinusoidal coordinates decides what relations are easy to express and how positions behave beyond the training range. A handcrafted encoding still carries assumptions about the world it is designed to describe.

17.4.3 Exercise 02

Exercise Title: Implement Learnable Positional Embeddings and Compare Against Sinusoidal Encoding on a Toy Task

Part 1 - Why this matters

Learnable positional embeddings assign an independent trainable vector to each supported location. Unlike sinusoidal encoding, they can adapt their geometry to the training task rather than following a fixed frequency construction. This flexibility may improve performance inside the trained range, but it also introduces parameters tied to a maximum length and provides no defined vector for unseen positions unless an extension rule is added.

The implementation is an embedding table indexed by position IDs. Position IDs must be created on the same device as the input and may need an offset during incremental decoding. The table should be initialized according to a recorded policy, included in the optimizer, and checked for gradient flow. A common bug is recreating the position tensor on CPU or detaching the embedding output before addition.

The comparison with sinusoidal encoding must control the rest of the model. Use identical token embeddings, attention architecture, dataset, seeds, optimizer budget, stopping rule, and evaluation splits. The learnable variant has extra parameters, so report that difference and include a no-position baseline. Evaluate both interpolation within trained lengths and extrapolation beyond them; for the learnable table, the latter requires a declared strategy such as failure, interpolation, or a larger randomly initialized table.

Use an order-sensitive task with known structure. Record training speed, validation quality, seed variance, gradient norms for positional parameters, and performance by sequence length. A result may legitimately show learnable positions winning inside the training range while sinusoidal positions fail less severely outside it.

Part 2 - Mathematical form and reasoning

For maximum length L,

$$E \in \mathbb{R}^{L \times d}, \qquad Y_{b,p,:} = X_{b,p,:} + E_{p,:}.$$

The positional parameter count is

$$N_{\text{learned}} = Ld, \qquad N_{\text{sinusoidal}} = 0$$

trainable parameters. For trial metric $m_{v,s,\ell}$ under variant v, seed s, and sequence length ℓ, summarize both

$$\overline{m}_{v,\ell} = \frac{1}{S} \sum_{s} m_{v,s,\ell}$$

and its dispersion. Aggregating all lengths into one number can hide a sharp failure beyond the training range.

Part 3 - Hints, controls, and evidence

1. Compare no position, sinusoidal position, and learnable position under the same surrounding architecture.
2. Fix dataset generation, seeds, initialization of shared weights, optimization steps, validation frequency, and checkpoint rule.
3. Report extra positional parameters and optimizer-state memory.
4. Measure quality separately for seen lengths, unseen token combinations, and lengths beyond the training maximum.
5. Inspect positional gradient norms and confirm every used index receives updates while unused rows do not.
6. State the learnable-table extrapolation policy explicitly; never silently clamp all unseen positions to the final row.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class LearnablePosition(nn.Module):
    def __init__(self, max_length, d_model):
        super().__init__()
        self.embedding = nn.Embedding(max_length, d_model)
```

```
    def forward(self, x, offset=0):
        length = x.shape[1]
        positions = torch.arange(offset, offset + length,
                                 device=x.device)
        # TODO: validate the range
        return x + self.embedding(positions)[None, :, :]

def controlled_trial(variant, seed, data, config):
    torch.manual_seed(seed)
    model = ...
    # TODO: identical training and evaluation protocol
    return {"variant": variant, "seed": seed,
            "curve": ..., "metrics_by_length": ...,
            "position_gradient_norms": ...}

def E02(variants, seeds=range(5)):
    data = ...
    return [controlled_trial(v, s, data, ...)
            for v in variants for s in seeds]
```

Part 5 - The Philosophy Behind the Exercise

Learnable positions allow a task to shape its own coordinate system. The model does not inherit a theory of distance; it discovers positional distinctions that reduce its loss. This can be efficient when the future resembles the training domain.

But adaptation and extrapolation pull in different directions. A free table can specialize strongly to known positions while lacking any principle for a new one. A fixed rule may fit the observed domain less perfectly while defining behavior everywhere its formula can be evaluated.

The comparison therefore reflects a recurring problem in learning: whether to encode prior structure or purchase flexibility with data. Neither answer is universally correct. The responsible choice follows the task's expected range, evidence, and failure costs.

17.4.4 Exercise 03

Exercise Title: Debug Positional Encoding Off-by-One Bugs in Token Indexing and Confirm Correct Sequence Alignment

Part 1 - Why this matters

An off-by-one error attaches a valid positional vector to the wrong token. All shapes remain correct, no exception is required, and training may still reduce loss. The model simply learns from a shifted coordinate system that can become inconsistent across training, evaluation, padding, special tokens, or cached generation. Because the error is semantic rather than dimensional, it must be debugged with traceable alignment tests.

Decide whether the first token uses position 0 or position 1 and apply that policy everywhere. Special tokens such as beginning-of-sequence may consume a position; padding may use an arbitrary ID whose embedding is later masked; left padding changes the relation between

storage index and content-relative position. Incremental decoding must begin the new token at the length already stored in the cache, not restart at zero on every call.

Build a ledger containing token ID, storage index, valid-token index, position ID, padding flag, and expected positional vector. Use deliberately different tokens and deterministic position values so a shift is visible. Test full sequence processing against token-by-token processing with an offset. Their representations should agree before any stochastic layer.

Inject specific failures: start at one in one path and zero in another, count padding as content under left padding, forget the beginning token, or use `offset=cache_length-1`. Each should be caught by the earliest alignment invariant and retained as a regression test.

Part 2 - Mathematical form and reasoning

For zero-based absolute positions and prefix cache length c, a block of length T should use

$$p_t = c + t, \qquad t = 0, \ldots, T-1.$$

For right-padded sequences with valid length ℓ_b, token positions may be

$$p_{b,t} = t \quad \text{for } t < \ell_b,$$

while padding is ignored by attention and loss. For content-relative positions under left padding mask $m_{b,t} \in \{0, 1\}$,

$$p_{b,t} = \max\left(0, \sum_{u=0}^{t} m_{b,u} - 1\right).$$

The correct rule depends on architecture and serving policy, but the same rule must be used consistently across all paths.

Part 3 - Hints, controls, and evidence

1. Replace the real table temporarily with rows containing their own position index so alignment is directly observable.
2. Print a row-wise token/position ledger for unpadded, right-padded, left-padded, prefixed, and incrementally decoded examples.
3. Compare full-sequence and cached block processing before attention and at the final output in evaluation mode.
4. Test beginning, end, padding, maximum table length, and empty-continuation boundaries.
5. Inject each off-by-one policy and ensure a dedicated assertion fails with the mismatched token and expected position.
6. Preserve the agreed indexing convention in module documentation and checkpoint metadata.

Part 4 - Python code skeleton

```
import torch

def content_positions(attention_mask):
    # attention_mask: 1 for content, 0 for padding
    positions = attention_mask.long().cumsum(dim=-1) - 1
    return positions.clamp_min(0)

def alignment_ledger(tokens, position_ids, attention_mask):
    rows = []
    for b in range(tokens.shape[0]):
        for t in range(tokens.shape[1]):
            rows.append({"batch": b, "storage_index": t,
                         "token": int(tokens[b, t]),
                         "position": int(position_ids[b, t]),
                         "valid": bool(attention_mask[b, t])})
    return rows

def E03(position_module):
    tokens, masks = ...
    position_ids = content_positions(masks)
    # TODO: full vs incremental parity and injected off-by-one tests
    return alignment_ledger(tokens, position_ids, masks)
```

Part 5 - The Philosophy Behind the Exercise

An off-by-one error is small in arithmetic and large in meaning. It reminds us that coordinates do not merely label data; they establish relationships among events. Moving every event by one position can preserve shapes while changing the system's history.

Alignment is a contract among tokenization, batching, modeling, and serving. No component can define position privately without risking contradiction with the others. Correctness emerges from shared convention.

The deeper debugging lesson is that valid values can still be wrongly associated. Range checks and finite checks cannot detect misplaced meaning. Some truths require identity-level traces that follow one item through the entire pipeline.

17.4.5 Exercise 04

Exercise Title: Demonstrate How Positional Encoding Changes Attention Maps Compared to No Position Information

Part 1 - Why this matters

Positional information changes queries and keys before their compatibility is calculated. Two equal token embeddings at different locations are identical to content-only attention, but become different after absolute positional vectors are added or after a relative mechanism modifies their score. Attention maps therefore offer a direct place to observe how order enters relational computation.

The comparison must use identical token content and projection weights. Run the same sequence with no positional signal, then with a chosen encoding. Include repeated tokens so content-only attention is forced to treat some locations symmetrically. Measure how score matrices, probabilities, and outputs change. Heat maps are useful, but numeric symmetry checks and controlled interventions are stronger evidence.

Avoid overinterpretation. A visible diagonal does not prove the model learned syntax, and a changed map does not guarantee improved task performance. Untrained projections may produce arbitrary patterns. Compare initialization and trained checkpoints, repeat seeds, and connect visual differences to an order-sensitive evaluation.

Position and content interact. Adding a large position vector can dominate token identity, while a tiny vector may have little effect. Sweep an encoding scale and record attention entropy, symmetry error, output difference, and task quality. The goal is to understand influence rather than to choose the most dramatic image.

Part 2 - Mathematical form and reasoning

Without position,

$$S_0 = \frac{(XW_Q)(XW_K)^\mathsf{T}}{\sqrt{d_h}}.$$

With additive position E and scale α,

$$S_\alpha = \frac{((X + \alpha E)W_Q)((X + \alpha E)W_K)^\mathsf{T}}{\sqrt{d_h}}.$$

Expanding the product reveals four interactions: content with content, content with position, position with content, and position with position. Compare maps with

$$\Delta_A = \frac{\|A_\alpha - A_0\|_F}{\max(\|A_0\|_F, \varepsilon)}$$

and measure how positional information breaks the symmetry between rows that were equal in the content-only case.

Part 3 - Hints, controls, and evidence

1. Create a sequence containing repeated token embeddings at several positions and prove their content-only score rows match where expected.
2. Freeze projections and change only the positional variant or scale.
3. Save logits, weights, entropy, row differences, outputs, and task metric instead of relying only on images.
4. Compare untrained and trained models across fixed probe examples and multiple seeds.
5. Use identical color limits when placing heat maps side by side.
6. Perturb token identity and position separately to isolate content and order sensitivity.

Part 4 - Python code skeleton

```
import torch

@torch.no_grad()
def positional_intervention(model, token_embeddings, position, scales):
    results = {}
    for scale in scales:
        x = token_embeddings + scale * position
        output, weights, debug = model.attend_with_debug(x)
        results[scale] = {
            "logits": debug["logits"].cpu(),
            "weights": weights.cpu(),
            "output": output.cpu(),
            "entropy": ...,
        }
    return results

def map_difference(reference, candidate):
    return ...

def E04(model):
    tokens = ...  # include repeated embeddings
    positions = ...
    results = positional_intervention(model, tokens, positions,
                                      [0.0, 0.1, 0.5, 1.0, 2.0])
    # TODO: symmetry tests, plots, and order-task evaluation
    return results
```

Part 5 - The Philosophy Behind the Exercise

Position does not enter attention as a label printed beside a token. It alters the geometry through which relevance is calculated. The question "what is related?" becomes inseparable from "where did it occur?"

This interaction reflects a broader truth about meaning: content and context are not independent layers that can always be analyzed separately. The same symbol can participate in different relations because its place changes the questions it asks and the keys it presents.

Visualization makes this transformation visible, but visibility is not explanation. A heat map becomes evidence only when paired with controls, quantitative differences, interventions, and behavior on a task whose required order is known.

17.4.6 Exercise 05

Exercise Title: Implement Relative Position Bias Conceptually and Compare Its Behavior Against Absolute Position Encoding

Part 1 - Why this matters

Absolute positional encoding attaches a representation to each location before attention. Relative position bias instead modifies compatibility according to the displacement between

query and key. A token at position 20 attending three steps backward receives the same relative category as a token at position 200 attending three steps backward, subject to clipping or bucketing. This can make translation of a local pattern easier to represent.

Implement a table indexed by relative displacement $j - i$. For maximum signed distance D, clip displacements to $[-D, D]$ and shift them into nonnegative indices. The table may contain one bias per head because different heads can prefer different distance patterns. The bias is added to logits before softmax, so it changes retrieval probability without changing values directly.

Compare relative bias with absolute additive encoding on tasks where the same relationship appears at different absolute locations. Use identical attention weights and training controls. Test shift equivariance by moving a pattern through the sequence: the relative-bias score contribution should move with the pattern, while an absolute table may encode location-specific behavior.

Relative bias is not automatically length-unlimited. A learned table with clipping collapses all large distances into edge buckets, and a full $2T - 1$ table grows with supported length. Document the indexing and extrapolation policy. Also clarify that relative bias expresses pairwise distance but may not uniquely identify an absolute slot when the task requires one.

Part 2 - Mathematical form and reasoning

For query position i, key position j, and head r,

$$S_{i,j}^{(r)} = \frac{q_i^{(r)\mathsf{T}} k_j^{(r)}}{\sqrt{d_h}} + b_{\rho(j-i)}^{(r)},$$

where

$$\rho(\delta) = \operatorname{clip}(\delta, -D, D) + D.$$

The index range is $0, \ldots, 2D$, so a per-head table has shape $H \times (2D + 1)$. Under a joint shift c,

$$(j + c) - (i + c) = j - i,$$

which preserves the relative-bias contribution as long as boundaries and masks do not change.

Part 3 - Hints, controls, and evidence

1. Construct the full displacement matrix manually for a short sequence and verify orientation: positive should mean the declared direction.

2. Test clipping at $-D$, D, and beyond both boundaries.

3. Give each bucket a recognizable value and verify the gathered bias matrix before adding content logits.

4. Compare shifted copies of the same pattern away from sequence boundaries.

5. Evaluate absolute, relative, combined, and no-position variants under matched training controls.

6. Report behavior on tasks requiring relative distance separately from tasks requiring absolute location.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class RelativePositionBias(nn.Module):
    def __init__(self, num_heads, max_distance):
        super().__init__()
        self.max_distance = max_distance
        self.table = nn.Parameter(
            torch.zeros(num_heads, 2 * max_distance + 1)
        )

    def forward(self, query_len, key_len, device):
        q = torch.arange(query_len, device=device)[:, None]
        k = torch.arange(key_len, device=device)[None, :]
        displacement = ...  # declare sign convention
        bucket = displacement.clamp(-self.max_distance,
                                    self.max_distance) + self.max_distance
        # TODO: gather -> (1,H,Tq,Tk)
        return ...

def E05():
    module = RelativePositionBias(num_heads=3, max_distance=4)
    # TODO: indexing, clipping, shift, gradient, and task comparisons
    return module(5, 7, torch.device("cpu"))
```

Part 5 - The Philosophy Behind the Exercise

Absolute position asks where an event exists in a global frame. Relative position asks how one event is situated with respect to another. These are different forms of knowledge: location and relation.

Many patterns survive translation because their internal distances remain the same. Relative bias makes that invariance easier to express, but it can also discard global identity that another task needs. Every invariance is both a generalization aid and a refusal to distinguish.

The exercise therefore turns positional design into a question about the world represented by the data. Does meaning belong to a slot, a distance, a direction, or a combination? The architecture should answer the task's actual geometry rather than follow fashion.

17.4.7 Exercise 06

Exercise Title: Implement Rotary Positional Embedding Conceptually and Explain Why It Helps Long Context Attention

Part 1 - Why this matters

Rotary positional embedding applies position-dependent rotations to query and key vector pairs rather than adding a vector to token representations. When a rotated query at position m is dotted with a rotated key at position n, the resulting compatibility depends on their relative displacement. Position is therefore embedded directly into the geometry of the attention score.

The implementation groups feature dimensions into two-dimensional pairs. Each pair is rotated by an angle determined by position and a frequency assigned to that pair. Rotation preserves the norm of each pair in exact arithmetic. Values are usually not rotated in standard RoPE because the mechanism is designed to modify addressing through Q/K compatibility, though variants exist and the chosen convention must be documented.

RoPE is often said to help long context, but this statement needs boundaries. Its relative phase structure can behave more naturally than a finite learned absolute table and can be evaluated at unseen indices. Yet high-frequency angles continue wrapping, finite precision degrades large-position phase calculation, and models trained on short contexts may not automatically use very long contexts correctly. Scaling methods modify the frequency schedule to extend usable range, but they introduce their own tradeoffs.

Prove the basic geometry on a tiny vector. Check norm preservation, position zero identity, inverse rotation, and the relative-dot-product property. Then compare exact float64 calculations with float32 and float16 at increasing positions before drawing conclusions about practical extrapolation.

Part 2 - Mathematical form and reasoning

For pair (x_{2i}, x_{2i+1}) and angle $\theta_{p,i} = p\omega_i$,

$$R(\theta) = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}, \qquad \widetilde{x}_{p,i} = R(\theta_{p,i})x_i.$$

Because rotations are orthogonal,

$$\|R(\theta)x\|_2 = \|x\|_2.$$

For a query at m and key at n,

$$(R(\theta_m)q)^{\mathsf{T}}(R(\theta_n)k) = q^{\mathsf{T}}R(\theta_n - \theta_m)k.$$

The dot product depends on relative phase $n - m$. A common frequency is

$$\omega_i = 10000^{-2i/d_{\text{rotary}}}.$$

Part 3 - Hints, controls, and evidence

1. Implement rotation on a two-dimensional pair manually before vectorizing across batches, heads, positions, and feature pairs.

2. Verify position zero, norm preservation, inverse rotation, and relative dot-product identity in float64.

3. Decide whether adjacent halves or interleaved pairs are used and retain the same convention when comparing with a library.

4. Test partial rotary dimensions and reject odd rotary widths.

5. Compare cached single-token rotation with full-sequence rotation using the same global offset.

6. Sweep large positions and dtypes, measuring phase error, dot-product error, and downstream retrieval quality.

Part 4 - Python code skeleton

```
import torch

def rotate_pairs(x):
    # Interleaved convention: (x0,x1),(x2,x3),...
    even = x[..., 0::2]
    odd = x[..., 1::2]
    return torch.stack((-odd, even), dim=-1).flatten(-2)

def rope_cache(seq_len, rotary_dim, base, device, dtype):
    positions = torch.arange(seq_len, device=device, dtype=torch.float32)
    inv_freq = ...
    angles = positions[:, None] * inv_freq[None, :]
    # TODO: expand pair frequencies to rotary_dim
    return ..., ...

def apply_rope(q, k, cos, sin, offset=0, rotary_dim=None):
    # q,k: (B,H,T,d_head)
    # TODO: rotate selected prefix and preserve remaining dimensions
    return ..., ...

def E06():
    q, k = ...
    cos, sin = rope_cache(...)
    rotated_q, rotated_k = apply_rope(q, k, cos, sin)
    # TODO: geometry, offset, dtype, and long-position tests
    return rotated_q, rotated_k
```

Part 5 - The Philosophy Behind the Exercise

RoPE represents position as transformation rather than annotation. A token is not merely given a positional label; its query and key are reoriented according to where the token exists. Relative order appears through the difference between orientations.

Rotation also preserves magnitude while changing direction. This separates one aspect of content strength from positional phase and illustrates a broader design idea: structure can be encoded through symmetries that preserve selected quantities.

Long-context claims reveal the difference between a formula being defined and a learned system remaining competent. RoPE can calculate a rotation at a new position, but the model's training, precision, and frequency schedule determine whether that rotation continues to support useful reasoning.

17.4.8 Exercise 07

Exercise Title: Build an Order-Sensitive Toy Task and Prove Model Fails Without Positional Encoding

Part 1 - Why this matters

A theoretical symmetry argument becomes stronger when it predicts an empirical failure. This exercise constructs a dataset in which examples share the same multiset of tokens but have different labels solely because of order. A model whose architecture is permutation-equivariant and whose readout is permutation- invariant receives no information capable of separating the paired examples. Its failure is structural, not the result of insufficient epochs.

One suitable task asks whether token A occurs before token B. For every sequence, include a paired permutation containing exactly the same tokens and opposite label. Avoid causal masks and position-dependent padding patterns in the no- position baseline because they would leak order through the architecture. Pool token outputs symmetrically, for example by mean pooling, so a specific readout slot does not act as a hidden positional signal.

Train three variants: no position, a correct positional mechanism, and a deliberately misaligned positional mechanism. Use identical data, shared-weight initialization, optimizer budget, and evaluation. The no-position model should remain near the ambiguity bound, while a correctly encoded model should solve the task. The misaligned model tests whether merely adding varying vectors is sufficient or whether token-position alignment is essential.

The proof should include paired-output equality before training. For two permuted sequences, inverse-permute token-level outputs and compare them, then compare the pooled logits. During training, record gradients and losses to show that the optimizer is active even though the representation lacks the required distinction.

Part 2 - Mathematical form and reasoning

Let x' be a permutation of x with opposite label, and let token encoder F satisfy

$$F(PX) = PF(X).$$

For mean pooling g,

$$g(PZ) = \frac{1}{T}\mathbf{1}^{\mathsf{T}}PZ = \frac{1}{T}\mathbf{1}^{\mathsf{T}}Z = g(Z).$$

Thus classifier c gives

$$c(g(F(PX))) = c(g(F(X))),$$

so it cannot assign different predictions to both members of every paired example. In a balanced binary dataset of perfect contradictory pairs, no deterministic classifier over this representation can exceed 50 percent accuracy on both members simultaneously.

Part 3 - Hints, controls, and evidence

1. Generate exact paired permutations and verify token histograms match while labels differ.
2. Remove accidental order channels: causal masks, length differences, position-dependent padding, slot-specific readout, or deterministic label sorting.
3. Prove pooled-logit equality at initialization for paired examples within numerical tolerance.
4. Train no-position, correct-position, and shifted-position variants with the same seeds and budgets.
5. Report pair consistency, accuracy, loss, convergence curves, and the fraction of contradictory pairs predicted identically.
6. Add a bag-of-tokens baseline to confirm the task contains no content-only shortcut.

Part 4 - Python code skeleton

```
import torch

def make_before_after_pairs(batch, seq_len, vocab_size):
    # TODO: same token multiset, opposite A-before-B label
    original = ...
    permuted = ...
    labels = ...
    paired_labels = 1 - labels
    return torch.cat([original, permuted]), torch.cat([labels, paired_labels])

def paired_logit_error(model, x, permutation):
    logits_a = model(x)
    logits_b = model(x[:, permutation])
    return (logits_a - logits_b).abs().max()

def E07(variants, seeds=range(5)):
    data = ...
    # TODO: controlled training, shortcut audit, and paired metrics
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Failure can be more informative than success when it follows from a precise symmetry. The model does not fail because it is unintelligent or poorly tuned; it fails because its representation

makes two different realities identical.

This is a boundary on learning itself. Optimization cannot recover information that the architecture does not expose. More data containing the same collapsed distinction only repeats the contradiction.

The exercise teaches that inductive bias is not merely a preference for one solution. It determines which questions can be answered at all. Positional encoding expands the model's ontology by allowing "before" and "after" to become representable differences.

17.4.9 Exercise 08

Exercise Title: Evaluate Positional Encoding Choices Under Sequence Length Extrapolation Beyond Training Length

Part 1 - Why this matters

Sequence models are often trained on a limited context range and later asked to process longer inputs. Positional methods differ sharply in what they do beyond that range. A learned absolute table may have no row for a new position. Sinusoidal and rotary formulas can be evaluated, but their phase patterns may enter regimes unseen by training. Relative biases may clip distant positions into the same bucket. Being numerically defined is not the same as preserving task competence.

Construct a task whose rule is independent of sequence length, such as copying a marked token, comparing tokens at a fixed relative offset, or detecting an ordered pair. Train only on lengths within a declared interval. Evaluate every positional method on a grid extending well beyond the training maximum while holding the learned model weights fixed. Report quality by length rather than one aggregate score.

Separate interpolation, mild extrapolation, and extreme extrapolation. Sinusoidal encoding may continue smoothly but create unseen combinations of phases. RoPE may experience phase wrapping and attention-logit changes. Learnable embeddings require a policy: reject, resize with interpolation, randomly initialize new rows, or preallocate a larger table whose unused rows remain untrained. Each policy answers a different question and must be labeled.

Also control computational difficulty. Longer sequences increase distractors and attention cost even with perfect positions. Include an oracle positional or rule-based baseline where possible, and compare performance at trained lengths after padding to larger tensors. This helps distinguish a positional failure from generic long-sequence difficulty.

Part 2 - Mathematical form and reasoning

Let training lengths satisfy $T \leq L_{\text{train}}$ and define

$$m_v(T) = \text{held-out metric for positional variant } v.$$

Normalize against in-range performance:

$$R_v(T) = \frac{m_v(T)}{m_v(L_{\text{train}})}$$

when the metric permits this ratio. A degradation threshold may define an empirical usable context

$$L_v^* = \max\{T : R_v(T) \geq \tau\}.$$

For a learned table $E \in \mathbb{R}^{L \times d}$, positions $p \geq L$ are undefined without an extension transformation. For relative clipping, $|j - i| > D$ maps to the same boundary bucket, removing distinctions among large distances.

Part 3 - Hints, controls, and evidence

1. Train only on a clearly recorded length distribution and prevent long examples from entering validation or augmentation.
2. Evaluate exact length bins from below the training maximum to several multiples above it.
3. Keep task rule, token distribution, model checkpoint, and decoding procedure fixed across positional variants.
4. Label every extension policy for learned tables and relative buckets.
5. Record accuracy or loss, attention entropy, distance error, latency, and memory by length.
6. Include controls for increased distractor count and generic quadratic cost so positional degradation is not inferred from runtime alone.

Part 4 - Python code skeleton

```
import torch

@torch.no_grad()
def evaluate_by_length(model, task_factory, lengths, device):
    report = {}
    model.eval()
    for length in lengths:
        loader = task_factory(length)
        report[length] = {
            "metric": ...,
            "loss": ...,
            "attention_entropy": ...,
            "latency": ...,
            "peak_memory": ...,
        }
    return report

def E08(variants, train_max=128):
    lengths = [32, 64, 128, 160, 256, 512, 1024]
    results = {}
    for name, model in variants.items():
```

```
        # TODO: train with T <= train_max, freeze, then evaluate grid
        results[name] = evaluate_by_length(model, ..., lengths, ...)
    return results
```

Part 5 - The Philosophy Behind the Exercise

Extrapolation asks whether a representation contains a rule or only a map of familiar territory. A formula can extend coordinates beyond experience, but a trained model may still have learned habits tied to the region it observed.

Long context therefore tests two kinds of generalization: the positional system's ability to describe new locations and the model's ability to reason under those descriptions. Confusing these levels produces overly simple claims about "supporting" a length.

The responsible language is empirical. A method is not long-context merely because it accepts a large index. It becomes useful at a length when measured behavior, numerical stability, and resource cost remain within declared requirements.

17.4.10 Exercise 09

Exercise Title: Create a Practical Guideline for Choosing Positional Encoding Method for a Given Task

Part 1 - Why this matters

Positional encoding choice should follow task geometry and deployment constraints, not a universal ranking. Some tasks depend on exact absolute slots, others on relative distance or direction, and others require stable extrapolation far beyond training length. The same method can be excellent in one regime and a source of avoidable failure in another.

The guideline must translate requirements into testable questions. Is the maximum sequence length fixed? Does the task shift patterns to new absolute locations? Are distances beyond a threshold distinguishable? Is incremental decoding required? Must the model load checkpoints across changed context lengths? What precision and latency budgets apply? Each answer narrows the reasonable choices.

Build the guide from chapter evidence. Absolute learnable embeddings may adapt well inside a fixed range. Sinusoidal encodings add no parameters and define unseen indices. Relative bias can make displacement patterns easier and allow per-head distance preferences. RoPE modifies Q/K geometry and integrates well with cached causal attention, but long-range phase and scaling require testing. Combinations are possible, though each added mechanism increases complexity.

The output should be a decision procedure with rejection conditions and required validation, not a table of slogans. Every recommendation must include the experiment that would falsify it. If two options satisfy requirements, prefer the simpler default until measured quality justifies complexity.

Part 2 - Mathematical form and reasoning

Represent a candidate v by a requirement vector

$$r_v = (q_{\text{in}}, q_{\text{extra}}, c_{\text{memory}}, c_{\text{latency}}, s_{\text{precision}}, u_{\text{cache}}),$$

where the components are measured rather than merely rated. A method is feasible only if hard constraints are satisfied:

$$q_{\text{extra}} \geq \tau_q, qquad c_{\text{memory}} \leq M_{\max}, qquad c_{\text{latency}} \leq L_{\max}.$$

Among feasible methods, a weighted score may summarize preferences, but the weights and normalization must be declared. Hard failures should never be hidden by averaging them with strengths elsewhere.

Part 3 - Hints, controls, and evidence

1. Begin with task questions about absolute location, relative distance, direction, maximum length, extrapolation, and decoding mode.
2. Separate hard constraints from preferences and benchmark every candidate under the target dtype and hardware.
3. Include failure signatures: out-of-range tables, off-by-one offsets, bucket saturation, rotary phase error, and padding misalignment.
4. Attach required tests for in-range quality, extrapolation, cached parity, precision, latency, memory, and checkpoint compatibility.
5. Use the simplest method that satisfies requirements as the provisional default, then document evidence for any deviation.
6. Revisit the choice when context length, data distribution, task geometry, or deployment environment changes.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class Requirements:
    needs_absolute_slots: bool
    needs_relative_distance: bool
    train_length: int
    deploy_length: int
    autoregressive_cache: bool
    max_latency_ms: float
    max_position_bytes: int

def evaluate_candidate(name, requirements, evidence):
    hard_checks = {
        "length_supported": ...,
        "quality_met": ...,
        "latency_met": ...,
```

```
        "memory_met": ...,
        "cache_parity": ...,
    }
    return {"name": name, "feasible": all(hard_checks.values()),
            "checks": hard_checks, "tradeoffs": ...}

def E09(requirements, chapter_artifacts):
    candidates = ["sinusoidal", "learnable", "relative_bias", "rope"]
    reports = [evaluate_candidate(c, requirements, chapter_artifacts[c])
               for c in candidates]
    # TODO: select only among feasible methods and justify default
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Engineering judgment is not the possession of one preferred technique. It is the ability to translate a situation into requirements, compare evidence, and choose while preserving the conditions of that choice.

A default is useful because it reduces decision cost, but it should remain a provisional belief rather than a doctrine. The moment task geometry changes, the evidence supporting the default must be reconsidered.

The guideline therefore teaches disciplined pluralism. Different positional methods embody different assumptions about order. The goal is not to crown one assumption, but to make the chosen assumption visible and accountable.

17.4.11 Exercise 10

Exercise Title: Run Positional Encoding Experiments on CUDA and Benchmark Overhead Compared to Baseline Attention

Part 1 - Why this matters

Positional mechanisms add work before or inside attention. Additive encodings perform table slicing or formula generation plus a tensor addition. Relative bias constructs or retrieves a score-shaped bias. RoPE calculates or loads sine/cosine values and rotates Q/K features. Their overhead may be negligible beside long-sequence attention, but significant for small batches, short sequences, cached single-token decoding, or an implementation that rebuilds large tables every step.

Benchmark the positional operation separately and as part of the complete attention path. A microbenchmark reveals operation cost; end-to-end timing shows whether that cost matters after kernel scheduling and fusion. Precompute constant tables outside the measured loop. Compare cold initialization, steady-state training, full-sequence inference, and one-token cached decoding as distinct scenarios.

CUDA timing requires warm-up and synchronization. Use CUDA events or explicit synchronization around wall-clock measurements, generate inputs beforehand, and prevent host-side logging from entering the timed region. Record median and tail latency, throughput, peak

allocated and reserved memory, and the precise backend and dtype.

Correctness must precede speed. For each method, compare CPU and CUDA outputs, offset behavior, masks, and gradients within declared tolerances. A fast RoPE implementation using the wrong pairing convention or a cached table with the wrong offset is not a valid optimization.

Part 2 - Mathematical form and reasoning

For baseline attention time t_0 and positional variant t_v, report

$$\Delta t_v = t_v - t_0, \qquad R_v = \frac{t_v - t_0}{t_0} \times 100\%.$$

Measure both operation-only and end-to-end ratios. Additive encoding has linear element work

$$\mathcal{O}(BTd),$$

while a materialized relative bias may contain BHT_qT_k logical entries even if generated from a smaller table. Dense attention remains $\mathcal{O}(BT^2d)$, so relative overhead can shrink as T grows while absolute memory remains important.

Part 3 - Hints, controls, and evidence

1. Benchmark no position, cached sinusoidal, learnable table, relative bias, and RoPE under matched attention code.
2. Separate table construction from table use and report cold and steady- state behavior.
3. Sweep batch, sequence length, head count, dtype, training/inference, and cached decoding.
4. Warm up, synchronize, repeat, and report median, p95, throughput, peak allocated memory, and peak reserved memory.
5. Check CPU–CUDA parity and full-sequence versus cached-offset parity before timing.
6. Profile unexpectedly expensive methods to identify allocation, indexing, trigonometric, broadcast, or fusion bottlenecks.

Part 4 - Python code skeleton

```
import statistics
import torch

def cuda_benchmark(fn, warmup=25, repeats=100):
    for _ in range(warmup):
        fn()
    torch.cuda.synchronize()
    samples = []
    for _ in range(repeats):
        start = torch.cuda.Event(enable_timing=True)
```

```
        end = torch.cuda.Event(enable_timing=True)
        start.record(); fn(); end.record()
        torch.cuda.synchronize()
        samples.append(start.elapsed_time(end))
    return {"median_ms": statistics.median(samples), "p95_ms": ...}

def benchmark_variant(attention, position_module, x, mode):
    torch.cuda.reset_peak_memory_stats()
    timing = cuda_benchmark(lambda: ...)
    return {**timing,
            "peak_allocated": torch.cuda.max_memory_allocated(),
            "peak_reserved": torch.cuda.max_memory_reserved()}

def E10(configurations):
    if not torch.cuda.is_available():
        return {"status": "skipped", "reason": "CUDA unavailable"}
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A representation has a computational form. Positional ideas that appear equivalent at the level of purpose can interact very differently with memory, kernel fusion, caching, and batch shape. Conceptual elegance does not determine runtime cost.

Overhead is relational rather than absolute. The same positional operation may be invisible inside a large training step and dominant inside one-token generation. Performance statements require a workload, not merely a method name.

The benchmark teaches that optimization begins with preservation of meaning. Only after parity and alignment are proved does faster execution become evidence of progress.

17.4.12 Exercise 11

Exercise Title: Compare float32 vs float16 Positional Encoding Stability and Detect Precision Edge Cases in Long Sequences

Part 1 - Why this matters

Long positions stress finite precision in ways that short-sequence tests do not reveal. If a large integer position is first converted to float16, adjacent indices may become identical because float16 cannot represent every large integer. Trigonometric arguments may lose phase precision, and adding a small positional vector to a large token activation may round away part of the signal. RoPE and sinusoidal methods are especially sensitive to phase calculation, while learned tables mainly face storage and addition precision.

Generate positions and angles in float32 or float64 even when the final model runs under float16 autocast. Then cast the completed sine/cosine table to the model dtype. Compare this safer path with direct float16 generation at increasing positions. Measure absolute phase error, cosine similarity between encodings, collisions between adjacent positions, norm preservation

for RoPE, and downstream attention-logit error.

Precision failure is not limited to NaN. Two positions can receive nearly identical encodings, a rotation can lose orthogonality, or a small positional difference can vanish when added to a large activation. Record representational separation and behavioral quality, not only finiteness.

Use float64 as a diagnostic reference, float32 as the standard path, and float16 or bfloat16 as reduced-precision candidates. Bfloat16 has a wider exponent but fewer mantissa bits, so its error pattern differs. State device support and actual autocast behavior rather than assuming every operation uses the requested dtype.

Part 2 - Mathematical form and reasoning

For encoding e_p, adjacent separation is

$$D(p) = \|e_{p+1} - e_p\|_2.$$

A precision collision occurs when

$$\widehat{e}_{p+1} = \widehat{e}_p$$

or when $D(p)$ falls below a declared tolerance relative to a higher-precision reference. Phase error for frequency ω_i is

$$E_\theta(p, i) = |\widehat{p\omega_i} - p\omega_i|.$$

For rotary transformation, measure norm error

$$E_{\text{norm}} = \frac{|\|R_{\widehat{\theta}}x\|_2 - \|x\|_2|}{\max(\|x\|_2, \varepsilon)}.$$

Part 3 - Hints, controls, and evidence

1. Compare positions constructed directly in reduced precision with positions constructed in float64 or float32 and cast only after encoding.
2. Sweep indices logarithmically and include adjacent positions around each precision boundary.
3. Test sinusoidal tables, RoPE angles, learned-table addition, and relative bias indexing separately.
4. Record finite values, phase error, adjacent separation, encoding cosine similarity, RoPE norm error, logits, and retrieval accuracy.
5. Test large activation magnitudes to observe positional information lost during addition.
6. Define dtype-specific tolerances before examining results and report the first boundary where a functional invariant fails.

Part 4 - Python code skeleton

```
import torch

def generate_encoding(positions, d_model, compute_dtype, output_dtype):
    work = positions.to(compute_dtype)
    frequencies = ...
    angles = work[:, None] * frequencies[None, :]
    encoding = ...
    return encoding.to(output_dtype), angles

def precision_metrics(reference, candidate):
    adjacent = candidate[1:] - candidate[:-1]
    return {"max_abs": ...,
            "adjacent_min_norm": adjacent.norm(dim=-1).min(),
            "collision_count": ...,
            "cosine_to_reference": ...,
            "finite": bool(torch.isfinite(candidate).all())}

def E11():
    positions = torch.tensor([...], dtype=torch.int64)
    reference, _ = generate_encoding(positions, 64,
                                     torch.float64, torch.float64)
    # TODO: direct and promoted fp32/fp16/bfloat16 paths
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Position appears discrete, but its encoding often passes through continuous functions represented by finite numbers. At large scale, the machine may no longer distinguish neighboring integers even though the mathematical sequence continues without ambiguity.

This is a reminder that “long context” is partly a numerical claim. Memory capacity and architectural formulas are insufficient if the coordinate system loses resolution where the model is asked to operate.

Promoting a small critical calculation to higher precision illustrates a general engineering strategy: precision should be allocated according to sensitivity. Efficiency does not require every operation to forget equally.

17.4.13 Exercise 12

Exercise Title: Visualize Learned Positional Embeddings and Interpret Whether They Encode Smooth Trends or Discrete Jumps

Part 1 - Why this matters

A learned positional table can develop global trends, local neighborhoods, periodic structure, special boundary vectors, or irregular slot-specific codes. Visualization helps form hypotheses about this geometry, but a two- dimensional plot cannot by itself determine what the model uses. The exercise combines plots with quantitative diagnostics and interventions.

Visualize individual dimensions over position, vector norms, adjacent cosine similarity, pairwise distance matrices, singular values, and low-dimensional projections. Compare the initialized table with several training checkpoints. A PCA or UMAP path may appear smooth even when important information lies in discarded dimensions, so always report explained variance and preserve direct high-dimensional measures.

Discrete jumps may correspond to task boundaries, special tokens, periodic roles, or simply optimization noise. Align plots with known data structure and repeat seeds. Shuffle or interpolate selected position vectors and measure task degradation. If smooth interpolation leaves behavior unchanged, the model may rely on a broad positional trend; if swapping two nearby rows causes a large failure, it may use slot-specific identity.

Attention-map interpretation remains limited. A smooth positional table does not prove smooth attention behavior because Q/K projections transform it. Analyze projected positional components and downstream outputs as well as the raw table.

Part 2 - Mathematical form and reasoning

For learned table $E \in \mathbb{R}^{L \times d}$, adjacent variation is

$$\Delta_p = \|E_{p+1} - E_p\|_2,$$

and adjacent cosine similarity is

$$c_p = \frac{E_p^{\mathsf{T}} E_{p+1}}{\|E_p\|_2 \|E_{p+1}\|_2}.$$

A discrete-jump score may compare local change with a neighborhood baseline:

$$J_p = \frac{\Delta_p}{\operatorname{median}(\Delta_{p-k:p+k}) + \varepsilon}.$$

For singular values σ_i, the fraction of variance retained by the first r principal directions is

$$V_r = \frac{\sum_{i=1}^{r} \sigma_i^2}{\sum_i \sigma_i^2}.$$

Part 3 - Hints, controls, and evidence

1. Save the same table at initialization and fixed checkpoints under several seeds.
2. Plot dimensions, norms, adjacent differences, cosine similarity, pairwise distances, singular spectrum, and PCA with explained variance.
3. Compare raw embeddings with their Q and K projected forms.
4. Mark known sequence boundaries or task roles without assuming they cause the observed pattern.
5. Interpolate, swap, shuffle, or smooth selected rows and measure held-out behavior.
6. Treat every visual interpretation as a hypothesis until an intervention supports it.

Part 4 - Python code skeleton

```
import torch

@torch.no_grad()
def position_statistics(table):
    delta = table[1:] - table[:-1]
    cosine = torch.nn.functional.cosine_similarity(table[1:], table[:-1])
    centered = table - table.mean(dim=0, keepdim=True)
    _, singular, right = torch.linalg.svd(centered, full_matrices=False)
    projected = centered @ right[:2].T
    return {"norm": table.norm(dim=-1),
            "delta_norm": delta.norm(dim=-1),
            "adjacent_cosine": cosine,
            "singular": singular,
            "pca2": projected,
            "explained_variance": ...}

def position_intervention(model, kind, indices):
    # TODO: swap, smooth, interpolate, or shuffle selected rows safely
    return ...

def E12(model, checkpoints, probe_loader):
    # TODO: statistics, plots, seed comparison, and behavioral interventions
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Visualization converts an invisible high-dimensional object into a form human perception can inspect. This is useful precisely because it is lossy: it offers a perspective, not the object itself.

Smoothness and discontinuity are interpretations relative to a coordinate and a scale. A vector path may look smooth in two principal components while changing sharply in a task-relevant discarded direction. Observation must remain aware of its projection.

The exercise teaches a mature relation between seeing and knowing. A pattern in a figure begins a question. Intervention, replication, and behavioral measurement decide whether that question becomes an explanation.

17.4.14 Exercise 13

Exercise Title: Implement Unit Tests for Positional Encoding Correctness and Verify It Works for Multiple Batch Sizes

Part 1 - Why this matters

Positional code sits near the beginning of every Transformer layer stack, so a small error propagates through the entire model. Unit tests should isolate its contract before training:

shape preservation, correct position values, broadcasting across batches, offset handling, gradient policy, device movement, dtype behavior, maximum-length boundaries, padding alignment, and serialization. The tests should be fast enough to run on every change.

Batch-size tests are essential because accidental broadcasting can pass at $B = 1$. A table shaped `(T,1,d)` may add correctly to a sequence-first tensor while silently misbehaving with batch-first data. Test several unequal batch and sequence sizes and compare each batch row with a single-example reference. Position should normally be shared across examples, while token content remains independent.

Each positional method needs specific invariants. Sinusoidal position zero and manual formula values can be exact within tolerance. Learnable tables require gradient and index-range tests. Relative bias requires displacement orientation and clipping tests. RoPE requires norm preservation, zero-position identity, pairing convention, and full versus cached-offset parity.

Add property-style random tests and explicit failure injection. Tests must fail for a wrong unsqueeze axis, an offset shift, a CPU-created position tensor on CUDA, an odd rotary dimension, and an out-of-range learned index. Demonstrating that a test catches its target bug validates the test itself.

Part 2 - Mathematical form and reasoning

Core additive-position invariants include

$$\text{shape}(f(X)) = \text{shape}(X),$$

$$f(X)_{b,t,:} - X_{b,t,:} = E_{t,:}$$

for every batch b, and offset consistency

$$f(X, c)_{:,t,:} - X_{:,t,:} = E_{c+t,:}.$$

For a batch split $X = [X^{(1)}; X^{(2)}]$,

$$f(X) = [f(X^{(1)}); f(X^{(2)})]$$

when examples are independent. RoPE additionally requires, within tolerance,

$$\|R_p x\|_2 = \|x\|_2.$$

Part 3 - Hints, controls, and evidence

1. Organize tests into shared contracts and method-specific contracts.
2. Parameterize batch sizes, lengths, widths, offsets, devices, and dtypes; include unequal dimensions and edge cases.
3. Compare batched execution with concatenated single-example references.
4. Test state-dictionary save/load and movement between CPU and CUDA when available.

5. Mark precision-dependent assertions with justified tolerances instead of weakening every test globally.

6. Inject known bugs and prove each test fails for the earliest relevant invariant.

Part 4 - Python code skeleton

```
import pytest
import torch

@pytest.mark.parametrize("batch,length,width", [
    (1, 1, 7), (2, 5, 8), (5, 3, 12)
])
def test_additive_shape_and_broadcast(batch, length, width):
    module = ...
    x = torch.randn(batch, length, width)
    y = module(x)
    assert y.shape == x.shape
    delta = y - x
    assert torch.allclose(delta, delta[:1].expand_as(delta))

def test_offset_matches_full_sequence():
    module = ...
    full = module(torch.zeros(1, 10, 8))
    block = module(torch.zeros(1, 4, 8), offset=6)
    assert torch.allclose(block, full[:, 6:10])

def E13():
    # TODO: sinusoidal, learned, relative, RoPE, device,
    # serialization, failure-injection, and property tests
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A unit test is a compact claim about the world of the program. It states what must remain true across refactoring, devices, batches, and future experiments. The collection of tests becomes an executable definition of the component.

Testing multiple batch sizes demonstrates that correctness is not one example that happened to fit. A representation should preserve its intended symmetry and alignment across the range of shapes its interface promises.

Failure injection gives tests credibility. A green test suite proves little if its assertions would remain green under the bug it was designed to prevent. Trust grows when the test is shown to distinguish correct and incorrect worlds.

17.4.15 Exercise 14

Exercise Title: Debug Variable-Length Sequence Handling with Positional Encoding and Ensure Padding Tokens Do Not Break It

Part 1 - Why this matters

Variable-length batches introduce two coordinate systems: storage positions in the padded tensor and logical positions among valid tokens. With right padding, these often agree for valid tokens. With left padding, a token's storage index depends on the amount of padding, so assigning absolute positions directly by column can make the same content token receive different position IDs across the batch. Whether this is a bug depends on the model's declared positional policy, but inconsistency between training and inference is always dangerous.

Padding tokens should not influence legal attention outputs. An additive positional vector may still be placed at padding slots, but key padding masks must prevent those slots from being retrieved, and loss masks must ignore their targets. Alternatively, position IDs for padding can be set to a safe row. Zeroing padding representations alone is insufficient if biases, layer normalization, or later operations can reintroduce nonzero values. The information boundary must be proved at attention and loss.

Compare unpadded single-sequence execution with right-padded and left-padded batched execution. Extract outputs at valid token positions and require parity within tolerance under the chosen policy. Then change padding token IDs, padding embeddings, and positional values by large amounts. Valid outputs must remain unchanged when masks are correct.

Packed or nested representations may reduce padding waste, but the logical position IDs must still follow each sequence. Incremental decoding introduces another length: cached valid length rather than padded tensor width. The exercise should test these boundaries before long-context training.

Part 2 - Mathematical form and reasoning

Let $m_{b,t} = 1$ for valid tokens. Content-relative position IDs are

$$p_{b,t} = \max\left(0, \sum_{u=0}^{t} m_{b,u} - 1\right).$$

For right padding this gives $0, 1, \ldots, \ell_b - 1$ followed by a safe repeated index. For left padding, valid tokens still begin at zero. If storage-relative positions are intentionally used, instead $p_{b,t} = t$; the policy must match training and serving.

For valid query i, padding invariance requires

$$A_{b,r,i,j} = 0 \quad \text{when } m_{b,j} = 0,$$

and therefore changing any padded $V_{b,r,j,:}$ cannot change $Z_{b,r,i,:}$.

Part 3 - Hints, controls, and evidence

1. Build identical logical sequences in unpadded, right-padded, and left-padded forms and print token, mask, storage index, and position ID.

2. Declare whether positions are storage-relative or content-relative and use the same rule in training, evaluation, and caching.
3. Compare valid-token outputs against independent unpadded references.
4. Replace padding token and position vectors with extreme values and prove valid outputs and loss are unchanged.
5. Test empty padding, one valid token, all-padding rejection, mixed lengths, and cached continuation.
6. Confirm both attention and loss masks are correct; one cannot substitute for the other.

Part 4 - Python code skeleton

```
import torch

def content_relative_positions(attention_mask):
    positions = attention_mask.long().cumsum(-1) - 1
    return positions.clamp_min(0)

@torch.no_grad()
def valid_output_parity(model, logical_sequences, padding_side):
    padded, mask = ...
    positions = content_relative_positions(mask)
    batch_output = model(padded, attention_mask=mask,
                         position_ids=positions)
    reference = ...  # independent unpadded runs
    # TODO: gather valid tokens and compare
    return ...

def E14(model):
    reports = {}
    for side in ["left", "right"]:
        reports[side] = valid_output_parity(model, ..., side)
    # TODO: extreme-padding intervention and cached continuation
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Padding is absence represented as data. Because hardware prefers regular rectangles, nothingness is given a token, an index, and storage. Correct masking preserves the distinction between the representation of absence and actual information.

Variable-length processing also shows that position is a convention. A storage column and a logical moment can coincide or diverge depending on padding. The model must know which coordinate system the application intends.

Robustness comes from proving irrelevance. If padding is declared meaningless, then changing it should not change valid behavior. Intervention turns that declaration into evidence.

17.4.16 Exercise 15

Exercise Title: Stress Test Long Context Lengths and Detect Memory and Runtime Costs of Large Positional Tables

Part 1 - Why this matters

Positional mechanisms have their own scaling costs in addition to attention. A learned absolute table grows as Ld. Cached sinusoidal or rotary tables have the same linear table size, although they are not optimizer parameters. Relative position bias may store a small bucket table but materialize a large score-shaped bias. A careless implementation may rebuild or repeat these tensors for every batch, turning a modest theoretical cost into a practical memory problem.

Stress testing should isolate table storage, per-step temporary memory, and full-model memory. Measure parameter memory, gradients, optimizer states, buffers, generated angle or bias tensors, attention activations, and allocator reserved memory separately. A learnable table under Adam can require weight, gradient, and two optimizer moments, while a deterministic buffer may require only one persistent copy.

Sweep context length while keeping other variables fixed. Compare eager generation, precomputed caches, sliced caches, broadcast views, repeated tensors, and on-demand block generation. Measure initialization time separately from steady-state use. For cached decoding, record the cost of extending a table or requesting positions beyond its original maximum.

Run potentially failing configurations in isolated processes and preserve a safety margin. The purpose is to identify scaling regimes and first failure boundaries, not to destabilize the workstation. Compare measured memory with formula-based estimates and explain discrepancies caused by dtype, optimizer, temporary tensors, alignment, or attention itself.

Part 2 - Mathematical form and reasoning

For table length L, width d, and element size s bytes,

$$M_{\text{table}} = Lds.$$

A learnable table with gradient and two float32 Adam moments may require approximately

$$M_{\text{train}} \approx M_{\text{weight}} + M_{\text{grad}} + 2M_{\text{moment}},$$

with additional master weights in some mixed-precision configurations. A materialized per-head relative bias has

$$M_{\text{bias}} = BHT_qT_ks,$$

although the learned bucket parameters may contain only $H(2D + 1)$ values.

Part 3 - Hints, controls, and evidence

1. Estimate every persistent and temporary positional tensor before running the sweep.
2. Measure learned, sinusoidal, relative-bias, and rotary implementations at the same lengths and dtypes.

3. Separate initialization, forward inference, backward training, and cached one-token decoding.
4. Compare slice/broadcast implementations with repeat/materialization and inspect storage and strides.
5. Record allocated and reserved peaks, table bytes, optimizer bytes, latency, and first failed configuration.
6. Use isolated processes and stop after the declared boundary rather than repeatedly exhausting the CUDA allocator.

Part 4 - Python code skeleton

```
import multiprocessing as mp
import torch

def parameter_bytes(module):
    return sum(p.numel() * p.element_size() for p in module.parameters())

def buffer_bytes(module):
    return sum(b.numel() * b.element_size() for b in module.buffers())

def isolated_position_case(config, queue):
    try:
        torch.cuda.reset_peak_memory_stats()
        module, x = ...
        # TODO: initialize, forward/backward, and synchronize
        queue.put({"status": "ok",
                   "parameter_bytes": parameter_bytes(module),
                   "buffer_bytes": buffer_bytes(module),
                   "peak_allocated": torch.cuda.max_memory_allocated(),
                   "peak_reserved": torch.cuda.max_memory_reserved(),
                   "latency_ms": ...})
    except torch.cuda.OutOfMemoryError as error:
        queue.put({"status": "oom", "message": str(error)})

def E15(configurations):
    # TODO: safe isolated sweep and theoretical-vs-measured report
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A coordinate system consumes resources. To remember or calculate where every token exists, the system must store parameters, buffers, phases, biases, or temporary relations. Position is conceptual structure embodied in memory.

Scaling exposes distinctions hidden at small size. Two methods that both add a minor tensor at 512 tokens may have very different optimizer, materialization, or caching behavior at

100,000 tokens. Small experiments reveal correctness; stress tests reveal architecture.

The goal is not to fear limits but to measure them. A known boundary enables planning, optimization, and honest claims. An unknown boundary becomes an incident.

17.4.17 Exercise 16

Exercise Title: Create a Checklist for Positional Encoding Bugs Including Indexing, Shapes, and Device Placement

Part 1 - Why this matters

Positional failures frequently survive until late training because their tensors have valid shapes and finite values. A systematic checklist should detect them before optimization: wrong starting index, shifted special tokens, incorrect batch/sequence layout, table overflow, padding-dependent alignment, stale decoding offset, CPU-created indices inside a CUDA path, unintended trainability, precision loss, and incompatible checkpoint resizing.

Order the checklist from contracts to behavior. Begin with method configuration and supported length. Continue through input layout, position-ID construction, shape and broadcast, device and dtype, method-specific invariants, masks and padding, full-versus-cached parity, gradients, serialization, and long-range stress. Later symptoms should be marked as blocked when an earlier invariant has already failed.

Each item needs an executable condition and useful evidence. "Check device" becomes an assertion listing devices of input, indices, tables, masks, and outputs. "Check indexing" becomes a token-position ledger with expected IDs. "Check RoPE" becomes position-zero identity, norm preservation, declared pair ordering, and offset parity.

Create an incident template that records hypothesis, formula, tensor contract, configuration, seed, device, precision, expected behavior, earliest violated invariant, cause, correction, and regression test. The checklist becomes valuable when it retains knowledge after the immediate bug is fixed.

Part 2 - Mathematical form and reasoning

Common invariants include

$$0 \le p_{b,t} < L_{\max},$$

$$\operatorname{shape}(X + E) = \operatorname{shape}(X),$$

$$\operatorname{device}(p) = \operatorname{device}(X) = \operatorname{device}(E),$$

and cached offset consistency

$$E(X_{c:c+T}, 0) = E(X_{0:T}, c)$$

when the notation denotes equivalent slices with global position offset c. For padding, valid-output invariance requires legal outputs to remain unchanged under arbitrary changes to padded token and positional values.

Part 3 - Hints, controls, and evidence

1. Group checks into configuration, indexing, shape, device/dtype, padding, method-specific geometry, caching, gradients, serialization, and stress.
2. Attach pass/fail conditions, evidence payload, and likely causes to every check.
3. Use asymmetric shapes and traceable position values so axis swaps and off-by-one errors cannot hide.
4. Inject wrong start index, wrong unsqueeze, CPU indices, stale offset, padding count, out-of-range table, and low-precision phase failures.
5. Stop at the earliest violated invariant and retain every repaired failure as an automated regression test.
6. Export a machine-readable checklist report suitable for continuous integration and experiment artifacts.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict

@dataclass
class PositionCheck:
    name: str
    passed: bool
    evidence: dict
    likely_causes: list
    blocked_by: str | None = None

def check_position_range(position_ids, max_length):
    passed = bool(((position_ids >= 0) &
                   (position_ids < max_length)).all())
    return PositionCheck("position_range", passed,
                         {"min": int(position_ids.min()),
                          "max": int(position_ids.max())},
                         ["off-by-one", "stale cache offset",
                          "table too short"])

def run_position_checklist(module, case):
    checks = []
    # TODO: ordered checks and blocked downstream diagnostics
    return {"passed": all(c.passed for c in checks),
            "checks": [asdict(c) for c in checks]}

def E16():
    # TODO: correct cases plus failure-injection matrix
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A checklist is a model of how failure propagates. Its order expresses a causal theory: indexing precedes alignment, alignment precedes meaningful attention, and correctness precedes performance.

Positional bugs are particularly instructive because they often preserve surface validity. The numbers exist, fit, and move through the network, yet they describe the wrong history. Engineering must test association, not only existence.

By turning failures into permanent checks, the project acquires memory beyond any individual researcher. The system becomes less dependent on remembering every past mistake and more capable of preventing its return.

17.4.18 Exercise 17

Exercise Title: Compare Training Speed and Convergence Differences Between Sinusoidal and Learnable Positional Encoding

Part 1 - Why this matters

Sinusoidal and learnable positions differ not only in final quality but in the optimization problem they create. A fixed encoding supplies stable coordinates from the first update. A learnable table begins from an initialization and must discover a useful geometry jointly with the model. This may adapt better, converge more slowly, overfit particular slots, or receive uneven gradients when some positions occur more frequently than others.

Training speed has several meanings. Wall-clock time per step measures systems cost. Updates or tokens required to reach a validation threshold measure sample and optimization efficiency. Best metric under a fixed budget measures final utility. Report all three. A method can have negligible runtime overhead yet require more training steps, or reach a better final metric while learning more slowly at the beginning.

Use shared initialization for every common parameter. The learnable variant contains extra positional parameters and optimizer states, which should be reported rather than silently ignored. Match dataset order, batch size, optimizer, learning-rate schedule, evaluation frequency, stopping rule, and random seeds. Repeat enough seeds to estimate variance.

Track positional gradient norms and row update counts. In a variable-length dataset, high position rows may be observed rarely, producing poorer estimates. Evaluate quality by position and sequence length so an aggregate metric does not hide tail-position failure.

Part 2 - Mathematical form and reasoning

Let $u_{v,s}(\tau)$ be the number of optimizer updates needed by variant v and seed s to reach metric threshold τ. Let $t_{v,s}(\tau)$ be wall-clock time and $n_{v,s}(\tau)$ processed tokens. Report all of

$$\overline{u}_v(\tau), \qquad \overline{t}_v(\tau), \qquad \overline{n}_v(\tau)$$

with dispersion. For learned table row p, accumulate exposure

$$C_p = \sum_{\text{batches}} \#\{(b,t) : p_{b,t} = p\}$$

and relate it to gradient magnitude and position-specific error without assuming correlation proves causality.

Part 3 - Hints, controls, and evidence

1. Initialize common parameters once and copy them into both variants; initialize only the positional component differently.
2. Match data order, optimization budget, schedule, batch, validation rule, checkpoint selection, and seeds.
3. Measure step latency with proper CUDA warm-up and synchronization outside the main training loop.
4. Report steps, tokens, and seconds to fixed validation thresholds plus best fixed-budget quality.
5. Log learned-row exposure, gradient norms, norm growth, and metrics by position and length.
6. Include no-position baseline and several seeds; retain failed or divergent runs in the summary.

Part 4 - Python code skeleton

```
import time
import torch

def train_trial(variant, shared_state, loaders, config, seed):
    torch.manual_seed(seed)
    model = ...
    model.load_shared_state_dict(shared_state)
    history = []
    position_exposure = ...
    start = time.perf_counter()
    for step, batch in enumerate(loaders["train"]):
        # TODO: update, log loss/metric/gradients/exposure
        if step % config["eval_every"] == 0:
            history.append(...)
    return {"variant": variant, "seed": seed,
            "history": history,
            "elapsed": time.perf_counter() - start,
            "position_exposure": position_exposure}

def E17(variants, seeds=range(5)):
    # TODO: matched shared initialization and threshold summaries
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Learning a coordinate system and learning within a coordinate system are different burdens. A fixed encoding gives the model a world already arranged; a learnable table asks it to negotiate the arrangement while solving the task.

Convergence is therefore a history, not a final score. Two models can arrive at similar performance through paths with different data requirements, stability, and compute. The path matters when resources and failure risk are finite.

The comparison teaches that flexibility has an optimization price. Whether that price is worthwhile depends on the value of adaptation and the evidence that the learned geometry improves what the task actually requires.

17.4.19 Exercise 18

Exercise Title: Produce a Report Explaining Positional Encoding Tradeoffs and Which One You Will Use as Default

Part 1 - Why this matters

This report converts the chapter's experiments into a defensible default for future Transformer chapters. It must explain the symmetry that makes position necessary, then compare sinusoidal, learnable absolute, relative-bias, and rotary methods across geometry, parameterization, extrapolation, precision, padding, cached decoding, speed, memory, training convergence, and debugging complexity.

The chosen default must be conditional. State the target model type, task, training-length range, deployment length, dtype, hardware, decoding mode, and checkpoint expectations. A default selected for a causal language model may not transfer to a fixed-length image or tabular Transformer. The report should include explicit conditions that would trigger reconsideration.

Every major statement should cite chapter evidence: permutation tests from E00, manual formula validation, toy-task comparisons, off-by-one regression tests, attention interventions, shift behavior, RoPE geometry, extrapolation curves, CUDA overhead, precision boundaries, visual hypotheses, batch tests, padding parity, stress limits, and convergence distributions. Negative results and unresolved questions belong beside successes.

Do not collapse hard requirements into an average score. A method that exceeds memory or cannot process required lengths is infeasible even if it has strong in-range quality. Among feasible methods, explain why the default offers the best evidence-weighted tradeoff and retain a simpler fallback where appropriate.

Part 2 - Mathematical form and reasoning

The report should compare at least the forms

$$Y = X + E_p,$$

$$S_{i,j} = \frac{q_i^\top k_j}{\sqrt{d_h}} + b_{j-i},$$

and rotary compatibility

$$(R_m q)^\mathsf{T}(R_n k) = q^\mathsf{T} R_{n-m} k.$$

For each method v, define a feasibility vector containing measured in-range quality, extrapolation quality, latency, memory, numerical boundary, cache parity, and engineering complexity. Hard constraints are evaluated first; preferences are compared only among feasible candidates.

Part 3 - Hints, controls, and evidence

1. Begin with the application contract and list hard positional requirements before presenting methods.
2. Create an evidence matrix mapping every claim to configuration, seeds, metric, artifact, and limitation.
3. Separate mathematical definition, implementation behavior, measured result, interpretation, and recommendation.
4. Include failure cases and conditions under which each method should be rejected.
5. Choose one default for the declared project rather than claiming a universal winner.
6. Finish with monitoring signals and explicit triggers for revisiting the default as context or deployment changes.

Part 4 - Python code skeleton

```
from pathlib import Path
import json

REQUIRED = ["permutation", "correctness", "toy_quality",
            "extrapolation", "cuda_overhead", "precision",
            "padding", "memory", "convergence", "debug_tests"]

def validate_evidence(artifacts):
    return {name: ... for name in REQUIRED}

def feasibility(method, requirements, evidence):
    return {"length": ..., "quality": ..., "latency": ...,
            "memory": ..., "precision": ..., "cache": ...}

def E18(artifact_directory, requirements, output_path):
    artifacts = ...
    checks = validate_evidence(artifacts)
    assert all(checks.values()), checks
    candidates = ...
    # TODO: reject infeasible methods, select conditional default,
    # and write evidence-linked report
    Path(output_path).write_text(..., encoding="utf-8")
    return {"report": str(output_path), "checks": checks}
```

Part 5 - The Philosophy Behind the Exercise

A default is a compressed decision. It carries the history of experiments into future work so the same comparison need not be repeated at every step. Its value depends on preserving the conditions under which it was chosen.

Tradeoff reports resist the desire for a single victorious method. They show that every coordinate system makes some relations natural, some expensive, and some invisible. Selection is an act of aligning those consequences with a purpose.

The report should therefore end with intellectual reversibility. A strong decision is not one that can never change; it is one whose evidence, limits, and revision triggers are clear enough that change can occur rationally.

17.4.20 Exercise 19

Exercise Title: Write a Deep Conceptual Explanation of How Transformers Encode Order Without Recurrence

Part 1 - Why this matters

The final exercise synthesizes the chapter into an explanation of how a model without recurrent state can still reason about sequence. A Transformer does not experience tokens one after another during parallel training. It receives a collection of representations together with structures that distinguish positions and regulate information flow. Order is encoded in coordinates, relative relations, rotations, masks, and learned transformations rather than in the physical order of a loop.

The explanation must begin from the symmetry of content-only self-attention. Because permuting tokens permutes token outputs, the architecture needs a symmetry-breaking signal for order-sensitive tasks. Absolute encodings attach slot identity. Relative biases attach distance and direction to query–key pairs. RoPE turns position into phase so score geometry depends on displacement. Causal masks create an oriented access graph in which the future is forbidden. These mechanisms encode different aspects of sequence and may be combined.

Clarify parallelism. During teacher-forced training, all known token positions can receive their positions and causal mask at once, so the layer processes the sequence through batched matrix operations. During autoregressive generation, the next token remains unknown until the previous output is sampled. Cached keys and values preserve past computation, while the new query receives an offset corresponding to its global position. The architecture is non-recurrent at the layer level, but generation still follows a causal sequence of decisions.

The explanation should include limits. A positional formula being defined at a large index does not guarantee extrapolation. Padding can corrupt alignment, reduced precision can erase phase distinctions, learned tables can bind models to maximum lengths, relative buckets can collapse distant relations, and dense attention remains quadratic. Order representation is necessary, but it does not by itself produce understanding or long-context reliability.

Use evidence from the complete chapter and connect it to the next architectural stage. Positional information becomes useful only through attention projections, residual pathways,

normalization, feed-forward transformations, and training. The next chapters will assemble these components into complete Transformer blocks.

Part 2 - Mathematical form and reasoning

Content-only self-attention satisfies

$$\mathrm{Attn}(PX) = P\,\mathrm{Attn}(X).$$

Order is introduced by position-dependent transformations such as

$$X'_p = X_p + E_p,$$

relative score terms

$$S_{i,j} = \frac{q_i^\mathsf{T} k_j}{\sqrt{d_h}} + b_{j-i},$$

or rotary transformations

$$\widetilde{q}_i = R_i q_i, qquad \widetilde{k}_j = R_j k_j, qquad \widetilde{q}_i^\mathsf{T} \widetilde{k}_j = q_i^\mathsf{T} R_{j-i} k_j.$$

Causal order is enforced by

$$M_{i,j} = \begin{cases} 0, & j \le i, \\ -\infty, & j > i. \end{cases}$$

Together these structures make sequence relations available without a hidden state transition $h_t = f(x_t, h_{t-1})$.

Part 3 - Hints, controls, and evidence

1. Organize the explanation around symmetry, coordinate construction, information access, parallel training, cached generation, and limitations.
2. Use the permutation proof and order-sensitive toy task to establish necessity rather than relying on analogy.
3. Compare absolute, sinusoidal, learnable, relative, and rotary approaches by the kind of order each makes easy to represent.
4. Distinguish positional identity from causal permission and training parallelism from sequential token generation.
5. Include extrapolation, padding, precision, memory, and runtime evidence as parts of the real architecture.
6. End with open questions about how full Transformer blocks preserve, transform, or lose positional information across depth.

Part 4 - Python code skeleton

```
from pathlib import Path

def load_chapter_evidence(directory):
    # TODO: load verified artifacts from E00--E18
    return ...

def conceptual_claims(evidence):
    return {
        "content_attention_symmetry": ...,
        "absolute_position": ...,
        "relative_position": ...,
        "rotary_geometry": ...,
        "causal_access": ...,
        "parallel_training": ...,
        "cached_generation": ...,
        "limits": ...,
    }

def E19(artifact_directory, output_path):
    evidence = load_chapter_evidence(artifact_directory)
    claims = conceptual_claims(evidence)
    assert all(item["supported"] for item in claims.values())
    # TODO: write a deep evidence-linked conceptual explanation
    Path(output_path).write_text(..., encoding="utf-8")
    return {"output": str(output_path), "claims": claims}
```

Part 5 - The Philosophy Behind the Exercise

Recurrence represents time as succession: the past is carried into the present through state. The Transformer represents order as structure: positions and permissions are available simultaneously, and attention constructs relations within that structured field. These are different computational metaphors for history.

Neither metaphor is time itself. Both are engineered representations that preserve selected distinctions and discard others. Absolute location, relative distance, causal direction, and phase are ways of making sequence legible to a machine.

The deeper achievement of the Transformer is not that it escaped order, but that it separated order from sequential execution. This separation aligned sequence modeling with parallel hardware while creating new responsibilities: coordinates must be designed, masks must be correct, numerical phase must remain stable, and extrapolation must be proved. Intelligence at scale emerged from this negotiation between representation, mathematics, and machines.

17.5 TRF03

Chapter Title: Transformer Block: Residuals, LayerNorm, and FFN
Specialization: Models and Training

17.5.1 Exercise 00

Exercise Title: Implement a Full Transformer Encoder Block from Scratch with Residual Connections and LayerNorm

Part 1 - Why this matters

A Transformer encoder block is the first point at which the earlier mechanisms become one trainable architecture. Multi-head self-attention mixes information across sequence positions. A position-wise feed-forward network transforms each position independently. Residual paths preserve a direct route for the existing representation, while LayerNorm controls feature statistics. Dropout adds stochastic regularization. Correctness depends not only on having these components, but on composing them in the intended order.

Implement the block without using `nn.TransformerEncoderLayer`. The scratch version should expose projected attention tensors, attention weights, residual inputs, normalized states, FFN hidden activations, and final outputs. This visibility is required because a model can preserve the external shape `(B,T,d_model)` while normalizing the wrong axis, applying dropout at the wrong location, or omitting a residual branch.

Choose and document a normalization convention. In a Pre-LN block, the input is normalized before each sublayer and the residual receives the sublayer output. In a Post-LN block, the sublayer operates on the current state and the sum is normalized afterward. This exercise may implement Pre-LN as the default, but the code should make the convention explicit rather than mixing both.

Validation should progress from identity interventions to library comparison. Set attention and FFN outputs to zero and prove that a Pre-LN residual block returns its input. Replace sublayers with simple known functions and calculate the result manually. Then match weights and settings with a PyTorch reference, checking forward values, masks, and gradients in evaluation mode.

Part 2 - Mathematical form and reasoning

One Pre-LN encoder block can be written

$$U = X + \mathrm{Dropout}(\mathrm{MHA}(\mathrm{LN}_1(X))),$$

$$Y = U + \mathrm{Dropout}(\mathrm{FFN}(\mathrm{LN}_2(U))).$$

The position-wise FFN is

$$\mathrm{FFN}(u) = W_2\phi(W_1u + b_1) + b_2,$$

with $W_1 \in \mathbb{R}^{d_{\mathrm{ff}} \times d}$ and $W_2 \in \mathbb{R}^{d \times d_{\mathrm{ff}}}$. Every residual addition requires

$$\mathrm{shape}(X) = \mathrm{shape}(\mathrm{MHA}(\cdot)) = \mathrm{shape}(\mathrm{FFN}(\cdot)) = (B, T, d).$$

Part 3 - Hints, controls, and evidence

1. Write a tensor contract for every component before implementing the forward pass.

2. Keep attention and FFN residual dropout as distinct modules so their behavior can be inspected independently.

3. Test identity interventions, traceable linear sublayers, padding masks, and asymmetric batch/sequence/model dimensions.

4. Verify LayerNorm acts over the final feature dimension for every token independently.

5. Match the scratch block with a library block using identical weights, activation, epsilon, dropout state, mask convention, and normalization order.

6. Compare input and parameter gradients as well as forward outputs.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ScratchEncoderBlock(nn.Module):
    def __init__(self, d_model, heads, d_ff, dropout=0.1):
        super().__init__()
        self.norm1 = nn.LayerNorm(d_model)
        self.norm2 = nn.LayerNorm(d_model)
        self.attention = ...
        self.ffn = nn.Sequential(
            nn.Linear(d_model, d_ff),
            nn.GELU(),
            nn.Linear(d_ff, d_model),
        )
        self.attn_dropout = nn.Dropout(dropout)
        self.ffn_dropout = nn.Dropout(dropout)

    def forward(self, x, mask=None, return_debug=False):
        normalized1 = self.norm1(x)
        attended, weights = self.attention(
            normalized1, normalized1, normalized1, mask
        )
        u = ...  # residual 1
        normalized2 = self.norm2(u)
        transformed = self.ffn(normalized2)
        y = ...  # residual 2
        if return_debug:
            return y, {"weights": weights, "u": u,
                       "normalized1": normalized1,
                       "normalized2": normalized2,
                       "ffn_output": transformed}
        return y

def E00():
```

```
block = ScratchEncoderBlock(16, 4, 64, dropout=0.0)
x = torch.randn(2, 5, 16)
# TODO: identity, manual, mask, library-parity, and gradient tests
return block(x, return_debug=True)
```

Part 5 - The Philosophy Behind the Exercise

The Transformer block is an architecture of transformation and preservation. Attention and the FFN propose changes; residual paths keep the previous state available; normalization shapes the conditions under which change is computed. Learning occurs through the negotiation among these roles.

No component alone explains the block's success. Attention without a stable residual pathway can be difficult to optimize. Residuals without expressive sublayers preserve but do not enrich. Normalization without a meaningful transformation standardizes an empty process.

The deeper lesson is compositional: intelligence in a network arises not only from powerful operations, but from interfaces that let information survive, interact, and change across depth.

17.5.2 Exercise 01

Exercise Title: Implement Feed-Forward Network (FFN) Sub-Layer and Explain Expansion Ratio and Non-Linearity Role

Part 1 - Why this matters

Self-attention moves information among positions, but its weighted value mixing does not replace a rich transformation at each position. The FFN applies the same two-layer network independently to every token. It expands the model width to a larger hidden dimension, applies a non-linearity, and projects back to the residual width. The shared parameters preserve sequence-length flexibility while allowing each token representation to be transformed deeply.

The expansion ratio $r = d_{\text{ff}}/d_{\text{model}}$ controls a major part of Transformer parameter count and compute. A larger hidden width provides more intermediate features but increases both dense-matrix work and activation memory. The common ratio of four is a historical design choice, not a law. Compare several ratios under matched attention and training settings.

Non-linearity is essential. Without it, the two linear transformations collapse into one affine map and expansion does not create a more expressive function. Compare ReLU and GELU, inspect activation sparsity and distribution, and include a deliberately linear variant to prove the collapse. Modern gated FFNs such as SwiGLU may be noted as extensions, but the basic two-layer mechanism should be fully understood first.

Verify that the same FFN function is applied at each position. Process a token alone and inside different sequence contexts after fixing its input vector; the FFN-only result should be identical. Context changes occur in attention, while the FFN performs a shared local transformation.

Part 2 - Mathematical form and reasoning

For token state $x \in \mathbb{R}^d$,

$$h = \phi(W_1 x + b_1), \qquad y = W_2 h + b_2,$$

where

$$W_1 \in \mathbb{R}^{d_{\text{ff}} \times d}, \qquad W_2 \in \mathbb{R}^{d \times d_{\text{ff}}}.$$

Ignoring biases, parameter count is

$$N_{\text{FFN}} = 2dd_{\text{ff}} = 2rd^2.$$

For a batch of sequences, dense work is approximately

$$\mathcal{O}(BTdd_{\text{ff}}).$$

If ϕ is the identity, then

$$y = W_2 W_1 x + (W_2 b_1 + b_2),$$

which is one affine transformation despite the expanded intermediate width.

Part 3 - Hints, controls, and evidence

1. Implement the FFN on a single vector, then prove vectorized batch and sequence execution matches independent token execution.
2. Compare expansion ratios under fixed dataset, attention, optimizer budget, seeds, and stopping rule.
3. Report parameters, FLOPs estimate, activation memory, latency, and task quality.
4. Compare identity activation, ReLU, and GELU while inspecting output and gradient distributions.
5. Verify the final projection restores d_{model} for residual addition.
6. Inject an accidental activation after the second projection and document how it changes residual behavior.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class PositionWiseFFN(nn.Module):
    def __init__(self, d_model, d_ff, activation=nn.GELU,
                 dropout=0.0):
        super().__init__()
        self.up = nn.Linear(d_model, d_ff)
        self.activation = activation()
        self.dropout = nn.Dropout(dropout)
        self.down = nn.Linear(d_ff, d_model)
```

```
    def forward(self, x, return_hidden=False):
        hidden = self.activation(self.up(x))
        output = self.down(self.dropout(hidden))
        return (output, hidden) if return_hidden else output

def E01():
    reports = {}
    for ratio in [1, 2, 4, 8]:
        ffn = PositionWiseFFN(32, ratio * 32)
        # TODO: token independence, parameter, speed, memory,
        # activation, gradient, and controlled quality tests
        reports[ratio] = ...
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Attention gathers context; the FFN interprets the gathered state. One changes who can communicate, while the other changes what the resulting representation can become. Their alternation is a rhythm of relation and transformation.

Expansion creates a temporary space larger than the shared residual language. The model can form many intermediate features and then compress their useful combination back into the common stream. Capacity is borrowed and returned.

Non-linearity marks the difference between rearranging coordinates and creating new decision boundaries. Depth becomes meaningful only when composition cannot be algebraically collapsed into one linear map.

17.5.3 Exercise 02

Exercise Title: Debug LayerNorm Placement and Compare Pre-LN vs Post-LN Stability Differences in Training

Part 1 - Why this matters

LayerNorm placement changes the path followed by activations and gradients through a deep Transformer. Pre-LN normalizes before a sublayer and leaves an unmodified identity residual path. Post-LN applies the sublayer, adds the residual, and then normalizes the sum. Both preserve external shape, so an incorrect implementation may train while behaving like a different architecture.

Implement both forms with separate classes or an explicit configuration. Do not reuse a forward pass whose conditional branches obscure the equation. Copy all compatible attention and FFN weights between variants, fix dropout and seeds, and compare shallow and deep stacks on the same task. Measure loss curves, gradient norm by depth, activation statistics, divergence frequency, and sensitivity to learning rate.

Pre-LN often improves optimization stability in deep stacks because the identity residual path carries gradients without passing through a normalization Jacobian at every block. Post-LN may produce different representation and final normalization behavior and can work well with suitable initialization, warmup, or residual scaling. The exercise should test these tendencies rather than turning them into universal claims.

Debug the axis as well as the location. Standard Transformer LayerNorm normalizes the final feature dimension independently for every batch and token. Normalizing sequence or batch axes changes the model's dependencies and can leak information across padding or examples.

Part 2 - Mathematical form and reasoning

For sublayer F, Pre-LN is

$$y = x + F(\mathrm{LN}(x)),$$

while Post-LN is

$$y = \mathrm{LN}(x + F(x)).$$

LayerNorm over d features is

$$\mu = \frac{1}{d}\sum_{i=1}^{d} x_i, qquad\sigma^2 = \frac{1}{d}\sum_{i=1}^{d}(x_i - \mu)^2,$$

$$\mathrm{LN}(x)_i = \gamma_i \frac{x_i - \mu}{\sqrt{\sigma^2 + \epsilon}} + \beta_i.$$

The residual Jacobian for Pre-LN contains an explicit identity term,

$$\frac{\partial y}{\partial x} = I + J_F J_{\mathrm{LN}},$$

which helps explain a direct gradient route without guaranteeing stability in every configuration.

Part 3 - Hints, controls, and evidence

1. Write both equations beside the corresponding forward code and capture intermediate tensors.
2. Verify LayerNorm statistics per token and confirm padding or other batch items do not affect a valid token's normalization.
3. Copy shared weights, match optimizer and schedule, and compare several depths, learning rates, and seeds.
4. Log per-layer activation mean/std, residual norm, gradient norm, loss, and non-finite events.
5. Use dropout zero for exact parity tests and restore it only for training comparisons.
6. Inject a misplaced norm and retain the earliest distinguishing invariant as a regression test.

Part 4 - Python code skeleton

```
import torch

class PreLNBlock(...):
    def forward(self, x, mask=None):
        x = x + self.attention(self.norm1(x), mask)
        x = x + self.ffn(self.norm2(x))
        return x

class PostLNBlock(...):
    def forward(self, x, mask=None):
        x = self.norm1(x + self.attention(x, mask))
        x = self.norm2(x + self.ffn(x))
        return x

def layer_diagnostics(model):
    # TODO: hooks for activations, residuals, and gradients
    return ...

def E02(depths=(2, 8, 24), seeds=range(5)):
    # TODO: matched trials across norm style, depth, and LR
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Normalization placement asks whether transformation occurs before or after a state is standardized. The same named parts form different dynamical systems when their order changes. Architecture includes sequence, not merely inventory.

Residual paths preserve continuity across depth, while normalization continually renegotiates scale. Pre-LN protects a direct identity route; Post-LN insists that each updated state re-enter a standardized coordinate system.

The comparison teaches that stability is produced by relationships among components. No layer is "stable" in isolation. Its effect depends on where it sits, what it surrounds, and how gradients must travel through the whole stack.

17.5.4 Exercise 03

Exercise Title: Validate Residual Connection Shapes and Debug Silent Broadcasting Bugs in Add Operations

Part 1 - Why this matters

Residual addition is intended to combine two representations of the same batch, token, and feature locations. PyTorch broadcasting can make incompatible semantic tensors add successfully. A sublayer output shaped `(B,1,d)` may broadcast across all tokens, or `(1,T,d)` across all examples. The result has the expected final shape but repeats information that should have

been position- or example-specific.

Never use successful addition as proof of residual compatibility. Require exact shape equality before every residual merge unless broadcasting is explicitly part of the design. Name axes and test unequal values for batch, sequence, and feature dimensions. Construct traceable tensors so an unintended repeated row is obvious.

Residuals also require semantic compatibility. Attention and FFN outputs must return to d_{model} and preserve batch/sequence alignment. A transposed `(T,B,d)` output may remain addable when $B = T$, hiding a layout bug. Primary tests should deliberately use $B \neq T$.

Inject silent failures: pooled attention output, dropped batch axis, wrong transpose, singleton feature output, and accidental bias-like tensor. The block should reject them at the residual boundary with an informative assertion and retain each as a regression test.

Part 2 - Mathematical form and reasoning

The intended operation is elementwise

$$Y_{b,t,f} = X_{b,t,f} + F(X)_{b,t,f}.$$

Therefore the contract is

$$\text{shape}(X) = \text{shape}(F(X)) = (B, T, d).$$

Broadcast addition with $Z \in \mathbb{R}^{B\times 1\times d}$ instead computes

$$Y_{b,t,f} = X_{b,t,f} + Z_{b,1,f}$$

for every t, a different function. Equal output shape does not imply equal index dependence.

Part 3 - Hints, controls, and evidence

1. Implement a strict residual helper that asserts equal shape, device, and dtype before addition.
2. Use asymmetric B, T, and d plus coordinate-encoded values.
3. Verify attention and FFN outputs separately before residual merging.
4. Test batch-first and sequence-first paths with explicit conversion at one documented boundary.
5. Inject singleton, transpose, pooled, and missing-axis failures and check that each is rejected immediately.
6. Add gradient checks to confirm every token receives its own residual identity path.

Part 4 - Python code skeleton

```
import torch

def strict_residual(x, update, name):
    assert x.shape == update.shape, (
        f"{name}: residual shape {x.shape} != update {update.shape}"
    )
    assert x.device == update.device
    assert x.dtype == update.dtype
    return x + update

def coordinate_tensor(batch, seq, width):
    b = torch.arange(batch)[:, None, None] * 10000
    t = torch.arange(seq)[None, :, None] * 100
    f = torch.arange(width)[None, None, :]
    return (b + t + f).float()

def E03():
    x = coordinate_tensor(2, 5, 8)
    correct = x * 0.1
    y = strict_residual(x, correct, "attention")
    # TODO: failure injection and per-token gradient identity tests
    return y
```

Part 5 - The Philosophy Behind the Exercise

Residual addition asserts identity: these two tensors describe the same locations in the same representational language. Broadcasting can satisfy arithmetic while violating that identity.

Convenience features are most dangerous when they transform errors into valid programs. Broadcasting is powerful when sharing is intended and deceptive when sharing is accidental. Explicit contracts preserve the distinction.

The exercise teaches that shape is not only size. It is a statement about which entities correspond. Correct addition requires correspondence before it requires arithmetic.

17.5.5 Exercise 04

Exercise Title: Implement Dropout in Transformer Block and Verify It Applies Only During Training Mode

Part 1 - Why this matters

Dropout changes a Transformer block stochastically during training and becomes an identity operation during evaluation. Applying it in evaluation makes predictions random; failing to apply it in training removes intended regularization. Because dropout may appear on attention probabilities, FFN hidden activations, and residual branch outputs, each location has a different effect and should be documented.

This exercise uses dropout on sublayer outputs before residual addition and optionally inside the FFN. Attention-probability dropout belongs inside the attention module and changes

which value contributions are retained. Residual dropout changes the proposed update while preserving the identity path. Do not create `nn.Dropout` inside `forward`; register modules so `train()` and `eval()` control them correctly.

Test statistical behavior rather than expecting a particular random mask. Across many training passes, outputs should vary and the mean should approximate the no-dropout expectation because inverted dropout rescales retained values. Across repeated evaluation passes, outputs should be exactly or numerically identical. Use fixed seeds only when verifying a known mask or reproducibility.

Also verify gradients. Dropped elements have zero local gradient for that pass, while retained elements receive scaled gradients. The residual identity path still permits gradients to reach the input. Compare dropout locations on a toy task, but keep the correctness tests independent of claims about generalization.

Part 2 - Mathematical form and reasoning

For keep probability $q = 1 - p$ and Bernoulli mask $m_i \sim \text{Bernoulli}(q)$, training dropout is

$$\text{Drop}(z_i) = \frac{m_i}{q} z_i.$$

Therefore

$$\mathbb{E}[\text{Drop}(z_i)] = z_i.$$

During evaluation,

$$\text{Drop}(z) = z.$$

For residual update,

$$y = x + \text{Drop}(F(x)),$$

the identity branch remains deterministic even when the proposed update is random during training.

Part 3 - Hints, controls, and evidence

1. Register separate dropout modules for attention residual, FFN hidden, and FFN residual locations.
2. Run repeated passes in `train()` and `eval()` and compare variance and exact repeatability.
3. Use a large constant tensor to estimate zero fraction and mean preservation statistically.
4. Set $p = 0$ and a high but legal p as boundary tests; reject $p = 1$ if the chosen API disallows it.
5. Inspect gradients through dropped updates and the residual identity path.
6. Ensure validation, generation, and benchmarking call `eval()` and restore prior mode when appropriate.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ResidualDropout(nn.Module):
    def __init__(self, probability):
        super().__init__()
        self.dropout = nn.Dropout(probability)

    def forward(self, residual, update):
        assert residual.shape == update.shape
        return residual + self.dropout(update)

def mode_report(module, residual, update, repeats=200):
    module.train()
    train_outputs = torch.stack([module(residual, update)
                                 for _ in range(repeats)])
    module.eval()
    eval_outputs = torch.stack([module(residual, update)
                                for _ in range(10)])
    return {"train_variance": ...,
            "train_mean_error": ...,
            "eval_repeat_error": ...}

def E04():
    # TODO: location-specific, mode, seed, boundary, and gradient tests
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Dropout creates temporary absence so the network cannot rely too completely on one computational route. During training, the architecture becomes a changing family of subnetworks; during evaluation, their learned expectation is used as one deterministic system.

Residual paths make this absence less destructive by preserving continuity. The model experiments with missing updates without losing the state from which those updates began.

The train/eval distinction also shows that a model is not one static function throughout its lifecycle. Its behavior depends on mode, and correctness requires the surrounding pipeline to state which mode the current purpose demands.

17.5.6 Exercise 05

Exercise Title: Implement Stacking of Multiple Encoder Blocks and Track How Representation Changes by Depth

Part 1 - Why this matters

One encoder block performs one round of contextual mixing and token-wise transformation. Stacking blocks allows representations to be repeatedly reconstructed, but depth also creates optimization, memory, and interpretability challenges. This exercise builds a stack with `nn.ModuleList`, verifies that parameters are independently registered, and instruments the model to observe change at every depth.

Do not accidentally reuse the same block object unless parameter sharing is the intent. Appending one instance repeatedly creates tied weights; deep copying or constructing each block separately creates independent layers. Test parameter identities and modify one layer to prove others do not change.

Track activation norm, token-wise mean and variance, residual-update ratio, cosine similarity between consecutive layers, attention entropy, and gradient norm. High consecutive similarity may indicate small updates, but does not alone prove a layer is useless. Probe-task quality or layer ablation provides stronger functional evidence. Compare initialized and trained checkpoints.

Depth experiments must control width, data, optimization budget, and seeds. Deeper models have more parameters and may require different learning-rate or warmup settings, so distinguish a direct controlled comparison from a tuned best-case comparison. Also measure activation memory and runtime growth.

Part 2 - Mathematical form and reasoning

For L blocks,

$$X^{(\ell+1)} = F_\ell(X^{(\ell)}), \qquad \ell = 0, \dots, L-1.$$

Representation change can be summarized by

$$R_\ell = \frac{\|X^{(\ell+1)} - X^{(\ell)}\|_F}{\max(\|X^{(\ell)}\|_F, \varepsilon)}$$

and cosine similarity

$$C_\ell = \frac{\langle X^{(\ell+1)}, X^{(\ell)} \rangle}{\|X^{(\ell+1)}\|_F \|X^{(\ell)}\|_F}.$$

For gradient $g^{(\ell)} = \partial \mathcal{L} / \partial X^{(\ell)}$, record $\|g^{(\ell)}\|_2$ across depth and training time.

Part 3 - Hints, controls, and evidence

1. Construct independent blocks and assert parameters from different layers do not share storage.
2. Return intermediate states only in debug mode to avoid retaining large graphs unintentionally.
3. Log activation, update, attention, and gradient statistics on a fixed probe set at selected checkpoints.
4. Compare depths under controlled settings and separately under tuned settings.

5. Measure parameters, peak activation memory, forward/backward latency, and held-out quality.

6. Ablate or replace selected layers with identity to test whether observed representation change is functionally important.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class EncoderStack(nn.Module):
    def __init__(self, block_factory, depth, final_norm=None):
        super().__init__()
        self.layers = nn.ModuleList([block_factory() for _ in range(depth)])
        self.final_norm = final_norm or nn.Identity()

    def forward(self, x, mask=None, return_states=False):
        states = [x] if return_states else None
        for layer in self.layers:
            x = layer(x, mask)
            if return_states:
                states.append(x)
        x = self.final_norm(x)
        return (x, states) if return_states else x

def depth_statistics(states):
    # TODO: norms, relative updates, cosine similarities, and gradients
    return ...

def E05(depths=(1, 2, 4, 8, 16)):
    # TODO: independence, controlled training, probes, ablations,
    # memory, and runtime
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Depth gives the model time measured in transformations rather than sequence steps. Every block revisits the same token positions with a representation changed by earlier context and computation.

Repeated processing does not guarantee progressive understanding. Layers may refine, preserve, overwrite, or redundantly reproduce information. Observing depth means asking what changes, what survives, and which changes affect behavior.

The residual stream acts as a history running through these transformations. Depth becomes useful when new computations can enter that history without destroying the conditions needed by later layers.

17.5.7 Exercise 06

Exercise Title: Implement Transformer Decoder Block with Masked Self-Attention and Cross-Attention Conceptually

Part 1 - Why this matters

An encoder block contextualizes a source sequence. A classical Transformer decoder block must do three things: model the target prefix through causally masked self-attention, retrieve relevant source information through cross- attention, and transform each target state through an FFN. Separate residual and normalization paths surround all three sublayers.

Masked self-attention uses target representations for queries, keys, and values and forbids future target positions. Cross-attention uses decoder states as queries but encoder outputs as keys and values. This distinction creates different sequence axes: target query length T_y and source memory length T_x. A square toy example can hide reversal, so tests must use unequal lengths.

Implement a Pre-LN conceptual decoder with independent norms for self-attention, cross-attention, and FFN. Pass target causal/padding masks separately from the source padding mask. A common failure is to apply the target mask to source memory or to normalize encoder memory with the decoder's query norm.

Prove information access through interventions. Changing a future target token must not affect earlier decoder outputs. Changing a permitted encoder memory position should affect outputs that attend to it, while changing padded source positions should not. Attention weights should have shapes `(B,H,Ty,Ty)` and `(B,H,Ty,Tx)` respectively.

Part 2 - Mathematical form and reasoning

For target state Y and encoder memory M, a Pre-LN decoder block is

$$U = Y + \mathrm{MaskedMHA}(\mathrm{LN}_1(Y)),$$

$$V = U + \mathrm{CrossMHA}(Q = \mathrm{LN}_2(U), K = M, V = M),$$

$$Z = V + \mathrm{FFN}(\mathrm{LN}_3(V)).$$

Masked self-attention has scores in $\mathbb{R}^{B\times H\times T_y\times T_y}$, while cross-attention has

$$S_{\mathrm{cross}} \in \mathbb{R}^{B\times H\times T_y\times T_x}.$$

The causal constraint is $A_{i,j} = 0$ for $j > i$ on the target self-attention map only.

Part 3 - Hints, controls, and evidence

1. Use unequal source and target lengths and label every query and key axis.
2. Keep target causal mask, target padding mask, and source padding mask as separate arguments with documented boolean conventions.
3. Test future-target intervention, valid-source intervention, and padded- source invariance.

4. Verify three residual shape contracts and three independent LayerNorm modules.
5. Set cross-attention output to zero and prove the remaining block behaves as target-only masked processing.
6. Compare with a library decoder layer only after aligning normalization order, weights, masks, dropout, and batch layout.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ScratchDecoderBlock(nn.Module):
    def __init__(self, d_model, heads, d_ff, dropout=0.0):
        super().__init__()
        self.norm1 = nn.LayerNorm(d_model)
        self.norm2 = nn.LayerNorm(d_model)
        self.norm3 = nn.LayerNorm(d_model)
        self.self_attention = ...
        self.cross_attention = ...
        self.ffn = ...
        self.dropout = nn.Dropout(dropout)

    def forward(self, target, memory, target_mask=None,
                memory_mask=None, return_weights=False):
        q = self.norm1(target)
        self_out, self_weights = self.self_attention(q, q, q, target_mask)
        u = ...
        cross_q = self.norm2(u)
        cross_out, cross_weights = self.cross_attention(
            cross_q, memory, memory, memory_mask
        )
        v = ...
        z = ...
        return (z, self_weights, cross_weights) if return_weights else z

def E06():
    # TODO: shape, causal, source-padding, intervention,
    # identity, library, and gradient tests
    return ...
```

Part 5 - The Philosophy Behind the Exercise

The decoder separates two forms of memory. Its own prefix is a history governed by causality; encoder output is an external field of source information. Self- attention and cross-attention answer different questions about these memories.

Generation therefore combines continuity and retrieval. The target state grows through its prior decisions while repeatedly consulting a representation that was constructed from the source.

The masks define an ethics of access inside the computation: what the decoder may know now, what remains future, and which stored positions are not real. Correct sequence generation begins with enforcing those boundaries.

17.5.8 Exercise 07

Exercise Title: Build a Minimal Encoder-Only Transformer Classifier and Validate Output Shapes and Loss Computation

Part 1 - Why this matters

An encoder-only classifier connects tokenization and positional information to a stack of encoder blocks and a task-specific decision. The architecture must turn variable-length token sequences into one representation without allowing padding to influence attention or pooling. This exercise builds the smallest complete classifier whose data, shapes, logits, targets, and loss can be verified end to end.

Use either a dedicated classification token or masked mean pooling and document the choice. A classification token provides a learned slot that attends to the sequence. Masked mean pooling treats valid token outputs symmetrically and must divide by the valid-token count rather than padded length. A plain mean over all storage positions creates length-dependent padding leakage.

The classifier head should output raw logits. For mutually exclusive classes, the cross-entropy loss expects shape `(B,C)` and integer targets `(B)`; applying softmax before this loss is unnecessary and can reduce numerical stability. Validate a manual log-softmax calculation on a tiny batch and confirm label indices lie in range.

Overfit a tiny dataset deliberately. Near-perfect fit is a high-value correctness test because it exercises embeddings, positions, masks, encoder blocks, pooling, classifier, loss, backward, and optimizer together. If the model cannot memorize a few examples, investigate the pipeline before tuning generalization.

Part 2 - Mathematical form and reasoning

Given token and position embeddings,

$$X^{(0)} = E_{\text{token}}(t) + E_{\text{position}}(p), \qquad X^{(L)} = \text{EncoderStack}(X^{(0)}, M).$$

Masked mean pooling is

$$z_b = \frac{\sum_{t=1}^{T} m_{b,t} X^{(L)}_{b,t,:}}{\max(1, \sum_t m_{b,t})}.$$

Logits are $\ell_b = W z_b + b$, and cross-entropy is

$$\mathcal{L} = -\frac{1}{B} \sum_{b=1}^{B} \log \frac{e^{\ell_{b,y_b}}}{\sum_{c=1}^{C} e^{\ell_{b,c}}}.$$

The stable library form operates directly on logits.

Part 3 - Hints, controls, and evidence

1. Record shapes for tokens, masks, embeddings, every block, pooled state, logits, labels, and scalar loss.
2. Test multiple batch sizes and sequence lengths, including padding and one valid token.
3. Change padded token IDs dramatically and prove valid logits remain unchanged.
4. Compare manual cross-entropy with the library loss on a tiny float64 example.
5. Verify every expected parameter receives finite gradients.
6. Overfit a tiny fixed dataset before measuring held-out performance.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class EncoderClassifier(nn.Module):
    def __init__(self, vocab, d_model, depth, classes):
        super().__init__()
        self.token = nn.Embedding(vocab, d_model)
        self.position = ...
        self.encoder = ...
        self.classifier = nn.Linear(d_model, classes)

    def forward(self, token_ids, attention_mask):
        x = self.position(self.token(token_ids))
        x = self.encoder(x, mask=attention_mask)
        valid = attention_mask[..., None].to(x.dtype)
        pooled = (x * valid).sum(dim=1) / valid.sum(dim=1).clamp_min(1)
        return self.classifier(pooled)

def E07():
    model = ...
    tokens, mask, labels = ...
    logits = model(tokens, mask)
    loss = nn.CrossEntropyLoss()(logits, labels)
    # TODO: manual loss, padding intervention, gradients, tiny overfit
    return logits, loss
```

Part 5 - The Philosophy Behind the Exercise

Classification compresses a structured sequence into one decision. The encoder preserves many token-level relations, while pooling and the head decide which summary is sufficient for

the task.

This compression is purposeful loss. A classifier does not need to reconstruct every detail, but it must retain distinctions relevant to its labels. Pooling is therefore not a neutral ending; it defines what evidence can survive.

The tiny-overfit test embodies humility. Before asking whether a model discovers general truth, we should prove that the complete mechanism can learn a small world whose answer is known.

17.5.9 Exercise 08

Exercise Title: Build a Minimal Decoder-Only Autoregressive Transformer and Validate Causal Mask Behavior Precisely

Part 1 - Why this matters

A decoder-only Transformer predicts each next token from the prefix available before it. During training, all target positions are processed in parallel, so a causal mask must prevent each query from accessing future tokens. A single mask error can produce deceptively low loss by leaking the answer. This exercise builds a minimal language model and proves its information boundary through intervention rather than visual inspection alone.

Inputs and targets are shifted: input position t contains token x_t, while the target is x_{t+1}. The model emits logits `(B,T,V)` and cross-entropy flattens matching token and vocabulary axes. Padding targets must use an ignored index or an explicit loss mask. Off-by-one alignment can make the model predict the current token instead of the next one.

For causal validation, create two sequences identical through position i and different afterward. Logits at positions up to i must be identical in evaluation mode. Future attention weights must be zero, legal rows must sum to one, and gradients of an early-position loss with respect to future token embeddings must be zero. These independent checks detect different failure classes.

Compare full-sequence evaluation with cached incremental decoding. With dropout disabled and positions offset correctly, the logits for each newly appended token should match the corresponding full forward pass within tolerance.

Part 2 - Mathematical form and reasoning

Autoregressive factorization is

$$p(x_{1:T}) = \prod_{t=1}^{T} p(x_t \mid x_{<t}).$$

The causal mask is

$$M_{i,j} = \begin{cases} 0, & j \le i, \\ -\infty, & j > i. \end{cases}$$

and next-token loss is

$$\mathcal{L} = -\frac{1}{N_{\text{valid}}} \sum_{b,t \text{ valid}} \log p_\theta(x_{b,t+1} \mid x_{b,\le t}).$$

Causality requires the Jacobian condition

$$\frac{\partial \ell_{b,i,:}}{\partial X_{b,j,:}} = 0 \quad \text{for } j > i.$$

Part 3 - Hints, controls, and evidence

1. Print input/target pairs and verify shift manually before training.
2. Combine causal and padding masks with explicit axis semantics.
3. Test attention zeros, row sums, future-token intervention, and future gradient zeros.
4. Use evaluation mode and dropout zero for deterministic causal tests.
5. Compare full and cached logits using correct global position offsets.
6. Include an intentionally missing mask and prove the test detects leakage and artificially improved training loss.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class DecoderOnlyLM(nn.Module):
    def __init__(self, vocab, d_model, depth):
        super().__init__()
        self.token = nn.Embedding(vocab, d_model)
        self.position = ...
        self.blocks = ...
        self.final_norm = nn.LayerNorm(d_model)
        self.lm_head = nn.Linear(d_model, vocab, bias=False)

    def forward(self, tokens, padding_mask=None, cache=None):
        # TODO: positions, combined mask, blocks, optional cache
        return ...

def future_intervention(model, prefix, suffix_a, suffix_b, boundary):
    logits_a = model(torch.cat([prefix, suffix_a], dim=1))
    logits_b = model(torch.cat([prefix, suffix_b], dim=1))
    return (logits_a[:, :boundary + 1] -
            logits_b[:, :boundary + 1]).abs().max()

def E08():
    # TODO: alignment, masks, intervention, Jacobian, tiny overfit,
    # and cached parity tests
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A causal model is defined as much by what it cannot know as by what it can compute. The mask creates an epistemic boundary: prediction must be formed from the past rather than copied from the future.

Parallel training does not abolish time. It makes all historical viewpoints available for simultaneous computation while preserving a different permitted past for each position.

The intervention test turns causality into an operational claim. If changing the future changes the past prediction, the architecture has violated the meaning of its task, regardless of how attractive its loss appears.

17.5.10 Exercise 09

Exercise Title: Debug NaNs in Transformer Block by Inspecting Softmax, LayerNorm, and Mixed Precision Settings

Part 1 - Why this matters

NaNs are late symptoms that may originate in attention logits, all-masked softmax rows, LayerNorm variance, FFN activations, loss scaling, optimizer states, or earlier data. A useful debugging process records the first non-finite tensor in execution order rather than inspecting only the final loss. This exercise builds hooks and assertions around every critical stage of a Transformer block.

Softmax failures can begin when QK products overflow or every key in a row is masked. Stable softmax prevents exponent overflow from finite logits but cannot repair infinities already produced by matrix multiplication. LayerNorm includes epsilon to avoid division by zero, yet reduced precision and extremely large activations can still produce invalid mean or variance. FFN expansion can amplify scale before a nonlinear activation.

Mixed precision adds dynamic loss scaling and dtype-specific limits. Log actual dtypes, autocast boundaries, scale values, skipped optimizer steps, and gradient finiteness. Repeat the failing batch in float32 and float64 where feasible. If the failure disappears, precision is implicated but the originating magnitude still needs explanation.

Inject failures deliberately: huge Q/K scale, all-masked row, zero epsilon in a custom norm, extreme FFN weights, high learning rate, and missing gradient unscale before clipping. Each injected case should be caught at its earliest stage and preserved as a diagnostic regression test.

Part 2 - Mathematical form and reasoning

Attention scores are

$$S = QK^{\mathsf{T}}/\sqrt{d_h} + M.$$

Require finite Q, K, unmasked scores, normalized weights, and outputs. LayerNorm computes

$$\widehat{x} = \frac{x - \mu}{\sqrt{\sigma^2 + \epsilon}}.$$

Track denominator minimum and activation maximum. For every stage Z_k, define

$$k^* = \min\{k : \neg\,\text{finite}(Z_k)\}.$$

The first non-finite stage k^* is the primary diagnostic target; later NaNs are propagation evidence rather than independent causes.

Part 3 - Hints, controls, and evidence

1. Validate raw inputs and targets before the model, then instrument Q/K/V, logits, masks, weights, norms, FFN activations, loss, gradients, and optimizer states.
2. Record min, max, mean, std, finite fraction, dtype, device, and shape.
3. Save the exact failing batch, model state, optimizer state, seed, and AMP scale before modifying anything.
4. Reproduce in evaluation, float32, reduced precision, and anomaly-detection modes as appropriate.
5. Stop at the earliest non-finite stage and test one causal change at a time.
6. Turn every root cause and correction into an automated failure-injection test.

Part 4 - Python code skeleton

```
import torch

def tensor_health(name, x):
    detached = x.detach()
    return {"name": name, "shape": tuple(x.shape),
            "dtype": str(x.dtype), "device": str(x.device),
            "finite": bool(torch.isfinite(x).all()),
            "min": detached.nan_to_num().min().item(),
            "max": detached.nan_to_num().max().item()}

class FiniteGuard:
    def __init__(self):
        self.records = []
    def check(self, name, tensor):
        record = tensor_health(name, tensor)
        self.records.append(record)
        if not record["finite"]:
            raise FloatingPointError(record)

def E09(block, failing_batch):
    # TODO: instrument stages and run injected-failure matrix
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A NaN is not a cause; it is the point at which numerical meaning has already collapsed. Debugging must reconstruct the path to the first operation that left the representable or defined domain.

The first-failure principle is a form of causal discipline. Many tensors become corrupted after one invalid state, but treating every corrupted tensor as a separate problem obscures the origin.

Numerical health is part of model knowledge. A network that produces an answer only while its scales remain within hidden limits is not fully understood until those limits are measured and protected.

17.5.11 Exercise 10

Exercise Title: Run Transformer Block Forward on CUDA and Confirm Device Placement for All Parameters and Buffers

Part 1 - Why this matters

Moving a Transformer block to CUDA must move every parameter and registered buffer while inputs and runtime-created tensors follow the same device. Hidden CPU objects often include positional tables not registered as buffers, masks created with default device, scalar constants wrapped as tensors, or caches initialized outside the module. These failures may appear only for particular sequence lengths or optional paths.

Build a device audit that walks named parameters, named buffers, input tensors, masks, intermediate states, outputs, gradients, and caches. Runtime-created indices should use `x.device` or an explicit device argument. Python scalars are generally safe, while newly constructed tensors inherit CPU unless specified.

Compare CPU and CUDA forward outputs from identical master weights and inputs in evaluation mode. Exact equality is not generally required because kernels may accumulate floating-point values differently. Use declared tolerances and check intermediate attention, norm, FFN, and final outputs to locate structural disagreement.

Begin with one GPU and no DDP. Distributed execution would add replication and communication variables before single-device correctness is established. Also test backward gradients and one optimizer step on CUDA, then verify the state dictionary can move back to CPU and reproduce the expected function.

Part 2 - Mathematical form and reasoning

For every parameter θ_i, buffer b_j, input x_k, and runtime mask m_l, require

$$\text{device}(\theta_i) = \text{device}(b_j) = \text{device}(x_k) = \text{device}(m_l) = D.$$

For CPU reference y and CUDA candidate $\widehat{y}$, use

$$|\widehat{y}_i - y_i| \leq \texttt{atol} + \texttt{rtol}|y_i|.$$

Repeat for parameter and input gradients after a shared scalar loss.

Part 3 - Hints, controls, and evidence

1. Skip with an explicit status when CUDA is unavailable; do not silently run a CPU substitute.
2. Audit named parameters and buffers before forward, then hook intermediate outputs and gradients.
3. Generate one master state and input on CPU, clone for CPU, and copy the same values to CUDA.
4. Test masks, positional buffers, causal paths, caches, and multiple sequence lengths.
5. Compare forward, backward, and one optimizer update within declared tolerances across several seeds.
6. Save hardware, PyTorch, CUDA, dtype, deterministic settings, and observed maximum errors.

Part 4 - Python code skeleton

```
import torch

def device_audit(module, expected):
    issues = []
    for name, parameter in module.named_parameters():
        if parameter.device != expected:
            issues.append(("parameter", name, str(parameter.device)))
    for name, buffer in module.named_buffers():
        if buffer.device != expected:
            issues.append(("buffer", name, str(buffer.device)))
    return issues

def paired_path(block, x, mask, device):
    block = block.to(device)
    x = x.to(device).detach().requires_grad_(True)
    mask = mask.to(device) if mask is not None else None
    output = block(x, mask)
    loss = ...
    loss.backward()
    return {
        "output": output.detach().cpu(),
        "input_gradient": x.grad.detach().cpu(),
        "device_issues": device_audit(block, device),
    }

def E10():
    if not torch.cuda.is_available():
        return {"status": "skipped", "reason": "CUDA unavailable"}
    # TODO: paired CPU/CUDA forward, backward, and optimizer checks
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A model is not independent of the place where its tensors exist. Device placement determines which physical memory, kernels, and communication paths realize the computation.

Moving a module is therefore a claim of completeness: every piece of persistent state and every runtime dependency must join the same computational world. One forgotten mask can reveal that the abstraction was incomplete.

Single-device correctness is the foundation of scale. Distribution should multiply a known function, not multiply uncertainty about whether the basic function is already coherent.

17.5.12 Exercise 11

Exercise Title: Benchmark Encoder Block Runtime and Identify Which Sub-Layer Dominates Cost for Long Sequences

Part 1 - Why this matters

An encoder block combines sublayers with different scaling laws. Attention score and value aggregation grow quadratically with sequence length, while FFN work grows linearly with sequence length but quadratically with model width through dense projections. LayerNorm, dropout, and residual addition are lower- order in arithmetic but may become memory-bandwidth or launch-overhead costs at small shapes. The dominant component therefore changes by regime.

Benchmark the complete block and instrument attention, FFN, norms, and residual operations separately. Use the same input already resident on GPU. Warm up, synchronize, repeat, and report median and tail latency. Measure forward inference and forward-plus-backward training separately because activation storage and gradient GEMMs change the cost distribution.

Sweep sequence length, batch, model width, FFN expansion ratio, heads, and dtype one factor at a time. At short sequences and large d, FFN projections may dominate. At long T, dense attention should increasingly dominate unless a memory-efficient fused kernel changes materialization and bandwidth. The measurement should locate the crossover rather than assume it.

Requesting attention weights or debug tensors can disable fusion and retain large intermediates. Profile production-like and observability modes separately. A debugging configuration is not a valid estimate of deployment throughput.

Part 2 - Mathematical form and reasoning

Approximate attention work is

$$C_{\text{attn}} = \mathcal{O}(BTd^2 + BT^2d),$$

including projections and dense pairwise interaction. FFN work is

$$C_{\text{ffn}} = \mathcal{O}(BTdd_{\text{ff}}) = \mathcal{O}(rBTd^2).$$

The rough crossover between pairwise attention and FFN terms occurs when T is on the order of rd, but constants, projection costs, fusion, and hardware efficiency determine the real boundary.

Part 3 - Hints, controls, and evidence

1. Add named timing ranges around norms, attention, residuals, FFN, and final output without changing their values.
2. Benchmark forward and training steps after warm-up using synchronization or CUDA events.
3. Sweep T, B, d, r, heads, and dtype while changing one factor at a time.
4. Record latency, tokens/s, peak allocated and reserved memory, and whether fusion or returned weights were enabled.
5. Compare sublayer sum with full-block time and explain launch, overlap, or measurement overhead.
6. Profile configurations near the observed crossover to verify the hotspot.

Part 4 - Python code skeleton

```
import statistics
import torch

def cuda_time(fn, warmup=20, repeats=100):
    for _ in range(warmup): fn()
    torch.cuda.synchronize()
    samples = []
    for _ in range(repeats):
        start = torch.cuda.Event(True); end = torch.cuda.Event(True)
        start.record(); fn(); end.record(); torch.cuda.synchronize()
        samples.append(start.elapsed_time(end))
    return {"median_ms": statistics.median(samples), "p95_ms": ...}

def benchmark_block(config):
    block, x, mask = ...
    # TODO: full block and instrumented sublayer measurements
    return ...

def E11(configurations):
    if not torch.cuda.is_available(): return {"status": "skipped"}
    return [benchmark_block(c) for c in configurations]
```

Part 5 - The Philosophy Behind the Exercise

An architecture is a distribution of work as well as a distribution of ideas. Attention and FFN may receive equal conceptual prominence while consuming very different resources under

a particular shape.

Dominance is conditional. The bottleneck moves when context, width, batch, precision, or kernel changes. Optimization knowledge therefore has a half-life and must remain attached to the measured regime.

Benchmarking transforms complexity from a slogan into a landscape. The useful question is not "which sublayer is expensive?" but "where, why, and under which workload does each sublayer become expensive?"

17.5.13 Exercise 12

Exercise Title: Implement Mixed Precision Forward and Detect Layers That Are Sensitive to fp16 Instability

Part 1 - Why this matters

Mixed precision accelerates dense operations and reduces activation memory, but a Transformer block contains numerically sensitive reductions and normalization. QK logits may overflow, softmax probabilities may underflow, LayerNorm variance may lose precision, and FFN activations may exceed float16 range. Autocast can promote selected operations, but the researcher must verify actual behavior and not assume every layer is safe.

Run a float32 reference and capture outputs after each norm, attention stage, residual, activation, and FFN projection. Repeat under float16 autocast and bfloat16 where supported. Compare finite values, maximum absolute and relative error, cosine similarity, attention top-index agreement, and output impact. Sweep input and weight scales to locate the first stage that violates a declared invariant.

Forward stability differs from training stability. This exercise emphasizes the forward pass but should retain gradients for a small follow-up and use gradient scaling when an optimizer step is tested. Residual additions may combine a small update with a large state, causing the update to round away even without overflow. Measure update-to-residual ratio before and after reduced precision.

Allow selective promotion as an intervention. Compute logits/softmax or LayerNorm statistics in float32 while keeping projections and FFN GEMMs in lower precision. Recompare speed, memory, and error to determine which promoted operations earn their cost.

Part 2 - Mathematical form and reasoning

For stage reference z and candidate $\widehat{z}$, report

$$E_{\text{abs}} = \max_i |\widehat{z}_i - z_i|, \qquad E_{\text{rel}} = \max_i \frac{|\widehat{z}_i - z_i|}{\max(|z_i|, \varepsilon)}.$$

Residual-update preservation can be measured by

$$R = \frac{\|F(x)\|_2}{\max(\|x\|_2, \varepsilon)}$$

and the difference between float32 and reduced-precision $x + F(x)$. A small finite error may still matter if it changes a discrete attention winner or erases most of a residual update.

Part 3 - Hints, controls, and evidence

1. Use identical master weights and inputs for float32, float16, and bfloat16 paths.
2. Instrument actual dtypes and health statistics after every critical stage.
3. Sweep input, Q/K, and FFN weight scales plus normal and extreme masks.
4. Record finite values, absolute/relative error, cosine similarity, attention ranking, and residual-update preservation.
5. Promote one sensitive operation at a time and measure recovered accuracy, latency, and memory.
6. Define tolerances before inspecting results and keep failing cases as regression tests.

Part 4 - Python code skeleton

```
import torch

def capture_forward(block, x, mask, amp_dtype=None):
    enabled = amp_dtype is not None and x.is_cuda
    with torch.autocast("cuda", dtype=amp_dtype, enabled=enabled):
        output, debug = block(x, mask, return_debug=True)
    return output, debug

def stage_metrics(reference, candidate):
    return {"max_abs": ..., "max_rel": ..., "cosine": ...,
            "finite": bool(torch.isfinite(candidate).all())}

def E12(block, scales, dtypes):
    reports = []
    for scale in scales:
        x, mask = ...
        ref = capture_forward(block, x.float(), mask, None)
        for dtype in dtypes:
            # TODO: candidate path and stage-by-stage comparison
            reports.append(...)
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Mixed precision is selective forgetting. The machine represents fewer numeric distinctions in exchange for speed and capacity. The engineering question is which distinctions the model can afford to lose.

Sensitivity is local. Matrix multiplication may tolerate reduced precision while a normalization statistic or phase boundary does not. Treating the whole block uniformly ignores the different numerical roles of its parts.

The best mixed-precision design is therefore not the lowest dtype everywhere, but the cheapest allocation of precision that preserves declared behavior.

17.5.14 Exercise 13

Exercise Title: Implement Gradient Check on Tiny Transformer Block and Validate Backward Correctness

Part 1 - Why this matters

A Transformer block contains multiple residual branches, normalizations, softmax, projections, activation functions, and masks. Autograd can compute a gradient for a program that is structurally wrong, and a decreasing loss does not prove every branch receives the intended derivative. Finite-difference gradient checking provides an independent local test on a tiny deterministic block.

Use float64, dropout zero, a small smooth configuration, and a scalar objective that depends on every output coordinate. Avoid saturated softmax and ReLU kink points; GELU is convenient for smooth checking. Check input gradients and selected entries from attention projections, LayerNorm scale/bias, FFN weights, and output projections.

Residual paths create useful expected behavior. If sublayer weights are set to zero in a Pre-LN block, the output equals the input and the input Jacobian should be identity. Masks create another expectation: a loss on an early causal position must have zero derivative with respect to future input positions.

Run `torch.autograd.gradcheck` and a manual centered-difference sweep. Vary epsilon to expose the balance between truncation and rounding. Inject a detach, wrong residual, and in-place modification; prove the checker or a related invariant detects each failure.

Part 2 - Mathematical form and reasoning

For scalar objective $L(\theta)$,

$$g_i^{\mathrm{FD}} = \frac{L(\theta + \epsilon e_i) - L(\theta - \epsilon e_i)}{2\epsilon}.$$

Compare with autograd through normalized error

$$E_i = \frac{|g_i^{\mathrm{AD}} - g_i^{\mathrm{FD}}|}{\max(1, |g_i^{\mathrm{AD}}|, |g_i^{\mathrm{FD}}|)}.$$

For a zero-update residual block $Y = X$, require

$$\frac{\partial Y}{\partial X} = I.$$

For causal output Y_i, require

$$\frac{\partial Y_i}{\partial X_j} = 0 \quad \text{for } j > i.$$

Part 3 - Hints, controls, and evidence

1. Use $B = 1$, short sequence, small width, two heads, float64, and dropout zero.
2. Choose moderate deterministic values and a smooth weighted scalar loss.

3. Check parameters from attention, both norms, and both FFN projections as well as input.
4. Sweep epsilon and report absolute and normalized error.
5. Test identity-residual and causal-zero-gradient properties separately.
6. Inject detach, wrong merge, and in-place failures and retain regression tests.

Part 4 - Python code skeleton

```
import torch

def objective(block, x, mask):
    y = block(x, mask)
    coefficients = torch.linspace(0.2, 1.1, y.numel(),
                                  dtype=y.dtype).reshape_as(y)
    return (y * coefficients).sum()

def centered_difference(loss_fn, tensor, index, epsilon):
    flat = tensor.view(-1)
    original = flat[index].item()
    with torch.no_grad(): flat[index] = original + epsilon
    plus = loss_fn().item()
    with torch.no_grad(): flat[index] = original - epsilon
    minus = loss_fn().item()
    with torch.no_grad(): flat[index] = original
    return (plus - minus) / (2 * epsilon)

def E13():
    block, x, mask = ...  # float64 and deterministic
    # TODO: gradcheck, manual epsilon sweep, identity Jacobian,
    # causal gradients, and failure injection
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Backpropagation is trusted because it follows the chain rule through a program, but that trust applies to the program that exists, not the architecture we intended. Gradient checking asks the function itself how it changes.

Residual and causal properties provide more than numerical comparison; they give structural expectations for derivatives. Correct gradients should reflect the model's declared routes of preservation and information access.

Independent evidence is the foundation of reliability. Forward parity, finite-difference sensitivity, and behavioral training each observe a different face of the same system. Agreement among them is stronger than confidence in any one test.

17.5.15 Exercise 14

Exercise Title: Stress Test Deep Transformer Stack and Observe Gradient Flow Differences Between Pre-LN and Post-LN

Part 1 - Why this matters

Differences between Pre-LN and Post-LN become most visible as depth increases. A shallow stack may train under either convention, while dozens of layers can amplify gradient attenuation, explosion, residual-scale drift, or sensitivity to initialization and learning rate. This exercise builds controlled deep stacks and measures gradient flow before committing expensive training runs.

Copy compatible attention and FFN weights between norm variants and use the same inputs, loss, masks, initialization policy, and seeds. Evaluate depth at initialization with a synthetic scalar loss, then train a small task under matched and separately tuned optimization settings. The controlled comparison isolates architecture; the tuned comparison answers what each architecture can achieve with appropriate support.

Record gradient norm for every block input and parameter group, activation norm, LayerNorm input variance, residual update ratio, and cosine similarity between successive states. Use logarithmic plots across depth. A single total gradient norm can hide early layers receiving almost no signal while later layers remain healthy.

Stress testing must remain safe. Increase depth, batch, and sequence length within known memory limits, use isolated runs for configurations expected to fail, and distinguish numerical divergence from OOM. Checkpoint initial states and failing batches so every instability can be reproduced.

Part 2 - Mathematical form and reasoning

For stack $X^{(\ell+1)} = F_\ell(X^{(\ell)})$, gradient propagation is

$$\frac{\partial \mathcal{L}}{\partial X^{(\ell)}} = \frac{\partial \mathcal{L}}{\partial X^{(L)}} \prod_{k=\ell}^{L-1} J_{F_k}.$$

Pre-LN residual Jacobians contain identity terms

$$J_{F_k} = I + J_{G_k} J_{\mathrm{LN}_k},$$

while Post-LN applies the normalization Jacobian after the sum. Monitor the gradient ratio

$$R_\ell = \frac{\|g^{(\ell)}\|_2}{\max(\|g^{(L)}\|_2, \varepsilon)}$$

and report non-finite or underflow boundaries by depth and configuration.

Part 3 - Hints, controls, and evidence

1. Compare depths such as 2, 8, 24, 48, and 96 within the safe memory envelope.
2. Copy shared weights and fix inputs, masks, loss, seeds, and dropout for initial gradient tests.

3. Log per-layer activation, update, normalization, and gradient statistics.
4. Run matched optimizer settings first, then tuned learning-rate/warmup settings as a separately labeled experiment.
5. Record divergence step, first non-finite layer, loss curve, peak memory, and runtime.
6. Retain the exact state and batch for the first unstable configuration and turn the observed invariant into a regression stress test.

Part 4 - Python code skeleton

```
import torch

def attach_depth_hooks(stack):
    records = {}
    # TODO: retain gradients on block inputs and log activations
    return records

def one_gradient_probe(model, x, mask, target):
    records = attach_depth_hooks(model)
    output = model(x, mask)
    loss = ...
    loss.backward()
    # TODO: collect ordered activation and gradient statistics
    return records

def E14(depths=(2, 8, 24, 48), seeds=range(5)):
    reports = []
    for norm_style in ["pre", "post"]:
        for depth in depths:
            for seed in seeds:
                # TODO: matched initialization, gradient probe,
                # controlled training, and safe failure reporting
                reports.append(...)
    return reports
```

Part 5 - The Philosophy Behind the Exercise

Depth multiplies consequences. A small difference in how one block routes a gradient becomes a repeated principle governing an entire stack. Architecture reveals its dynamics through repetition.

Residuals preserve possibility: even when learned transformations are weak or unstable, an identity route remains available. Normalization decides how that route interacts with scale at every layer.

Stress testing asks not only whether a system works, but how far its organizing principles remain effective. The boundary is part of the model's identity and should be measured before scale turns it into a costly surprise.

17.5.16 Exercise 15

Exercise Title: Implement Activation Checkpointing in Transformer Stack and Quantify Memory Savings and Time Cost

Part 1 - Why this matters

Backpropagation normally stores intermediate activations from every Transformer block so gradients can be computed later. Deep stacks and long sequences make these saved tensors a dominant memory cost. Activation checkpointing stores selected boundary states and recomputes internal forward operations during backward, trading additional computation for lower peak memory.

Wrap blocks or groups of blocks with PyTorch checkpointing. The checkpointed function must be deterministic with respect to its inputs and preserve required random-number behavior for dropout. Modern non-reentrant checkpointing is often preferred, but record API choices and framework version. Inputs requiring gradient, nested outputs, masks, and keyword arguments need explicit tests.

Compare identical model weights, inputs, dropout mode, loss, and optimizer step with and without checkpointing. Verify forward outputs, loss, input gradients, parameter gradients, and updated parameters within tolerance. Then measure peak allocated and reserved CUDA memory, forward time, backward time, and total step time. Synchronize timings and reset memory statistics around isolated trials.

Sweep checkpoint granularity. Checkpointing every block can save more activation memory but causes more recomputation and overhead. Grouping several blocks changes the tradeoff. The best policy depends on sequence length, depth, block cost, available GPU memory, and target throughput.

Part 2 - Mathematical form and reasoning

For composition

$$y = F_L \circ \cdots \circ F_1(x),$$

ordinary backward stores intermediate $x_1, \ldots, x_{L-1}$. Checkpointing a segment stores its boundaries and recomputes

$$x_{k+1}, \ldots, x_{k+m-1}$$

during backward. Report memory saving

$$S_M = 1 - \frac{M_{\text{checkpoint}}}{M_{\text{baseline}}}$$

and time overhead

$$O_t = \frac{t_{\text{checkpoint}} - t_{\text{baseline}}}{t_{\text{baseline}}}.$$

These measurements must use the same workload and include backward.

Part 3 - Hints, controls, and evidence

1. Establish exact or tolerant forward/backward parity with dropout zero before testing stochastic training.
2. Compare no checkpointing, every block, and grouped-block policies.
3. Record API mode, RNG preservation, model depth, sequence length, dtype, and whether compilation is enabled.
4. Reset peaks, synchronize CUDA, and measure forward, backward, and optimizer time separately.
5. Report allocated and reserved memory plus throughput, not only whether a larger batch fits.
6. Test masks, keyword arguments, cached debug outputs, and failure cases that violate checkpoint function requirements.

Part 4 - Python code skeleton

```
import torch
from torch.utils.checkpoint import checkpoint

class CheckpointedStack(torch.nn.Module):
    def __init__(self, layers, enabled=True):
        super().__init__()
        self.layers = torch.nn.ModuleList(layers)
        self.enabled = enabled

    def forward(self, x, mask=None):
        for layer in self.layers:
            if self.enabled and self.training:
                x = checkpoint(lambda state: layer(state, mask),
                               x, use_reentrant=False)
            else:
                x = layer(x, mask)
        return x

def measured_step(model, batch):
    # TODO: synchronized forward/backward/update timing and memory peaks
    return ...

def E15(configurations):
    # TODO: parity and granularity tradeoff sweep
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Checkpointing exchanges memory for time by refusing to remember every detail of the forward pass. When the past is needed, it is reconstructed from preserved boundaries.

This is a computational form of selective memory. The system decides which states are worth storing and which can be regenerated more cheaply than they can be retained.

The technique reveals that efficiency is not one dimension. Less memory can enable a deeper model or larger batch while requiring more computation. The right choice follows the scarce resource and the purpose of the run.

17.5.17 Exercise 16

Exercise Title: Create Unit Tests that Validate Shapes, Dtypes, and Masking Across Encoder and Decoder Blocks

Part 1 - Why this matters

Encoder and decoder blocks preserve external tensor width while containing many internal layouts and mask semantics. A reusable test suite should validate their contracts independently of a training task: output shapes, intermediate attention shapes, dtype/device preservation, residual equality, LayerNorm axis, dropout mode, padding invariance, causal non-leakage, cross-attention source alignment, gradients, and serialization.

Parameterize asymmetric dimensions. Equal source and target length hides cross-attention axis swaps; batch one hides broadcasting; $B = T$ hides layout transposes; float32 alone hides autocast boundaries. Test several batches, source/target lengths, model widths, heads, dtypes, and devices while keeping the smoke suite small enough for continuous use.

Method-specific behavior matters. Encoder self-attention must ignore padded keys. Decoder self-attention must ignore both padding and future targets. Cross-attention must ignore padded source memory without applying causal target rules to the source. Every valid row must preserve probability normalization or follow a documented all-masked policy.

Build failure injection for wrong norm axis, missing causal mask, swapped source and target masks, residual broadcasting, dropout active in evaluation, and CPU buffers. A test suite is credible when it fails under the defects it claims to prevent.

Part 2 - Mathematical form and reasoning

Encoder contract:

$$(B, T_x, d) \to (B, T_x, d), \qquad A \in \mathbb{R}^{B \times H \times T_x \times T_x}.$$

Decoder contract:

$$(B, T_y, d), (B, T_x, d) \to (B, T_y, d),$$

$$A_{\text{self}} \in \mathbb{R}^{B \times H \times T_y \times T_y}, \quad A_{\text{cross}} \in \mathbb{R}^{B \times H \times T_y \times T_x}.$$

Mask invariants require zero forbidden weights and causal Jacobian zeros for future target positions.

Part 3 - Hints, controls, and evidence

1. Divide tests into fast shared contracts, encoder behavior, decoder behavior, dtype/device, gradients, and slower parity/stress groups.
2. Parameterize unequal batch, source length, target length, heads, and width.
3. Compare batched examples with independent single-example references.
4. Use future-token and padded-memory interventions in addition to weight matrix assertions.
5. Save/load state dictionaries and rerun deterministic outputs.
6. Inject every targeted bug and confirm the earliest intended test fails.

Part 4 - Python code skeleton

```
import pytest
import torch

@pytest.mark.parametrize("batch,source,target,width,heads", [
    (1, 3, 2, 8, 2), (2, 5, 3, 12, 3), (4, 2, 7, 16, 4)
])
def test_encoder_decoder_shapes(batch, source, target, width, heads):
    encoder, decoder = ...
    memory = encoder(torch.randn(batch, source, width), ...)
    output, self_w, cross_w = decoder(
        torch.randn(batch, target, width), memory,
        ..., ..., return_weights=True
    )
    assert output.shape == (batch, target, width)
    assert self_w.shape == (batch, heads, target, target)
    assert cross_w.shape == (batch, heads, target, source)

def E16():
    # TODO: dtype, device, residual, norm, dropout, padding,
    # causal, gradient, serialization, and failure-injection tests
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A block interface is a promise that many internal transformations preserve specific external meanings. Unit tests turn that promise into executable constraints.

Encoder and decoder tests also encode laws of information access. Shapes say which entities may correspond; masks say which correspondences are permitted; gradients reveal which paths actually connect.

The suite becomes a durable specification. It allows implementation to change for speed or clarity while preserving the behavior on which later chapters depend.

17.5.18 Exercise 17

Exercise Title: Profile GPU Kernels and Identify MatMul Hotspots in FFN and Attention Portions

Part 1 - Why this matters

The Transformer block is dominated by matrix multiplication, but those GEMMs have different shapes and scaling. Q/K/V and output projections operate on flattened token batches; attention score and value products contain the quadratic sequence dimension; FFN up/down projections use the expanded hidden width. A profiler reveals which kernels dominate for the actual workload and whether fusion, memory traffic, or launch overhead changes the expected result.

Instrument logical ranges around attention projections, QK, mask/softmax, AV, output projection, FFN up, activation, FFN down, norms, and residuals. Use a scheduled capture after warm-up and record shapes and memory. Avoid returning large debug tensors in the production-like profile because doing so can disable fused attention or retain outputs that would otherwise be freed.

Compare short-wide and long-narrow regimes, inference and training, float32 and mixed precision, explicit and fused attention, and several FFN expansion ratios. Sort by self CUDA time, total CUDA time, call count, and memory. A large total time can come from many small calls; a high self time identifies the kernel's own contribution.

Turn one observed hotspot into an intervention: fuse QKV projection, use a memory-efficient attention path, change FFN activation implementation, or compile the block. Re-profile and verify output/gradient parity. Optimization is complete only when measured cost falls without violating model behavior.

Part 2 - Mathematical form and reasoning

Attention matrix products include

$$(BH, T, d_h)@(BH, d_h, T) \to (BH, T, T)$$

and

$$(BH, T, T)@(BH, T, d_h) \to (BH, T, d_h).$$

FFN products include

$$(BT, d)@(d, d_{\text{ff}}) \to (BT, d_{\text{ff}})$$

and the reverse projection. The attention products require approximately $\mathcal{O}(BT^2d)$ work. The FFN products require approximately $\mathcal{O}(BTdd_{\text{ff}})$ work. Kernel occupancy and memory bandwidth determine achieved performance.

Part 3 - Hints, controls, and evidence

1. Warm up before a short scheduled profile and annotate logical sublayers with named ranges.

2. Record shapes, stacks only when necessary, CPU/CUDA activity, and memory.
3. Profile several regimes and keep debug-weight-returning mode separate from production mode.
4. Identify GEMM shapes, softmax/reduction kernels, copies, and unexpected synchronization.
5. Propose an optimization from the measured trace, then rerun both profiler and correctness tests.
6. Report environment, backend selection, dtype, compile/fusion state, and input configuration with every trace.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, record_function, ProfilerActivity

def profiled_step(block, x, mask, training):
    with record_function("transformer_block"):
        output = block(x, mask)
        if training:
            output.square().mean().backward()
    return output

def profile_configuration(block, x, mask, training):
    schedule = torch.profiler.schedule(wait=1, warmup=2, active=3)
    with profile(activities=[ProfilerActivity.CPU,
                             ProfilerActivity.CUDA],
                 schedule=schedule, record_shapes=True,
                 profile_memory=True) as prof:
        for _ in range(8):
            profiled_step(block, x, mask, training)
            prof.step()
    return prof.key_averages().table(sort_by="self_cuda_time_total")

def E17(configurations):
    # TODO: regime sweep, trace export, optimization, and parity
    return ...
```

Part 5 - The Philosophy Behind the Exercise

Profiling reveals how a conceptual block becomes physical work. The names “attention” and “FFN” dissolve into matrix shapes, reductions, memory movement, and kernel schedules.

This translation matters because performance is produced by alignment between algorithm and machine. The same equation can be fast or slow depending on how its dimensions fit the hardware.

Evidence-driven optimization preserves intellectual honesty. We improve the system that actually runs, not the one imagined from reading source code.

17.5.19 Exercise 18

Exercise Title: Build a Transformer Block Debugging Checklist Covering Masking, Norm Placement, and Precision Issues

Part 1 - Why this matters

A Transformer block can fail through configuration, geometry, information access, normalization, stochastic mode, numerics, gradients, device placement, or performance. A checklist orders these possibilities so debugging begins with the earliest cheap invariant instead of tuning hyperparameters around a broken implementation.

Begin with configuration and tensor contracts: divisible heads, positive FFN width, supported positions, exact residual shapes, devices, and dtypes. Continue through attention masks, probability invariants, LayerNorm axis and placement, dropout mode, FFN dimensions, residual update ratios, finite values, gradients, CPU/CUDA parity, and only then profiling. Decoder checks add target causality and source-memory separation.

Every item should return pass/fail, evidence, likely causes, and whether later checks are blocked. "Loss is NaN" is too late and too vague. A useful report states that QK logits first became infinite in layer 7 under float16 at a particular scale, or that a causal mask broadcast along the head axis instead of the query axis.

Use failure injection to test the checklist: missing causal mask, all-masked row, wrong norm placement, sequence-axis normalization, residual broadcasting, dropout active in eval, detached FFN, CPU buffer, oversized logits, and checkpointing parity failure. Retain every detected case.

Part 2 - Mathematical form and reasoning

The checklist enforces, in order,

$$d = Hd_h, qquadd_{\text{ff}} > 0,$$

$$\text{shape}(X) = \text{shape}(F(X)),$$

$$A_{\text{forbidden}} = 0, qquad \sum_j A_{b,h,i,j} = 1,$$

$$\text{LN acts over the final feature axis,}$$

and finiteness of each ordered stage. Let $Z_1, \ldots, Z_K$ be captured tensors; the primary failure is

$$k^* = \min\{k : \text{invariant}_k(Z_k) = \text{false}\}.$$

Part 3 - Hints, controls, and evidence

1. Group checks into configuration, shapes, masks, norm, mode, numerics, backward, device, parity, and performance.
2. Give each check an assertion, evidence payload, likely causes, and repair test.

3. Stop at or emphasize the earliest violated invariant and mark downstream checks as blocked.
4. Include tiny encoder, decoder, causal, padding, cross-attention, and mixed- precision cases.
5. Inject every targeted failure and verify the intended check catches it.
6. Save a machine-readable incident report with seed, configuration, state, batch, cause, correction, and regression test.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict

@dataclass
class BlockCheck:
    name: str
    passed: bool
    evidence: dict
    likely_causes: list
    blocked_by: str | None = None

def check_residual(name, residual, update):
    return BlockCheck(name,
        residual.shape == update.shape and
        residual.dtype == update.dtype and
        residual.device == update.device,
        {"residual": tuple(residual.shape),
         "update": tuple(update.shape)},
        ["wrong projection", "silent broadcasting", "layout swap"])

def run_block_checklist(block, case):
    checks = []
    # TODO: ordered execution and earliest-failure logic
    return {"passed": all(c.passed for c in checks),
            "checks": [asdict(c) for c in checks]}

def E18():
    # TODO: correct matrix and injected-failure matrix
    return ...
```

Part 5 - The Philosophy Behind the Exercise

A debugging checklist is a map of dependence. It records which truths must hold before later truths are meaningful. Performance has no meaning before correctness; gradient health has limited meaning before information access is correct.

The earliest violated invariant is valuable because it is closest to the first departure from intention. Later symptoms are consequences accumulating along the computational graph.

By preserving failures as tests, the project develops institutional memory. Understanding becomes embedded not only in people and prose, but in executable barriers against regression.

17.5.20 Exercise 19

Exercise Title: Produce an Engineering Report Explaining Transformer Block Design Decisions and Their Practical Effects

Part 1 - Why this matters

The final report must explain how attention, FFN, residuals, LayerNorm, dropout, masks, and depth form a Transformer block rather than presenting them as an unconnected list. Every design decision should be linked to mathematical role, tensor contract, optimization behavior, measured systems cost, failure modes, and evidence from the chapter.

Begin with the chosen encoder and decoder equations. State Pre-LN or Post-LN, FFN width and activation, dropout locations, mask conventions, positional interface, final normalization, and parameter initialization. Explain why each residual addition is shape-safe and how padding, causality, and cross-attention boundaries are enforced.

Use artifacts from E00–E18: scratch/library parity, FFN expansion sweeps, norm-stability curves, broadcasting failures, dropout statistics, depth probes, classifier and language-model tiny-overfit tests, NaN incidents, CUDA parity, runtime crossover, mixed-precision boundaries, gradient checks, deep-stack flow, checkpointing tradeoffs, unit tests, and profiler traces. Conditional and negative findings are part of the engineering answer.

Separate controlled comparisons from tuned best-case results. Distinguish theoretical complexity from observed kernel time, logical head or layer ablation from real speedup, numerically finite execution from stable learning, and accepted tolerance from exact identity. Preserve environment, seeds, hardware, dtypes, and stopping rules.

End with a default block configuration for the next chapter, explicit reasons for that default, rejection conditions, monitoring signals, and unresolved questions about training complete Transformer systems.

Part 2 - Mathematical form and reasoning

Anchor the report in the selected block equations, for example Pre-LN:

$$U = X + \mathrm{Dropout}(\mathrm{MHA}(\mathrm{LN}_1(X))),$$

$$Y = U + \mathrm{Dropout}(W_2\phi(W_1\,\mathrm{LN}_2(U) + b_1) + b_2).$$

Include parameter and cost estimates

$$N_{\text{attention}} \approx 4d^2, \qquad N_{\text{FFN}} \approx 2dd_{\text{ff}},$$

$$C_{\text{block}} = \mathcal{O}(BTd^2 + BT^2d + BTdd_{\text{ff}}),$$

plus exact mask, residual, normalization, gradient, and numerical invariants used to validate the implementation.

Part 3 - Hints, controls, and evidence

1. Open with the intended workload and a precise block specification.
2. Map every design claim to equations, configuration, experiment, raw artifact, observed behavior, limitation, and recommendation.
3. Include encoder and decoder information-access proofs, not only shape tests.
4. Report stability, precision, runtime, memory, checkpointing, and depth as measured trade-offs.
5. Include an incident appendix containing injected bugs, earliest failed invariants, causes, corrections, and regression tests.
6. Finish with a conditional default and explicit triggers for revisiting its norm style, width, dropout, precision, or checkpoint policy.

Part 4 - Python code skeleton

```
from pathlib import Path

REQUIRED = ["encoder_parity", "ffn", "norm_stability",
            "residuals", "dropout", "depth", "decoder_masks",
            "tiny_overfit", "nan_debug", "cuda", "benchmark",
            "mixed_precision", "gradcheck", "checkpointing",
            "unit_tests", "profiler", "debug_checklist"]

def validate_artifacts(artifacts):
    return {name: ... for name in REQUIRED}

def build_decisions(artifacts, workload):
    # TODO: observation, interpretation, limitation, and decision
    return ...

def E19(artifact_directory, workload, output_path):
    artifacts = ...
    checks = validate_artifacts(artifacts)
    assert all(checks.values()), checks
    report = build_decisions(artifacts, workload)
    Path(output_path).write_text(report, encoding="utf-8")
    return {"report": str(output_path), "checks": checks}
```

Part 5 - The Philosophy Behind the Exercise

The Transformer block is a compact theory of deep computation. It assumes that representations should communicate globally, transform locally, preserve a continuing state, and

regulate scale as they pass through depth.

Engineering reveals that this theory lives inside constraints. Masks define knowledge, residuals define continuity, normalization shapes gradients, precision bounds numeric distinctions, and hardware determines the cost of every design.

A final report makes these relationships accountable. Understanding is not the ability to recite the block diagram; it is the ability to predict how the block behaves, detect when it departs from intention, and justify why each component remains in the design.

17.6 TRF04

Chapter Title: Tokenization, Embeddings, and Vocabulary Pipeline
Specialization: Models and Training

17.6.1 Exercise 00

Exercise Title: Implement Basic Tokenization and Build Vocabulary Mapping with Special Tokens and Correct Index Handling

Part 1 - Why this matters

A Transformer never receives text. It receives integer identifiers whose meaning is fixed by a tokenizer and a vocabulary. The mapping may look like a minor data preprocessing detail, yet it is part of the model contract: changing the ID of one token while reusing the same embedding weights silently changes the meaning of the model. A checkpoint is therefore incomplete unless its vocabulary, normalization rules, and special-token policy are recoverable.

Build a deliberately small word-level tokenizer before using a production library. Specify whether text is lowercased, how punctuation is separated, and whether repeated whitespace is normalized. Reserve stable IDs for `<pad>`, `<unk>`, `<bos>`, and `<eos>`; then assign ordinary tokens using a deterministic ordering such as decreasing frequency with lexical tie-breaking. Build the vocabulary from training data only. A vocabulary built from validation or test text leaks information even if labels were never inspected.

The implementation must support encoding and decoding. Encoding adds boundary tokens according to an explicit policy and maps unseen items to `<unk>`. Decoding must distinguish exact reconstruction from a readable rendering that removes special tokens. Test empty text, repeated tokens, punctuation, unknown tokens, and Unicode input. Finally, serialize the mapping and prove that loading it produces exactly the same IDs. Never rebuild a vocabulary when loading model weights.

Part 2 - Mathematical form and reasoning

Let the tokenizer be $\tau : s \mapsto (u_1, \ldots, u_n)$ and let $\mathcal{V}$ be an ordered vocabulary. The encoder is

$$e(s) = \big[i_{\text{bos}}, v(u_1), \ldots, v(u_n), i_{\text{eos}}\big], \qquad v(u) = \begin{cases} \text{id}(u), & u \in \mathcal{V}, \\ i_{\text{unk}}, & u \notin \mathcal{V}. \end{cases}$$

The range invariant is $0 \leq e(s)_j < |\mathcal{V}|$. The four special IDs must be distinct, and the inverse mapping must satisfy $v^{-1}(v(u)) = u$ for every known ordinary token. Determinism means that the same training corpus and configuration produce the same ordered mapping, not merely the same set of tokens.

Part 3 - Hints, controls, and evidence

1. Write the normalization and boundary-token policies before writing code.
2. Use two corpora with equal-frequency tokens in different input orders; prove that lexical tie-breaking gives identical vocabularies.
3. Report vocabulary size, unknown-token rate, round-trip accuracy, and a hash of the serialized vocabulary.
4. Inject a failure by swapping two IDs after saving. Show that shapes remain valid while decoded meaning changes.
5. Reject duplicate special tokens, missing inverse entries, and IDs outside the contiguous interval $[0, |\mathcal{V}|)$.

Part 4 - Python code skeleton

```
import json, re
from collections import Counter

SPECIALS = ["<pad>", "<unk>", "<bos>", "<eos>"]

def tokenize(text):
    text = text.lower().strip()
    return re.findall(r"\w+|[^\w\s]", text, flags=re.UNICODE)

def build_vocab(train_texts, min_freq=1):
    counts = Counter(tok for s in train_texts for tok in tokenize(s))
    kept = sorted((t for t, c in counts.items() if c >= min_freq),
                  key=lambda t: (-counts[t], t))
    tokens = SPECIALS + [t for t in kept if t not in SPECIALS]
    token_to_id = {t: i for i, t in enumerate(tokens)}
    assert len(token_to_id) == len(tokens)
    return token_to_id, tokens

def encode(text, stoi):
    ids = [stoi["<bos>"]]
    ids += [stoi.get(t, stoi["<unk>"]) for t in tokenize(text)]
    ids += [stoi["<eos>"]]
    assert all(0 <= i < len(stoi) for i in ids)
    return ids

def decode(ids, itos, remove_special=False):
```

```
    tokens = [itos[i] for i in ids]
    if remove_special:
        tokens = [t for t in tokens if t not in SPECIALS]
    return " ".join(tokens)

def E00():
    train = ["Red fox jumps.", "Blue fox waits!"]
    stoi, itos = build_vocab(train)
    ids = encode("Green fox jumps.", stoi)
    payload = json.dumps({"tokens": itos}, ensure_ascii=False)
    restored = json.loads(payload)["tokens"]
    assert restored == itos and len(set(SPECIALS)) == 4
    return {"ids": ids, "decoded": decode(ids, itos),
            "unknown_rate": ids.count(stoi["<unk>"]) / len(ids)}
```

Part 5 - The Philosophy Behind the Exercise

Tokenization creates the ontology through which the model can perceive text. The model cannot discover that two IDs were accidentally exchanged; it simply learns within the world it was given. This makes vocabulary construction an act of definition, not clerical preprocessing.

The deeper engineering principle is identity preservation. A token ID has no intrinsic meaning. Its meaning exists only through the agreement among the tokenizer, embedding table, output head, checkpoint, and serving pipeline. A reliable system makes that agreement explicit, versioned, and testable.

17.6.2 Exercise 01

Exercise Title: Implement Embedding Layer Usage and Verify Output Shape (batch, seq, d_model) and Dtype Correctness

Part 1 - Why this matters

An embedding layer converts symbolic token IDs into continuous vectors that a Transformer can transform. It is not a dense layer applied to the numerical value of an ID. It is an indexed lookup: ID 900 is not inherently larger or more important than ID 9. Confusing these views destroys the categorical semantics of tokens.

Create input IDs with shape `(B,T)` and dtype `torch.long`. For a table with V rows and d_{model} columns, verify that the output has shape `(B,T,d_model)` and the same floating dtype and device as the embedding weights. Show that repeated IDs produce identical vectors and that changing a single ID changes only the corresponding output position. Test an invalid negative or out-of-range ID and record the resulting failure rather than silently clipping it.

Use `padding_idx` and inspect its exact behavior. PyTorch keeps the padding row from receiving an ordinary embedding gradient, but this does not automatically prevent padded positions from influencing attention or loss. Those are separate responsibilities handled by masks. This separation is a critical pipeline invariant.

Part 2 - Mathematical form and reasoning

Let $E \in \mathbb{R}^{V \times d}$ and $I \in \{0, \ldots, V-1\}^{B \times T}$. Embedding lookup is

$$X_{b,t,:} = E_{I_{b,t},:}, \qquad X \in \mathbb{R}^{B \times T \times d}.$$

If a scalar loss L depends on X, gradients for repeated IDs accumulate in the same row:

$$\frac{\partial L}{\partial E_{j,:}} = \sum_{(b,t):I_{b,t}=j} \frac{\partial L}{\partial X_{b,t,:}}.$$

This equation explains both weight sharing across token occurrences and the frequency dependence of embedding updates.

Part 3 - Hints, controls, and evidence

1. Use unequal values for B, T, and d so an axis swap cannot pass by coincidence.
2. Compare lookup with direct row indexing, `weight[input_ids]`.
3. Backpropagate `output.sum()` and inspect gradients for used, unused, repeated, and padding rows.
4. Test float32 and float64 weights; IDs must remain integer in both cases.
5. Record shape, dtype, device, parameter count, and gradient-row norms.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E01(dtype=torch.float32, device="cpu"):
    V, d, pad = 11, 7, 0
    layer = nn.Embedding(V, d, padding_idx=pad,
                         device=device, dtype=dtype)
    ids = torch.tensor([[1, 2, 2, 0], [3, 1, 4, 0]],
                       dtype=torch.long, device=device)
    out = layer(ids)
    assert out.shape == (2, 4, d)
    assert out.dtype == layer.weight.dtype
    assert out.device == layer.weight.device
    assert torch.equal(out[0, 0], out[1, 1])
    assert torch.equal(out, layer.weight[ids])

    out.sum().backward()
    row_norms = layer.weight.grad.norm(dim=1)
    assert row_norms[pad] == 0
    assert row_norms[5] == 0
    assert row_norms[2] > row_norms[3]
    return out.detach(), row_norms
```

Part 5 - The Philosophy Behind the Exercise

Embeddings replace arbitrary names with learnable geometry. Tokens begin as discrete identities and acquire relations only through the gradients created by their contexts. The table is therefore a meeting point between symbolic data and continuous optimization.

The philosophical warning is equally important: geometry does not erase identity. Before similarity can be learned, ID integrity must be preserved. Meaningful representation depends on a correct index contract.

17.6.3 Exercise 02

Exercise Title: Implement Padding, Attention Masks, and Loss Masks and Prove They Align Correctly Across Batches

Part 1 - Why this matters

Variable-length sequences are usually padded into a rectangular batch, but a padding token is storage, not language. Three related objects must remain distinct. `input_ids` holds tokens including padding. An attention mask controls which key positions may supply information. A loss mask controls which target positions contribute to the objective. Reusing one tensor without stating its semantics invites silent mistakes.

Create a batch containing different lengths and construct all three objects. For causal language modeling, combine a lower-triangular causal rule with the key-padding rule. Replace ignored labels with `-100` and use the same `ignore_index` in cross entropy. Prove alignment by changing the ID stored in padded cells: logits at valid positions and the mean valid-token loss must remain unchanged when the mask is correct. Then remove the attention mask or loss mask and show which invariant fails.

Be precise about query padding. Masking padded keys prevents valid tokens from reading padding. Padded query rows may still produce finite outputs; they are harmless only if later consumers and the loss ignore them. Avoid fully masked softmax rows or define a stable policy for them.

Part 2 - Mathematical form and reasoning

For validity mask $P_{b,j} \in \{0, 1\}$ and causal rule $j \leq i$, define

$$M_{b,i,j} = \begin{cases} 0, & P_{b,j} = 1 \text{ and } j \leq i, \\ -\infty, & \text{otherwise.} \end{cases}$$

Attention weights are $A = \text{softmax}(QK^\top/\sqrt{d_k} + M)$. If labels are $y_{b,t}$ and $R_{b,t}$ marks valid targets, the mean loss is

$$L = -\frac{1}{\sum R_{b,t}} \sum_{b,t} R_{b,t} \log p_{b,t}(y_{b,t}).$$

Changing a padded token must not change either sum or any allowed attention distribution.

Part 3 - Hints, controls, and evidence

1. Print masks as integer matrices before converting them to additive form.

2. Assert every valid query assigns zero probability to padded and future keys and that each valid attention row sums to one.

3. Compare mean loss against a manual sum divided by the number of valid targets, not by $B \times T$.

4. Include lengths one, maximum length, and a batch with heavy padding.

5. Inject separate attention-mask and loss-mask faults; name the earliest violated invariant for each.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def make_batch(sequences, pad_id=0, ignore_index=-100):
    B, T = len(sequences), max(map(len, sequences))
    ids = torch.full((B, T), pad_id, dtype=torch.long)
    valid = torch.zeros(B, T, dtype=torch.bool)
    for b, seq in enumerate(sequences):
        ids[b, :len(seq)] = torch.tensor(seq)
        valid[b, :len(seq)] = True
    labels = torch.full_like(ids, ignore_index)
    labels[:, :-1] = ids[:, 1:]
    label_valid = torch.zeros_like(valid)
    label_valid[:, :-1] = valid[:, :-1] & valid[:, 1:]
    labels[~label_valid] = ignore_index
    causal = torch.tril(torch.ones(T, T, dtype=torch.bool))
    allowed = causal[None, :, :] & valid[:, None, :]
    return ids, valid, allowed, labels, label_valid

def E02():
    ids, valid, allowed, labels, loss_mask = make_batch(
        [[2, 5, 6, 3], [2, 8, 3]])
    B, T = ids.shape
    scores = torch.randn(B, T, T)
    weights = scores.masked_fill(~allowed, float("-inf")).softmax(-1)
    assert torch.all(weights.masked_select(~allowed) == 0)
    logits = torch.randn(B, T, 12)
    loss = F.cross_entropy(logits.flatten(0, 1), labels.flatten())
    manual = F.cross_entropy(logits[loss_mask], labels[loss_mask])
    assert torch.allclose(loss, manual)
    return ids, allowed, labels, loss
```

Part 5 - The Philosophy Behind the Exercise

Padding reveals a broad principle: physical representation and semantic content are not the same thing. Rectangular tensors are chosen for efficient computation, while masks restore the

irregular structure of the data.

A mask is therefore a statement of permission. It declares which information may be read and which predictions may become evidence for learning. Correct masking is not cleanup around the model; it defines the computation the model is allowed to perform.

17.6.4 Exercise 03

Exercise Title: Implement Subword Tokenization Conceptually and Compare It to Character Tokenization on Vocabulary Size

Part 1 - Why this matters

Character tokenization has excellent coverage and a small vocabulary, but it creates long sequences. Word tokenization creates shorter sequences but an unmanageable vocabulary and severe unknown-token behavior. Subword methods occupy the space between them: frequent patterns become single tokens while rare words remain representable as smaller pieces.

Implement a small pair-merging tokenizer inspired by byte-pair encoding. Begin with characters plus an end-of-word marker, count adjacent symbol pairs, merge the most frequent pair with deterministic tie-breaking, and repeat for a fixed budget. This pedagogical version need not reproduce a production BPE library; its purpose is to expose how the vocabulary and segmentation co-evolve. Save the ordered merge rules because tokenization cannot be reproduced from the final vocabulary alone.

Compare character and subword representations on the same train and evaluation texts. Measure vocabulary size, average tokens per word, sequence length, unknown rate, and round-trip fidelity. Include common compounds, rare words, misspellings, and text from outside the training domain. A smaller token count is not automatically better if the vocabulary table becomes expensive or segmentation becomes brittle.

Part 2 - Mathematical form and reasoning

At merge step m, let $c_m(a, b)$ be the frequency of adjacent pair (a, b) in the segmented training corpus. Select

$$(a_m, b_m) = \arg\max_{(a,b)} c_m(a, b)$$

using a declared tie rule, replace each non-overlapping occurrence by $a_m \cdot b_m$, and append that rule to an ordered list. The practical cost is governed by both table size V and token length T: embedding parameters scale as Vd, while dense self-attention scales approximately as $T^2 d$. Tokenization chooses a tradeoff between these costs.

Part 3 - Hints, controls, and evidence

1. Keep the end-of-word symbol so concatenation remains reversible and word boundaries are not guessed during decoding.
2. Apply learned merges in their recorded order at evaluation time.
3. Plot vocabulary size against mean and percentile sequence lengths across several merge budgets.

4. Separate training coverage from evaluation coverage and never learn merges from evaluation text.

5. Inspect segmentations individually; averages can hide catastrophic splits for names, numbers, or another writing system.

Part 4 - Python code skeleton

```
from collections import Counter

def word_symbols(word):
    return tuple(list(word) + ["</w>"])

def pair_counts(corpus):
    counts = Counter()
    for symbols, freq in corpus.items():
        for pair in zip(symbols, symbols[1:]):
            counts[pair] += freq
    return counts

def merge_pair(symbols, pair):
    out, i = [], 0
    while i < len(symbols):
        if i + 1 < len(symbols) and tuple(symbols[i:i+2]) == pair:
            out.append(symbols[i] + symbols[i+1]); i += 2
        else:
            out.append(symbols[i]); i += 1
    return tuple(out)

def train_merges(words, steps):
    corpus = Counter(word_symbols(w) for w in words)
    merges = []
    for _ in range(steps):
        counts = pair_counts(corpus)
        if not counts: break
        pair = min(counts, key=lambda p: (-counts[p], p))
        corpus = Counter({merge_pair(list(s), pair): f
                          for s, f in corpus.items()})
        merges.append(pair)
    return merges

def E03():
    words = "low lower lowest new newer widest".split()
    merges = train_merges(words, steps=8)
    # TODO: encode held-out words and compare with characters.
    return merges
```

Part 5 - The Philosophy Behind the Exercise

No tokenization is a neutral discovery of the units already present in language. It is a compression scheme that decides which patterns deserve an atomic name. Those decisions redistribute difficulty between the vocabulary, the sequence, and the model.

Subwords are powerful because they refuse the false choice between complete memorization and complete decomposition. They let frequent structure become convenient while preserving a path for novelty.

17.6.5 Exercise 04

Exercise Title: Debug Off-by-One Token Alignment Bugs in Next-Token Prediction Dataset Building

Part 1 - Why this matters

Next-token prediction is defined by a one-position shift. For a token sequence `[BOS, a, b, EOS]`, the inputs are `[BOS, a, b]` and the labels are `[a, b, EOS]`. A zero shift teaches copying; a two-position shift teaches a different forecasting task. All three pipelines produce compatible tensor shapes, finite losses, and gradients, so shape checks alone cannot find the error.

Build a token-by-token alignment ledger showing input position, visible prefix, target ID, and decoded target. Assert semantic relationships before batching. Then deliberately create zero-shift, two-shift, and wrap-around variants and observe their behavior on a simple sequence. A suspiciously easy loss may be evidence of label leakage rather than successful learning.

Define boundary behavior explicitly. The first input often begins with BOS; the last prediction may target EOS. Sliding windows must not use `roll` without removing the wrapped token. Document whether the model returns logits that a loss function shifts internally or whether the dataset already provides shifted labels; applying both conventions creates a double shift.

Part 2 - Mathematical form and reasoning

For full sequence $z = (z_0, \ldots, z_L)$, the causal training pair is

$$x_t = z_t, \qquad y_t = z_{t+1}, \qquad 0 \le t < L.$$

The log-likelihood factorization is

$$\log p(z_1, \ldots, z_L \mid z_0) = \sum_{t=0}^{L-1} \log p(z_{t+1} \mid z_0, \ldots, z_t).$$

This formula is the semantic oracle: label y_t must be the token immediately after the last token available at input position t. Equality of shapes does not imply equality of this conditional prediction task.

Part 3 - Hints, controls, and evidence

1. Begin with a sequence of unique, readable tokens so every shift is visible.
2. Assert `inputs[1:] == labels[:-1]` before padding.

3. Verify window start/end indices and forbid cross-document targets unless documents are intentionally packed with boundary tokens.

4. Decode at least the first and last training examples after collation.

5. Record loss for correct, copy-label, and shuffled-label controls; explain why the copy-label control can look deceptively strong.

Part 4 - Python code skeleton

```
import torch

def causal_pair(full_ids):
    assert len(full_ids) >= 2
    x = torch.tensor(full_ids[:-1], dtype=torch.long)
    y = torch.tensor(full_ids[1:], dtype=torch.long)
    assert torch.equal(x[1:], y[:-1])
    return x, y

def windows(ids, context):
    examples = []
    for start in range(0, len(ids) - context):
        chunk = ids[start:start + context + 1]
        x, y = causal_pair(chunk)
        examples.append((x, y))
    return examples

def alignment_ledger(x, y, itos):
    return [{"position": t, "input": itos[x[t].item()],
             "target": itos[y[t].item()]}
            for t in range(len(x))]

def E04():
    itos = ["<pad>", "<bos>", "A", "B", "C", "<eos>"]
    ids = [1, 2, 3, 4, 5]
    x, y = causal_pair(ids)
    wrong_copy = x.clone()
    assert not torch.equal(y, wrong_copy)
    return alignment_ledger(x, y, itos)
```

Part 5 - The Philosophy Behind the Exercise

Supervision is a claim about time: given this information, predict what comes next. An off-by-one bug alters that claim without altering the tensor's appearance. The model then optimizes faithfully for a task the engineer never intended.

This exercise teaches that semantics must be tested at the boundary where data becomes a learning objective. Numerical success cannot rescue a falsely stated question.

17.6.6 Exercise 05

Exercise Title: Build Dataset and Collate Function that Produces Input IDs, Attention Masks, and Labels for Training

Part 1 - Why this matters

The dataset defines examples; the collate function turns several examples into one tensor contract. Keeping those responsibilities separate makes variable lengths, dynamic padding, truncation, and debugging manageable. A collator that returns plausible tensors can still corrupt training by padding labels with a token ID, shifting after padding, or truncating EOS without recording the policy.

Implement a dataset that stores complete encoded sequences and creates causal input/label pairs without padding. The collator should pad each batch only to its local maximum length. It may optionally round that maximum to a convenient hardware multiple. Return `input_ids`, a Boolean attention mask, and `labels` padded with `-100`. State every axis: all three tensors are batch-first, and every location refers to the same example and time step.

Test the pipeline at three boundaries: inspect individual dataset items, inspect the first collated batch, and decode selected rows after collation. Prove that reordering the examples reorders rows but does not change each example's content. Measure padding ratio because dynamic batching may be correct yet waste most computation when lengths differ greatly.

Part 2 - Mathematical form and reasoning

For item n with causal pair $(x^{(n)}, y^{(n)})$ of length L_n, let $T = \max_n L_n$. The collated tensors satisfy

$$X_{n,t} = \begin{cases} x_t^{(n)} & t < L_n \\ i_{\text{pad}} & t \geq L_n, \end{cases} \qquad P_{n,t} = \mathbb{1}[t < L_n], \qquad Y_{n,t} = \begin{cases} y_t^{(n)} & t < L_n \\ -100 & t \geq L_n. \end{cases}$$

The useful-token fraction is $\rho = \sum_n L_n/(BT)$. Reporting $1 - \rho$ reveals padding waste independently of model throughput.

Part 3 - Hints, controls, and evidence

1. Reject sequences shorter than two tokens before creating a pair.
2. Apply truncation before the one-token shift and state whether EOS is preserved or replaced at the boundary.
3. Assert `attention_mask == (labels != -100)` for the simple causal case; document exceptions for other tasks.
4. Use a batch with lengths 2, 5, and 9 to make padding visible.
5. Return lengths or example IDs in debug mode so a failing row can be traced to its raw source.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import Dataset

class CausalDataset(Dataset):
    def __init__(self, encoded, max_full_length=None):
        self.examples = []
        for full in encoded:
            if max_full_length is not None:
                full = full[:max_full_length]
            if len(full) >= 2:
                self.examples.append(torch.tensor(full, dtype=torch.long))
    def __len__(self): return len(self.examples)
    def __getitem__(self, i):
        z = self.examples[i]
        return {"input_ids": z[:-1], "labels": z[1:], "id": i}

def collate_causal(items, pad_id=0, multiple=1):
    B = len(items)
    T0 = max(len(x["input_ids"]) for x in items)
    T = ((T0 + multiple - 1) // multiple) * multiple
    ids = torch.full((B, T), pad_id, dtype=torch.long)
    labels = torch.full((B, T), -100, dtype=torch.long)
    mask = torch.zeros(B, T, dtype=torch.bool)
    for b, item in enumerate(items):
        L = len(item["input_ids"])
        ids[b, :L] = item["input_ids"]
        labels[b, :L] = item["labels"]
        mask[b, :L] = True
    assert torch.equal(mask, labels.ne(-100))
    return {"input_ids": ids, "attention_mask": mask,
            "labels": labels, "example_ids": [x["id"] for x in items]}

def E05():
    ds = CausalDataset([[1, 4, 2], [1, 7, 8, 9, 2]])
    return collate_causal([ds[0], ds[1]], multiple=4)
```

Part 5 - The Philosophy Behind the Exercise

A batch is not merely several examples stacked together. It is a temporary agreement that maps irregular semantic objects into regular computation. Collation is where that agreement becomes executable.

Good data engineering preserves provenance while enabling efficiency. The ideal batch is fast to process, but it must also remain possible to point from any tensor cell back to the token, example, and rule that created it.

17.6.7 Exercise 06

Exercise Title: Implement Label Smoothing for Language Modeling and Measure Its Effect on Perplexity and Calibration

Part 1 - Why this matters

Ordinary cross entropy treats the observed target as probability one and every other token as probability zero. Natural-language supervision is rarely that certain: several continuations can be reasonable, annotation may be noisy, and a finite corpus does not describe the whole distribution. Label smoothing reduces the reward for extreme confidence by assigning a small target mass to alternative classes.

Implement smoothed cross entropy manually before using the framework option. Apply it only to valid target positions; padding must not receive either the one-hot or uniform component. Decide whether the smoothing distribution covers all vocabulary IDs or excludes structurally impossible special tokens, and document the choice. Compare $\epsilon = 0$ with several nonzero values under the same initialization and training budget.

Measure validation negative log-likelihood, token accuracy, expected calibration error, confidence histograms, and perplexity. Compute reported perplexity from the ordinary unsmoothed validation NLL even when training uses smoothing; exponentiating the smoothed training objective produces a number that is not directly comparable to standard perplexity. A better calibration score accompanied by worse likelihood is a tradeoff, not an automatic win.

Part 2 - Mathematical form and reasoning

For target class y, vocabulary size V, and smoothing ϵ, one common target distribution is

$$q_k = \begin{cases} 1 - \epsilon, & k = y, \\ \epsilon/(V-1), & k \neq y. \end{cases} \qquad L_{\text{smooth}} = -\sum_{k=1}^{V} q_k \log p_k.$$

For valid positions $\mathcal{I}$, the batch loss is $|\mathcal{I}|^{-1} \sum_{i \in \mathcal{I}} L_i$. Standard perplexity remains

$$\text{PPL} = \exp\left(-\frac{1}{|\mathcal{I}|} \sum_{i \in \mathcal{I}} \log p_i(y_i) \right).$$

Part 3 - Hints, controls, and evidence

1. Verify the manual loss equals ordinary cross entropy at $\epsilon = 0$.
2. Assert every smoothed target row sums to one and ignored rows contribute exactly zero.
3. Fit calibration bins using predicted confidence and correctness on held- out valid tokens only.
4. Repeat with matched seeds and report mean and dispersion, not only the best smoothing value.
5. Inspect rare tokens separately; uniform smoothing can affect them differently from frequent tokens.

Part 4 - Python code skeleton

```
import math, torch
import torch.nn.functional as F

def smoothed_ce(logits, labels, eps, ignore_index=-100):
    V = logits.size(-1)
    flat_logits = logits.reshape(-1, V)
    flat_labels = labels.reshape(-1)
    valid = flat_labels.ne(ignore_index)
    logp = F.log_softmax(flat_logits[valid].float(), dim=-1)
    y = flat_labels[valid]
    nll = -logp.gather(1, y[:, None]).squeeze(1)
    other = -(logp.sum(1) - logp.gather(1, y[:, None]).squeeze(1))
    other = other / (V - 1)
    return ((1 - eps) * nll + eps * other).mean()

@torch.no_grad()
def standard_nll_and_ppl(logits, labels):
    loss = F.cross_entropy(logits.flatten(0, 1).float(),
                           labels.flatten(), ignore_index=-100)
    return loss.item(), math.exp(loss.item())

def E06():
    torch.manual_seed(6)
    logits = torch.randn(3, 5, 17, requires_grad=True)
    labels = torch.randint(0, 17, (3, 5)); labels[1, 4] = -100
    base = smoothed_ce(logits, labels, 0.0)
    ref = F.cross_entropy(logits.flatten(0, 1), labels.flatten())
    assert torch.allclose(base, ref)
    return {e: smoothed_ce(logits, labels, e).item()
            for e in (0.0, 0.05, 0.1, 0.2)}
```

Part 5 - The Philosophy Behind the Exercise

Label smoothing distinguishes learning from certainty. The objective should encourage the model to prefer the observed answer without pretending that the dataset is an infallible description of every possible future.

Yet humility cannot be inserted blindly. Smoothing changes the question being optimized, so its value must be judged through likelihood, calibration, and task behavior together. Responsible uncertainty is measured uncertainty.

17.6.8 Exercise 07

Exercise Title: Implement Tied Input-Output Embeddings and Explain Why Weight Tying Improves Parameter Efficiency

Part 1 - Why this matters

A language model first uses an embedding matrix to convert token IDs into vectors, then uses an output matrix to compare hidden states with vocabulary classes. Both matrices connect the same vocabulary to the same model space. Weight tying uses one *Parameter* for both roles instead of learning two independent tables. This can reduce a large fraction of model parameters and encourage a coherent input/output geometry.

Implement an embedding and a bias-free language-model head, then assign `lm_head.weight = token_embedding.weight`. Verify object identity and storage identity; merely copying equal values is not tying. The hidden dimension must equal the embedding dimension unless an additional projection is inserted. Count unique parameters before and after tying, perform a backward pass, and show that the shared table receives gradients from both lookup and output-logit paths.

Test checkpoint save/load and optimizer construction. Tie weights before creating the optimizer so a single shared parameter is updated once. Consider the padding row carefully: `padding_idx` suppresses gradient from the lookup path, but the same row can still receive output-head gradient because PAD is one of the classes. Masking labels is not equivalent to removing PAD from the output normalization.

Part 2 - Mathematical form and reasoning

With $E \in \mathbb{R}^{V \times d}$ and hidden state $h_t \in \mathbb{R}^d$,

$$x_t = E_{i_t,:}, \qquad z_t = Eh_t + b, \qquad p_t = \text{softmax}(z_t).$$

Untied input and output matrices use $2Vd$ weights; tying uses Vd weights, saving Vd parameters. The total gradient is the sum of contributions from both computational uses:

$$\nabla_E L = (\nabla_E L)_{\text{input}} + (\nabla_E L)_{\text{output}}.$$

Part 3 - Hints, controls, and evidence

1. Compare `id(weight)`, `data_ptr()`, and optimizer parameter IDs; equality of tensor values is insufficient.
2. Modify one element under `no_grad` and prove both modules observe the change.
3. Measure parameter count and checkpoint size for tied and untied variants.
4. Isolate gradient paths by detaching the input use, then the output use.
5. Verify tying survives state-dict loading and device/dtype conversion.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class TiedLanguageHead(nn.Module):
    def __init__(self, vocab_size, d_model, pad_id=0, tied=True):
```

```
        super().__init__()
        self.embedding = nn.Embedding(vocab_size, d_model,
                                      padding_idx=pad_id)
        self.lm_head = nn.Linear(d_model, vocab_size, bias=False)
        if tied:
            self.lm_head.weight = self.embedding.weight
    def forward(self, ids):
        hidden = self.embedding(ids)
        return self.lm_head(hidden)

def unique_parameters(module):
    return {id(p): p for p in module.parameters()}

def E07():
    model = TiedLanguageHead(101, 32, tied=True)
    assert model.embedding.weight is model.lm_head.weight
    input_ptr = model.embedding.weight.data_ptr()
    output_ptr = model.lm_head.weight.data_ptr()
    assert input_ptr == output_ptr
    assert sum(p.numel() for p in unique_parameters(model).values()) == 101*32
    ids = torch.tensor([[1, 4, 9, 2]])
    model(ids).sum().backward()
    assert model.embedding.weight.grad is model.lm_head.weight.grad
    return model
```

Part 5 - The Philosophy Behind the Exercise

Weight tying expresses a symmetry: the space used to understand a token can also be used to ask which token a hidden state resembles. It turns two interfaces into two views of one representational language.

Parameter efficiency here is not compression after thought; it is a structural hypothesis about meaning. Sharing is valuable when the roles genuinely belong to the same geometry, and dangerous when that assumption is left unexamined.

17.6.9 Exercise 08

Exercise Title: Implement Positional Encoding Integration into Embeddings and Confirm Shapes and Device Placement

Part 1 - Why this matters

Token embeddings say what appears; positional representations say where it appears. Their sum is the actual input to the first Transformer block. Because both tensors share the external shape `(B,T,d_model)`, an off-by-one position offset or a device mismatch can hide until a later stage. Build the integration as a named module with a written contract rather than an anonymous addition in the training loop.

Implement token lookup, optional multiplication by $\sqrt{d}$, selection of positional rows, addition, and dropout. Support an explicit `offset` so cached autoregressive generation can assign

positions continuing after a prefix. Assert that `offset + T` does not exceed the supported maximum. Position tensors must be on the same device as token states and must have a compatible floating dtype. Token IDs remain integer.

Padding masks are not added to embeddings. A padded location may receive a token and position vector for rectangular computation, but attention and loss masks decide whether it participates semantically. Compare two identical token sequences with different offsets and two different batches at the same offset to confirm exactly which values should match.

Part 2 - Mathematical form and reasoning

For token ID $I_{b,t}$ and absolute position $o + t$,

$$H^{(0)}_{b,t,:} = \alpha E_{I_{b,t},:} + P_{o+t,:}, \qquad \alpha \in \{1, \sqrt{d}\}.$$

$E \in \mathbb{R}^{V \times d}$, $P \in \mathbb{R}^{T_{\max} \times d}$, and the result has shape $B \times T \times d$. Broadcasting of $P[o : o + T]$ over the batch axis is intentional; broadcasting over a feature or sequence axis is not.

Part 3 - Hints, controls, and evidence

1. Use registered buffers for fixed encodings and Parameters for learned positions. Then device conversion will behave correctly.
2. Test $B \neq T \neq d$, offsets zero and nonzero, and the exact maximum supported length.
3. Disable dropout for deterministic equality tests, then verify stochastic behavior appears only in training mode.
4. Inspect state dicts: learned positions belong in parameters; fixed encodings may be persistent or reproducibly regenerated by policy.
5. Deliberately leave positions on CPU during a CUDA pass and confirm the device audit finds the error before addition.

Part 4 - Python code skeleton

```
import math, torch
from torch import nn

class InputEmbeddings(nn.Module):
    def __init__(self, vocab, d_model, max_length, pad_id=0, dropout=0.1):
        super().__init__()
        self.tokens = nn.Embedding(vocab, d_model, padding_idx=pad_id)
        self.positions = nn.Embedding(max_length, d_model)
        self.scale = math.sqrt(d_model)
        self.dropout = nn.Dropout(dropout)
    def forward(self, input_ids, offset=0):
        B, T = input_ids.shape
        if offset < 0 or offset + T > self.positions.num_embeddings:
            raise ValueError("position range exceeds configured maximum")
        position_ids = torch.arange(offset, offset + T,
```

```
                                    device=input_ids.device)
        x = self.tokens(input_ids) * self.scale
        p = self.positions(position_ids)[None, :, :]
        assert x.device == p.device and x.dtype == p.dtype
        return self.dropout(x + p)

def E08(device="cpu"):
    module = InputEmbeddings(50, 12, 32, dropout=0.0).to(device)
    ids = torch.tensor([[1, 5, 2], [1, 5, 2]], device=device)
    y0, y4 = module(ids, 0), module(ids, 4)
    assert y0.shape == (2, 3, 12) and torch.equal(y0[0], y0[1])
    assert not torch.equal(y0, y4)
    return y0, y4
```

Part 5 - The Philosophy Behind the Exercise

Representation is formed by superposition: identity and location become one state that later layers can reinterpret. The addition is simple, but the conceptual result is profound—the same token can mean something different because of where it occurs.

Interfaces of great consequence are often numerically small. A single tensor addition can encode the distinction between a bag of symbols and an ordered sequence. Simplicity of code must not be mistaken for simplicity of meaning.

17.6.10 Exercise 09

Exercise Title: Build a Full Tokenization Debugging Checklist Covering Special Tokens, Padding Rules, and Shifted Labels

Part 1 - Why this matters

Token-pipeline failures are unusually deceptive. A changed vocabulary order, missing EOS, inverted mask, or double-shifted label can leave every tensor finite and every matrix multiplication legal. A debugging checklist must therefore test semantic properties at successive boundaries, not merely run the model and wait for an exception.

Turn the checklist into executable checks. Cover normalization and pre- tokenization, stable special IDs, vocabulary uniqueness, encode/decode behavior, unknown-token policy, range checks, causal shifting, truncation, padding, attention masks, loss masks, position indices, dtype/device placement, serialization, and training/serving parity. Each failure message should include the example ID and the earliest boundary at which the contract broke.

Build a fault-injection table. Swap BOS and EOS, pad labels with PAD rather than `-100`, invert a mask, shift labels twice, rebuild the vocabulary with a different tie order, and remove a Unicode normalization step. For each fault, state which test should fail first. A useful checklist is judged by detection latency and diagnostic specificity, not by length.

Part 2 - Mathematical form and reasoning

Model the pipeline as functions

$$s \xrightarrow{\tau} u \xrightarrow{v} z \xrightarrow{g} (x, y) \xrightarrow{c} (X, Y, P) \xrightarrow{m} L.$$

If an end-to-end property fails, search for the smallest k such that the output of stage k violates its local invariant. Examples include $v^{-1}(v(u)) = u$ for known tokens, $x_{t+1} = y_t$ for causal pairs, and $P_{b,t} = 0 \Rightarrow Y_{b,t} = -100$ for the basic collator. Local invariants convert an opaque bad loss into a bounded diagnosis.

Part 3 - Hints, controls, and evidence

1. Store golden encoded examples, including punctuation, Unicode, empty text, unknowns, and maximum-length input.
2. Separate universal invariants from configurable policies. Record every selected policy.
3. Check tokenizer and vocabulary fingerprints when loading every checkpoint.
4. Decode random training batches periodically; raw IDs conceal semantic errors that become obvious in text.
5. Run every injected fault and record whether it was detected, at which stage, and with what message.

Part 4 - Python code skeleton

```
import hashlib, json, torch

def vocab_fingerprint(tokens, config):

    return checks
```

Part 5 - The Philosophy Behind the Exercise

A checklist is institutional memory made executable. It preserves lessons that would otherwise be rediscovered only after another expensive training run. Its purpose is not bureaucracy; it is to move reasoning from emergency response to routine prevention.

The best diagnostic system follows causality backward. It does not merely say that the final metric is wrong. It identifies the earliest broken promise from which the later failure became inevitable.

17.6.11 Exercise 10

Exercise Title: Train Embedding and Tokenization Pipeline on CUDA Efficiently and Benchmark Host-to-Device Transfer Costs

Part 1 - Why this matters

Moving a model to CUDA does not make the data pipeline fast. Text normalization and tokenization are usually CPU operations; batches of integer IDs are then copied to the accelerator. If tokenization, collation, or transfer takes longer than the training step, the GPU waits idle. Conversely, moving many tiny tensors individually can cost more than the useful computation.

Build an end-to-end benchmark with separate timers for CPU preparation, host-to-device transfer, forward/backward computation, and optimizer update. Use pinned host memory and `non_blocking=True` only as a matched pair, then verify whether they overlap transfer with computation in the actual pipeline. Pre-tokenize static text when appropriate, collate into contiguous batch tensors, and transfer a small dictionary of tensors once per step. Do not attempt to move Python strings to CUDA.

CUDA launches are asynchronous, so wall-clock timing without synchronization is misleading. Use CUDA events for GPU intervals or synchronize immediately before and after a measured region. Include warm-up iterations, multiple repetitions, median and percentile latency, tokens per second, and peak allocated memory. Validate output parity before interpreting speed.

Part 2 - Mathematical form and reasoning

Let N be valid tokens processed in measured time

$$t_{\text{step}} = t_{\text{prepare}} + t_{\text{transfer}} + t_{\text{compute}} - t_{\text{overlap}}.$$

Throughput is N/t_{step}. The transfer fraction $r = t_{\text{transfer}}/t_{\text{step}}$ is diagnostic only when intervals were measured consistently. Approximate transfer bandwidth is $B_{\text{copy}} = S/t_{\text{transfer}}$ for S bytes. The theoretical byte count must include IDs, masks, and labels; it must not include Python object memory that never reaches the device.

Part 3 - Hints, controls, and evidence

1. Establish a CPU correctness baseline and compare one fixed batch on CPU and CUDA before benchmarking.
2. Warm up allocator, kernels, and compilation paths; exclude warm-up from statistics.
3. Compare pageable/blocking, pinned/blocking, and pinned/nonblocking configurations with identical batches.
4. Record valid tokens and padded tokens separately; samples per second can hide padding waste.
5. Test several batch/sequence sizes because transfer dominance changes with arithmetic intensity.

Part 4 - Python code skeleton

```
import time, torch

def move_batch(batch, device):
    return {k: v.to(device, non_blocking=True)
            for k, v in batch.items() if torch.is_tensor(v)}

def benchmark_step(model, batch, repeats=50):
    assert torch.cuda.is_available()
    device = torch.device("cuda")
    model.to(device).train()
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    times = []
    for i in range(10 + repeats):
        gpu_batch = move_batch(batch, device)
        start.record()
        logits = model(gpu_batch["input_ids"],
                       gpu_batch["attention_mask"])
        loss = torch.nn.functional.cross_entropy(
            logits.flatten(0, 1), gpu_batch["labels"].flatten(),
            ignore_index=-100)
        loss.backward(); model.zero_grad(set_to_none=True)
        end.record(); end.synchronize()
        if i >= 10: times.append(start.elapsed_time(end))
    valid = batch["attention_mask"].sum().item()
    return {"median_ms": torch.tensor(times).median().item(),
            "valid_tokens_per_step": valid}

def E10(model, pinned_batch):
    assert all((not v.is_cuda) for v in pinned_batch.values()
               if torch.is_tensor(v))
    return benchmark_step(model, pinned_batch)
```

Part 5 - The Philosophy Behind the Exercise

Acceleration is a property of a system, not a device label. A fast GPU cannot compute data that has not arrived, and asynchronous execution can make poor measurement look like improvement.

The broader lesson is that performance claims require a causal accounting of time. Optimization begins by finding where the system waits, then changing the specific boundary responsible for that wait.

17.6.12 Exercise 11

Exercise Title: Benchmark DataLoader Performance for Token Sequences and Optimize num_workers, pin_memory, and prefetching

Part 1 - Why this matters

A DataLoader connects storage and CPU preprocessing to accelerator training. Its tuning parameters are not universal performance switches. `num_workers` can parallelize expensive tokenization, but too many workers increase process startup, memory duplication, and scheduling overhead. `pin_memory` can accelerate transfer to CUDA, but costs page-locked host memory. `prefetch_factor` hides latency only when future batches can be prepared without exhausting RAM.

Construct a configuration grid across worker counts, pinned versus pageable memory, persistent workers, and prefetch depths. Benchmark two stages: loader- only throughput on CPU and end-to-end training throughput on CUDA. A loader can produce batches quickly in isolation yet still fail to overlap with training. Use the same dataset order, batch size, collation policy, and number of measured valid tokens for every configuration.

Separate cold-start from steady state. Persistent workers can improve later epochs while making the first epoch appear unchanged. Control randomness by seeding each worker and dataset sampler. Detect duplicate or missing example IDs; faster batches are invalid if multi-worker partitioning silently repeats data.

Part 2 - Mathematical form and reasoning

If batch preparation time is t_p and consumption time is t_c, ideal overlap approaches

$$\max(t_p, t_c)$$

per batch rather than $t_p + t_c$. Define starvation fraction

$$s = \frac{t_{\text{waiting for next batch}}}{t_{\text{epoch}}}.$$

Report useful-token throughput

$$R = \frac{\sum_b \sum_t P_{b,t}}{t_{\text{measured}}},$$

not only raw batches per second. Different length distributions can make these metrics disagree.

Part 3 - Hints, controls, and evidence

1. Run each configuration several times after warm-up and randomize the configuration order to reduce thermal and cache bias.
2. Monitor host RAM, pinned memory, CPU utilization, queue wait, GPU utilization, and valid-token throughput.
3. Use `persistent_workers` only when `num_workers > 0`.
4. Measure pre-tokenized and on-the-fly-tokenized datasets separately.
5. Select the smallest configuration statistically indistinguishable from the fastest one; spare resources improve system stability.

Part 4 - Python code skeleton

```
import random, time, torch
from torch.utils.data import DataLoader

def seed_worker(worker_id):
    seed = torch.initial_seed() % (2**32)
    random.seed(seed)

def loader_trial(dataset, collate_fn, cfg, batches=100):
    kwargs = dict(batch_size=cfg["batch_size"], shuffle=False,
                  num_workers=cfg["workers"],
                  pin_memory=cfg["pin_memory"],
                  collate_fn=collate_fn, worker_init_fn=seed_worker)
    if cfg["workers"] > 0:
        kwargs.update(prefetch_factor=cfg["prefetch"],
                      persistent_workers=cfg["persistent"])
    loader = DataLoader(dataset, **kwargs)
    seen, tokens = [], 0
    start = time.perf_counter()
    for i, batch in enumerate(loader):
        seen.extend(batch["example_ids"])
        tokens += batch["attention_mask"].sum().item()
        if i + 1 == batches: break
    elapsed = time.perf_counter() - start
    assert len(seen) == len(set(seen))
    return {"seconds": elapsed, "valid_tokens_s": tokens / elapsed}

def E11(dataset, collate_fn):
    configs = [{"batch_size": 32, "workers": w,
                "pin_memory": p, "prefetch": 2,
                "persistent": w > 0}
               for w in (0, 2, 4, 8) for p in (False, True)]
    return [(c, loader_trial(dataset, collate_fn, c)) for c in configs]
```

Part 5 - The Philosophy Behind the Exercise

Concurrency is useful only when it removes a real dependency. More workers do not create information or computation; they rearrange when preparation happens and what resources remain occupied.

Performance tuning is therefore empirical resource coordination. The chosen configuration should be fast, reproducible, and stable within the limits of the whole machine, not merely the maximum of one benchmark column.

17.6.13 Exercise 12

Exercise Title: Compare float32 vs mixed precision embedding stability and detect overflow or underflow edge cases

Part 1 - Why this matters

Embedding lookup performs no long reduction; it gathers rows. This can make the layer seem automatically safe in reduced precision. Training behavior is more subtle. Embedding values are consumed by additions, normalization, attention, and output logits; rare-token gradients may be small, repeated-token gradients may be large, and tied output embeddings participate in vocabulary-wide matrix multiplication. Mixed precision affects the surrounding computation and the optimizer update even when indexing itself is exact.

Compare float32 with autocast mixed precision using identical initial weights, IDs, masks, labels, and optimizer steps. Inspect forward embeddings, logits, loss, row-wise gradients, and parameter deltas. Sweep the scale of embedding weights and upstream hidden states until nonfinite values, saturation, or updates rounded to zero appear. Include frequent, rare, unused, and padding rows. Keep IDs as `torch.long`; converting IDs to floating point is never part of mixed precision.

Use gradient scaling for CUDA training and log scale changes and skipped optimizer steps. Do not declare mixed precision stable because the scalar loss is finite: compare the exact rows that should have changed. In common optimizers, master parameters or optimizer states may remain float32 even when activations use lower precision; record the actual policy.

Part 2 - Mathematical form and reasoning

For rounding operator fl_q in precision q, lookup produces $\widehat{x} = \mathrm{fl}_q(E_i)$. A useful forward error measure is

$$\epsilon_x = \frac{\|x_{32} - \widehat{x}_q\|_2}{\|x_{32}\|_2 + \delta}.$$

For an update $\Delta E = -\eta g$, reduced precision may satisfy

$$\mathrm{fl}_q(E + \Delta E) = \mathrm{fl}_q(E)$$

when the update is below local representable spacing. This update-loss test is more informative than checking whether g was nonzero before casting.

Part 3 - Hints, controls, and evidence

1. Clone one float32 reference state into every precision condition.
2. Compare bfloat16 and float16 separately where hardware supports them; their range and precision differ.
3. Record absolute error, relative error, cosine similarity, non-finite counts, zero-gradient rows, and zero-update rows.
4. Force extreme scales in an isolated experiment, not in a valuable long training run.
5. Recheck tied embeddings because the output projection creates different numerical pressure than lookup alone.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def one_step(model, ids, labels, use_amp):
    model.zero_grad(set_to_none=True)
    before = model.embedding.weight.detach().float().clone()
    device_type = ids.device.type
    amp_dtype = torch.float16 if device_type == "cuda" else torch.bfloat16
    with torch.autocast(device_type=device_type, dtype=amp_dtype,
                        enabled=use_amp):
        logits = model(ids)
        loss = F.cross_entropy(logits.flatten(0, 1), labels.flatten())
    loss.backward()
    grad = model.embedding.weight.grad.detach().float().clone()
    with torch.no_grad():
        model.embedding.weight.add_(model.embedding.weight.grad, alpha=-1e-3)
    delta = model.embedding.weight.detach().float() - before
    return {"loss": loss.detach().float(), "grad": grad, "delta": delta,
            "finite": bool(torch.isfinite(logits).all())}

def E12(make_model, ids, labels):
    ref = make_model().to(ids.device)
    amp = make_model().to(ids.device); amp.load_state_dict(ref.state_dict())
    a = one_step(ref, ids, labels, False)
    b = one_step(amp, ids, labels, True)
    return {"fp32": a, "mixed": b,
            "delta_error": (a["delta"] - b["delta"]).abs().max().item()}
```

Part 5 - The Philosophy Behind the Exercise

Precision is a budget for distinctions. Reduced precision is valuable when it removes distinctions irrelevant to learning; it is harmful when it erases a small but necessary update or turns a large value into infinity.

The correct question is not whether a dtype is "accurate." It is whether the entire training process preserves the distinctions needed for the intended decision. Stability must be observed across values, gradients, and updates.

17.6.14 Exercise 13

Exercise Title: Visualize Embedding Space with Dimensionality Reduction Conceptually and Inspect Token Similarities

Part 1 - Why this matters

An embedding table may contain thousands of dimensions and cannot be inspected directly. Dimensionality reduction and nearest-neighbor analysis can reveal collapsed rows, frequency bands, outliers, duplicated special tokens, or local semantic structure. They are diagnostic lenses, not proofs that the model understands a concept. A two-dimensional projection discards information and can create apparent clusters that do not exist in the original geometry.

Extract trained embeddings together with token strings and training frequencies. Compare raw Euclidean neighborhoods with cosine neighborhoods after row normalization. Center the table before PCA and record how much variance the selected components explain. If using a nonlinear method such as t-SNE or UMAP, run multiple seeds and settings; local visual proximity may be sensitive to those choices. Always compare against the randomly initialized table.

Select queries before looking at the plot: frequent function tokens, rare tokens, morphological variants, punctuation, BOS/EOS/PAD, and known domain terms. Report nearest neighbors in the original d-dimensional space as the primary evidence and use the projection to organize questions. Test whether frequency or vector norm explains the pattern before calling it semantic.

Part 2 - Mathematical form and reasoning

Cosine similarity is

$$s(i,j) = \frac{E_i^\top E_j}{\|E_i\|_2 \|E_j\|_2}.$$

For centered table $E_c = E - \mathbf{1}\mu^\top$, PCA finds orthonormal directions W_k maximizing retained variance, and the projection is $Z = E_c W_k$. The explained variance ratio

$$r_k = \frac{\sum_{j=1}^{k} \lambda_j}{\sum_{j=1}^{d} \lambda_j}$$

states how much global linear variance remains. It does not measure preserved semantic meaning.

Part 3 - Hints, controls, and evidence

1. Exclude or separately label PAD and other special tokens; their training roles differ from ordinary text.
2. Compare initialized, partially trained, and final tables using the same queries and metrics.
3. Color by log frequency and size points by vector norm to expose confounding structure.
4. Report neighbor overlap across seeds and checkpoints rather than choosing one attractive figure.

5. Use downstream probes or controlled interventions before claiming that a visible direction causally represents an attribute.

Part 4 - Python code skeleton

```
import torch

def cosine_neighbors(weight, query_id, k=8, exclude=()):
    w = torch.nn.functional.normalize(weight.float(), dim=1)
    scores = w @ w[query_id]
    scores[list(exclude) + [query_id]] = -float("inf")
    values, ids = scores.topk(k)
    return list(zip(ids.tolist(), values.tolist()))

def pca_projection(weight, dimensions=2):
    x = weight.detach().float().cpu()
    x = x - x.mean(0, keepdim=True)
    _, singular, vectors = torch.pca_lowrank(x, q=min(x.shape))
    z = x @ vectors[:, :dimensions]
    explained = singular.square()
    ratio = explained[:dimensions].sum() / explained.sum()
    return z, ratio.item()

def E13(model, itos, query_ids, frequencies):
    weight = model.embedding.weight.detach()
    z, retained = pca_projection(weight)
    neighbors = {itos[q]: [(itos[i], s) for i, s in
                 cosine_neighbors(weight, q)] for q in query_ids}
    return {"projection": z, "variance_retained": retained,
            "neighbors": neighbors, "frequencies": frequencies}
```

Part 5 - The Philosophy Behind the Exercise

Visualization translates an inaccessible space into a human-scale question. It is valuable because it guides attention, but dangerous when the translation is mistaken for the original object. A map can reveal where to investigate; it cannot certify what the territory means.

Interpretability begins with disciplined modesty. Patterns become knowledge only when they survive alternative projections, quantitative tests, controls, and interventions.

17.6.15 Exercise 14

Exercise Title: Create Unit Tests that Validate Tokenization, Padding, and Label Alignment for Multiple Sequence Lengths

Part 1 - Why this matters

The token pipeline is deterministic enough to test exactly and important enough that approximate validation is inadequate. Unit tests should catch errors before a GPU training run

begins. They must cover both golden examples with known outputs and general properties over many lengths and token values.

Create tests for normalization, token boundaries, special IDs, unknowns, encode/decode round trips, vocabulary serialization, causal pairs, dynamic padding, attention masks, ignored labels, truncation, and position limits. Parameterize them over empty input, minimum valid length, typical lengths, maximum length, and mixed-length batches. Include Unicode, punctuation, repeated tokens, and unknown items. An all-empty batch should be rejected with a useful message rather than producing a zero-denominator loss.

Add fault-injection or mutation tests. Change one line of expected behavior— invert a mask, copy inputs into labels, use PAD as the ignored target, or swap special IDs—and prove at least one focused test fails. A suite that passes only the implementation that inspired it can miss shared assumptions; property tests and an independently written manual oracle reduce this risk.

Part 2 - Mathematical form and reasoning

Define an invariant set $\mathcal{C}$ over pipeline output. Examples are

$$0 \le X_{b,t} < V, \qquad P_{b,t} = 0 \Rightarrow X_{b,t} = i_{\text{pad}} \wedge Y_{b,t} = -100,$$

$$x_{t+1}^{(n)} = y_t^{(n)}, \qquad \text{decode}(\text{encode}(s)) \sim s,$$

where $\sim$ means equality under the declared normalization policy. A test suite samples inputs from the valid domain and verifies all applicable members of $\mathcal{C}$, while golden tests verify exact expected outputs.

Part 3 - Hints, controls, and evidence

1. Keep five-token golden cases readable enough to verify without code.
2. Use unequal sequence lengths and shuffle example order to expose hidden axis and state assumptions.
3. Test serialization round trips in a temporary directory and compare a stable vocabulary fingerprint.
4. Separate policy tests from universal invariants so intentional config changes require explicit golden-output updates.
5. Run the suite on CPU and, for tensor integration, one available CUDA device; tokenizer string logic remains a CPU concern.

Part 4 - Python code skeleton

```
import torch

def assert_batch_contract(batch, pad_id, vocab_size):
    x, y, p = batch["input_ids"], batch["labels"], batch["attention_mask"]
```

```
    assert x.shape == y.shape == p.shape
    assert x.dtype == y.dtype == torch.long and p.dtype == torch.bool
    assert ((0 <= x) & (x < vocab_size)).all()
    assert (x[~p] == pad_id).all() and (y[~p] == -100).all()
    assert (y[p] >= 0).all() and (y[p] < vocab_size).all()

def test_shift():
    full = torch.tensor([1, 8, 5, 2])
    x, y = full[:-1], full[1:]
    assert torch.equal(x[1:], y[:-1])
    assert x.tolist() == [1, 8, 5]
    assert y.tolist() == [8, 5, 2]

def test_lengths(dataset, collate, pad_id, vocab_size):
    for indices in ([0], [0, 1], [2, 0, 1]):
        batch = collate([dataset[i] for i in indices])
        assert_batch_contract(batch, pad_id, vocab_size)

def E14(dataset, collate, pad_id, vocab_size):
    test_shift()
    test_lengths(dataset, collate, pad_id, vocab_size)
    # TODO: golden tokenization, Unicode, unknown, truncation, serialization,
    # property cases, and injected faults.
    return "all pipeline tests passed"
```

Part 5 - The Philosophy Behind the Exercise

Tests are executable definitions of what the system means. They protect not only against syntax errors, but against gradual changes in normalization, special-token identity, and temporal alignment that would redefine the task.

The strongest test suite makes invisible assumptions visible. It allows the pipeline to evolve while forcing every semantic change to become a conscious, reviewable decision.

17.6.16 Exercise 15

Exercise Title: Implement Streaming Dataset Conceptually and Prevent Memory Blowups When Training on Large Text

Part 1 - Why this matters

Large corpora cannot always be tokenized and held in RAM before training. Streaming changes the data contract: examples arrive incrementally from ordered shards, and the pipeline must tokenize, buffer, shuffle, pack, and batch without materializing the entire corpus. Memory usage becomes bounded, but exact global shuffling and arbitrary indexing are no longer available.

Implement an `IterableDataset` that assigns disjoint shards to workers, reads records lazily, tokenizes each record, and emits causal chunks. Use a bounded shuffle buffer: fill it, choose a random item, replace it from the stream, and drain it at the end. This approximates shuffling

within a known memory budget. Record shard ID and record offset with every sample so duplicate or missing data can be diagnosed.

Define document-boundary policy. Either reset chunks at each document or pack documents with EOS separators; never let the target cross an invisible boundary. For distributed training, partition by rank as well as DataLoader worker. Design checkpoint resume around a recoverable cursor, RNG state, shard order, and buffer state. An epoch in a stream must have a declared meaning, such as a fixed manifest pass or a fixed token budget.

Part 2 - Mathematical form and reasoning

Let shards be $S_0, \ldots, S_{K-1}$ and let there be R ranks with W workers per rank. A simple disjoint assignment uses global consumer index $c = rW + w$ and selects shard S_j when

$$j \bmod (RW) = c.$$

If the shuffle buffer holds at most M encoded examples of maximum size L, its token storage is $O(ML)$ rather than $O(NL)$ for corpus size N. This bound must include Python and tokenizer object overhead in measured host memory, not only tensor bytes.

Part 3 - Hints, controls, and evidence

1. Test worker/rank assignments by collecting provenance IDs and proving pairwise disjointness and expected coverage.

2. Keep a manifest with stable shard checksums; resume is unsafe if source content changes under the same name.

3. Measure resident set size while consuming far more records than the buffer capacity; memory should reach a plateau.

4. Compare buffer sizes using neighbor correlation and token distribution, not the claim of perfect global shuffle.

5. Inject interruption, save state, resume, and prove no sample is silently replayed or skipped under the selected guarantee.

Part 4 - Python code skeleton

```
import random
from torch.utils.data import IterableDataset, get_worker_info

class StreamingText(IterableDataset):
    def __init__(self, shards, read_shard, encode, buffer_size=1024,
                 rank=0, world_size=1, seed=0):
        self.shards, self.read_shard, self.encode = shards, read_shard, encode
        self.buffer_size = buffer_size
        self.rank, self.world_size, self.seed = rank, world_size, seed
    def __iter__(self):
        info = get_worker_info()
        wid, workers = (0, 1) if info is None else (info.id, info.num_workers)
```

```
        consumer = self.rank * workers + wid
        consumers = self.world_size * workers
        rng, buffer = random.Random(self.seed), []
        for sid, shard in enumerate(self.shards):
            if sid % consumers != consumer: continue
            for offset, text in enumerate(self.read_shard(shard)):
                item = {"ids": self.encode(text),
                        "source": (sid, offset)}
                if len(buffer) < self.buffer_size:
                    buffer.append(item); continue
                j = rng.randrange(len(buffer))
                yield buffer[j]; buffer[j] = item
        rng.shuffle(buffer)
        yield from buffer

def E15(shards, read_shard, encode):
    return StreamingText(shards, read_shard, encode, buffer_size=256)
```

Part 5 - The Philosophy Behind the Exercise

Streaming replaces possession with disciplined passage. The system no longer needs to hold the dataset as one object; it needs guarantees about what enters, what has been consumed, and what can be reconstructed after interruption.

This is a shift from static data structure to temporal protocol. Bounded memory is achieved not by ignoring state, but by making the necessary state smaller, explicit, and recoverable.

17.6.17 Exercise 16

Exercise Title: Build a Minimal Training Dataset for Autoregressive Transformer and Verify Loss Decreases Correctly

Part 1 - Why this matters

Before training on a real corpus, a Transformer pipeline should deliberately overfit a tiny, inspectable dataset. This is not a generalization test. It is an integration test of tokenization, shifting, padding, causal masking, embeddings, logit dimensions, loss reduction, gradients, optimizer order, and generation. If a model with sufficient capacity cannot memorize a few repeated sequences, the pipeline is probably wrong.

Create several deterministic patterns containing BOS and EOS, split each into input and next-token labels, and train a minimal decoder-only model. Freeze the vocabulary after construction. Record the initial loss relative to the uniform baseline $\log V$, train until near-perfect token accuracy, and decode greedy continuations. Validate that loss decreases because the correct next-token probability rises, not because PAD labels leaked into the denominator or future tokens became visible.

Run negative controls. Shuffle labels while preserving their marginal distribution; remove causal masking; create copy labels; and freeze embeddings. The no-mask model may achieve an illegitimately easy loss, while shuffled labels should resist memorization unless capacity is

extreme. Inspect per-position loss because an average can hide a broken boundary token or one always-ignored column.

Part 2 - Mathematical form and reasoning

For valid target set $\mathcal{I}$,

$$L(\theta) = -\frac{1}{|\mathcal{I}|} \sum_{(b,t)\in\mathcal{I}} \log p_\theta(y_{b,t} \mid x_{b,\le t}).$$

A uniform model has expected NLL $\log V$. On a deterministic tiny corpus, a correct expressive model can approach $L \to 0$ and valid-token accuracy $\to 1$. The causal condition $x_{b,\le t}$ is essential: lower loss obtained from access to $x_{b,>t}$ does not validate autoregressive learning.

Part 3 - Hints, controls, and evidence

1. Use a vocabulary and sequences small enough to print in full.
2. Log gradients for token embeddings, positional embeddings, attention, FFN, and output head on the first step.
3. Track per-position NLL, valid-token accuracy, gradient norm, and selected next-token probabilities.
4. Generate from BOS after training; teacher-forced accuracy alone does not test autoregressive feedback.
5. Require the correct pipeline to pass and each injected fault to produce its predicted signature.

Part 4 - Python code skeleton

```
import math, torch
import torch.nn.functional as F

def train_tiny(model, loader, steps=500, lr=3e-3):
    optimizer = torch.optim.AdamW(model.parameters(), lr=lr)
    history = []
    iterator = iter(loader)
    for step in range(steps):
        try: batch = next(iterator)
        except StopIteration:
            iterator = iter(loader); batch = next(iterator)
        optimizer.zero_grad(set_to_none=True)
        logits = model(batch["input_ids"], batch["attention_mask"])
        loss = F.cross_entropy(logits.flatten(0, 1),
                               batch["labels"].flatten(),
                               ignore_index=-100)
        loss.backward(); optimizer.step()
        with torch.no_grad():
            valid = batch["labels"].ne(-100)
```

```
            predicted = logits.argmax(-1)[valid]
            expected = batch["labels"][valid]
            acc = (predicted == expected).float().mean()
        history.append((loss.item(), acc.item()))
    return history

def E16(model, loader, vocab_size):
    history = train_tiny(model, loader)
    assert history[-1][0] < min(math.log(vocab_size), history[0][0])
    assert history[-1][1] > 0.98
    # TODO: greedy generation and no-mask/copy/shuffled-label controls.
    return history
```

Part 5 - The Philosophy Behind the Exercise

The tiny-overfit test asks whether the entire learning machine can realize one small truth. It reduces complexity until excuses disappear. If memorization fails, adding more data and compute will conceal the defect rather than cure it.

Scientific confidence grows through controlled simplification. A small system whose behavior can be predicted is often a stronger foundation than a large system whose improving metric cannot be explained.

17.6.18 Exercise 17

Exercise Title: Stress Test Token Pipeline with Very Long Sequences and Detect Performance Bottlenecks and Memory Waste

Part 1 - Why this matters

Long context stresses every stage differently. Tokenization and Python object creation grow roughly with text length. Padding may multiply the number of stored tokens. Embeddings grow linearly with BTd, while dense attention-score storage grows with BHT^2. Positional tables and mask construction may become unexpected bottlenecks. A failure reported as "out of memory" is therefore not a diagnosis.

Build a safe stress matrix over sequence length, batch size, length variance, and vocabulary strategy. Increase one dimension at a time and run each case in an isolated process or with a conservative memory ceiling. Measure tokenization latency, collation latency, padding ratio, host memory, transfer time, device peak memory, forward/backward time, and valid tokens per second. Stop before resource exhaustion using an explicit threshold.

Partition memory conceptually into input IDs/masks/labels, embeddings, model parameters and optimizer states, attention/FFN activations, gradients, and allocator reserve. Compare measured increments with simple predictions. Test length bucketing, dynamic padding, document packing, truncation, and reduced batch size. These strategies change different terms, so report exactly which bottleneck each removes and what information tradeoff it introduces.

Part 2 - Mathematical form and reasoning

Approximate storage in bytes with element widths s_i and s_a:

$$M_{\text{ids}} \approx 2BTs_i + BTs_{\text{mask}}, \qquad M_{\text{embed}} \approx BTd\, s_a,$$

$$M_{\text{score}} \approx BHT^2 s_a.$$

Padding efficiency is $\rho = \sum_b L_b/(BT)$ and useful throughput is $R_{\text{useful}} = \rho BT/t$. Doubling T approximately quadruples the score term but only doubles ID and embedding terms. Deviations from these estimates help identify fused kernels, activation recomputation, or allocator effects.

Part 3 - Hints, controls, and evidence

1. Include a no-model loader benchmark, an embedding-only benchmark, a forward-only benchmark, and a full training benchmark.
2. Reset and read peak CUDA memory for each isolated configuration; record allocated and reserved memory separately.
3. Use synthetic length distributions as well as repeated fixed lengths to separate padding waste from quadratic attention cost.
4. Validate truncated/packed labels and document boundaries after every optimization.
5. Present Pareto points for context retained, useful throughput, and memory; do not recommend speed without its information cost.

Part 4 - Python code skeleton

```
import time, torch

def stress_case(model, make_batch, B, T, device="cuda"):
    if device == "cuda":
        torch.cuda.empty_cache(); torch.cuda.reset_peak_memory_stats()
    batch = make_batch(B, T)
    start = time.perf_counter()
    batch = {k: v.to(device) for k, v in batch.items()}
    if device == "cuda": torch.cuda.synchronize()
    transfer_s = time.perf_counter() - start
    start = time.perf_counter()
    logits = model(batch["input_ids"], batch["attention_mask"])
    loss = torch.nn.functional.cross_entropy(
        logits.flatten(0, 1), batch["labels"].flatten(), ignore_index=-100)
    loss.backward()
    if device == "cuda": torch.cuda.synchronize()
    compute_s = time.perf_counter() - start
    valid = batch["attention_mask"].sum().item()
    peak = (torch.cuda.max_memory_allocated() if device == "cuda" else None)
    return {"B": B, "T": T, "transfer_s": transfer_s,
            "compute_s": compute_s, "peak_bytes": peak,
            "useful_tokens_s": valid / compute_s}
```

```
def E17(model, make_batch):
    return [stress_case(model, make_batch, B, T)
            for T in (128, 256, 512, 1024) for B in (1, 4)]
```

Part 5 - The Philosophy Behind the Exercise

Scale does not merely enlarge a system; it changes which constraints dominate. An implementation correct at short length may reveal a quadratic assumption, an inefficient mask, or a hidden copy only when context grows.

Stress testing makes limits explicit before users discover them. Its purpose is not to force failure, but to learn the shape of the safe operating region and the price of extending it.

17.6.19 Exercise 18

Exercise Title: Build a Practical Guide for Choosing Tokenization Strategy and Maximum Sequence Length for Your Use Case

Part 1 - Why this matters

Tokenizer type, vocabulary size, and maximum sequence length are coupled system decisions. Character or byte units offer robust coverage but lengthen sequences. Large subword vocabularies shorten common text but enlarge embeddings and output projection, may fragment new domains poorly, and increase checkpoint size. Maximum length controls retained context while strongly affecting training memory and inference latency. There is no universally correct setting.

Build a decision guide beginning with requirements: languages and scripts, domain terminology, noise and spelling variation, reversibility, unknown-token tolerance, context needed for the target, memory ceiling, latency objective, data size, and deployment environment. Train candidate tokenizers on the same training split. Evaluate on in-domain and shifted data using unknown rate, tokens per character/word/document, tail sequence lengths, round-trip fidelity, vocabulary memory, and downstream quality under matched compute.

Choose maximum length from the distribution of information-bearing spans, not from the largest value the hardware can barely accept. Report the fraction of examples and targets truncated, the padding ratio after batching, and the quality/throughput curve. Consider chunking with overlap or retrieval when documents are long but the task depends on local evidence. Version every chosen artifact and list conditions that trigger reevaluation.

Part 2 - Mathematical form and reasoning

For tokenizer τ and maximum length T, define empirical coverage

$$C(T) = \frac{1}{N} \sum_{n=1}^{N} \mathbb{1}\left[|\tau(s_n)| \le T\right],$$

and retained-token ratio

$$R(T) = \frac{\sum_n \min(|\tau(s_n)|, T)}{\sum_n |\tau(s_n)|}.$$

A candidate can be represented by vector $(Q, R_{\text{useful}}, M, L, C)$ for quality, throughput, memory, latency, and coverage. Prefer Pareto-optimal candidates; a single weighted score should be used only when weights come from explicit product or research requirements.

Part 3 - Hints, controls, and evidence

1. Compare character, byte, word, and at least two subword vocabulary budgets on identical data splits.
2. Report percentiles, not only mean sequence length; the tail often controls memory and truncation policy.
3. Inspect languages, domains, rare terms, numbers, code, and whitespace separately.
4. Benchmark full model cost because a shorter sequence and larger vocabulary change different layers.
5. Write a default, rejected alternatives with evidence, and revision triggers such as new language coverage or a changed latency budget.

Part 4 - Python code skeleton

```
import statistics

def tokenizer_metrics(tokenizer, texts, max_length):
    lengths, unknowns, total = [], 0, 0
    for text in texts:
        ids = tokenizer.encode(text)
        lengths.append(len(ids)); total += len(ids)
        unknowns += sum(i == tokenizer.unk_id for i in ids)
    ordered = sorted(lengths)
    percentile = lambda q: ordered[min(len(ordered)-1,
                                       int(q * (len(ordered)-1)))]
    return {"vocab_size": tokenizer.vocab_size,
            "mean_length": statistics.mean(lengths),
            "p95_length": percentile(.95), "p99_length": percentile(.99),
            "unknown_rate": unknowns / max(total, 1),
            "example_coverage": (
                sum(x <= max_length for x in lengths) / len(lengths)),
            "retained_token_ratio": sum(min(x, max_length) for x in lengths)
                                    / max(sum(lengths), 1)}

def E18(candidates, train_texts, eval_slices, lengths=(128, 256, 512)):
    report = {}
    for name, tokenizer in candidates.items():
        tokenizer.train(train_texts)
        report[name] = {slice_name: {T: tokenizer_metrics(tokenizer, texts, T)
                         for T in lengths}
                        for slice_name, texts in eval_slices.items()}
    return report
```

Part 5 - The Philosophy Behind the Exercise

Choosing tokens and context length chooses what the model can see conveniently and what it must reconstruct through effort. These are epistemic boundaries implemented as engineering parameters.

A mature decision guide does not hide uncertainty behind a default. It connects each choice to requirements, measurements, rejected alternatives, and the future evidence that would justify change.

17.6.20 Exercise 19

Exercise Title: Produce a Full Tokenization and Embedding Engineering Report Summarizing Pipeline Choices and Failure Modes

Part 1 - Why this matters

The final report turns twenty experiments into an auditable pipeline contract. Without it, knowledge remains scattered among code, notebooks, plots, and the memory of whoever debugged the last incident. The report must allow another engineer to reproduce token IDs, construct identical batches, load embedding weights safely, interpret performance limits, and recognize known failure signatures.

Describe the complete path from raw bytes or text to model input: corpus split and provenance, normalization, pre-tokenization, learned subword rules, vocabulary ordering, special IDs, BOS/EOS insertion, unknown behavior, truncation, causal shifting, dynamic padding, attention/loss masks, embedding and positional integration, weight tying, and serialization. Include the exact shape, dtype, device, and semantics of every returned tensor. Record tokenizer and vocabulary fingerprints beside checkpoint versions.

Summarize correctness evidence from golden examples, property tests, fault injection, tiny overfitting, CPU/CUDA parity, and checkpoint reload. Summarize engineering evidence from DataLoader sweeps, transfer timing, mixed precision, streaming memory plateaus, and long-sequence scaling. Separate observation from interpretation. Document unresolved risks, supported operating bounds, fallback behavior, owners, and revision triggers. A report that lists only successful results is incomplete; failure modes are part of the design knowledge.

Part 2 - Mathematical form and reasoning

Organize the report around a chain of contracts

$$s \xrightarrow{\tau} u \xrightarrow{v} z \xrightarrow{\text{shift}} (x, y) \xrightarrow{\text{collate}} (X, Y, P) \xrightarrow{E+P_{\text{pos}}} H^{(0)}.$$

For every arrow f_k, specify domain $\mathcal{D}_k$, codomain $\mathcal{D}_{k+1}$, configuration c_k, invariant set $\mathcal{C}_k$, and evidence artifact a_k. Reproducibility requires

$$(s, c_1, \ldots, c_K, \text{artifact versions}) \mapsto (X, Y, P)$$

to be deterministic wherever promised. Performance claims should identify the valid region in $(B, T, V, d, \text{dtype}, \text{device})$, not be stated as a context-free speedup.

Part 3 - Hints, controls, and evidence

1. Begin with an executive decision table: chosen policy, evidence, tradeoff, rejected alternative, and revision trigger.
2. Include a schema example containing raw text, tokens, IDs, shifted labels, masks, and decoded verification in one traceable row.
3. Link every quantitative claim to configuration, seed, hardware/software environment, raw measurement, and aggregation method.
4. Maintain a failure registry with symptom, earliest violated invariant, root cause, detector, fix, and regression test.
5. End with a training/serving parity checklist and an incident procedure for fingerprint mismatch, excessive unknowns, non-finite values, or throughput regression.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict
import json

@dataclass
class PipelineDecision:
    name: str
    choice: str
    evidence: list
    tradeoffs: list
    rejected: list
    revision_triggers: list

def validate_report(report):
    required = ["provenance", "normalization", "tokenizer", "vocabulary",
                "special_tokens", "shift_policy", "padding_and_masks",
                "embeddings", "position_policy", "precision", "performance",
                "tests", "failure_registry", "serving_parity"]
    missing = [key for key in required if key not in report]
    if missing: raise ValueError(f"missing report sections: {missing}")
    assert report["vocabulary"]["fingerprint"]
    assert report["tests"]["tiny_overfit_passed"]
    return True

def E19(artifacts, decisions, failures):
    report = {**artifacts,
              "decisions": [asdict(x) for x in decisions],
              "failure_registry": failures}
    validate_report(report)
    with open("trf04_engineering_report.json", "w", encoding="utf-8") as f:
        json.dump(report, f, ensure_ascii=False, indent=2)
    return report
```

Part 5 - The Philosophy Behind the Exercise

An engineering report is the memory of a system made independent of an individual. It preserves not just what was built, but why it was built, where it fails, and what evidence would justify rebuilding it differently.

The chapter began by turning text into IDs. It ends by turning experiments into shared knowledge. Both acts require stable identity, explicit contracts, and a faithful path back to meaning.

17.7 TRF05

Chapter Title: Training Loop, Optimization, and Stability
Specialization: Models and Training

17.7.1 Exercise 00

Exercise Title: Build Full Transformer Training Loop with Correct Train Eval Modes, Loss Computation, and Gradient Zeroing

Part 1 - Why this matters

A training loop is the control system that turns model outputs into parameter changes. Each individual operation is simple, but their order defines the algorithm. The essential training sequence is: enter training mode, obtain a batch, clear stale gradients, compute logits, compute a masked loss, run backpropagation, optionally inspect or transform gradients, update parameters, and advance the scheduler at its documented frequency. Validation uses evaluation mode and disables gradient recording, but never updates the model.

Implement one transparent epoch before adding mixed precision, accumulation, distributed training, or compilation. For causal language modeling, flatten logits from `(B,T,V)` to `(BT,V)` and labels from `(B,T)` to `(BT)`, preserving the same position order. Use `ignore_index=-100` for padded targets and aggregate epoch loss by the number of valid target tokens, not by an unweighted mean of batch losses. The latter biases results when batches contain different amounts of padding.

Prove that the loop really updates what it should. Snapshot parameters before a step, inspect nonzero finite gradients after `backward`, and verify that at least one trainable parameter changes after `step`. Then inject two faults: omit `zero_grad` and call `eval()` during training. Show gradient accumulation in the first case and disabled dropout behavior in the second. Log sample IDs so a loss spike can be traced back to data.

Part 2 - Mathematical form and reasoning

For valid target positions $\mathcal{I}$, token loss is

$$L(\theta) = -\frac{1}{|\mathcal{I}|} \sum_{(b,t)\in\mathcal{I}} \log p_\theta(y_{b,t} \mid x_{b,\le t}).$$

One optimizer step computes

$$g_k = \nabla_\theta L_k(\theta_k), \qquad \theta_{k+1} = \mathcal{U}(\theta_k, g_k, s_k),$$

where s_k is optimizer state. Without gradient clearing, PyTorch instead stores $g_k \leftarrow g_{k-1} + \nabla L_k$, changing the effective algorithm. For an epoch, the correct aggregate is $\sum_k n_k L_k / \sum_k n_k$, where n_k is the valid-token count.

Part 3 - Hints, controls, and evidence

1. Write the exact order of operations and scheduler frequency before coding.
2. Assert logits, labels, masks, parameters, and loss share compatible devices and that all trainable gradients are finite after backward.
3. Compare a vectorized loss with a manual valid-token calculation on a tiny batch.
4. Track loss numerator and valid-token denominator separately across the epoch.
5. Save parameter-delta norms, gradient norms, learning rate, sample IDs, and train/eval mode for every debug step.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def token_loss(logits, labels):
    V = logits.size(-1)
    return F.cross_entropy(logits.reshape(-1, V), labels.reshape(-1),
                           ignore_index=-100, reduction="sum")

def train_epoch(model, loader, optimizer, device, scheduler=None):
    model.train()
    loss_sum, token_count = 0.0, 0
    for batch in loader:
        batch = {k: v.to(device, non_blocking=True)
                 for k, v in batch.items() if torch.is_tensor(v)}
        optimizer.zero_grad(set_to_none=True)
        logits = model(batch["input_ids"], batch["attention_mask"])
        summed = token_loss(logits, batch["labels"])
        valid = batch["labels"].ne(-100).sum()
        loss = summed / valid
        loss.backward()
        assert all(p.grad is None or torch.isfinite(p.grad).all()
                   for p in model.parameters())
        optimizer.step()
        if scheduler is not None: scheduler.step()
        loss_sum += summed.detach().item(); token_count += valid.item()
    return loss_sum / token_count

@torch.no_grad()
def evaluate(model, loader, device):
```

```
    model.eval()
    total, tokens = 0.0, 0
    for batch in loader:
        batch = {k: v.to(device) for k, v in batch.items()
                 if torch.is_tensor(v)}
        logits = model(batch["input_ids"], batch["attention_mask"])
        total += token_loss(logits, batch["labels"]).item()
        tokens += batch["labels"].ne(-100).sum().item()
    return total / tokens

def E00(model, train_loader, valid_loader, optimizer, device):
    before = {n: p.detach().clone() for n, p in model.named_parameters()}
    train_nll = train_epoch(model, train_loader, optimizer, device)
    changed = [not torch.equal(before[n], p)
               for n, p in model.named_parameters()]
    assert any(changed)
    return train_nll, evaluate(model, valid_loader, device)
```

Part 5 - The Philosophy Behind the Exercise

Training is not the existence of gradients; it is a disciplined sequence of state transitions. Model mode, gradient buffers, optimizer moments, and scheduler time all carry memory. A misplaced operation changes that memory and therefore changes the experiment.

The loop is where mathematical intent becomes temporal behavior. Reliability begins when every transition is explicit enough to inspect, test, interrupt, and reproduce.

17.7.2 Exercise 01

Exercise Title: Train a Tiny Transformer Until Overfitting to Validate End-to-End Correctness and Debug Pipeline Issues

Part 1 - Why this matters

Overfitting a tiny dataset is one of the strongest end-to-end correctness tests for a training system. The goal is not generalization. The goal is to remove data complexity and ask whether tokenization, causal shifting, masks, positions, forward computation, loss, backward propagation, optimizer updates, and generation cooperate well enough to memorize a few deterministic examples. If a sufficiently expressive Transformer cannot do this, scaling the dataset is unlikely to fix the root cause.

Construct four to sixteen short sequences with a tiny frozen vocabulary. Print every input and target pair and keep dropout disabled for the strict test. Train on the same examples repeatedly until valid-token accuracy is nearly one and NLL is far below the uniform baseline $\log V$. Then generate from BOS or a known prefix without teacher forcing and compare the whole continuation. A low teacher-forced loss can coexist with broken autoregressive state handling.

Use failure signatures to diagnose the pipeline. If loss remains near $\log V$, inspect gradients, learning rate, detached tensors, and label alignment. If accuracy is high but generation is

wrong, inspect causal masks, position offsets, EOS handling, model mode, and decoding. If loss becomes near zero instantly, test for target leakage or copy labels. Run shuffled-label and future-visible controls to prove the test distinguishes learning from cheating.

Part 2 - Mathematical form and reasoning

For deterministic examples, empirical risk is

$$\widehat{L}(\theta) = -\frac{1}{N_{\text{tok}}} \sum_{n,t} \log p_\theta(y_t^{(n)} \mid x_{\le t}^{(n)}).$$

A uniform distribution gives $\widehat{L} \approx \log V$. Successful memorization approaches $\widehat{L} \to 0$ and

$$\frac{1}{N_{\text{tok}}} \sum_{n,t} \mathbb{1}[\arg\max_v p_\theta(v \mid x_{\le t}^{(n)}) = y_t^{(n)}] \to 1.$$

These conditions are necessary integration evidence, not evidence of useful generalization.

Part 3 - Hints, controls, and evidence

1. Use a fixed seed, one small batch, no augmentation, no dropout, and no weight decay for the initial correctness test.
2. Log per-position loss so BOS/EOS or one ignored column cannot hide behind the mean.
3. Inspect gradient norms layer by layer on the first and final steps.
4. Compare teacher-forced predictions with free-running greedy generation.
5. Preserve this dataset, configuration, and expected threshold as a fast regression test after every training-loop refactor.

Part 4 - Python code skeleton

```
import math, torch
import torch.nn.functional as F

def overfit_tiny(model, batch, steps=1000, lr=3e-3):
    optimizer = torch.optim.AdamW(model.parameters(), lr=lr, weight_decay=0.0)
    history = []
    model.train()
    for step in range(steps):
        optimizer.zero_grad(set_to_none=True)
        logits = model(batch["input_ids"], batch["attention_mask"])
        loss = F.cross_entropy(logits.flatten(0, 1),
                               batch["labels"].flatten(), ignore_index=-100)
        loss.backward(); optimizer.step()
        with torch.no_grad():
            valid = batch["labels"].ne(-100)
            pred = logits.argmax(-1)
            acc = (pred[valid] == batch["labels"][valid]).float().mean()
        history.append((loss.item(), acc.item()))
```

```
        if loss.item() < 0.02 and acc.item() > 0.995: break
    return history

def E01(model, batch, vocab_size, generate):
    history = overfit_tiny(model, batch)
    assert history[-1][0] < min(0.05, 0.05 * math.log(vocab_size))
    assert history[-1][1] > 0.99
    model.eval()
    generated = generate(model, batch["input_ids"][:, :1])
    # TODO: compare complete generated sequences and run leakage controls.
    return {"history": history, "generated": generated}
```

Part 5 - The Philosophy Behind the Exercise

A tiny-overfit test asks the system to demonstrate one small competence beyond reasonable doubt. By making the data completely inspectable, it forces failures to reveal themselves as failures of mechanism rather than mysteries of scale.

Complex systems become trustworthy through a ladder of solvable worlds. Before asking a model to learn language, prove that the learning machinery can learn a handful of exact relationships without hidden shortcuts.

17.7.3 Exercise 02

Exercise Title: Implement Learning Rate Warmup and Scheduler and Prove Warmup Prevents Early Training Divergence

Part 1 - Why this matters

At initialization, Transformer representations, attention distributions, and optimizer moments are not calibrated. A large target learning rate can move parameters aggressively before Adam's estimates stabilize, producing loss spikes or non-finite values. Warmup increases the learning rate gradually, then hands control to a decay schedule. It is a hypothesis about early optimization, not a ritual that should be accepted without a matched experiment.

Implement a scheduler as an explicit function of optimizer update count. Decide whether the first update uses zero, a small positive rate, or one warmup increment; then test that exact convention. Do not use epoch count when gradient accumulation means several microbatches form one optimizer update. Plot the first steps, the warmup boundary, and the final step. Save and restore scheduler state with checkpoints.

Compare no warmup, short warmup, and longer warmup under identical seeds, batches, initialization, peak rate, and total optimizer updates. Record early loss, gradient norm, update-to-weight ratio, non-finite events, and final validation quality. To claim prevention of divergence, choose a peak rate that causes an early instability without warmup, then show that warmup delays the large updates until the model reaches a stable region. Also show that excessive warmup wastes budget and can undertrain.

Part 2 - Mathematical form and reasoning

For update $u \geq 1$, warmup length W, total updates U, and peak rate $\eta_{\max}$, a linear-warmup/cosine-decay schedule can be

$$\eta(u) = \begin{cases} \eta_{\max}\, u/W, & u \leq W, \\ \frac{\eta_{\max}}{2}\left[1 + cos\left(\pi \frac{u-W}{U-W}\right)\right], & W < u \leq U. \end{cases}$$

The relative update magnitude $r_u = \|\theta_{u+1} - \theta_u\|_2 / (\|\theta_u\|_2 + \epsilon)$ links schedule values to actual parameter motion.

Part 3 - Hints, controls, and evidence

1. Unit-test exact rates at updates 1, W, $W + 1$, and U.
2. Call the scheduler at one documented location relative to `optimizer.step`; an off-by-one call changes the first rate.
3. Log optimizer-update count separately from batch and epoch counts.
4. Repeat several seeds and define divergence before observing results, such as non-finite loss or a sustained loss increase beyond a threshold.
5. Resume halfway through warmup and prove the next learning rate matches an uninterrupted run.

Part 4 - Python code skeleton

```
import math

def lr_multiplier(update, warmup, total):
    if not 1 <= update <= total: raise ValueError("invalid update")
    if update <= warmup:
        return update / max(warmup, 1)
    progress = (update - warmup) / max(total - warmup, 1)
    return 0.5 * (1.0 + math.cos(math.pi * progress))

def make_scheduler(optimizer, warmup, total):
    # The offset defines the first scheduled update explicitly.
    return __import__("torch").optim.lr_scheduler.LambdaLR(
        optimizer, lambda epoch: lr_multiplier(epoch + 1, warmup, total))

def E02(make_run, peak_lr=3e-3, total=1000):
    results = {}
    for warmup in (0, 50, 200):
        results[warmup] = make_run(peak_lr=peak_lr, warmup=warmup,
                                   total_updates=total, seed=22)
    # TODO: assert rate curve, compare early stability, and repeat seeds.
    return results
```

Part 5 - The Philosophy Behind the Exercise

Warmup recognizes that the same action can have different consequences at different stages of learning. Early parameters and optimizer statistics are fragile; later ones can absorb larger steps. Time is therefore part of the optimization problem.

A schedule is a policy for when the system should move boldly and when it should refine. Its legitimacy comes from measured dynamics, not from becoming a default incantation.

17.7.4 Exercise 03

Exercise Title: Implement AdamW Correctly and Explain Weight Decay Decoupling vs L2 Regularization Differences

Part 1 - Why this matters

In plain SGD, adding $\lambda\|\theta\|_2^2/2$ to the objective yields a gradient term $\lambda\theta$ that resembles multiplicative weight decay. In Adam, gradients are divided coordinate-wise by adaptive second-moment estimates. If the L2 term is placed inside that gradient, the apparent shrinkage is also preconditioned. AdamW decouples shrinkage from the loss gradient, giving parameters a direct multiplicative decay independent of moment normalization.

Implement a small Adam and AdamW update by hand for a vector parameter. Match the manual AdamW step to PyTorch with identical hyperparameters, gradient, initial moment states, and epsilon. Then compare three conditions: no regularization, L2 added to the loss, and decoupled weight decay. Use unequal gradient magnitudes across coordinates so adaptive effects are visible. Equal results under a symmetric toy case do not prove equivalence.

Create parameter groups deliberately. Biases and normalization scale/shift are commonly excluded from decay, while matrix weights are decayed; the exact policy should be justified and logged. Classify by module/parameter role rather than a fragile substring rule when possible. Assert every trainable parameter appears in exactly one group. Record data loss separately from any explicit L2 penalty so comparisons remain interpretable.

Part 2 - Mathematical form and reasoning

Adam moments are

$$m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t, \qquad v_t = \beta_2 v_{t-1} + (1-\beta_2) g_t^2,$$

with bias-corrected $\widehat{m}_t$ and $\widehat{v}_t$. AdamW updates

$$\theta_{t+1} = (1-\eta_t\lambda)\theta_t - \eta_t \frac{\widehat{m}_t}{\sqrt{\widehat{v}_t}+\epsilon}.$$

L2-in-Adam instead replaces g_t by $g_t + \lambda\theta_t$ before both moment updates. The regularization contribution is therefore filtered through m_t and v_t and is not the same coordinate-independent decay.

Part 3 - Hints, controls, and evidence

1. Start from one scalar step, then use a two-coordinate asymmetric example.

2. Set the data gradient to zero and verify AdamW produces exactly $(1 - \eta\lambda)\theta$.
3. Compare multiple steps because moment history amplifies the difference between L2 and decoupled decay.
4. Audit parameter-group coverage, duplicates, decay values, and group learning rates before training.
5. Track weight norms, training data loss, validation loss, and final quality across matched decay sweeps.

Part 4 - Python code skeleton

```
import torch

def adamw_manual(theta, grad, m, v, step, lr, beta1=.9, beta2=.999,
                 eps=1e-8, weight_decay=.01):
    m = beta1 * m + (1 - beta1) * grad
    v = beta2 * v + (1 - beta2) * grad.square()
    m_hat = m / (1 - beta1 ** step)
    v_hat = v / (1 - beta2 ** step)
    theta = theta * (1 - lr * weight_decay)
    theta = theta - lr * m_hat / (v_hat.sqrt() + eps)
    return theta, m, v

def parameter_groups(model, decay):
    decayed, excluded, seen = [], [], set()
    for module in model.modules():
        for name, p in module.named_parameters(recurse=False):
            if not p.requires_grad or id(p) in seen: continue
            seen.add(id(p))
            is_bias = name.endswith("bias")
            is_norm = module.__class__.__name__.endswith("Norm")
            if is_bias or is_norm:
                excluded.append(p)
            else: decayed.append(p)
    expected = {id(p) for p in model.parameters() if p.requires_grad}
    assert seen == expected
    return [{"params": decayed, "weight_decay": decay},
            {"params": excluded, "weight_decay": 0.0}]

def E03():
    theta = torch.tensor([1.0, 10.0])
    grad = torch.tensor([.1, 3.0])
    zero = torch.zeros_like(theta)
    return adamw_manual(theta, grad, zero, zero, 1, lr=1e-3)
```

Part 5 - The Philosophy Behind the Exercise

Two algorithms can share the word "regularization" while expressing different beliefs about parameter motion. L2 changes the gradient evidence; AdamW adds an independent preference for smaller weights. The distinction is structural, not terminological.

Optimization becomes intelligible when every force on a parameter is named. Separating data-driven motion from prior shrinkage makes both the code and the scientific claim easier to reason about.

17.7.5 Exercise 04

Exercise Title: Implement Gradient Clipping in Transformer Training and Measure Its Effect on Stability and Convergence

Part 1 - Why this matters

Transformer gradients can spike because of an unusual batch, an unstable attention distribution, excessive learning rate, or accumulated signal through depth. Global-norm clipping limits one update from being dominated by an exceptional gradient. It is a safety mechanism, not a cure for every instability: if clipping activates almost every step, it may be hiding a bad learning rate, incorrect loss scaling, broken normalization, or corrupt data.

Compute the global norm immediately after backward and, under mixed precision, after `scaler.unscale_(optimizer)`. Clipping scaled gradients enforces a threshold in an artificial scale-dependent space. Record the norm before clipping, the norm after clipping, and whether the threshold was active. Then call the optimizer. Use one global norm across the intended parameter set; per-layer clipping is a different algorithm and must be named separately.

Compare no clipping with several thresholds under matched seeds, data order, learning rate, and update budget. Measure non-finite events, loss spikes, gradient-norm percentiles, fraction of clipped steps, update norms, convergence speed, and final validation quality. Inject a controlled outlier batch so the mechanism is exercised. A threshold so low that all steps are clipped changes both direction and effective step size enough to slow learning.

Part 2 - Mathematical form and reasoning

For concatenated gradient vector g and maximum norm $c > 0$, global clipping is

$$\widetilde{g} = g \min\left(1, \frac{c}{\|g\|_2 + \epsilon}\right).$$

If $\|g\|_2 \le c$, the gradient is unchanged. Otherwise, all coordinates are multiplied by the same positive factor, preserving the global direction while limiting its magnitude. The clipping rate over U updates is

$$r_c = \frac{1}{U} \sum_{u=1}^{U} \mathbb{1}[\|g_u\|_2 > c].$$

This rate helps distinguish rare protection from permanent suppression.

Part 3 - Hints, controls, and evidence

1. Verify a hand-built two-parameter gradient against the manual formula.

2. Check the return value of `clip_grad_norm_`; it is the pre-clip norm and should be logged before conversion to a Python scalar.

3. Set `error_if_nonfinite=True` during debugging so NaNs are not silently scaled.

4. Sweep thresholds around observed norm percentiles rather than arbitrary orders of magnitude.

5. Separate a successful emergency intervention from improved final optimization; report both stability and quality.

Part 4 - Python code skeleton

```
import torch

def clipped_step(model, optimizer, loss, max_norm, scaler=None):
    optimizer.zero_grad(set_to_none=True)
    if scaler is None:
        loss.backward()
    else:
        scaler.scale(loss).backward()
        scaler.unscale_(optimizer)
    before = torch.nn.utils.clip_grad_norm_(
        model.parameters(), max_norm, error_if_nonfinite=True)
    active = bool(before > max_norm)
    after = min(float(before), float(max_norm))
    if scaler is None:
        optimizer.step()
    else:
        scaler.step(optimizer); scaler.update()
    return {"norm_before": float(before), "norm_after_bound": after,
            "clipped": active}

def E04(make_run):
    return {threshold: make_run(clip_norm=threshold, same_seed=4,
                                inject_outlier=True)
            for threshold in (None, 0.1, 1.0, 5.0)}
```

Part 5 - The Philosophy Behind the Exercise

Gradient clipping places a boundary on how much one piece of evidence may alter the model at once. It encodes caution in the presence of rare or unstable signals while leaving ordinary learning untouched.

A safeguard becomes dangerous when it conceals the condition that repeatedly activates it. Good engineering records both the rescue and the reason rescue was needed.

17.7.6 Exercise 05

Exercise Title: Implement Mixed Precision Training with GradScaler and Detect Silent Overflows in fp16 Attention Softmax

Part 1 - Why this matters

Mixed precision can reduce activation memory and increase Tensor Core throughput, but float16 has limited exponent range. Large attention scores can overflow before or during exponentiation, and small gradients can underflow to zero. Autocast chooses lower precision for many operations while retaining safer precision for others. GradScaler multiplies the loss before backward so small gradients survive, then unscales them before clipping and the optimizer step.

Implement the complete order: autocast forward, scaled backward, unscale, finite-gradient inspection, optional clipping, `scaler.step`, and `scaler.update`. Detect whether an optimizer step was skipped after a non-finite gradient by comparing parameters or the scaler state. Log attention score ranges before masking, count non-finite logits/probabilities, and assert every valid softmax row sums to one. A finite final loss does not prove every intermediate attention row was healthy.

Construct an extreme-score test by scaling queries and keys. Compare a naive float16 softmax, a stable max-subtracted implementation in float32, CUDA autocast, and bfloat16 where supported. Use a finite negative mask value appropriate to the dtype or apply a Boolean masked operation; avoid arithmetic that combines infinities into NaN. Compare throughput, peak memory, loss, gradient parity, skipped steps, and validation quality against float32.

Part 2 - Mathematical form and reasoning

Stable attention probabilities for score row s are

$$p_i = \frac{\exp(s_i - m)}{\sum_j \exp(s_j - m)}, \qquad m = \max_j s_j.$$

Subtracting m makes the largest exponent one and leaves softmax unchanged in exact arithmetic. If loss scale is S, backward computes Sg; before update, GradScaler restores $g = (Sg)/S$. When Sg is non-finite, the optimizer step is skipped and the scale is reduced. Clipping must operate on the unscaled g.

Part 3 - Hints, controls, and evidence

1. Match initial weights and batches for float32 and mixed-precision runs.
2. Register temporary hooks around attention score, masked score, softmax, and output tensors; remove them after diagnosis.
3. Log loss scale, skipped-step count, zero-gradient fraction, non-finite count, and maximum absolute score.
4. Test normal and extreme inputs. Stability on ordinary batches does not establish a safe numerical boundary.
5. Use bfloat16 as a distinct condition, not as another name for float16. Its wider range changes overflow behavior.

Part 4 - Python code skeleton

```
import torch

def amp_step(model, batch, optimizer, scaler, clip_norm=1.0):
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        logits, debug = model(batch["input_ids"],
                              batch["attention_mask"], return_debug=True)
        flat_logits = logits.flatten(0, 1)
        flat_labels = batch["labels"].flatten()
        loss = torch.nn.functional.cross_entropy(
            flat_logits, flat_labels, ignore_index=-100)
    assert torch.isfinite(debug["attention_scores"].float()).all()
    assert torch.isfinite(logits.float()).all()
    old_scale = scaler.get_scale()
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    norm = torch.nn.utils.clip_grad_norm_(model.parameters(), clip_norm,
                                          error_if_nonfinite=True)
    before = [p.detach().clone() for p in model.parameters()]
    scaler.step(optimizer); scaler.update()
    changed = any(not torch.equal(a, b) for a, b in
                  zip(before, model.parameters()))
    return {"loss": loss.item(), "grad_norm": float(norm),
            "old_scale": old_scale, "new_scale": scaler.get_scale(),
            "parameter_step_happened": changed}

def E05(model, batch, optimizer):
    scaler = torch.amp.GradScaler("cuda")
    return amp_step(model, batch, optimizer, scaler)
```

Part 5 - The Philosophy Behind the Exercise

Mixed precision is an agreement about which numerical distinctions the system may temporarily compress. Speed is earned by using fewer bits, while scaling and stable kernels protect distinctions essential to learning.

The deepest failure is silent invalidity: a training run that continues while updates are skipped or attention distributions are corrupted. Performance is valuable only when accompanied by observability.

17.7.7 Exercise 06

Exercise Title: Debug NaN Loss by Inspecting Attention Scores, LayerNorm, and Learning Rate and Implement Automatic Checks

Part 1 - Why this matters

A NaN loss is the final symptom of an earlier invalid value. The first NaN may appear in input data, embedding output, attention scores, a fully masked softmax row, residual activations, LayerNorm statistics, logits, gradients, or optimizer state. Checking only the scalar loss destroys the causal trail. The objective is to identify the earliest violated invariant and preserve the batch and state that reproduced it.

Instrument the model with forward hooks and gradient hooks that record shape, dtype, minimum, maximum, mean, standard deviation, and non-finite counts. Pay special attention to $QK^\top/\sqrt{d_k}$ before and after masking and to the variance entering LayerNorm. Assert that every valid query has at least one allowed key. Record the current learning rate, loss scale, gradient norm, parameter norm, and sample IDs. When a check fails, stop before the optimizer corrupts additional state and save a compact incident checkpoint.

Create a diagnostic matrix rather than changing many settings at once. Replay the failing batch in float64 or float32, lower the learning rate, disable mixed precision, replace the mask, and reduce input scale one factor at a time. Inject known failures: a fully masked row, extreme Q/K scale, zero LayerNorm epsilon, corrupt input, and excessive learning rate. Prove each is detected close to its origin with a specific message.

Part 2 - Mathematical form and reasoning

LayerNorm computes

$$\mathrm{LN}(x) = \gamma \odot \frac{x - \mu}{\sqrt{\sigma^2 + \epsilon}} + \beta.$$

Finite inputs can become invalid if variance or epsilon handling is broken. Attention uses

$$A = \mathrm{softmax}\left(QK^\top/\sqrt{d_k} + M\right).$$

A row containing no finite allowed score has an undefined normalized distribution. Define earliest failure index $k^* = \min\{k : z_k \notin \mathbb{R}^{n_k}\}$ over ordered intermediate tensors; diagnosis should target the operation producing z_{k^*}.

Part 3 - Hints, controls, and evidence

1. Use `torch.autograd.detect_anomaly()` only for a small replay; it is valuable but too expensive for routine training.
2. Save the pre-step model, optimizer, scaler, RNG state, batch, and configuration when an incident occurs.
3. Check optimizer moments as well as parameters; corrupted state can reintroduce NaNs after parameters are restored alone.
4. Prefer bounded summaries to copying every activation to CPU each step.
5. Convert the final root cause into a cheap permanent assertion and a regression test.

Part 4 - Python code skeleton

```
import torch

class FiniteMonitor:
    def __init__(self): self.handles, self.records = [], []
    def attach(self, model):
        for name, module in model.named_modules():
            if len(list(module.children())): continue
            hook = module.register_forward_hook(self._hook(name))
            self.handles.append(hook)
    def _hook(self, name):
        def check(module, inputs, output):
            tensors = output if isinstance(output, tuple) else (output,)
            for i, value in enumerate(tensors):
                if not torch.is_tensor(value): continue
                x = value.detach().float()
                record = {"module": name, "output": i,
                          "shape": tuple(x.shape),
                          "finite": bool(torch.isfinite(x).all()),
                          "min": x.nan_to_num().min().item(),
                          "max": x.nan_to_num().max().item()}
                self.records.append(record)
                if not record["finite"]:
                    message = f"first invalid output: {record}"
                    raise FloatingPointError(message)
        return check
    def close(self):
        for h in self.handles: h.remove()

def E06(model, replay_step):
    monitor = FiniteMonitor(); monitor.attach(model)
    try: result = replay_step(model)
    finally: monitor.close()
    return result, monitor.records
```

Part 5 - The Philosophy Behind the Exercise

NaN is not a cause; it is the collapse of a numerical statement somewhere upstream. Debugging succeeds by restoring the history that the final scalar has erased.

Observability gives failure a location and a time. Once the first broken invariant is known, an apparently chaotic training collapse becomes a specific operation under specific conditions.

17.7.8 Exercise 07

Exercise Title: Implement Activation Checkpointing and Quantify Memory Savings vs Extra Computation Cost

Part 1 - Why this matters

Backpropagation normally stores intermediate activations from the forward pass. For a deep Transformer with long sequences, this activation memory can dominate parameters and prevent the desired batch or context length from fitting on the GPU. Activation checkpointing stores only selected boundary tensors and recomputes the omitted forward regions during backward. It trades additional computation for lower peak memory.

Wrap groups of Transformer blocks with the PyTorch checkpoint utility while keeping the model's external contract unchanged. Compare no checkpointing, checkpoint every block, and checkpoint groups of several blocks. Measure peak allocated memory, peak reserved memory, forward time, backward time, total step time, useful tokens per second, and maximum feasible batch/context. Synchronize CUDA around timed regions and warm up before measurement.

Correctness requires more than a finite loss. Start from identical weights and inputs, disable stochastic layers, and compare outputs, input gradients, and parameter gradients. Then enable dropout and verify RNG-state preservation or document the chosen semantics. Beware of side effects inside checkpointed functions: the forward function runs again during backward. Logging counters, cache mutations, and random sampling may therefore occur twice. Test the framework's non-reentrant checkpoint mode explicitly.

Part 2 - Mathematical form and reasoning

Suppose a network is $f = f_L \circ \cdots \circ f_1$. Standard backward retains intermediate states $h_l = f_l(h_{l-1})$. Checkpointing a segment stores its input h_a and recomputes

$$h_{a+1}, \ldots, h_b = f_{a+1:b}(h_a)$$

during backward. If stored activation memory is approximately M_a and checkpointing retains fraction $r < 1$, memory becomes roughly $M_{\text{other}} + rM_a$, while compute increases by the cost of recomputed forward segments. Actual savings must be measured because kernels and allocator state change the estimate.

Part 3 - Hints, controls, and evidence

1. Establish forward and gradient parity in float64 or float32 on a tiny deterministic model before measuring speed.

2. Reset peak memory statistics for every configuration in an isolated trial.

3. Time forward, backward, and optimizer stages separately. Checkpointing primarily adds recomputation during backward.

4. Confirm at least one input or parameter requires gradients and avoid detaching tensors inside the checkpointed function.

5. Report the Pareto frontier between peak memory and step time rather than declaring one checkpoint granularity universally best.

Part 4 - Python code skeleton

```
import torch
from torch.utils.checkpoint import checkpoint

class CheckpointedStack(torch.nn.Module):
    def __init__(self, blocks, use_checkpoint=True):
        super().__init__(); self.blocks = torch.nn.ModuleList(blocks)
        self.use_checkpoint = use_checkpoint
    def forward(self, x, attention_mask):
        for block in self.blocks:
            if self.use_checkpoint and self.training:
                def run(hidden, mask, layer=block):
                    return layer(hidden, attention_mask=mask)
                x = checkpoint(run, x, attention_mask, use_reentrant=False,
                               preserve_rng_state=True)
            else:
                x = block(x, attention_mask=attention_mask)
        return x

def measure_peak(step):
    torch.cuda.empty_cache(); torch.cuda.reset_peak_memory_stats()
    start, end = (torch.cuda.Event(enable_timing=True),
                  torch.cuda.Event(enable_timing=True))
    start.record(); step(); end.record(); end.synchronize()
    return {"milliseconds": start.elapsed_time(end),
            "peak_allocated": torch.cuda.max_memory_allocated(),
            "peak_reserved": torch.cuda.max_memory_reserved()}

def E07(make_step):
    return {mode: measure_peak(make_step(checkpointing=mode))
            for mode in (False, True)}
```

Part 5 - The Philosophy Behind the Exercise

Checkpointing treats memory and computation as exchangeable resources. It chooses to remember fewer intermediate facts and reconstruct them when needed. The mathematics remains the same, but the temporal strategy changes.

This is a recurring systems principle: when storage is scarce and computation is available, recomputation can expand what is possible. The exchange is useful only when correctness and the true cost are measured together.

17.7.9 Exercise 08

Exercise Title: Implement Gradient Accumulation to Simulate Larger Batch Training Under GPU Memory Constraints

Part 1 - Why this matters

Gradient accumulation processes a logical batch as several microbatches while delaying the optimizer update. It reduces peak activation memory, but exact equivalence to a large batch

depends on loss normalization, stochastic layers, optimizer timing, scheduler timing, and batch-dependent operations. Dividing each microbatch mean loss by the number of microbatches is correct only when all microbatches contain the same number of valid targets. Variable padding breaks that assumption.

For strict equivalence, accumulate the *sum* of valid-token losses and normalize by the total number of valid tokens represented by the logical batch. One practical method is to know the token total before backward and scale each microbatch summed loss by that total. Clear gradients once at the start, run backward for every microbatch, then unscale, clip, update, and advance the scheduler once. An incomplete final accumulation window needs its actual token denominator, not the planned full-window size.

Compare a true large batch with accumulated microbatches using dropout disabled and identical sample order. Inspect loss, every parameter gradient, parameter delta, and optimizer state after one update. Then enable dropout and explain why different random masks can prevent bitwise equivalence while preserving the same expected objective. If using distributed training, suppress unnecessary gradient synchronization on non-final microbatches and verify the final result.

Part 2 - Mathematical form and reasoning

Let microbatch j contain valid-token set $\mathcal{I}_j$ and summed loss $S_j = \sum_{i \in \mathcal{I}_j} \ell_i$. The logical-batch objective is

$$L = \frac{\sum_{j=1}^{K} S_j}{N}, \qquad N = \sum_{j=1}^{K} |\mathcal{I}_j|.$$

Therefore

$$\nabla_\theta L = \sum_{j=1}^{K} \nabla_\theta \left(\frac{S_j}{N} \right).$$

This equality justifies accumulation. Replacing N by $K|\mathcal{I}_j|$ for unequal microbatches changes token weights and no longer simulates the same large-batch objective.

Part 3 - Hints, controls, and evidence

1. Begin with deterministic layers, one logical update, and float64 on a small model to establish gradient parity.
2. Count optimizer and scheduler steps; both must equal logical batches, not microbatches.
3. Clip only after all microbatch gradients are accumulated and AMP gradients are unscaled.
4. Test unequal valid-token counts and an incomplete final window.
5. Report peak memory, total step time, useful tokens per second, and gradient-parity error as separate outcomes.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def accumulated_update(model, microbatches, optimizer, scaler=None):
    optimizer.zero_grad(set_to_none=True)
    total_tokens = sum(b["labels"].ne(-100).sum().item()
                       for b in microbatches)
    loss_sum = 0.0
    for batch in microbatches:
        with torch.autocast("cuda", enabled=scaler is not None):
            logits = model(batch["input_ids"], batch["attention_mask"])
            summed = F.cross_entropy(logits.flatten(0, 1),
                batch["labels"].flatten(), ignore_index=-100, reduction="sum")
            normalized = summed / total_tokens
        if scaler is None: normalized.backward()
        else: scaler.scale(normalized).backward()
        loss_sum += summed.detach().item()
    if scaler is not None: scaler.unscale_(optimizer)
    norm = torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)
    if scaler is None: optimizer.step()
    else: scaler.step(optimizer); scaler.update()
    return {"nll": loss_sum / total_tokens, "grad_norm": float(norm)}

def E08(make_equivalent_batches, make_models):
    large, micros = make_equivalent_batches()
    direct, accumulated = make_models(same_state=True, dropout=0.0)
    # TODO: perform one update both ways and compare gradients and parameters.
    return large, micros, direct, accumulated
```

Part 5 - The Philosophy Behind the Exercise

Accumulation separates when evidence is observed from when a decision is made. Several microbatches contribute to one update, provided their contributions are weighted exactly as the intended logical batch.

Simulation is an equality claim, not a visual resemblance. To say that a large batch was simulated is to prove equivalence of objective, gradient, update timing, and state transitions under declared assumptions.

17.7.10 Exercise 09

Exercise Title: Debug Training Where Loss Improves But Generation Quality Does Not Improve and Identify Root Causes

Part 1 - Why this matters

Teacher-forced next-token loss and free-running generation measure related but different behavior. During training, every prediction receives the true prefix. During generation, each sampled token becomes part of the next prefix, so one error can move the model into contexts absent from training. A decreasing loss can also be dominated by frequent easy tokens while

rare structure, long-range dependencies, or EOS behavior remains poor.

Build an evaluation ladder. First verify label alignment, causal masking, and validation NLL on a leakage-free split. Next inspect accuracy and NLL by token frequency, position, sequence length, and example. Then run deterministic greedy generation in evaluation mode from fixed prompts. Finally compare temperature, top-k, and nucleus sampling with fully logged seeds and parameters. Separate model defects from decoding choices: a model may assign reasonable probability mass while an extreme sampling configuration produces incoherent text.

Investigate common root causes systematically: train/eval mode mismatch, dropout active during inference, hidden future leakage, wrong position offset in cached generation, tokenizer mismatch, repeated BOS/EOS, missing context window, validation contamination, class imbalance, loss computed on PAD, insufficient capacity, and exposure bias. Compare cached and uncached logits for identical prefixes. Save probability traces, not only final strings, so repetition and premature EOS can be connected to distributions.

Part 2 - Mathematical form and reasoning

Teacher-forced objective evaluates

$$L_{\mathrm{TF}} = -\sum_{t} \log p_\theta(y_t \mid y_{<t}),$$

while generation produces $\widehat{y}_t \sim p_\theta(\cdot \mid \widehat{y}_{<t})$. After the first error, $\widehat{y}_{<t}$ may lie outside the distribution of gold prefixes. Decompose validation NLL into groups G:

$$L = \sum_{g} \frac{|G_g|}{N} L_g.$$

An improved total can coexist with degraded L_g for rare but important groups. This is why aggregate loss cannot be the sole quality claim.

Part 3 - Hints, controls, and evidence

1. Freeze a prompt suite before tuning and include exact-copy, long- dependency, rare-token, and EOS-sensitive cases.

2. Compare greedy output first; stochastic sampling adds variance that can mask deterministic implementation bugs.

3. Log entropy, maximum probability, selected-token probability, repetition rate, EOS position, and NLL by position.

4. Test cached generation against full-prefix recomputation at every step.

5. Assign every failure to data, objective, model, decoding, or evaluation, then validate the proposed cause with a one-factor intervention.

Part 4 - Python code skeleton

```
import torch

@torch.no_grad()
def trace_greedy(model, prompt, max_new, eos_id):
    model.eval(); ids = prompt.clone(); trace = []
    for step in range(max_new):
        logits = model(ids)[:, -1].float()
        probs = logits.softmax(-1)
        next_id = probs.argmax(-1, keepdim=True)
        trace.append({"step": step, "token": next_id.item(),
                      "probability": probs.gather(1, next_id).item(),
                      "entropy": (-(probs * probs.clamp_min(1e-12).log())
                                  .sum()).item()})
        ids = torch.cat([ids, next_id], dim=1)
        if next_id.item() == eos_id: break
    return ids, trace

def E09(model, fixed_prompts, eos_id, cached_generate):
    report = []
    for prompt in fixed_prompts:
        full_ids, trace = trace_greedy(model, prompt, 64, eos_id)
        cached_ids = cached_generate(model, prompt, 64, eos_id)
        report.append({"prompt": prompt.cpu(), "generated": full_ids.cpu(),
                       "trace": trace,
                       "cache_parity": torch.equal(full_ids, cached_ids)})
    return report
```

Part 5 - The Philosophy Behind the Exercise

An objective is a proxy: it describes what the system is rewarded for under a particular observation process. Generation exposes the model to consequences of its own choices, a condition teacher forcing does not fully represent.

Improving a proxy is evidence, not proof of the desired capability. Good research keeps the objective, evaluation environment, and human notion of quality distinct enough to discover when they diverge.

17.7.11 Exercise 10

Exercise Title: Train Transformer Fully on CUDA and Validate DataLoader Transfers, Pin Memory, and Correct Device Placement

Part 1 - Why this matters

End-to-end CUDA training requires a consistent device contract across model parameters, registered buffers, input IDs, masks, labels, temporary tensors, loss, gradients, and optimizer state. A model can be moved correctly while a causal mask created inside `forward` remains on CPU. It can also run correctly but slowly because batches are copied synchronously from pageable memory or because many small tensors are transferred one at a time.

Create the model on CPU, move it once to the selected CUDA device, then construct the optimizer from the moved parameters. Configure the DataLoader with pinned memory and transfer batch tensors using `non_blocking=True`. This flag permits asynchronous copies only when the source and execution context support it; benchmark rather than assuming overlap. Create internal tensors with `x.new_*` or an explicit device derived from inputs. Register persistent or fixed tensors as buffers so device conversion and checkpointing include them.

Before the first training step, audit every parameter and buffer. After the first step, audit gradients and optimizer tensor states. Compare one fixed CPU and CUDA batch in evaluation mode at float32 with tolerances appropriate to the kernels. Then time preparation, transfer, forward, backward, and update using correct synchronization. Report useful tokens per second and padding ratio; raw batch throughput can reward wasted padding.

Part 2 - Mathematical form and reasoning

Let $D(z)$ return the device of tensor z. For every operation $f(z_1, \ldots, z_k)$ that does not explicitly copy data, require

$$D(z_1) = \cdots = D(z_k) = D(f(z_1, \ldots, z_k)).$$

End-to-end step time can be decomposed as

$$t_{\text{step}} = t_{\text{wait}} + t_{H \to D} + t_{\text{forward}} + t_{\text{backward}} + t_{\text{update}} - t_{\text{overlap}}.$$

Useful throughput is $N_{\text{valid}}/t_{\text{step}}$, and transfer optimization matters only to the fraction not hidden by overlap.

Part 3 - Hints, controls, and evidence

1. Fail early if CUDA is unavailable or the requested device index is invalid; do not silently change the benchmark condition.
2. Use a recursive device auditor for nested batches, parameters, buffers, gradients, and optimizer state.
3. Warm up CUDA kernels and synchronize only at measurement boundaries.
4. Compare pageable/blocking, pinned/blocking, and pinned/nonblocking copies with identical batches.
5. Monitor allocated and reserved memory and verify that memory does not grow across steady-state iterations.

Part 4 - Python code skeleton

```
import torch

def assert_model_device(model, device):
    wrong = [(n, str(t.device)) for n, t in
             list(model.named_parameters()) + list(model.named_buffers())
             if t.device != device]
```

```
    if wrong: raise RuntimeError(f"device mismatch: {wrong}")

def move_batch(batch, device):
    return {k: v.to(device, non_blocking=True)
            for k, v in batch.items() if torch.is_tensor(v)}

def audit_optimizer(optimizer, device):
    for state in optimizer.state.values():
        for value in state.values():
            if torch.is_tensor(value) and value.device != device:
                raise RuntimeError("optimizer state is on the wrong device")

def E10(model, loader, make_optimizer, device_index=0):
    device = torch.device(f"cuda:{device_index}")
    model = model.to(device); assert_model_device(model, device)
    optimizer = make_optimizer(model.parameters())
    batch = move_batch(next(iter(loader)), device)
    optimizer.zero_grad(set_to_none=True)
    logits = model(batch["input_ids"], batch["attention_mask"])
    loss = torch.nn.functional.cross_entropy(
        logits.flatten(0, 1), batch["labels"].flatten(), ignore_index=-100)
    loss.backward(); optimizer.step(); audit_optimizer(optimizer, device)
    return loss.item()
```

Part 5 - The Philosophy Behind the Exercise

A device is a location with movement costs and execution rules, not a decorative property on a model. CUDA training is correct only when the whole stateful system inhabits a coherent computational world.

Acceleration becomes engineering when placement, transfer, overlap, and memory are observable. The fastest hidden copy is the one eliminated by a clear data contract.

17.7.12 Exercise 11

Exercise Title: Profile GPU Utilization During Transformer Training and Fix Under-Utilization Bottlenecks in Data Pipeline

Part 1 - Why this matters

Low average GPU utilization is a symptom, not a root cause. The accelerator may wait for storage, tokenization, collation, host-to-device copies, Python control flow, synchronization, tiny kernels, or frequent evaluation and logging. It may also alternate between short intense kernels and unavoidable gaps, making one coarse utilization percentage misleading. Profiling must reconstruct the step timeline.

Instrument a representative training window with PyTorch Profiler after warmup. Capture CPU activities, CUDA kernels, shapes, memory, and a small number of stacks. Add named regions for data wait, transfer, forward, backward, clipping, optimizer, and logging. Compare profiler events with independent step timing and a system-level GPU timeline. Profile only

enough steps to answer the question; continuous detailed profiling can change the performance being measured.

Apply one intervention per diagnosed bottleneck. Pre-tokenize static data or add workers when CPU preparation dominates. Use length bucketing to reduce padding. Use pinned memory and nonblocking copies to expose overlap. Increase batch size or use accumulation when kernels are too small. Reduce per-step `item()` calls and synchronization-heavy logging. Consider fused or compiled operations only after correctness parity. Re-profile and report the change in useful tokens per second, latency distribution, memory, and quality.

Part 2 - Mathematical form and reasoning

Define step utilization proxy

$$u = \frac{t_{\text{active CUDA}}}{t_{\text{wall step}}},$$

recognizing that overlapping kernels must not be double-counted. If stages form a pipeline, achievable steady-state time approaches the maximum stage time, while a serialized implementation approaches their sum. Useful throughput is

$$R = \frac{\sum_{b,t} \mathbb{1}[Y_{b,t} \neq -100]}{t_{\text{wall}}}.$$

An optimization that increases device occupancy but processes more padding may raise hardware activity while reducing R.

Part 3 - Hints, controls, and evidence

1. Profile a steady-state window with the same model, batch distribution, precision, and logging policy used in the baseline.
2. Look for CPU gaps before kernels, memory copies without overlap, many tiny kernels, forced synchronizations, and oversized optimizer work.
3. Record p50, p95, and p99 step time; averages hide periodic stalls.
4. Validate numerical outputs and short-run training loss after each performance change.
5. Keep a before/after table linking each intervention to the timeline evidence that motivated it.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, ProfilerActivity, record_function

def profiled_steps(step_fn, iterator, output_dir, steps=8):
    schedule = torch.profiler.schedule(
        wait=1, warmup=1, active=steps, repeat=1)
    with profile(activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
                 schedule=schedule, record_shapes=True, profile_memory=True,
```

```
                on_trace_ready=torch.profiler.tensorboard_trace_handler(
                    output_dir)) as prof:
        for _ in range(steps + 2):
            with record_function("data_wait"):
                batch = next(iterator)
            with record_function("training_step"):
                step_fn(batch)
            prof.step()
    return prof.key_averages().table(sort_by="self_cuda_time_total",
                                     row_limit=30)

def E11(make_step, loader, output_dir="traces/trf05_e11"):
    iterator = iter(loader)
    baseline_step = make_step(optimized=False)
    baseline = profiled_steps(baseline_step, iterator, output_dir)
    # TODO: apply one evidence-backed intervention and profile again.
    return baseline
```

Part 5 - The Philosophy Behind the Exercise

Utilization is the visible rhythm of dependencies. Idle time means some required fact, resource, or permission did not arrive when the accelerator was ready. The timeline makes that dependency concrete.

Optimization should be a sequence of explanations: observe a gap, identify its cause, change the cause, and verify that the gap and end-to-end cost changed as predicted.

17.7.13 Exercise 12

Exercise Title: Benchmark Training Throughput Across Sequence Lengths and Identify Practical Maximum Context for Your GPU

Part 1 - Why this matters

Dense self-attention makes sequence length a dominant systems variable. IDs, embeddings, and many FFN activations scale approximately linearly with T, but attention interactions scale as T^2. The longest sequence that survives one forward pass is not a practical training context. A usable configuration needs headroom for backward, optimizer state, allocator variation, evaluation, and unusually long or padded batches.

Benchmark a matrix of context lengths and batch sizes using the real model, precision, optimizer, gradient accumulation, and activation-checkpoint policy. For each point, warm up and measure forward time, backward time, full update time, peak allocated/reserved memory, valid tokens per second, samples per second, and padding efficiency. Use fixed-length synthetic batches to isolate computational scaling, then repeat with the real length distribution to include collation and padding. Run risky points in isolated processes so an OOM does not leave the main benchmark in a fragmented state.

Define a practical maximum before inspecting results. Require several consecutive successful steps, stable latency percentiles, no non-finite values, and a memory reserve such as

10–20 percent for operational variation. Compare batch reduction, accumulation, checkpointing, mixed precision, Flash/SDPA kernels where appropriate, and length bucketing. The final choice should be a Pareto decision among retained context, throughput, memory, and learning quality.

Part 2 - Mathematical form and reasoning

For batch B, heads H, sequence T, head width d_h, and activation byte width s, an explicit score tensor costs approximately

$$M_{\text{score}} = BHT^2 s,$$

while token representations cost approximately $BTd_{\text{model}}s$. Define memory headroom

$$h = 1 - \frac{M_{\text{peak reserved}}}{M_{\text{device}}}.$$

A practical maximum T^* is the largest tested context satisfying the chosen headroom, stability, and latency constraints, not merely the largest T for which one allocation succeeded.

Part 3 - Hints, controls, and evidence

1. Reset peak statistics and synchronize timing boundaries for every trial.
2. Hold model and valid-token budget constant when isolating sequence-length effects, then separately study realistic batch construction.
3. Record kernel/backend selection because fused attention can change memory scaling constants substantially.
4. Repeat points near the limit and report p50/p95 step time; allocator and shape variation matter there.
5. Validate loss and gradient parity after enabling any memory-efficient attention or checkpointing implementation.

Part 4 - Python code skeleton

```
import torch

def benchmark_context(make_step, B, T, repeats=20):
    torch.cuda.empty_cache(); torch.cuda.reset_peak_memory_stats()
    step = make_step(batch_size=B, sequence_length=T)
    for _ in range(5): step()
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    times = []
    for _ in range(repeats):
        start.record(); metrics = step(); end.record(); end.synchronize()
        times.append(start.elapsed_time(end))
    values = torch.tensor(times)
    return {"batch": B, "sequence": T,
```

```
            "median_ms": values.median().item(),
            "p95_ms": values.quantile(.95).item(),
            "peak_allocated": torch.cuda.max_memory_allocated(),
            "peak_reserved": torch.cuda.max_memory_reserved(),
            "valid_tokens_s": metrics["valid_tokens"]/(values.median()/1000)}

def E12(make_step):
    return [benchmark_context(make_step, B, T)
            for T in (128, 256, 512, 1024, 2048) for B in (1, 2, 4)]
```

Part 5 - The Philosophy Behind the Exercise

A hardware limit is not a single wall; it is a boundary shaped by context, batching, precision, algorithms, and required safety margin. Engineering asks not "Can it run once?" but "Can it run reliably under the real distribution?"

Maximum context is meaningful only alongside its cost. A responsible choice states what additional information is retained and what throughput, memory, or operational resilience is surrendered to retain it.

17.7.14 Exercise 13

Exercise Title: Evaluate Determinism and Reproducibility and Document When CUDA Transformers Become Non-Deterministic

Part 1 - Why this matters

Reproducibility has levels. Exact continuation asks whether the same state and next batch produce identical tensors. Repeatability asks whether two runs under the same environment reproduce a trajectory. Statistical reproducibility asks whether independent seeds support the same conclusion. CUDA kernels, reduction order, atomics, data-worker scheduling, dropout, mixed precision, compiler selection, and distributed communication can prevent bitwise identity even when training is scientifically stable.

Create a reproducibility manifest containing code revision, configuration, dataset/tokenizer fingerprints, package and driver versions, GPU model, precision, compiler flags, seeds, deterministic settings, and selected kernels. Seed Python and PyTorch, seed DataLoader workers, pass a seeded generator to the sampler, and enable deterministic algorithms for the strict condition. Configure backend options deliberately and record any operation that fails because no deterministic implementation exists. Do not silently replace the strict test with a best-effort run.

Compare two same-seed runs at increasing resolution: sample order, initial state hash, first logits, first loss, first gradients, first update, checkpoint hashes, and final metrics. Locate the first divergence rather than comparing only final loss. Then run multiple different seeds and report distributions. Document the performance cost of deterministic settings and distinguish exact, tolerance-based, and statistical guarantees.

Part 2 - Mathematical form and reasoning

Let the training transition be

$$s_{t+1} = F(s_t, b_t, r_t, e),$$

where s_t includes model/optimizer/scheduler state, b_t is the batch, r_t is random state, and e is the software/hardware environment. Bitwise reproducibility requires all arguments and the realized implementation of F to match. For statistical comparison across n seeds, report mean and standard deviation

$$\bar{m} = \frac{1}{n}\sum_i m_i, qquads_m = \sqrt{\frac{1}{n-1}\sum_i (m_i - \bar{m})^2}.$$

Exact equality and stable distributions answer different questions.

Part 3 - Hints, controls, and evidence

1. Set environment-dependent deterministic configuration before CUDA work begins, then record it in the manifest.
2. Hash ordered sample IDs per epoch and state dictionaries at defined steps.
3. Disable dropout first to isolate kernel/data nondeterminism, then re-enable it with restored RNG states.
4. Test CPU, single-GPU, and the intended multi-GPU condition separately.
5. Treat tolerance selection as part of the claim; justify absolute and relative thresholds from dtype and operation behavior.

Part 4 - Python code skeleton

```
import hashlib, random, torch

def configure_determinism(seed):
    random.seed(seed)
    torch.manual_seed(seed)
    torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(True)
    torch.backends.cudnn.benchmark = False
    torch.backends.cudnn.deterministic = True

def state_hash(model):
    digest = hashlib.sha256()
    for name, tensor in sorted(model.state_dict().items()):
        digest.update(name.encode())
        digest.update(tensor.detach().cpu().contiguous().numpy().tobytes())
    return digest.hexdigest()

def compare_runs(run_a, run_b):
    for key in ("sample_ids", "initial_hash", "first_loss",
                "first_gradient_hash", "first_update_hash"):
```

```
        if run_a[key] != run_b[key]: return {"first_divergence": key}
    return {"first_divergence": None}

def E13(run_training, seed=13):
    configure_determinism(seed); a = run_training(seed)
    configure_determinism(seed); b = run_training(seed)
    return {"comparison": compare_runs(a, b), "run_a": a, "run_b": b}
```

Part 5 - The Philosophy Behind the Exercise

Reproducibility is the ability to say which parts of a result belong to the idea and which belong to circumstance. Exact repetition controls circumstance tightly; multi-seed evidence asks whether the conclusion survives variation.

Honest research names the level it achieved. "Deterministic" is not a mood of confidence but a testable contract over state, data, randomness, implementation, and environment.

17.7.15 Exercise 14

Exercise Title: Implement Checkpoint Save and Resume Including Optimizer and Scheduler States and Verify Exact Continuation

Part 1 - Why this matters

A model state dictionary is enough for inference, but not for exact training continuation. Adam moments, scheduler position, GradScaler state, global update, epoch/batch or data-stream cursor, sampler state, gradient-accumulation boundary, RNG states, tokenizer identity, and configuration all influence the next transition. Omitting one can produce a run that loads successfully and then silently follows a different trajectory.

Design a versioned checkpoint schema and write atomically: save to a temporary file, flush and close it, then rename within the same filesystem. Include model, optimizer, scheduler, scaler, counters, RNG state for Python/CPU/CUDA, and data position. Store hashes of the tokenizer/vocabulary and dataset manifest and reject incompatible resumes. Save at an optimizer-step boundary unless partial accumulated gradients and microstep index are intentionally supported. Map the checkpoint to CPU for portability, then restore tensors to the target device through model and optimizer loading.

Prove exact continuation with a fork experiment. Run K updates, save, continue M updates, and record batches, learning rates, losses, scales, gradients, and parameter hashes. Independently reload the K checkpoint and run the same M updates. Under deterministic conditions, every recorded value should match. Also simulate interruption during write and corruption; the last complete checkpoint must remain usable and integrity verification must fail early.

Part 2 - Mathematical form and reasoning

Define complete state

$$S_k = (\theta_k, o_k, q_k, a_k, r_k, d_k, c),$$

for model, optimizer, scheduler, AMP scaler, RNG, data cursor, and immutable configuration. Exact continuation requires

$$F^M(S_K) = F^M(\text{load}(\text{save}(S_K))).$$

A hash verifies byte integrity of the serialized artifact, while schema and fingerprint checks verify semantic compatibility. Both are required: an intact checkpoint can still belong to the wrong tokenizer or dataset.

Part 3 - Hints, controls, and evidence

1. Record a schema version and implement explicit migration or rejection; never guess missing fields.
2. Restore RNG and sampler/data state before requesting the next batch.
3. Inspect optimizer-state devices after loading and before the first step.
4. Retain more than one checkpoint and a manifest so a corrupt newest file does not eliminate recovery.
5. Compare uninterrupted and resumed trajectories step by step, not merely their final validation metric.

Part 4 - Python code skeleton

```
import os, random, torch

def capture_rng():
    cuda_state = (torch.cuda.get_rng_state_all()
                  if torch.cuda.is_available() else None)
    return {"python": random.getstate(), "cpu": torch.get_rng_state(),
            "cuda": cuda_state}

def restore_rng(state):
    random.setstate(state["python"]); torch.set_rng_state(state["cpu"])
    if state["cuda"] is not None: torch.cuda.set_rng_state_all(state["cuda"])

def save_checkpoint(path, model, optimizer, scheduler, scaler,
                    progress, meta):
    payload = {"schema": 1, "model": model.state_dict(),
               "optimizer": optimizer.state_dict(),
               "scheduler": scheduler.state_dict(),
               "scaler": None if scaler is None else scaler.state_dict(),
               "progress": progress, "rng": capture_rng(), "meta": meta}
    temporary = path + ".temporary"
    torch.save(payload, temporary); os.replace(temporary, path)

def load_checkpoint(path, model, optimizer, scheduler, scaler):
    state = torch.load(path, map_location="cpu", weights_only=False)
    if state["schema"] != 1: raise ValueError("unsupported checkpoint schema")
    model.load_state_dict(state["model"])
```

```
    optimizer.load_state_dict(state["optimizer"])
    scheduler.load_state_dict(state["scheduler"])
    if scaler is not None: scaler.load_state_dict(state["scaler"])
    restore_rng(state["rng"])
    return state["progress"], state["meta"]

def E14(fork_continuation_test):
    return fork_continuation_test(save_checkpoint, load_checkpoint)
```

Part 5 - The Philosophy Behind the Exercise

A checkpoint is a promise that time can be interrupted without changing the future. Saving weights preserves the model's location, but exact continuation also requires momentum, schedule, randomness, and place in the data stream.

Recovery is trustworthy when interruption becomes a tested state transition, not an emergency hope. The artifact must preserve both bytes and the meaning of those bytes.

17.7.16 Exercise 15

Exercise Title: Build Monitoring That Tracks Gradient Norms, Learning Rate, and Loss Spikes and Triggers Automatic Alerts

Part 1 - Why this matters

Training can remain alive while becoming invalid or wasteful. Loss may spike, gradients may vanish or explode, the learning rate may advance at the wrong frequency, AMP may skip many updates, throughput may collapse, or validation may degrade. Monitoring converts these hidden dynamics into time-indexed evidence and enables a fast response before a long run consumes its budget.

Define a compact per-update record: global update, microstep, epoch/data cursor, train loss, valid-token count, learning rate per group, gradient norm before and after clipping, parameter norm, update norm, AMP scale and skipped-step flag, step time, tokens per second, peak memory, and sample IDs for anomalies. Add periodic validation metrics and generation probes. Aggregate expensive layer- wise statistics less frequently. Avoid forcing a CUDA synchronization every step merely to log a scalar.

Implement alerts as explicit rules with warmup, robust baselines, persistence, and cooldown. Examples include any non-finite value, loss exceeding a rolling median by several median absolute deviations, clipping active for a sustained fraction of steps, repeated AMP skips, learning rate differing from the expected schedule, or throughput below a baseline. Classify actions: log only, save an incident snapshot, pause safely, or terminate. Test every rule with synthetic metric streams and record false positives.

Part 2 - Mathematical form and reasoning

For recent loss window W_t, define robust center $m_t = \text{median}(W_t)$ and deviation

$$d_t = \text{median}_{x \in W_t} |x - m_t|.$$

A spike score is

$$z_t = \frac{L_t - m_t}{1.4826 d_t + \epsilon}.$$

An alert may require $z_t > z_{\max}$ for q of the last r updates, reducing reaction to one harmless noisy batch. Rule thresholds and action severity are part of the experimental configuration and must be versioned.

Part 3 - Hints, controls, and evidence

1. Separate raw event capture from dashboards and alerts; retain raw values for later reinterpretation.
2. Use update count as the primary training time axis and also record valid tokens seen.
3. Include configuration, seed, code revision, device, and checkpoint ID in every run-level record.
4. Replay healthy and injected-failure streams to measure detection delay, missed alerts, and false alarms.
5. Ensure alert handling cannot corrupt the checkpoint it attempts to save.

Part 4 - Python code skeleton

```
from collections import deque
import math, statistics

class TrainingMonitor:
    def __init__(self, window=100, spike_z=8.0):
        self.losses = deque(maxlen=window); self.spike_z = spike_z
        self.events = []
    def observe(self, record):
        alerts = []
        for key in ("loss", "grad_norm", "learning_rate"):
            if not math.isfinite(record[key]):
                alerts.append(f"nonfinite:{key}")
        if len(self.losses) >= 20:
            center = statistics.median(self.losses)
            mad = statistics.median(abs(x-center) for x in self.losses)
            z = (record["loss"]-center)/(1.4826*mad+1e-12)
            if z > self.spike_z: alerts.append(f"loss_spike:{z:.2f}")
        self.losses.append(record["loss"])
        self.events.append({**record, "alerts": alerts})
        return alerts

def E15(metric_stream):
    monitor = TrainingMonitor()
    triggered = [monitor.observe(record) for record in metric_stream]
    # TODO: test each alert rule with injected metric streams.
    return monitor.events, triggered
```

Part 5 - The Philosophy Behind the Exercise

Monitoring is attention directed at the training process itself. It allows the system to become an object of observation while it learns, preserving signals that would otherwise vanish into a final checkpoint.

An alert is an operational hypothesis: this pattern predicts danger strongly enough to justify action. Like any hypothesis, it must be calibrated, tested, and revised from evidence rather than fear.

17.7.17 Exercise 16

Exercise Title: Implement Early Stopping and Compare Against Longer Training With Regularization for Small Datasets

Part 1 - Why this matters

On small datasets, training loss may continue falling after validation quality has stopped improving. Early stopping selects a checkpoint using a held-out signal and prevents additional updates that appear to specialize to the training set. It is a sequential model-selection procedure, not merely a way to save time. Repeatedly observing the same validation set also adapts decisions to that set, so a final untouched test set remains necessary.

Implement direction-aware improvement, a minimum meaningful delta, patience, warmup before monitoring, and restoration of the best complete checkpoint. The patience unit must be explicit: validation evaluations, not training batches. Handle ties and non-finite metrics deliberately. Save the best model, optimizer, scheduler, scaler, and progress if training may resume from that point; saving only weights is enough only for final inference evaluation.

Compare at least three matched strategies across several seeds: longer training without regularization, early stopping, and longer training with tuned weight decay/dropout or another declared regularizer. Give each the same maximum update budget and validation cadence. Report best validation update, final and restored metrics, test quality, generalization gap, wall time, and seed dispersion. Early stopping may be preferable, complementary, or inferior depending on noise and the task; the experiment should discover the relationship.

Part 2 - Mathematical form and reasoning

For validation metric m_k evaluated at checkpoints k, maximization with minimum delta δ accepts improvement when

$$m_k > m^* + \delta.$$

Otherwise a counter increments. Training stops after P consecutive non-improving evaluations and returns

$$k^* = \arg\max_{k \le k_{\text{stop}}} m_k.$$

For loss minimization, reverse the inequality. This adaptive choice means the reported validation maximum is optimistically selected; unbiased final claims should use an untouched test set.

Part 3 - Hints, controls, and evidence

1. Unit-test maximization and minimization, ties, delta, patience, warmup, NaN metrics, and restoration.
2. Save a new best checkpoint atomically at the moment improvement is accepted.
3. Smooth only if the policy is declared in advance; smoothing changes stopping delay and selection behavior.
4. Use several seeds because noisy small validation sets can select very different stopping points.
5. Evaluate the restored best checkpoint, not the final in-memory parameters.

Part 4 - Python code skeleton

```
import math

class EarlyStopping:
    def __init__(self, patience, min_delta=0.0, mode="min", warmup=0):
        self.patience, self.min_delta = patience, min_delta
        self.mode, self.warmup = mode, warmup
        self.best, self.bad, self.best_step = None, 0, None
    def update(self, metric, step):
        if not math.isfinite(metric): return {"improved": False, "stop": True}
        better = (self.best is None or
                  (metric < self.best-self.min_delta if self.mode == "min"
                   else metric > self.best+self.min_delta))
        if better:
            self.best, self.best_step, self.bad = metric, step, 0
        elif step >= self.warmup:
            self.bad += 1
        return {"improved": better,
                "stop": step >= self.warmup and self.bad >= self.patience}

def E16(run_strategy):
    return {name: [run_strategy(name, seed) for seed in (1, 2, 3, 4, 5)]
            for name in ("long_unregularized", "early_stop",
                         "long_regularized")}
```

Part 5 - The Philosophy Behind the Exercise

Early stopping treats continued learning as a decision that must remain justified by external evidence. More optimization is not automatically more knowledge; after a point it may become narrower accommodation to the observed sample.

Knowing when to stop is part of learning. The decision is credible when its criterion, uncertainty, and comparison with alternatives are made explicit.

17.7.18 Exercise 17

Exercise Title: Build a Misclassification or Bad-Generation Collector and Save Worst Samples for Manual Analysis

Part 1 - Why this matters

Aggregate metrics compress thousands of different outcomes into one number. Manual analysis needs the examples that most strongly contradict the desired behavior: high-confidence wrong classifications, high-NLL tokens, early EOS, repetition loops, target continuations assigned low probability, or generations that violate a task-specific rule. A collector turns these failures into a ranked, traceable dataset rather than a collection of memorable anecdotes.

Define a task-specific badness score before reading examples. During evaluation mode with gradients disabled, preserve example ID, split, source reference, decoded input, target, prediction, token IDs, mask, per-token loss, confidence or entropy, generation settings, checkpoint ID, tokenizer fingerprint, and selected internal diagnostics. Keep only the worst K samples using a bounded heap so large validation sets do not exhaust memory. Store references rather than private raw text when governance requires it.

Stratify the collector. A global top-K may contain only long sequences because summed NLL grows with length, or only one frequent class. Use mean valid-token NLL for length normalization and keep separate queues by class, length bin, language/domain, or failure type. Deduplicate repeated windows from the same document. Compare collectors across checkpoints to distinguish newly fixed, persistent, and newly introduced failures. Manual tags should feed regression tests and data/model hypotheses, not be treated as ground truth automatically.

Part 2 - Mathematical form and reasoning

For sequence n with valid set $\mathcal{I}_n$, define normalized NLL

$$s_n = \frac{1}{|\mathcal{I}_n|} \sum_{t \in \mathcal{I}_n} -\log p_\theta(y_{n,t} \mid x_{n,\le t}).$$

A high-confidence classification error can use $s_n = \max_c p_\theta(c \mid x_n)$ when prediction is wrong. Repetition metrics may measure duplicate n-gram fraction. Ranking defines what enters human attention, so its bias must be documented and countered with stratified samples.

Part 3 - Hints, controls, and evidence

1. Unit-test ranking with hand-constructed scores, ties, duplicate IDs, and fewer than K examples.
2. Decode with the exact checkpoint tokenizer and preserve IDs for forensic reconstruction.
3. Include random and median-quality controls beside worst samples; without them reviewers lose a reference distribution.
4. Never feed validation/test examples back into training without recording the resulting split contamination and creating a fresh evaluation set.
5. Version human failure categories and measure reviewer disagreement when labels are subjective.

Part 4 - Python code skeleton

```
import heapq, torch

class WorstCollector:
    def __init__(self, k): self.k, self.heap, self.counter = k, [], 0
    def add(self, score, example_id, payload):
        self.counter += 1
        item = (float(score), str(example_id), self.counter, payload)
        if len(self.heap) < self.k: heapq.heappush(self.heap, item)
        elif item[:2] > self.heap[0][:2]: heapq.heapreplace(self.heap, item)
    def sorted(self): return sorted(self.heap, reverse=True)

@torch.inference_mode()
def collect_bad_generations(model, loader, tokenizer, generate, k=50):
    model.eval(); collector = WorstCollector(k)
    for batch in loader:
        logits = model(batch["input_ids"], batch["attention_mask"])
        per_token = torch.nn.functional.cross_entropy(
            logits.transpose(1, 2), batch["labels"],
            ignore_index=-100, reduction="none")
        valid = batch["labels"].ne(-100)
        scores = (per_token*valid).sum(1)/valid.sum(1).clamp_min(1)
        for i, score in enumerate(scores):
            collector.add(score, batch["example_ids"][i],
                          {"input_ids": batch["input_ids"][i].cpu(),
                           "target_ids": batch["labels"][i].cpu()})
    return collector.sorted()

def E17(model, loader, tokenizer, generate):
    return collect_bad_generations(model, loader, tokenizer, generate)
```

Part 5 - The Philosophy Behind the Exercise

Metrics describe populations; failures restore individuality. The worst-sample collector gives concrete form to what an average hides and directs scarce human attention toward consequential uncertainty.

But selection shapes perception. A ranking is not a neutral window onto failure; it is a policy about which failures deserve to be seen. Diversity and provenance make that policy more honest.

17.7.19 Exercise 18

Exercise Title: Achieve Near-Perfect Performance on a Simple Synthetic Task and Use It as a Regression Test for Stability

Part 1 - Why this matters

A synthetic task can isolate one Transformer capability and provide an exact data generator, known solution, and strict success threshold. Unlike a single fixed tiny dataset, fresh synthetic examples can test generalization within a controlled rule. Once the system repeatedly solves the task, the experiment becomes a regression test: future changes to masks, precision, optimizer order, checkpointing, or kernels must preserve the capability and stability envelope.

Choose a task that needs the mechanism being tested, such as copying a marked token from an earlier position, reversing a short sequence, or retrieving a value associated with a key. Create disjoint train and validation streams from the same rule and a harder extrapolation split with longer sequences or more distractors. Establish chance performance and a simpler baseline. Train under a fixed compute budget and require near-perfect validation performance over multiple seeds, not merely one lucky run.

Package the data generator, configuration, seeds, thresholds, timeout, expected learning curve, and failure artifacts. Include invariance checks: permuting irrelevant distractors should not change the answer, causal models must not see future targets, and CPU/CUDA outputs should agree within tolerance. Add stress variants for high learning rate, mixed precision, checkpoint resume, and gradient accumulation. A regression test should fail loudly with the first diagnostic difference, not only a final low score.

Part 2 - Mathematical form and reasoning

For generated sample $(x, y) \sim G_\phi$, empirical validation accuracy is

$$\widehat{A} = \frac{1}{N} \sum_{n=1}^{N} \mathbb{1}[f_\theta(x_n) = y_n].$$

If the task has C balanced outputs, chance accuracy is $1/C$. A regression contract may require, for every seed s in a fixed suite,

$$\widehat{A}_s \geq A_{\min}, \quad L_s \leq L_{\max}, \quad u_s \leq U_{\max}, \quad \text{all monitored tensors finite},$$

where u_s is updates required to cross the performance threshold.

Part 3 - Hints, controls, and evidence

1. Make generation deterministic per sample seed and save failing seeds for exact replay.
2. Verify dataset logic with a manual oracle independent of the model and training implementation.
3. Include train-rule validation and length/distractor extrapolation as separate claims.
4. Select thresholds from repeated healthy reference runs with justified margin, not from the single best run.
5. Keep the regression small enough for routine execution while retaining a nightly stress variant for broader configurations.

Part 4 - Python code skeleton

```
import torch

def make_retrieval_batch(seed, batch_size, pairs, vocab=32):
    g = torch.Generator().manual_seed(seed)
    keys = torch.randint(2, vocab, (batch_size, pairs), generator=g)
    values = torch.randint(2, vocab, (batch_size, pairs), generator=g)
    query_index = torch.randint(0, pairs, (batch_size,), generator=g)
    query = keys[torch.arange(batch_size), query_index]
    target = values[torch.arange(batch_size), query_index]
    # Interleave key/value pairs, then append a query marker and query key.
    sequence = torch.stack([keys, values], dim=-1).flatten(1)
    sequence = torch.cat([sequence, torch.ones(batch_size, 1,
                          dtype=torch.long), query[:, None]], dim=1)
    return sequence, target

def E18(train_and_evaluate):
    runs = []
    for seed in (18, 19, 20):
        result = train_and_evaluate(seed=seed, task=make_retrieval_batch,
                                    max_updates=1000)
        assert result["validation_accuracy"] >= 0.99
        assert result["all_finite"] and result["updates"] <= 1000
        runs.append(result)
    return runs
```

Part 5 - The Philosophy Behind the Exercise

Synthetic tasks are microscopes: they simplify the world so one mechanism can be observed without the noise of natural data. Their artificiality is a strength when the claim is kept narrow and explicit.

A regression test transforms past understanding into a future boundary. It says that improvement may change the implementation, but must not erase a capability already demonstrated under controlled conditions.

17.7.20 Exercise 19

Exercise Title: Produce a Full Transformer Training Debugging Playbook Covering All Common Failure Scenarios

Part 1 - Why this matters

The final playbook turns chapter experiments into an operational decision system. Transformer failures cross data, objective, model, numerics, optimization, hardware, and recovery boundaries. Randomly changing learning rate, precision, masks, and batch size destroys evidence and can produce a temporary improvement without identifying the cause. A playbook preserves a consistent order: contain the incident, reproduce it, locate the earliest broken invariant, run a discriminating intervention, verify the repair, and add a regression test.

Organize entries by symptom: loss does not fall, loss spikes, NaN/Inf, zero or exploding gradients, repeated clipping, AMP skipped steps, improving loss with poor generation, overfitting, underfitting, OOM, slow/variable steps, low GPU utilization, nondeterminism, checkpoint mismatch, and resume drift. For each, list likely causes in causal order, required artifacts, immediate safe action, diagnostic tests, expected observations, corrective actions, and proof of resolution. Link symptoms to exercises rather than duplicating untested advice.

Define a standard incident bundle: configuration, revision, environment, tokenizer and data fingerprints, checkpoint, RNG state, data cursor, batch IDs, loss/gradient/LR/scale timeline, intermediate tensor summaries, profiler trace when relevant, and the last healthy comparison. Include severity and authority: which conditions warn, pause, save, roll back, or terminate. Rehearse the playbook using injected failures and measure time to detection, localization, and verified recovery.

Part 2 - Mathematical form and reasoning

Represent training as ordered contracts

$$D \to B \to Z \to L \to G \to U \to S',$$

for data, batch, logits, loss, gradients, update, and next state. Each transition f_k has invariant set $\mathcal{C}_k$. Given a symptom, seek

$$k^* = \min\{k : f_k(z_{k-1}) \notin \mathcal{C}_k\}.$$

A repair is accepted only when the original reproduction no longer violates $\mathcal{C}_{k^*}$, downstream contracts recover, and a regression test fails under the injected defect but passes under the corrected implementation.

Part 3 - Hints, controls, and evidence

1. Begin every branch with data identity, tensor contract, mode, device, dtype, finiteness, and update-order checks before hyperparameter speculation.
2. Preserve the failing state before experimenting; otherwise the incident may become irreproducible.
3. Change one factor per diagnostic run and state mutually exclusive expected outcomes that distinguish hypotheses.
4. Record owner, severity, detection rule, rollback point, root cause, fix, and regression-test ID for every resolved incident.
5. Review the playbook after real incidents and remove advice that has never been validated.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict
import json

@dataclass
```

```
class FailureEntry:
    symptom: str
    severity: str
    likely_causes: list
    required_evidence: list
    diagnostic_steps: list
    stop_conditions: list
    verified_fixes: list
    regression_tests: list

REQUIRED_SYMPTOMS = {"loss_flat", "loss_spike", "nonfinite", "bad_generation",
                     "oom", "low_utilization", "resume_drift",
                     "nondeterminism"}

def validate_playbook(entries):
    symptoms = {e.symptom for e in entries}
    missing = REQUIRED_SYMPTOMS - symptoms
    if missing:
        message = f"missing failure branches: {sorted(missing)}"
        raise ValueError(message)
    for entry in entries:
        assert entry.required_evidence and entry.diagnostic_steps
        assert entry.verified_fixes and entry.regression_tests

def E19(entries, drill_results, path="trf05_debugging_playbook.json"):
    validate_playbook(entries)
    report = {"schema": 1, "entries": [asdict(e) for e in entries],
              "failure_injection_drills": drill_results}
    with open(path, "w", encoding="utf-8") as handle:
        json.dump(report, handle, indent=2)
    return report
```

Part 5 - The Philosophy Behind the Exercise

A debugging playbook is accumulated causal knowledge. It replaces improvisation under pressure with a sequence of observations that protects evidence and narrows uncertainty. Its value lies not in containing every possible answer, but in teaching the system how to ask the next decisive question.

The chapter ends where mature engineering begins: failure is no longer treated as an interruption external to learning. It becomes a reproducible experiment, a refined invariant, and a permanent improvement in collective memory.

17.8 TRF06

Chapter Title: Decoder-Only Language Modeling and Generation
Specialization: Models and Training

17.8.1 Exercise 00

Exercise Title: Implement a Minimal Decoder-Only Transformer and Validate Causal Mask and Next-Token Prediction Dataset

Part 1 - Why this matters

A decoder-only Transformer learns one rule: at position t, predict the next token using only the prefix available through t. The architecture looks like an encoder stack—token and positional embeddings, repeated self-attention and feed-forward blocks, normalization, and a vocabulary projection—but causal masking changes its information contract. A model that can see future tokens may obtain an excellent training loss while learning a computation impossible during generation.

Build the smallest complete model without using `nn.Transformer`. Start from a full sequence `[BOS,a,b,EOS]`, form inputs `[BOS,a,b]` and labels `[a,b,EOS]`, and keep padding labels at `-100`. Construct an allowed-attention matrix in which query i may read key j exactly when $j \leq i$ and the key is not padding. Track shapes through `(B,T)`, `(B,T,d)`, heads `(B,H,T,d_h)`, attention scores `(B,H,T,T)`, and logits `(B,T,V)`.

Validate causality through intervention, not inspection alone. Create two sequences with identical prefixes and different future suffixes. Logits for positions inside the shared prefix must be equal in evaluation mode. Remove the causal mask and prove the invariant fails. Also verify that the model can accept different batch sizes, rejects sequences beyond its positional capacity, and computes loss only for valid shifted labels.

Part 2 - Mathematical form and reasoning

The language-model factorization is

$$p_\theta(z_1, \ldots, z_T \mid z_0) = \prod_{t=0}^{T-1} p_\theta(z_{t+1} \mid z_0, \ldots, z_t).$$

For attention scores $S = QK^\top/\sqrt{d_h}$, define

$$M_{i,j} = \begin{cases} 0, & j \leq i, \\ -\infty, & j > i, \end{cases} \qquad A = \mathrm{softmax}(S + M).$$

The loss over valid targets $\mathcal{I}$ is

$$L = -\frac{1}{|\mathcal{I}|} \sum_{(b,t)\in\mathcal{I}} \log p_\theta(y_{b,t} \mid x_{b,\leq t}).$$

The architectural contract and dataset shift express the same temporal claim.

Part 3 - Hints, controls, and evidence

1. Use unequal values for batch, sequence, heads, and head width so swapped axes cannot pass by coincidence.
2. Print the Boolean allowed matrix before converting masked locations to a large negative value.

3. Assert every valid attention row sums to one and every future weight is zero.

4. Compare shared-prefix logits under changed suffixes, both with and without the causal mask.

5. Record parameter count, shapes, mask semantics, loss denominator, and the first violated invariant for every injected failure.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class DecoderOnlyModel(nn.Module):
    def __init__(self, vocabulary_size, model_width, heads, layers,
                 maximum_length):
        super().__init__()
        self.token_embedding = nn.Embedding(vocabulary_size, model_width)
        self.position_embedding = nn.Embedding(maximum_length, model_width)
        block = nn.TransformerEncoderLayer(
            model_width, heads, 4 * model_width, batch_first=True,
            norm_first=True)
        self.blocks = nn.TransformerEncoder(block, layers)
        self.final_norm = nn.LayerNorm(model_width)
        self.output = nn.Linear(model_width, vocabulary_size, bias=False)

    def forward(self, input_ids, padding_mask=None):
        batch_size, sequence_length = input_ids.shape
        positions = torch.arange(sequence_length, device=input_ids.device)
        hidden = self.token_embedding(input_ids)
        hidden = hidden + self.position_embedding(positions)[None, :, :]
        future_mask = torch.triu(torch.ones(sequence_length, sequence_length,
                                 device=input_ids.device, dtype=torch.bool), 1)
        hidden = self.blocks(hidden, mask=future_mask,
                             src_key_padding_mask=padding_mask)
        return self.output(self.final_norm(hidden))

def E00(model, prefix_a, prefix_b):
    model.eval()
    with torch.no_grad():
        logits_a = model(prefix_a)
        logits_b = model(prefix_b)
    shared_length = 3
    assert torch.allclose(logits_a[:, :shared_length],
                          logits_b[:, :shared_length])
    return logits_a, logits_b
```

Part 5 - The Philosophy Behind the Exercise

Causality is a boundary on knowledge. The model is powerful not because it may read everything, but because it learns to act under the same information limits that will exist when the future has not yet been generated.

Architecture and supervision must agree about time. When they do, next-token prediction becomes a valid bridge from a static corpus to sequential creation.

17.8.2 Exercise 01

Exercise Title: Train a Small Decoder-Only Model and Confirm Loss Decreases and Generation Becomes Less Random Over Time

Part 1 - Why this matters

A decreasing teacher-forced loss proves that the model is assigning more probability to observed next tokens, but it does not automatically show how free-running generations change. Early in training, the distribution is close to random; later, frequent local patterns should become visible, entropy should decline where the corpus is predictable, and generated samples should respect more structure. This exercise connects optimization evidence to behavioral evidence without pretending that one pleasant sample measures quality.

Train a small decoder on a tiny corpus or controlled pattern dataset. Freeze the tokenizer and split documents before building windows. Save checkpoints at initialization and at several fixed update counts. At every checkpoint, evaluate validation NLL and perplexity, then generate from the same prompt suite with the same decoding method, seed, temperature, and maximum length. Preserve raw probabilities or entropy traces so changes can be explained.

Track valid-token accuracy, NLL by position, entropy, EOS frequency, repetition, and exact pattern success. A model becoming less random does not necessarily mean it becomes better: it can collapse into high-confidence repetition. Compare against a unigram baseline and a memorization control. Overfit a tiny batch first to validate the entire pipeline, then train the intended split. If training loss falls while validation loss rises, describe overfitting rather than calling the generation improvement complete.

Part 2 - Mathematical form and reasoning

At checkpoint k, validation perplexity is

$$\mathrm{PPL}_k = \exp\left(-\frac{1}{N}\sum_{i=1}^{N}\log p_{\theta_k}(y_i \mid x_{\le i})\right).$$

Distribution uncertainty at generation step t is

$$H_t = -\sum_{v=1}^{V} p_t(v)\log p_t(v).$$

Lower entropy is evidence of greater concentration, not automatically greater correctness. Behavioral improvement requires concentration to move toward tokens consistent with the task or held-out data.

Part 3 - Hints, controls, and evidence

1. Save the initial untrained model as checkpoint zero; it is the true random reference.
2. Use fixed prompts and decoding seeds at every checkpoint.
3. Separate teacher-forced validation metrics from autoregressive generation metrics in every plot and report.
4. Inspect multiple prompts and checkpoints; one selected output is not representative evidence.
5. Include a shuffled-label run to show that optimizer activity alone does not create meaningful structure.

Part 4 - Python code skeleton

```
import math
import torch
import torch.nn.functional as F

def train_step(model, batch, optimizer):
    model.train()
    optimizer.zero_grad(set_to_none=True)
    logits = model(batch["input_ids"], batch["padding_mask"])
    flat_logits = logits.reshape(-1, logits.size(-1))
    flat_labels = batch["labels"].reshape(-1)
    loss = F.cross_entropy(flat_logits, flat_labels, ignore_index=-100)
    loss.backward()
    optimizer.step()
    return loss.item()

def E01(model, loader, optimizer, evaluate, generate, checkpoints):
    report = []
    iterator = iter(loader)
    maximum_update = max(checkpoints)
    for update in range(maximum_update + 1):
        if update in checkpoints:
            validation_nll = evaluate(model)
            samples = generate(model)
            report.append({"update": update,
                           "validation_nll": validation_nll,
                           "perplexity": math.exp(validation_nll),
                           "samples": samples})
        if update == maximum_update:
            break
        try:
            batch = next(iterator)
        except StopIteration:
            iterator = iter(loader)
            batch = next(iterator)
```

```
        train_step(model, batch, optimizer)
    return report
```

Part 5 - The Philosophy Behind the Exercise

Learning changes a distribution before it produces an impressive artifact. Watching checkpoints reveals that transformation as a process rather than judging intelligence from one final string.

Randomness and certainty are not opposites of quality. The goal is calibrated structure: confidence where evidence supports it and uncertainty where several continuations remain plausible.

17.8.3 Exercise 02

Exercise Title: Implement Greedy Decoding and Explain Why It Often Produces Repetitive Output in Practice

Part 1 - Why this matters

Greedy decoding selects the highest-probability token at every step. It is deterministic, inexpensive, and extremely useful for debugging because the same prompt and model produce the same path. However, the locally most probable token need not begin the globally best continuation. Once a repeated phrase becomes slightly more probable than alternatives, feeding it back into the model can increase its own probability and create a stable loop.

Implement generation as an explicit loop. Start in evaluation mode, disable gradients, run the current prefix, take the final-position logits, select `argmax`, append the token, and stop on EOS or the token budget. Record the chosen token, its probability, distribution entropy, and whether the new n-gram already appeared. Do not sample and do not apply temperature in the greedy baseline.

Test a hand-constructed probability tree in which the best first token leads to a lower total sequence probability than the second-best first token. Then run real prompts and quantify repeated unigrams, bigrams, and longer n-grams. Compare teacher-forced next-token predictions with free-running output to show how feedback changes contexts. Greedy decoding is valuable as a reproducible baseline, but poor repetition does not prove the model itself assigns no mass to better alternatives.

Part 2 - Mathematical form and reasoning

Greedy decoding computes

$$\widehat{y}_t = \arg\max_{v \in \mathcal{V}} p_\theta(v \mid x, \widehat{y}_{<t}).$$

The sequence probability is a product of conditional probabilities,

$$p(\widehat{y}_{1:T} \mid x) = \prod_{t=1}^{T} p(\widehat{y}_t \mid x, \widehat{y}_{<t}).$$

Maximizing each factor myopically is not guaranteed to maximize the product over complete sequences because the first choice changes all later conditionals.

Part 3 - Hints, controls, and evidence

1. Assert the generated token at every step equals the raw-logit argmax.
2. Stop finished sequences immediately and never append useful-looking tokens after EOS.
3. Trace probability and entropy before and during a repetition loop.
4. Compare cached and uncached greedy generation; exact tokens and logits should match within tolerance.
5. Report deterministic outputs over a fixed prompt suite rather than one manually selected example.

Part 4 - Python code skeleton

```
import torch

@torch.inference_mode()
def greedy_decode(model, prompt_ids, eos_id, maximum_new_tokens):
    model.eval()
    generated = prompt_ids.clone()
    trace = []
    for generation_step in range(maximum_new_tokens):
        logits = model(generated)
        final_logits = logits[:, -1, :].float()
        probabilities = torch.softmax(final_logits, dim=-1)
        next_token = torch.argmax(final_logits, dim=-1, keepdim=True)
        selected_probability = probabilities.gather(1, next_token)
        trace.append({"step": generation_step,
                      "token": next_token.item(),
                      "probability": selected_probability.item()})
        generated = torch.cat((generated, next_token), dim=1)
        if next_token.item() == eos_id:
            break
    return generated, trace

def E02(model, prompt_ids, eos_id):
    first, trace_first = greedy_decode(model, prompt_ids, eos_id, 64)
    second, trace_second = greedy_decode(model, prompt_ids, eos_id, 64)
    assert torch.equal(first, second)
    assert trace_first == trace_second
    return first, trace_first
```

Part 5 - The Philosophy Behind the Exercise

Greedy decoding embodies immediate certainty: choose the best-looking next step and never reconsider. Its failures demonstrate that local rationality can produce a globally poor

path when decisions reshape the future.

Determinism makes greedy decoding scientifically valuable even when it is not creatively satisfying. It offers a stable mirror in which model and cache bugs cannot hide behind sampling variance.

17.8.4 Exercise 03

Exercise Title: Implement Temperature Sampling and Analyze Diversity vs Coherence Tradeoff Carefully

Part 1 - Why this matters

Temperature changes the sharpness of the next-token distribution before sampling. Values below one amplify logit differences and make output more conservative; values above one flatten differences and increase access to lower- probability tokens. Temperature does not improve the model or introduce new knowledge. It changes how aggressively generation explores probability mass the model already assigned.

Implement sampling by dividing logits by temperature and then applying softmax. Use an explicit `torch.Generator`. Reject nonpositive temperatures. For a very small positive value, verify behavior approaches greedy selection without dividing by zero. Cast logits to float32 for probability computation when lower-precision model execution makes the softmax fragile. Preserve the unmodified logits for diagnostics and log entropy, selected-token rank, probability, and seed.

Evaluate several temperatures under matched prompts, seeds, token budgets, and model checkpoint. Generate many samples per condition. Measure validation or reference likelihood, distinct-n, repetition, EOS rate, novelty relative to the training corpus, and task-specific correctness. Human review should be blinded to temperature. A high-temperature sample can be novel but incoherent; a low-temperature sample can be fluent but repetitive. Present a tradeoff curve rather than declaring one universal best value.

Part 2 - Mathematical form and reasoning

For logits z_v and temperature $\tau > 0$,

$$p_\tau(v) = \frac{\exp(z_v/\tau)}{\sum_u \exp(z_u/\tau)}.$$

For any two tokens a, b,

$$\frac{p_\tau(a)}{p_\tau(b)} = \exp\left(\frac{z_a - z_b}{\tau}\right).$$

Thus lower τ magnifies odds ratios and higher τ compresses them. As $\tau \to 0^+$ the distribution concentrates on the maxima; as $\tau \to \infty$ it approaches uniform over finite logits.

Part 3 - Hints, controls, and evidence

1. Verify probabilities are finite, nonnegative, and sum to one for normal and extreme logits.
2. Use the same list of random seeds for every temperature.

3. Report distributions of metrics across samples, not one sample per value.
4. Keep all other filters and penalties disabled while isolating temperature.
5. Inspect selected-token ranks; diversity can rise because generation enters the model's low-confidence tail.

Part 4 - Python code skeleton

```
import torch

def sample_with_temperature(logits, temperature, generator):
    if temperature <= 0.0:
        raise ValueError("temperature must be positive")
    scaled_logits = logits.float() / temperature
    probabilities = torch.softmax(scaled_logits, dim=-1)
    if not torch.isfinite(probabilities).all():
        raise FloatingPointError("invalid sampling probabilities")
    next_token = torch.multinomial(probabilities, 1, generator=generator)
    return next_token, probabilities

def E03(logits, temperatures=(0.2, 0.7, 1.0, 1.5)):
    report = {}
    for temperature in temperatures:
        tokens = []
        entropies = []
        for seed in range(100):
            generator = torch.Generator(device=logits.device)
            generator.manual_seed(seed)
            token, probabilities = sample_with_temperature(
                logits, temperature, generator)
            tokens.append(token.item())
            entropy = -(probabilities * probabilities.clamp_min(1e-12).log())
            entropies.append(entropy.sum().item())
        report[temperature] = {"tokens": tokens,
                               "mean_entropy": sum(entropies)/len(entropies)}
    return report
```

Part 5 - The Philosophy Behind the Exercise

Temperature is a dial between concentration and exploration. It reminds us that a probability distribution contains more possibilities than its maximum, and generation policy decides how much of that possibility space becomes real.

Creativity without coherence is noise; coherence without variation is repetition. The appropriate balance belongs to the purpose of generation and must be supported by evidence across many outputs.

17.8.5 Exercise 04

Exercise Title: Implement Top-k Sampling and Compare to Temperature Sampling for Stability and Diversity

Part 1 - Why this matters

Temperature reshapes the entire vocabulary distribution, so at high values even extremely implausible tokens can receive enough probability to be sampled. Top-k sampling first keeps only the k largest logits, sets all others to negative infinity, renormalizes, and samples from that fixed-size candidate set. It protects generation from the far tail, but the same k is used whether the model is highly certain or deeply uncertain.

Implement filtering with `torch.topk` and a Boolean keep mask. Validate $1 \leq k \leq V$, preserve ties according to the framework's returned indices, and compute softmax in float32. Apply temperature before top-k so ranking is unchanged for positive temperature while the retained probabilities are reshaped. Assert filtered tokens receive exactly zero probability and retained probabilities sum to one. Test $k = 1$ against greedy decoding and $k = V$ against unfiltered temperature sampling using the same random generator.

Compare several k values and temperatures on fixed prompts and seeds. Record candidate probability mass before renormalization, entropy after filtering, selected rank, repetition, distinct-n, novelty, EOS rate, and task quality. Small k can stabilize output but erase valid alternatives; large k can admit a noisy tail. Candidate count alone is not comparable across contexts whose probability concentrations differ.

Part 2 - Mathematical form and reasoning

Let $K_k(z)$ be the indices of the k largest logits. Define

$$\widetilde{z}_v = \begin{cases} z_v/\tau, & v \in K_k(z), \\ -\infty, & v \notin K_k(z), \end{cases} \qquad p(v) = \operatorname{softmax}(\widetilde{z})_v.$$

The retained pre-filter probability mass under temperature τ is

$$m_k = \sum_{v \in K_k} p_\tau(v).$$

Renormalization divides retained probabilities by m_k. When m_k is already near one, filtering changes little; when it is small, the policy strongly distorts the model distribution.

Part 3 - Hints, controls, and evidence

1. Test known logits where the top-k indices and probabilities can be computed manually.
2. Verify $k = 1$ always returns an argmax and $k = V$ preserves the unfiltered distribution.
3. Keep prompts, seeds, temperature, and token budget matched across k.
4. Log retained mass as well as candidate count; it explains why the same k behaves differently across steps.
5. Include flat and sharply peaked synthetic distributions as boundary cases.

Part 4 - Python code skeleton

```
import torch

def top_k_distribution(logits, k, temperature=1.0):
    vocabulary_size = logits.size(-1)
    if k < 1 or k > vocabulary_size:
        raise ValueError("k must be inside the vocabulary range")
    if temperature <= 0.0:
        raise ValueError("temperature must be positive")
    scaled = logits.float() / temperature
    top_values, top_indices = torch.topk(scaled, k, dim=-1)
    filtered = torch.full_like(scaled, -torch.inf)
    filtered.scatter_(-1, top_indices, top_values)
    probabilities = torch.softmax(filtered, dim=-1)
    return probabilities

def E04(logits, generator):
    report = {}
    vocabulary_size = logits.size(-1)
    for k in (1, 5, 20, vocabulary_size):
        probabilities = top_k_distribution(logits, k, temperature=0.8)
        token = torch.multinomial(probabilities, 1, generator=generator)
        positive_count = probabilities.gt(0).sum(dim=-1)
        assert torch.all(positive_count <= k)
        report[k] = {"token": token, "probabilities": probabilities}
    return report
```

Part 5 - The Philosophy Behind the Exercise

Top-k makes possibility finite at every step. It exchanges fidelity to the full distribution for protection against its least plausible tail.

The fixed candidate count is simple, but simplicity is a policy choice. A responsible decoder measures how much probability and meaning that fixed gate removes in different contexts.

17.8.6 Exercise 05

Exercise Title: Implement Top-p (Nucleus) Sampling and Compare Its Behavior Across Multiple p Values

Part 1 - Why this matters

Top-p sampling adapts candidate count to the model's uncertainty. It sorts tokens by probability and keeps the smallest prefix whose cumulative mass is at least p. A confident distribution may retain one or two tokens; a flat distribution may retain many. This makes the policy responsive, but sorting the vocabulary costs more than a fixed top-k filter and boundary implementation details matter.

Implement temperature softmax, descending sort, cumulative sum, and a shifted removal mask that always keeps the token crossing the threshold. Scatter the filtered sorted probabilities back into vocabulary order or sample directly in sorted space and map the selected index back. Validate $0 < p \leq 1$, keep at least one token, and prove retained mass before renormalization is at least p while removing any last retained token would usually fall below it. Test peaked, flat, and tied distributions.

Compare multiple p values using matched prompts, seeds, temperature, and generation length. At every step log nucleus size, retained mass, entropy, selected rank, and latency. Evaluate repetition, distinct-n, novelty, EOS behavior, and task correctness. A high p does not guarantee useful diversity if the model distribution itself is collapsed; a low p may behave like greedy decoding in confident contexts.

Part 2 - Mathematical form and reasoning

Let probabilities be ordered $p_{(1)} \geq p_{(2)} \geq \cdots \geq p_{(V)}$. Define

$$k^* = \min \left\{ k : \sum_{i=1}^{k} p_{(i)} \geq p_0 \right\},$$

where p_0 is the nucleus threshold. The retained distribution is

$$q_{(i)} = \begin{cases} p_{(i)} / \sum_{j=1}^{k^*} p_{(j)}, & i \leq k^*, \\ 0, & i > k^*. \end{cases}$$

Unlike top-k, the candidate count k^* is a function of context and changes at every generation step.

Part 3 - Hints, controls, and evidence

1. Use a four-token manual distribution to verify the crossing token remains inside the nucleus.
2. Test p close to zero, common values such as 0.9 and 0.95, and $p = 1$.
3. Log the distribution of nucleus sizes, not only its mean.
4. Compare top-p and top-k at similar retained mass as well as similar quality.
5. Keep temperature fixed during the isolated p sweep because temperature changes both ordering margins and cumulative mass.

Part 4 - Python code skeleton

```
import torch

def top_p_distribution(logits, nucleus_probability, temperature=1.0):
    if nucleus_probability <= 0.0 or nucleus_probability > 1.0:
        raise ValueError("top-p must be in (0, 1]")
    probabilities = torch.softmax(logits.float() / temperature, dim=-1)
    sorted_probabilities, sorted_indices = torch.sort(
```

```
        probabilities, dim=-1, descending=True)
    cumulative = torch.cumsum(sorted_probabilities, dim=-1)
    remove = cumulative > nucleus_probability
    shifted_remove = remove.clone()
    shifted_remove[..., 1:] = remove[..., :-1]
    shifted_remove[..., 0] = False
    sorted_probabilities = sorted_probabilities.masked_fill(
        shifted_remove, 0.0)
    sorted_probabilities = sorted_probabilities / sorted_probabilities.sum(
        dim=-1, keepdim=True)
    restored = torch.zeros_like(probabilities)
    restored.scatter_(-1, sorted_indices, sorted_probabilities)
    return restored

def E05(logits):
    report = {}
    for nucleus_probability in (0.5, 0.8, 0.9, 0.95, 1.0):
        distribution = top_p_distribution(logits, nucleus_probability)
        assert torch.allclose(distribution.sum(-1),
                              torch.ones_like(distribution.sum(-1)))
        report[nucleus_probability] = distribution
    return report
```

Part 5 - The Philosophy Behind the Exercise

Top-p defines possibility by probability mass rather than a fixed number of names. It expands when the model is uncertain and contracts when the model is confident.

This adaptability is valuable because uncertainty is contextual. Yet the nucleus inherits every error in the model's confidence, so adaptive selection still requires evaluation rather than trust.

17.8.7 Exercise 06

Exercise Title: Implement Repetition Penalty or Frequency Penalty Conceptually and Measure Reduction in Loops

Part 1 - Why this matters

Autoregressive feedback can create loops: once a token or phrase is generated, the resulting context may make it even more likely to appear again. Penalties modify logits using generation history before filtering and sampling. A presence penalty reacts to whether a token appeared; a frequency penalty grows with count; a multiplicative repetition penalty changes positive and negative logits differently. These are distinct algorithms and should not be mixed under one vague name.

Implement one penalty precisely and keep special tokens under an explicit policy. For additive frequency penalty λ, subtract λc_v from logit z_v, where c_v counts generated occurrences after the prompt or in the whole context according to configuration. Test a known history and logits manually. Apply penalties before temperature and top-k or top-p. Preserve original

logits so the magnitude and target of every change can be inspected.

Compare penalty strengths under matched prompts, seeds, sampling policy, and token budget. Measure repeated unigram and n-gram rates, longest loop, distinct-n, task correctness, EOS behavior, and semantic necessity. Repetition is not always wrong: names, syntax, code variables, refrains, or copied keys may need recurrence. Strong penalties can force synonyms, grammatical errors, or premature topic drift. Add prompts where repetition is required to expose this cost.

Part 2 - Mathematical form and reasoning

For generated history h and token count $c_v(h) = \sum_t \mathbb{1}[h_t = v]$, additive frequency penalty is

$$\tilde{z}_v = z_v - \lambda c_v(h), \qquad \lambda \geq 0.$$

A presence penalty uses

$$\tilde{z}_v = z_v - \alpha \mathbb{1}[c_v(h) > 0].$$

After modification, a later softmax renormalizes every probability, so reducing one repeated token redistributes mass across all alternatives. Penalties are decoding priors, not changes to the trained model.

Part 3 - Hints, controls, and evidence

1. Decide whether prompt tokens count toward the penalty and record the choice.
2. Exclude PAD and handle BOS/EOS explicitly; penalizing EOS may prevent termination.
3. Use a frequency vector updated once after each selected token and verify it cannot drift from the generated sequence.
4. Compare no penalty and several strengths over many fixed seeds.
5. Include both unwanted-loop prompts and repetition-required prompts in the evaluation suite.

Part 4 - Python code skeleton

```
import torch

def apply_frequency_penalty(logits, token_counts, penalty):
    if penalty < 0.0:
        raise ValueError("penalty must be nonnegative")
    if logits.shape != token_counts.shape:
        raise ValueError("counts must align with vocabulary logits")
    adjusted = logits.float() - penalty * token_counts.float()
    return adjusted

def update_counts(token_counts, selected_token):
```

```
    increment = torch.ones_like(selected_token, dtype=token_counts.dtype)
    token_counts.scatter_add_(-1, selected_token, increment)

def E06(logits, generated_ids, vocabulary_size):
    batch_size = logits.size(0)
    counts = torch.zeros(batch_size, vocabulary_size, device=logits.device)
    for position in range(generated_ids.size(1)):
        token = generated_ids[:, position:position + 1]
        update_counts(counts, token)
    report = {}
    for penalty in (0.0, 0.1, 0.5, 1.0):
        report[penalty] = apply_frequency_penalty(logits, counts, penalty)
    return report
```

Part 5 - The Philosophy Behind the Exercise

A repetition penalty inserts memory into the decoder's policy: previous choices become reasons to avoid the same choice again. It can break pathological loops, but it also imposes a human preference for variation.

Not all recurrence is failure. The ethical and engineering task is to penalize mechanical collapse without erasing repetition that carries identity, syntax, precision, or meaning.

17.8.8 Exercise 07

Exercise Title: Implement KV Cache Conceptually for Faster Autoregressive Decoding and Benchmark Speed Improvement

Part 1 - Why this matters

Without a KV cache, generation recomputes keys and values for every previous token at every step. The prefix does not change, so most of this work is redundant. A cache stores projected keys and values for each layer. On the next step, the model projects only the new token's query, key, and value, appends the new key/value to the cache, and attends the new query over all cached positions. This reduces repeated computation but introduces state, memory growth, and position bookkeeping.

Implement cache support at the attention layer with shape `(B,H,T_cached,d_h)`. During prompt prefill, process the whole prompt and create caches. During decode, accept one new token, concatenate its key and value along the sequence axis, and return updated caches. Position IDs for the new token must start at cached length, not zero. The new token's query has no future positions, so an explicit triangular mask is often unnecessary for a single-token decode, but padding and batch semantics still matter.

Prove parity before measuring speed. For every step, compare cached next-token logits with logits obtained by recomputing the full prefix; compare every layer's cache to keys/values computed from that prefix. Then benchmark prefill time, first-token latency, per-token decode latency, total generation time, and cache bytes across prompt and generation lengths. The cache improves compute while growing linearly with total stored context and may become the dominant memory cost.

Part 2 - Mathematical form and reasoning

At layer l and step t, cached tensors are

$$K_{1:t}^{(l)} = [K_{1:t-1}^{(l)}; K_t^{(l)}], \qquad V_{1:t}^{(l)} = [V_{1:t-1}^{(l)}; V_t^{(l)}].$$

The new output is

$$O_t = \text{softmax}\left(Q_t (K_{1:t})^\top / \sqrt{d_h}\right) V_{1:t}.$$

For L layers, batch B, heads H, stored length T, head width d_h, and element size s, cache memory is approximately

$$M_{KV} = 2LBHTd_h s = 2LBTd_{\text{model}} s.$$

Part 3 - Hints, controls, and evidence

1. Separate prompt prefill from one-token decode in the API and benchmarks.
2. Assert cache length increases by exactly one per decoding step and never changes during read-only use.
3. Compare cached and full-prefix logits at every step for several layers, batch sizes, and prompt lengths.
4. Use CUDA events and warmup; synchronize at measurement boundaries.
5. Report speedup together with cache memory and the context length where memory becomes the practical limit.

Part 4 - Python code skeleton

```
import torch

def append_kv(previous_key, previous_value, new_key, new_value):
    if previous_key is None:
        return new_key, new_value
    key = torch.cat((previous_key, new_key), dim=2)
    value = torch.cat((previous_value, new_value), dim=2)
    return key, value

@torch.inference_mode()
def cached_generate(model, prompt_ids, new_tokens):
    model.eval()
    logits, cache = model(prompt_ids, cache=None, use_cache=True)
    generated = prompt_ids.clone()
    for generation_step in range(new_tokens):
        next_token = torch.argmax(logits[:, -1, :], dim=-1, keepdim=True)
        generated = torch.cat((generated, next_token), dim=1)
        position = prompt_ids.size(1) + generation_step
```

```
        logits, cache = model(next_token, cache=cache, use_cache=True,
                              position_offset=position)
        expected_length = position + 1
        for layer_cache in cache:
            assert layer_cache[0].size(2) == expected_length
    return generated

def E07(model, prompt_ids, compare_full_prefix):
    cached = cached_generate(model, prompt_ids, 32)
    full = compare_full_prefix(model, prompt_ids, 32)
    assert torch.equal(cached, full)
    return cached
```

Part 5 - The Philosophy Behind the Exercise

The KV cache is computational memory: it preserves work whose meaning remains valid so the system does not repeatedly rediscover its own past.

Efficiency comes from recognizing invariance. Yet memory creates new duties. State must remain aligned with tokens, positions, layers, and batches. Saved work is valuable only while its identity is trustworthy.

17.8.9 Exercise 08

Exercise Title: Debug Generation Bugs Caused by Wrong Masking, Wrong Cache Concatenation, or Wrong Position Updates

Part 1 - Why this matters

Generation bugs often preserve legal shapes and finite outputs. A transposed causal mask may reveal the future during training. A cache concatenated along the head or feature axis may fail only after several steps. Position IDs reset to zero can make cached generation disagree with full-prefix recomputation while still producing fluent-looking text. Because sampling adds randomness, these defects can be mistaken for ordinary variation.

Build a deterministic debugging mode using evaluation mode, greedy decoding, float32, fixed prompts, and no penalties. Treat full-prefix recomputation as the reference. At every step save token IDs, position IDs, attention masks, logits, selected token, and per-layer key/value cache shapes. Compare next-token logits before selection. Locate the first step and layer whose values diverge rather than inspecting only the final string.

Inject three faults separately. Reverse or omit the causal rule and run the shared-prefix intervention. Concatenate cache along the wrong axis and assert that sequence length fails to increase by one. Reset positions during cached decoding and compare cached versus uncached logits. Add tests for prompt padding, variable lengths, context truncation, and finished rows. Each diagnosis must name the earliest broken contract and convert the repair into a permanent test.

Part 2 - Mathematical form and reasoning

For reference logits z_t^{full} and cached logits z_t^{cache}, define parity error

$$e_t = \frac{\|z_t^{\text{full}} - z_t^{\text{cache}}\|_\infty}{\|z_t^{\text{full}}\|_\infty + \epsilon}.$$

Correct cache growth requires

$$\text{shape}(K_t) = (B, H, T_0 + t, d_h),$$

and the new token uses absolute position T_0+t-1. Causal invariance requires that changing suffix $x_{>r}$ leaves logits $z_{\le r}$ unchanged. These three properties isolate position, cache, and mask faults.

Part 3 - Hints, controls, and evidence

1. Remove sampling variance before debugging numerical parity.
2. Use asymmetric dimensions so concatenating along the wrong axis cannot hide behind equal sizes.
3. Compare layer outputs and caches from earliest to latest; downstream differences are consequences.
4. Log whether masks mean “allowed” or “blocked” at every API boundary.
5. Preserve the failing prompt, checkpoint hash, tokenizer fingerprint, precision, and backend with the incident.

Part 4 - Python code skeleton

```
import torch

@torch.inference_mode()
def cache_parity_trace(model, prompt_ids, steps):
    model.eval()
    full_prefix = prompt_ids.clone()
    cached_logits, cache = model(prompt_ids, use_cache=True)
    trace = []
    for step in range(steps):
        full_logits = model(full_prefix, use_cache=False)
        reference = full_logits[:, -1, :].float()
        candidate = cached_logits[:, -1, :].float()
        error = (reference - candidate).abs().max().item()
        trace.append({"step": step, "maximum_logit_error": error})
        if not torch.allclose(reference, candidate, atol=1e-5, rtol=1e-4):
            raise AssertionError(f"cache divergence at step {step}")
        next_token = reference.argmax(-1, keepdim=True)
        full_prefix = torch.cat((full_prefix, next_token), dim=1)
        position = prompt_ids.size(1) + step
        cached_logits, cache = model(next_token, cache=cache, use_cache=True,
                                     position_offset=position)
    return trace
```

```
def E08(model, prompt_ids):
    return cache_parity_trace(model, prompt_ids, 16)
```

Part 5 - The Philosophy Behind the Exercise

Generation turns a pure function into a stateful process. Once past computation is cached, correctness depends on history remaining aligned across several representations of the same sequence.

Debugging restores one source of truth. Full recomputation, explicit positions, and stepwise comparison transform a vague bad output into the first broken agreement.

17.8.10 Exercise 09

Exercise Title: Evaluate Generation Quality with Perplexity and Simple Metrics Like Repetition Rate and Novelty Rate

Part 1 - Why this matters

Generation quality has no single sufficient metric. Perplexity evaluates teacher-forced probability on held-out text, not the coherence of free-running samples. Repetition measures loops but can punish legitimate reuse. Novelty measures difference from a reference corpus but can reward meaningless strings. The purpose is to build a metric panel whose disagreements reveal behavior, then connect those signals to blind manual review or task-specific correctness.

Compute validation NLL and perplexity only over valid targets with the same tokenizer. For generations, report distinct-n, repeated-n-gram fraction, longest repeated span, EOS completion, length, and novelty relative to training n-grams. Normalize carefully across different lengths. Define whether prompt tokens are excluded, whether special tokens count, and how whitespace or subword boundaries are decoded. Preserve per-sample values rather than only a mean.

Evaluate greedy, temperature, top-k, top-p, and penalty settings using the same prompts, seeds, and maximum budget. Include reference text and a random or unigram baseline to calibrate metrics. A model can have better perplexity yet more repetitive greedy output; a high novelty rate can coincide with lower human quality. Create a table of metric correlations and inspect counterexamples where metrics strongly disagree.

Part 2 - Mathematical form and reasoning

Perplexity is

$$\mathrm{PPL} = \exp\left(-\frac{1}{N}\sum_{i=1}^{N}\log p_\theta(y_i \mid x_{\le i})\right).$$

For generated n-gram multiset G_n and unique set U_n,

$$\mathrm{Distinct}_n = \frac{|U_n|}{|G_n|}, \qquad \mathrm{Repetition}_n = 1 - \mathrm{Distinct}_n\,.$$

If T_n is the set of training n-grams, novelty can be

$$\text{Novelty}_n = \frac{|\{g \in U_n : g \notin T_n\}|}{|U_n|}.$$

These definitions must be fixed before comparisons.

Part 3 - Hints, controls, and evidence

1. Calculate small examples manually to validate off-by-one n-gram windows and duplicate counting.
2. Report metrics by prompt and generation length bin as well as overall.
3. Keep prompt text out of generated-continuation novelty unless the research question explicitly includes it.
4. Bootstrap confidence intervals or repeat seeds for sampling-based metrics.
5. Review high-novelty/low-quality and low-novelty/high-quality samples to expose metric limitations.

Part 4 - Python code skeleton

```
def make_ngrams(tokens, n):
    ngrams = []
    final_start = len(tokens) - n
    for start in range(final_start + 1):
        ngram = tuple(tokens[start:start + n])
        ngrams.append(ngram)
    return ngrams

def generation_metrics(tokens, training_ngrams, n=3):
    generated_ngrams = make_ngrams(tokens, n)
    if len(generated_ngrams) == 0:
        return {"distinct": 0.0, "repetition": 0.0, "novelty": 0.0}
    unique_ngrams = set(generated_ngrams)
    novel_count = 0
    for ngram in unique_ngrams:
        if ngram not in training_ngrams:
            novel_count += 1
    distinct = len(unique_ngrams) / len(generated_ngrams)
    novelty = novel_count / len(unique_ngrams)
    return {"distinct": distinct, "repetition": 1.0 - distinct,
            "novelty": novelty}

def E09(generation_records, training_ngrams):
    report = []
    for record in generation_records:
        metrics = generation_metrics(record["tokens"], training_ngrams, n=3)
        report.append({"id": record["id"], "metrics": metrics})
    return report
```

Part 5 - The Philosophy Behind the Exercise

Metrics are partial languages for describing behavior. Each makes some property visible by ignoring others. Perplexity sees probability, repetition sees reuse, and novelty sees distance from memory.

Evaluation becomes mature when disagreement is treated as information. The goal is not to find one number that ends judgment, but a set of measurements that makes judgment more disciplined.

17.8.11 Exercise 10

Exercise Title: Run Decoder-Only Training and Generation on CUDA and Benchmark End-to-End Throughput Including Sampling

Part 1 - Why this matters

Training and generation stress CUDA differently. Training processes many tokens in parallel and is usually dominated by large matrix operations. Autoregressive generation has a parallel prompt-prefill phase followed by many small sequential decode steps. Sampling, cache updates, synchronization, and Python control flow can dominate even when the model runs on the GPU. One throughput number cannot describe both workloads.

Build separate end-to-end benchmarks for training, prefill, and decode. Training reports valid tokens per second including data transfer, forward, backward, and optimizer update. Generation reports prompt tokens per second, time to first generated token, decode tokens per second, total request latency, and cache memory. Include the actual sampling policy rather than benchmarking logits only. Keep logits, token counts, masks, model parameters, caches, and random generator on compatible devices. Avoid calling `item()` inside each decode step unless EOS handling requires a synchronized decision.

Use pinned batches and nonblocking transfer for training, warm up kernels, and measure with CUDA events or explicit synchronization. Benchmark greedy and sampling policies, cached and uncached generation, multiple prompt lengths, output lengths, and batch sizes. Verify output parity before speed comparisons. On two RTX 3070 GPUs, keep the single-device baseline clear before introducing distributed training; generation latency does not automatically improve by splitting a small model across devices.

Part 2 - Mathematical form and reasoning

Training throughput is

$$R_{\text{train}} = \frac{N_{\text{valid}}}{t_{\text{transfer}} + t_{\text{fwd}} + t_{\text{bwd}} + t_{\text{update}} - t_{\text{overlap}}}.$$

Generation separates prefill and decode:

$$t_{\text{request}} = t_{\text{prefill}} + \sum_{u=1}^{U} (t_{\text{model,u}} + t_{\text{sample,u}} + t_{\text{state,u}}).$$

Decode rate is $U/(t_{\text{request}} - t_{\text{prefill}})$. Report both batch-level and per-sequence rates so batching does not conceal user-visible latency.

Part 3 - Hints, controls, and evidence

1. Warm up each shape and policy because kernel selection and compilation can change first-run timing.
2. Use fixed generated length for throughput tests and a separate realistic EOS-terminated test.
3. Record peak allocated and reserved memory and bytes occupied by the cache.
4. Compare GPU time with wall time; their gap exposes CPU and synchronization overhead.
5. Save hardware, driver, PyTorch, precision, shapes, and sampling settings with every table.

Part 4 - Python code skeleton

```
import time
import torch

def timed_cuda_region(function):
    torch.cuda.synchronize()
    wall_start = time.perf_counter()
    event_start = torch.cuda.Event(enable_timing=True)
    event_end = torch.cuda.Event(enable_timing=True)
    event_start.record()
    result = function()
    event_end.record()
    event_end.synchronize()
    wall_seconds = time.perf_counter() - wall_start
    gpu_seconds = event_start.elapsed_time(event_end) / 1000.0
    return result, wall_seconds, gpu_seconds

def E10(training_step, generate, valid_tokens, generated_tokens):
    for warmup_step in range(5):
        training_step()
    training_result, train_wall, train_gpu = timed_cuda_region(training_step)
    generation_result, generation_wall, generation_gpu = timed_cuda_region(
        generate)
    training_rate = valid_tokens / train_wall
    generation_rate = generated_tokens / generation_wall
    return {"training_valid_tokens_per_second": training_rate,
            "generation_tokens_per_second": generation_rate,
            "training_gpu_seconds": train_gpu,
            "generation_gpu_seconds": generation_gpu,
            "generation": generation_result,
            "training": training_result}
```

Part 5 - The Philosophy Behind the Exercise

The same model participates in two different temporal economies. Training gains power from parallel evidence; generation must wait for each choice before the next can exist.

Performance measurement should respect the actual experience being optimized. Throughput, first-token latency, and per-token delay answer different human and systems questions.

17.8.12 Exercise 11

Exercise Title: Compare float32 vs float16 Generation Stability and Detect Softmax Instabilities During Long Generation

Part 1 - Why this matters

Long generation repeatedly feeds model outputs back as inputs. Small numerical differences between float32 and float16 can change a close sampling decision; after that token differs, later contexts are no longer comparable. This normal path divergence must be distinguished from numerical instability such as NaN, Inf, collapsed probabilities, cache corruption, or systematically changed termination. Sampling softmax and normalization deserve explicit float32 handling even when model matrix operations use float16.

Start with deterministic parity. Use greedy decoding, identical weights, prompts, cache policy, and evaluation mode. At each step compare float32 and float16 logits, top-token agreement, probability sums, entropy, and cache finiteness before the generated paths diverge. Then evaluate sampling statistically across matched seeds; exact token equality is not expected after small distribution changes. Record failure step, score range, selected-token margin, and AMP/autocast settings.

Inject extreme activation and logit scales in an isolated test. Compare naive float16 exponentiation, stable softmax, float32 softmax on float16 logits, and bfloat16 where supported. Test masks containing fully blocked rows and large negative values. Measure latency, memory, non-finite counts, EOS rate, repetition, and quality across long outputs. A run that stays finite can still be unstable if probability mass collapses or output statistics change sharply.

Part 2 - Mathematical form and reasoning

Stable softmax uses

$$p_i = \frac{\exp(z_i - m)}{\sum_j \exp(z_j - m)}, \qquad m = \max_j z_j.$$

Logit error at step t can be measured by

$$e_t = \frac{\|z_t^{32} - z_t^{16}\|_\infty}{\|z_t^{32}\|_\infty + \epsilon}.$$

The greedy choice is sensitive when the margin $\Delta_t = z_{(1)} - z_{(2)}$ is comparable to numerical error. Once different tokens are selected, later logit comparison measures different contexts and must be labeled accordingly.

Part 3 - Hints, controls, and evidence

1. Compare logits only while token prefixes remain identical; after divergence compare distributional outcomes instead.
2. Compute probability normalization and sampling in float32 as a controlled condition.
3. Monitor every layer's cache for finite values and expected dtype/device.
4. Include long runs that reach the intended maximum generation length.

5. Report speed and memory gains beside parity errors, non-finite counts, and behavioral changes.

Part 4 - Python code skeleton

```
import torch

def stable_sampling_probabilities(logits, temperature):
    scaled = logits.float() / temperature
    maximum = scaled.max(dim=-1, keepdim=True).values
    exponentials = torch.exp(scaled - maximum)
    probabilities = exponentials / exponentials.sum(dim=-1, keepdim=True)
    if not torch.isfinite(probabilities).all():
        raise FloatingPointError("non-finite probability during generation")
    return probabilities

@torch.inference_mode()
def E11(model_float32, model_float16, prompt, steps=128):
    prefix32 = prompt.clone()
    prefix16 = prompt.clone()
    report = []
    for step in range(steps):
        logits32 = model_float32(prefix32)[:, -1, :].float()
        logits16 = model_float16(prefix16)[:, -1, :].float()
        same_prefix = torch.equal(prefix32, prefix16)
        error = None
        if same_prefix:
            error = (logits32 - logits16).abs().max().item()
        token32 = logits32.argmax(-1, keepdim=True)
        token16 = logits16.argmax(-1, keepdim=True)
        report.append({"step": step, "same_prefix": same_prefix,
                       "maximum_logit_error": error,
                       "same_token": torch.equal(token32, token16)})
        prefix32 = torch.cat((prefix32, token32), dim=1)
        prefix16 = torch.cat((prefix16, token16), dim=1)
    return report
```

Part 5 - The Philosophy Behind the Exercise

Precision determines which distinctions a computation can preserve. In a feedback process, one erased distinction can redirect the entire future without implying that either path is numerically invalid.

Stability is therefore more than absence of NaN. It is an evidence-backed claim that compressed arithmetic preserves the distributions and decisions important to the intended generation behavior.

17.8.13 Exercise 12

Exercise Title: Implement Beam Search Conceptually and Compare Its Output to Sampling-Based Methods on a Small Example

Part 1 - Why this matters

Beam search keeps several high-scoring partial sequences instead of committing to one greedy path. At each step it expands every active beam with candidate tokens, adds log probabilities, and retains the best fixed number of combined hypotheses. It approximates sequence-level search and can recover a continuation whose first token is not locally best. Unlike sampling, standard beam search is deterministic and prioritizes model likelihood rather than diversity.

Implement the algorithm first on a tiny hand-defined probability tree. Store token sequence, cumulative log probability, finished flag, and optional cache for every beam. Finished beams must not be expanded except through a formal identity transition used for tensorized bookkeeping. Apply length normalization or length penalty explicitly, because raw log probability decreases with each additional token and favors short EOS hypotheses. Keep search score separate from raw model log probability in the report.

Then compare greedy, beam widths, and sampling methods on fixed prompts. Measure raw likelihood, normalized score, length, EOS completion, repetition, diversity, task correctness, and latency. Beam search can produce high-likelihood but bland or repetitive output, and larger beams can worsen length bias. When using a KV cache, reorder every layer's cache according to selected parent-beam indices; failure here can combine tokens from one hypothesis with state from another.

Part 2 - Mathematical form and reasoning

For beam hypothesis $h = (y_1, \ldots, y_t)$, cumulative score is

$$s(h) = \sum_{i=1}^{t} \log p_\theta(y_i \mid x, y_{<i}).$$

At step t, expand beam set $\mathcal{B}_{t-1}$ and keep

$$\mathcal{B}_t = \operatorname{TopB}\left\{(h \oplus v,\ s(h) + \log p(v \mid x, h)) : h \in \mathcal{B}_{t-1}, v \in \mathcal{V}\right\}.$$

A simple normalized score is $s(h)/|h|^\alpha$. The exponent α changes the search objective and must be tuned and reported.

Part 3 - Hints, controls, and evidence

1. Verify beam width one matches greedy decoding exactly when scoring and EOS rules are aligned.
2. Use a probability tree where greedy is provably not the best complete sequence.
3. Track parent beam index, emitted token, raw score, normalized score, and finished state at every step.
4. Test all beams finishing early, no beam reaching EOS, score ties, and maximum-length termination.

5. Compare quality under matched request budgets and report beam-search latency and cache-memory growth.

Part 4 - Python code skeleton

```
import torch

def beam_search(model, prompt, eos_id, beam_width, maximum_new_tokens,
                length_power=0.7):
    beams = [{"tokens": prompt.clone(), "log_probability": 0.0,
              "finished": False}]
    for step in range(maximum_new_tokens):
        candidates = []
        for beam in beams:
            if beam["finished"]:
                candidates.append(beam)
                continue
            logits = model(beam["tokens"])[:, -1, :].float()
            log_probabilities = torch.log_softmax(logits, dim=-1)
            values, indices = torch.topk(
                log_probabilities, beam_width, dim=-1
            )
            for candidate_index in range(beam_width):
                token = indices[:, candidate_index:candidate_index + 1]
                tokens = torch.cat((beam["tokens"], token), dim=1)
                token_score = values[0, candidate_index].item()
                score = beam["log_probability"] + token_score
                candidates.append({"tokens": tokens, "log_probability": score,
                                   "finished": token.item() == eos_id})
        def normalized(candidate):
            generated_length = candidate["tokens"].size(1) - prompt.size(1)
            denominator = max(generated_length, 1) ** length_power
            return candidate["log_probability"] / denominator
        candidates.sort(key=normalized, reverse=True)
        beams = candidates[:beam_width]
        if all(beam["finished"] for beam in beams):
            break
    return beams

def E12(model, prompt, eos_id):
    return beam_search(model, prompt, eos_id, beam_width=4,
                       maximum_new_tokens=32)
```

Part 5 - The Philosophy Behind the Exercise

Beam search postpones commitment. It preserves several futures long enough to compare their accumulated consequences rather than trusting the first local preference.

But search can only optimize the probabilities and score it is given. A wider search is not wiser when the model distribution or length objective misstates what humans value.

17.8.14 Exercise 13

Exercise Title: Implement Batched Generation and Manage Padding and Stopping Conditions Correctly for Variable Prompt Lengths

Part 1 - Why this matters

Batched generation improves throughput by processing several requests together, but variable prompt lengths create alignment problems. If prompts are right- padded and logits are blindly taken from the final tensor column, shorter rows use a PAD position rather than their last real token. Left padding can simplify last-column selection, but absolute position IDs must count valid tokens rather than padding columns. KV caches also contain padded regions whose attention must remain blocked.

Implement an explicit batch state containing token buffer, attention mask, position IDs, prompt lengths, finished mask, generated counts, and per-row stopping reason. For right padding, gather prefill logits at `prompt_length - 1`. During decode, append one column for every active batch row; finished rows receive a harmless filler token, their cache shape stays compatible, and their output is ignored. Sampling should not advance their RNG or counts. Stop when every row is finished or its individual maximum is reached.

Prove batched parity by comparing each row against separate single-sequence generation with matched seeds. Test prompts of length one, equal lengths, highly different lengths, a prompt already ending in EOS, and rows finishing at different steps. Verify no row attends to another row, padding does not alter valid logits, and decoding removes filler tokens from returned sequences.

Part 2 - Mathematical form and reasoning

For row b with prompt length L_b, right-padded prefill chooses

$$z_b = z_{b,L_b-1,:}.$$

Its position IDs can be constructed from validity mask P as

$$r_{b,t} = \max\left(\sum_{j=0}^{t} P_{b,j} - 1, 0\right).$$

Finished state evolves monotonically:

$$F_b^{(u+1)} = F_b^{(u)} \vee [y_b^{(u)} = \text{EOS}] \vee [u + 1 \geq U_b].$$

Once true, a row must never become active again.

Part 3 - Hints, controls, and evidence

1. Choose left or right padding and document the resulting logit-selection and position rules.
2. Maintain a Boolean active mask on the GPU and assert finished state is monotonic.
3. Use one generator per sequence when exact parity with independent sampling runs is required.
4. Check returned lengths, stopping reasons, and absence of filler tokens.

5. Benchmark uniform-length batches and mixed-length batches separately; padding waste may erase batching gains.

Part 4 - Python code skeleton

```
import torch

def final_prompt_logits(logits, prompt_lengths):
    batch_size = logits.size(0)
    row_indices = torch.arange(batch_size, device=logits.device)
    column_indices = prompt_lengths - 1
    return logits[row_indices, column_indices, :]

@torch.inference_mode()
def batched_greedy(model, input_ids, attention_mask, eos_id,
                   maximum_new_tokens):
    model.eval()
    prompt_lengths = attention_mask.sum(dim=1)
    logits, cache = model.prefill(input_ids, attention_mask)
    next_logits = final_prompt_logits(logits, prompt_lengths)
    generated_columns = []
    finished = torch.zeros(input_ids.size(0), dtype=torch.bool,
                           device=input_ids.device)
    for step in range(maximum_new_tokens):
        selected = next_logits.argmax(dim=-1)
        selected = torch.where(finished, torch.full_like(selected, eos_id),
                               selected)
        generated_columns.append(selected)
        finished = finished | selected.eq(eos_id)
        if bool(finished.all()):
            break
        active_rows = ~finished
        next_logits, cache = model.decode(
            selected[:, None], cache, active_rows=active_rows
        )
        next_logits = next_logits[:, -1, :]
    return torch.stack(generated_columns, dim=1), finished

def E13(model, batch, eos_id):
    return batched_greedy(model, batch["input_ids"],
                          batch["attention_mask"], eos_id, 64)
```

Part 5 - The Philosophy Behind the Exercise

Batching asks unlike sequences to share one computational clock. Efficiency comes from synchrony, while correctness requires preserving each sequence's independent history, position, and right to stop.

Uniform tensors should not erase individual temporal structure. Good batching coordinates computation without confusing one request's padding, randomness, or completion with another's meaning.

17.8.15 Exercise 14

Exercise Title: Implement Stop Tokens and EOS Handling and Prove Generation Terminates Correctly Without Cutting Useful Content

Part 1 - Why this matters

Generation needs a formal termination contract. EOS is a model token representing completion; stop sequences are application-level token patterns; maximum length is a safety limit rather than semantic completion. String matching after decoding can fail because one visible phrase may have several tokenizations or because partial stop patterns span decoding steps. Stopping too late exposes unwanted text, while stopping too early cuts a valid answer.

Implement token-level EOS and multiple stop sequences. After each selected token, update an incremental matcher or compare only suffixes up to the longest stop pattern. Decide whether the returned output includes or excludes matched stop tokens. Define precedence when EOS and a stop sequence complete on the same step. Add a minimum-new-token rule only if the application needs it; during the minimum, mask EOS and stop-completing candidates carefully and report that the decoder distribution was altered.

Test stop sequences of different lengths, overlapping prefixes, patterns split across steps, EOS in the prompt, EOS sampled immediately, no stop before maximum, and batched rows ending differently. Return a stopping reason and matched pattern for every sequence. Prove no token is generated after terminal state and no useful prefix is removed beyond the exact configured stop span. Measure premature EOS and maximum-length rates on a prompt suite to distinguish model behavior from termination code.

Part 2 - Mathematical form and reasoning

Let generated suffix through step t be $g_{1:t}$ and stop-pattern set $\mathcal{S}$. Termination event is

$$T_t = [g_t = \mathrm{EOS}] \vee \bigvee_{s \in \mathcal{S}} [g_{t-|s|+1:t} = s] \vee [t = U_{\max}].$$

The terminal step is

$$t^* = \min\{t : T_t = 1\}.$$

The returned sequence is a deterministic function of $g_{1:t^*}$ and the declared inclusion policy. No decoder step may occur for that row after t^*.

Part 3 - Hints, controls, and evidence

1. Match token IDs, not decoded substrings, and store stop sequences using the same tokenizer/version as generation.

2. Sort or prioritize overlapping stop patterns explicitly.

3. Keep semantic completion, application stop, and safety maximum as distinct stopping reasons.

4. Unit-test returned output both when matched tokens are included and when they are removed.

5. Count model forward calls to prove termination prevents further work.

Part 4 - Python code skeleton

```
def matched_stop(generated_tokens, stop_sequences):
    for stop_index in range(len(stop_sequences)):
        stop_sequence = stop_sequences[stop_index]
        stop_length = len(stop_sequence)
        if len(generated_tokens) < stop_length:
            continue
        suffix = generated_tokens[-stop_length:]
        if suffix == stop_sequence:
            return stop_index, stop_length
    return None, 0

def apply_stopping(generated_tokens, selected_token, eos_id,
                   stop_sequences, include_stop=False):
    generated_tokens.append(int(selected_token))
    if selected_token == eos_id:
        return True, "eos", generated_tokens
    stop_index, stop_length = matched_stop(generated_tokens, stop_sequences)
    if stop_index is not None:
        if not include_stop:
            del generated_tokens[-stop_length:]
        return True, f"stop_sequence_{stop_index}", generated_tokens
    return False, None, generated_tokens

def E14(scripted_tokens, eos_id, stop_sequences):
    generated = []
    for selected_token in scripted_tokens:
        finished, reason, generated = apply_stopping(
            generated, selected_token, eos_id, stop_sequences)
        if finished:
            return {"tokens": generated, "reason": reason}
    return {"tokens": generated, "reason": "maximum_length"}
```

Part 5 - The Philosophy Behind the Exercise

Termination defines when a possibility becomes a completed artifact. EOS lets the model express completion; stop patterns let the application define a boundary; maximum length protects finite resources.

These authorities should not be confused. A trustworthy generator records not only what it produced, but why it believed the act of producing should end.

17.8.16 Exercise 15

Exercise Title: Profile GPU Utilization During Generation and Identify Whether Model Compute or Sampling Logic Dominates

Part 1 - Why this matters

Autoregressive decode often underutilizes a GPU because each step launches small kernels and waits for sequential control logic. With a small model or batch, Python, cache concatenation, top-p sorting, host synchronization, and stopping checks may take as long as model compute. A high utilization percentage during prefill can coexist with poor per-token latency during decode. Profiling must separate these phases and name the actual bottleneck.

Use PyTorch Profiler over a short steady-state generation window and add named ranges for prefill, model decode, logits processing, sampling, cache update, and stopping logic. Record CPU and CUDA activities, shapes, memory, kernel launches, and synchronization events. Also collect wall time and CUDA-event time per phase. Detailed profiling changes latency, so use it for attribution and a lighter timer for final numbers.

Compare greedy, top-k, and top-p at several vocabulary sizes, batch sizes, prompt lengths, and cache lengths. If sampling dominates, vectorize filters, keep state on device, reduce sorting scope, or use fused operations. If model decode dominates, increase batch, use optimized attention/cache layouts, compilation, or suitable precision after parity checks. If Python gaps dominate, reduce per-token `item()` calls and move stopping state to device. Re- profile after one change and report end-to-end improvement, not isolated kernel speed.

Part 2 - Mathematical form and reasoning

Per-step wall time is

$$t_u = t_{\text{model}} + t_{\text{logits}} + t_{\text{sample}} + t_{\text{cache}} + t_{\text{stop}} + t_{\text{sync}} - t_{\text{overlap}}.$$

Phase fraction is $r_i = t_i/t_u$. The largest non-overlapped fraction gives the first optimization target. Amortized decode throughput for batch B is B/t_u, while user-visible latency remains approximately t_u per token. An optimization can improve throughput without improving single-request latency.

Part 3 - Hints, controls, and evidence

1. Profile prefill and decode separately and exclude profiler warmup.
2. Avoid accidental synchronizations in the baseline, especially token conversion to Python inside each step.
3. Measure p50, p95, and p99 token latency because periodic stalls disappear in an average.
4. Keep output tokens or distribution parity checks after every optimization.
5. Link each intervention to a specific observed timeline region and re-run the same workload.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, ProfilerActivity, record_function

def profiled_generation(prefill, decode_step, sampling_step, steps=16):
    with profile(activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],

```

Part 5 - The Philosophy Behind the Exercise

A generation timeline shows where sequential dependence becomes waiting. The GPU, CPU, cache, and sampling policy take turns determining when the next token may exist.

Optimization is not the pursuit of constant activity. It is the removal of the dependency that most delays the outcome users actually experience.

17.8.17 Exercise 16

Exercise Title: Export Decoder-Only Model Using TorchScript or ONNX and Validate Output Parity and Latency

Part 1 - Why this matters

Export is not a file-conversion ritual. It defines a stable inference contract that another runtime can execute without silently changing causal behavior. A decoder-only generator contains two different systems: a tensor program that maps tokens and state to logits, and a control program that chooses tokens, updates stopping rules, and schedules the next call. Export the tensor program first. Keep sampling and request policy outside the graph until their semantics are tested independently.

Define separate contracts for prefill and cached decode. Prefill accepts prompt IDs and their attention mask, processes every prompt position, and returns next-token logits plus one

key/value state per layer. Decode accepts new tokens, the previous cache, valid lengths or positions, and returns new logits and an extended cache. Dynamic axes must be intentional: batch size, prompt length, new-token length, and cached length may vary, whereas layer count, head count, and head dimension normally remain fixed.

Validate more than one happy-path tensor. Test several batches, prompt lengths, padding patterns, and cache lengths. Compare native and exported logits, every cache tensor, greedy next tokens, and a short deterministic generation trace. Tracing may freeze Python-dependent branches or shapes; scripting may reject unsupported Python; ONNX runtimes may lower operators differently. A successful export therefore proves only serialization. Parity tests establish semantic portability. Benchmark only after warm-up, with synchronization around device timing, and report graph compilation or session-start cost separately from steady-state latency.

Part 2 - Mathematical form and reasoning

The deployment interface can be written as

$$f_\theta(X, M, K_{<t}, P_t) \longrightarrow (Z_t, K_{\leq t}),$$

where X is the new token block, M its visibility mask, $K_{<t}$ the past key/value state, P_t position information, and Z_t the logits. For reference output Z and exported output $\widehat{Z}$, record

$$e_{\max} = \max_i |Z_i - \widehat{Z}_i|, \qquad e_{\text{rel}} = \frac{\|Z - \widehat{Z}\|_2}{\|Z\|_2 + \varepsilon}.$$

Numeric closeness is necessary, while equality of $\arg\max Z$ checks whether small errors alter deterministic decoding. Split latency into export or compile time, runtime initialization, prefill, and per-token decode.

Part 3 - Hints, controls, and evidence

Freeze one checkpoint, tokenizer, special-token policy, and precision. Put the model in evaluation mode and disable gradients. Make masks explicit instead of relying on runtime defaults. For TorchScript, compare tracing and scripting only where supported. For ONNX, declare dynamic axes and execute the result in the target runtime; inspecting the saved graph is insufficient. Use strict float32 tolerances and documented wider reduced-precision tolerances. Save failing inputs and the first cache component that diverges. Report median and tail latency after warm-up, plus model size and peak memory. The evidence is a parity table across shapes and a latency table with a precise measurement boundary.

Part 4 - Python code skeleton

```
import time
import torch
from torch import nn

class LogitExportWrapper(nn.Module):
    def __init__(self, model):
        super().__init__()
        self.model = model

    def forward(self, input_ids, attention_mask):
```

```
        output = self.model(input_ids, attention_mask=attention_mask)
        return output.logits

def compare_logits(reference, candidate, atol, rtol):
    absolute_error = (reference - candidate).abs()
    max_error = float(absolute_error.max().item())
    denominator = reference.norm() + 1e-12
    difference_norm = (reference - candidate).norm()
    relative_error = float(difference_norm.div(denominator).item())
    same_token = torch.equal(reference.argmax(-1), candidate.argmax(-1))
    close = torch.allclose(reference, candidate, atol=atol, rtol=rtol)
    return close, same_token, max_error, relative_error

def synchronized_latency(function, iterations, device):
    for _ in range(10):
        function()
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    started = time.perf_counter()
    for _ in range(iterations):
        function()
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    return (time.perf_counter() - started) / iterations

device = torch.device("cuda" if torch.cuda.is_available() else "cpu")
wrapper = LogitExportWrapper(model).eval().to(device)
example_ids = torch.randint(0, vocab_size, (2, 12), device=device)
example_mask = torch.ones_like(example_ids)

with torch.inference_mode():
    example_inputs = (example_ids, example_mask)
    traced = torch.jit.trace(wrapper, example_inputs, strict=False)
    for length in (4, 12, 31):
        ids = torch.randint(0, vocab_size, (2, length), device=device)
        mask = torch.ones_like(ids)
        native_logits = wrapper(ids, mask)
        exported_logits = traced(ids, mask)
        result = compare_logits(native_logits, exported_logits, 1e-5, 1e-4)
        print("length", length, "parity", result)

    native_time = synchronized_latency(
        lambda: wrapper(example_ids, example_mask), 100, device
    )
    exported_time = synchronized_latency(
        lambda: traced(example_ids, example_mask), 100, device
    )
    print("native seconds", native_time)
```

```
print("exported seconds", exported_time)
```

Extend the wrapper to expose flattened cache tensors, or create separate prefill and decode wrappers. Reconstruct the cache in a fixed documented order and verify every component before claiming cached export parity.

Part 5 - The Philosophy Behind the Exercise

Deployment is a change of execution authority. A model that worked in its training process is not yet the same model in another runtime. Trust comes from making the boundary explicit and testing meaning across it. Portability is not the ability to open a file; it is preservation of causal computation, state, decisions, and measurable performance.

17.8.18 Exercise 17

Exercise Title: Stress Test Long Generation With Large Context and Detect Memory Leaks or Cache Growth Bugs

Part 1 - Why this matters

Short demonstrations hide the two costs that dominate long autoregressive generation: attention over a growing context and storage of the key/value cache. Memory should increase predictably as tokens are appended. A leak is different: memory or retained Python state continues to grow beyond the tensors required by the declared context. Confusing expected cache growth with a leak can cause unsafe fixes; overlooking a leak can crash a long-lived inference service.

Construct a stress matrix over prompt length, requested output length, batch size, layer count, precision, and cache policy. Begin with one request and a modest sequence, then increase one axis at a time. At every decode step log logical context length, cache tensor shapes and bytes, CUDA memory allocated, CUDA memory reserved, peak memory, and token latency. Do not retain full logits, attention matrices, or tensors with computation graphs merely to plot them later. Store scalar summaries on the CPU and run under inference mode.

A correct unbounded cache grows linearly in generated length, while attention work per decode step grows with attended context. Reserved allocator memory may remain above allocated memory and need not fall after a request; that alone is not a leak. Repeat identical requests after releasing request-local state and synchronizing. Stable allocated memory at the same checkpoint is stronger evidence than visually inspecting reserved memory. Assert that every layer's cache length grows by exactly the number of newly processed tokens. Duplicate concatenation, stale cache references, accidental full-prefix recomputation, and retained autograd graphs produce distinct signatures that the report must name.

Part 2 - Mathematical form and reasoning

For L layers, batch B, H heads, cache length T, head width d_h, and s bytes per scalar, approximate key/value storage is

$$M_{\mathrm{KV}}(T) = 2LBHTd_hs.$$

Appending ΔT tokens should add approximately $2LBH\Delta Td_hs$ bytes, apart from allocator rounding and metadata. For repeated trials r at the same maximum length, define checkpoint drift as

$$D_r = M^{(r)}_{\text{allocated,end}} - M^{(1)}_{\text{allocated,end}}.$$

Persistent positive drift indicates retained state and deserves object- and tensor-level investigation. A sliding window bounds cache memory but changes the model's available context; it is a semantic policy, not a free cleanup.

Part 3 - Hints, controls, and evidence

Establish an analytic expected-cache curve before measuring CUDA memory. Record both allocated and reserved bytes, but interpret them separately. Synchronize before timing and before reading final memory. Repeat with cache disabled to reveal accidental full-prefix work, and with batch one to isolate request mixing. Test EOS early, maximum length, and forced long output. Add assertions for cache layer count, matching key/value shapes, batch dimension, head dimension, and monotonic length. If using a bounded window, prove cache length never exceeds the bound and separately measure quality loss. Evidence includes per-step curves, repeated-run end checkpoints, failure thresholds, the first violating step, and a minimal reproduction.

Part 4 - Python code skeleton

```
import gc
import time
import torch

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def cache_summary(past_key_values):
    total_bytes = 0
    lengths = []
    for layer_index, layer_cache in enumerate(past_key_values):
        key, value = layer_cache
        if key.shape != value.shape:
            raise RuntimeError("key/value shape mismatch")
        total_bytes += tensor_bytes(key)
        total_bytes += tensor_bytes(value)
        lengths.append(int(key.shape[-2]))
        print("layer", layer_index, "cache shape", tuple(key.shape))
    return total_bytes, lengths

@torch.inference_mode()
def stress_decode(model, input_ids, steps, device):
    torch.cuda.reset_peak_memory_stats(device)
    output = model(input_ids=input_ids, use_cache=True)
    cache = output.past_key_values
    token = output.logits[:, -1, :].argmax(-1, keepdim=True)
    previous_length = int(input_ids.shape[1])
    records = []

    for step in range(steps):
```

```
        torch.cuda.synchronize(device)
        started = time.perf_counter()
        output = model(input_ids=token, past_key_values=cache, use_cache=True)
        torch.cuda.synchronize(device)
        elapsed = time.perf_counter() - started
        cache = output.past_key_values
        token = output.logits[:, -1, :].argmax(-1, keepdim=True)

        cache_bytes, lengths = cache_summary(cache)
        for length in lengths:
            if length != previous_length + 1:
                raise RuntimeError("cache length did not grow by one")
        previous_length += 1
        records.append({
            "step": step,
            "context": previous_length,
            "cache_bytes": cache_bytes,
            "allocated": torch.cuda.memory_allocated(device),
            "reserved": torch.cuda.memory_reserved(device),
            "peak": torch.cuda.max_memory_allocated(device),
            "seconds": elapsed,
        })
    return records

def release_request_state():
    gc.collect()
    if torch.cuda.is_available():
        torch.cuda.synchronize()

# Run identical trials and compare allocated memory at equal checkpoints.
```

For real models, adapt the cache-length axis to the library's cache layout. Avoid empty-cache functions inside the measured request; they can hide ownership bugs and produce unrealistic service behavior.

Part 5 - The Philosophy Behind the Exercise

Resource growth must be interpreted through the model's declared state. Memory that represents useful history is a cost; memory that survives without serving future computation is a defect. Engineering maturity lies in predicting the first, detecting the second, and admitting when a bounded resource policy also changes the meaning of the model.

17.8.19 Exercise 18

Exercise Title: Build a Full Generation Debugging Checklist Covering Masking, Cache, Sampling, and Precision Issues

Part 1 - Why this matters

Generation failures are deceptive because a pipeline can remain syntactically valid while being semantically wrong. A causal-mask error may leak future tokens during training. A

padding error may affect only shorter prompts. A KV cache may work for the first step and corrupt positions afterward. Sampling can produce valid token IDs from an invalid probability distribution, and reduced precision can turn a rare extreme prompt into NaNs. Reading generated prose is therefore a weak debugging method; the system needs executable invariants.

Organize diagnosis in dependency order. First freeze artifacts and inputs: checkpoint identity, tokenizer fingerprint, vocabulary size, special-token IDs, prompt tokens, seed, dtype, device, and generation configuration. Then verify model state and tensor contracts: evaluation mode, disabled gradients, batch and sequence axes, attention-mask convention, causal visibility, position IDs, and finite logits. Next compare cached and uncached execution token by token. Only after logits agree should sampling, batching, EOS logic, export parity, and performance be investigated. This ordering prevents a late symptom from hiding an early violation.

Every checklist entry needs a machine-checkable assertion, a deliberately failing example, and a saved diagnostic artifact. For example, alter a masked future token and assert earlier logits do not change; insert padding and assert valid-token logits remain stable; compare full-prefix logits with single-token cached logits; confirm probability rows are finite, nonnegative, and sum to one; confirm finished sequences never change; and compare batch generation with independent single-item runs. A checklist that merely says "check the mask" is not a test. A useful checklist states what invariant must hold and what evidence will be emitted when it does not.

Part 2 - Mathematical form and reasoning

View generation as a composition of contracts

$$X \xrightarrow{\mathcal{T}} I \xrightarrow{\mathcal{M}} (Z, K) \xrightarrow{\mathcal{P}} p \xrightarrow{\mathcal{S}} y \xrightarrow{\mathcal{C}} (y, \text{status}),$$

where tokenization $\mathcal{T}$, model execution $\mathcal{M}$, logits policy $\mathcal{P}$, selection $\mathcal{S}$, and stopping controller $\mathcal{C}$ each have independent invariants. Debugging should find the earliest map whose output violates its contract. Important checks include

$$\sum_v p(v) = 1, \quad p(v) \geq 0, \quad Z_t^{\text{cached}} \approx Z_t^{\text{full}}, \quad y_{b,t} = y_{b,t}^{\text{single}}$$

under matched settings. Later equality is meaningful only when earlier inputs and random-number streams are controlled.

Part 3 - Hints, controls, and evidence

Run the suite first with greedy decoding because it removes random selection. Use a tiny model and handcrafted prompts so attention visibility can be inspected exactly. Include left and right padding, batch one and many, prompt length one, early EOS, no EOS, repeated tokens, extreme logits, and maximum context. Check float32 before reduced precision. Log the first divergent step, top competing logits, mask row, position ID, cache shapes, RNG state, and stop reason. Do not automatically "fix" a failure by loosening tolerance until its scale and decision effect are understood. Keep correctness tests separate from benchmarks so profiler overhead and synchronization cannot disguise behavior.

Part 4 - Python code skeleton

```
import torch

class GenerationAudit:
    def __init__(self):
        self.results = []

    def record(self, name, passed, details):
        entry = {"name": name, "passed": bool(passed), "details": details}
        self.results.append(entry)
        if not passed:
            raise AssertionError(str(entry))

def check_probabilities(probabilities, audit):
    finite = bool(torch.isfinite(probabilities).all())
    nonnegative = bool((probabilities >= 0).all())
    row_sums = probabilities.sum(dim=-1)
    expected = torch.ones_like(row_sums)
    normalized = torch.allclose(row_sums, expected, atol=1e-5)
    audit.record("probabilities finite", finite, {})
    audit.record("probabilities nonnegative", nonnegative, {})
    audit.record(
        "probabilities normalized",
        normalized,
        {"row_sums": row_sums.detach().cpu().tolist()},
    )

def compare_cached_step(full_logits, cached_logits, step, audit):
    difference = (full_logits - cached_logits).abs()
    maximum = float(difference.max().item())
    full_choice = full_logits.argmax(-1)
    cached_choice = cached_logits.argmax(-1)
    same_choice = torch.equal(full_choice, cached_choice)
    audit.record(
        "cache parity step " + str(step),
        torch.allclose(full_logits, cached_logits, atol=1e-5, rtol=1e-4),
        {"maximum_error": maximum, "same_greedy_token": same_choice},
    )

def check_finished_is_monotonic(previous_finished, current_finished, audit):
    revived = previous_finished & (~current_finished)
    audit.record(
        "finished state is monotonic",
        not bool(revived.any()),
        {"revived_rows": revived.nonzero().flatten().cpu().tolist()},
    )

def run_core_audit(probabilities, full_trace, cached_trace, finish_trace):
    audit = GenerationAudit()
```

```
    check_probabilities(probabilities, audit)
    if len(full_trace) != len(cached_trace):
        raise AssertionError("trace lengths differ")
    for step in range(len(full_trace)):
        compare_cached_step(full_trace[step], cached_trace[step], step, audit)
    for step in range(1, len(finish_trace)):
        check_finished_is_monotonic(
            finish_trace[step - 1], finish_trace[step], audit
        )
    return audit.results

# Add causal intervention, padding invariance, batch parity, EOS, dtype,
# export parity, cache-size, and latency-budget tests to the same registry.
```

Run each test once in its correct form and once with an intentional bug. If the test does not fail under the known bug, it is not yet protective evidence.

Part 5 - The Philosophy Behind the Exercise

Debugging is the reconstruction of causality, not the collection of suspicions. The pipeline should be trusted only to the depth at which its contracts have survived adversarial tests. By turning assumptions into executable invariants, the engineer replaces intuition about fluent output with evidence about the mechanism that produced it.

17.8.20 Exercise 19

Exercise Title: Produce a Full Decoder-Only Language Modeling Report Covering Training, Decoding, Failures, and Fixes

Part 1 - Why this matters

The final report is the evidence boundary of the entire chapter. It must allow another engineer to reproduce the model, understand why its generation policy was selected, identify where it is reliable, and know which conditions make it fail. A page of final loss and attractive samples cannot do this. Decoder-only systems connect data alignment, causal training, optimization, cache semantics, sampling policy, stopping rules, numerical precision, hardware behavior, and deployment runtime. The report must preserve those dependencies.

Begin with the experimental identity: code and environment versions, dataset and split fingerprints, tokenizer and special-token IDs, sequence construction, model dimensions, parameter count, seed policy, precision, device, optimizer, schedule, checkpoint, and resume history. Present training and validation loss, perplexity, gradient statistics, throughput, memory, and the tiny-task correctness test. State whether the model was trained with the same context and mask semantics used for evaluation.

Then report decoding as a controlled study. Compare greedy, temperature, top-k, top-p, frequency penalty, and beam search on identical prompts and seeds where applicable. Record likelihood-related metrics, repetition, novelty, length, EOS success, task correctness, latency, and qualitative samples chosen by a predeclared rule. Document KV-cache parity, batched versus single-request parity, stop reasons, float32 versus reduced-precision differences, export parity, long-context memory curves, and profiler attribution. Include failed runs and negative

results: a technique that did not help is part of the model's engineering history. End with recommended defaults, the evidence supporting them, known limitations, and explicit triggers for revisiting each decision.

Part 2 - Mathematical form and reasoning

Separate model fit from generation utility. A report may summarize model fit by

$$\mathrm{PPL} = \exp\left(-\frac{1}{N}\sum_{i=1}^{N}\log p_\theta(x_i \mid x_{<i})\right),$$

but deployment selection is multi-objective. For policy g, define a vector

$$R(g) = (Q_g, D_g, S_g, L_g, M_g, F_g),$$

containing task quality, diversity, stop correctness, latency, memory, and failure rate. Do not collapse this vector into one score unless weights and normalizations are justified. Every comparison should include uncertainty or variation across prompts and seeds, not only its mean. A production limit is a measured boundary with a failure criterion, not the largest successful run seen once.

Part 3 - Hints, controls, and evidence

Use a fixed report schema and link each claim to a table, plot, saved sample, or test result. Distinguish measurements from interpretations and interpretations from recommendations. State denominators, excluded samples, warm-up rules, hardware, batching, and timing boundaries. Include a failure registry with symptom, reproduction, root cause, correction, regression test, and remaining risk. Redact sensitive text while preserving reproducible synthetic cases. Record exceptions to the default decoding policy by workload. Before release, have the report validator reject missing sections, unversioned artifacts, unbounded generation settings, or recommendations with no cited evidence.

Part 4 - Python code skeleton

```
import json
from pathlib import Path

}
save_report(report, "reports/trf06_decoder_only_report.json")
```

Generate human-readable tables and plots from this structured record so the narrative and machine-checkable evidence cannot silently disagree.

Part 5 - The Philosophy Behind the Exercise

A final report is not a celebration of completion; it is a transfer of responsibility. It tells the next researcher what is known, how it became known, what remains uncertain, and which observations would justify changing course. The deepest result of this chapter is therefore not a generated sequence. It is a disciplined chain from causal objective to operational evidence, with enough honesty that future work can begin from reality rather than mythology.

17.9 TRF07

Chapter Title: Encoder-Decoder, Cross-Attention, and Seq2Seq
Specialization: Models and Training

17.9.1 Exercise 00

Exercise Title: Explain Encoder-Decoder Transformer and Why Cross-Attention Enables Conditional Generation

Part 1 - Why this matters

A decoder-only model predicts a continuation from one growing stream. An encoder-decoder Transformer solves a different structural problem: it receives a complete source sequence, constructs a contextual memory of that source, and then produces a target sequence conditioned on the memory. Translation, summarization, transcription, structured conversion, and many question-answer tasks naturally have this two-sequence form. Treating source and target as one undifferentiated stream is possible, but it changes masking, compute reuse, and the inductive organization of the task.

The encoder reads all valid source positions bidirectionally. Its output at each source position is not a token probability; it is a contextual memory vector. The decoder has two attention operations. Masked self-attention lets a target position use only earlier target positions, preserving autoregressive factorization. Cross-attention then uses decoder states as queries and encoder memory as keys and values. It asks, for every target position, which parts of the source are relevant now and what source information should be retrieved. Thus the decoder is simultaneously constrained by its generated history and conditioned on the entire visible source.

Build a conceptual trace before training anything. Give a tiny source and a partially shifted target unique token IDs. Record source embeddings, encoder memory, decoder self-attention states, cross-attention weights, logits, and the next-token target. Repeat after changing one source token while holding the target prefix fixed. Decoder logits should change because the condition changed. Then replace encoder memory with zeros; the model may still use target

history, but source-specific evidence disappears. This intervention distinguishes true conditional generation from a decoder that learns only target-side regularity.

Part 2 - Mathematical form and reasoning

For source $x_{1:S}$ and target $y_{1:T}$, the model factorizes

$$p_\theta(y_{1:T} \mid x_{1:S}) = \prod_{t=1}^{T} p_\theta(y_t \mid y_{<t}, x_{1:S}).$$

The encoder constructs memory

$$H = \text{Encoder}(E_x(x) + P_x), \qquad H \in \mathbb{R}^{B\times S\times d}.$$

After masked target self-attention produces $U \in \mathbb{R}^{B\times T\times d}$, one cross-attention head computes

$$Q = UW_Q, \quad K = HW_K, \quad V = HW_V,$$

$$A = \text{softmax}\left(\frac{QK^\top}{\sqrt{d_k}} + M_{\text{source}}\right), \qquad C = AV.$$

The target causal mask belongs to decoder self-attention; the source padding mask belongs to cross-attention. Cross-attention normally has no triangular mask because every real source position is already known. A has shape (B, H, T, S): each target query owns a probability distribution over source positions. The output projection and feed-forward layers transform retrieved context into logits over the target vocabulary.

Part 3 - Hints, controls, and evidence

Use distinct source and target sequence lengths so swapped axes are visible. Start with batch one, one head, no dropout, and fixed weights. Assert that every cross-attention row sums to one over unmasked source positions and assigns zero mass to padding. Prove target causality separately by changing a future target token and checking earlier logits. Then prove conditioning by changing a valid source token and checking at least one target logit changes. Compare three ablations: correct memory, shuffled memory positions, and zero memory. Save shape traces and intervention errors rather than relying on an attention heatmap alone. Attention weights describe retrieval inside the model; they are useful diagnostics but are not automatically a complete causal explanation.

Part 4 - Python code skeleton

```
import torch

@torch.inference_mode()
def conditionality_probe(model, source_ids, target_prefix, source_mask):
    model.eval()
    memory = model.encode(source_ids, source_mask)
    logits, cross_weights = model.decode(
        target_prefix, memory, source_mask, return_cross_weights=True
    )

    changed_source = source_ids.clone()
```

```
    replacement = changed_source[0, 0] + 1
    changed_source[0, 0] = replacement % model.source_vocab_size
    changed_memory = model.encode(changed_source, source_mask)
    changed_logits, _ = model.decode(
        target_prefix, changed_memory, source_mask,
        return_cross_weights=True
    )

    zero_memory = torch.zeros_like(memory)
    zero_logits, _ = model.decode(
        target_prefix, zero_memory, source_mask,
        return_cross_weights=True
    )

    source_effect = (logits - changed_logits).abs().max().item()
    memory_ablation_effect = (logits - zero_logits).abs().max().item()
    expanded_source_mask = source_mask[:, None, None, :]
    valid_mass = cross_weights.masked_fill(~expanded_source_mask, 0.0)
    row_sums = valid_mass.sum(dim=-1)

    assert source_effect > 0.0
    assert memory_ablation_effect > 0.0
    assert torch.allclose(row_sums, torch.ones_like(row_sums), atol=1e-5)
    return {
        "encoder_memory_shape": tuple(memory.shape),
        "cross_attention_shape": tuple(cross_weights.shape),
        "source_effect": source_effect,
        "memory_ablation_effect": memory_ablation_effect,
    }

def E00(model, source_ids, target_prefix, source_mask):
    return conditionality_probe(model, source_ids, target_prefix, source_mask)
```

The model interface is intentionally explicit: encoding and decoding are separate so memory reuse and conditionality can be inspected directly.

Part 5 - The Philosophy Behind the Exercise

Conditional generation is a disciplined conversation between two forms of knowledge: what the source says and what the target has already said. The encoder preserves the source as addressable memory; the decoder decides what to ask of that memory at each step. Cross-attention matters because conditioning is not passive storage. It is repeated, context-dependent retrieval. The model does not compress the whole source into one final state and hope it survives; it returns to the source whenever the evolving target requires new evidence.

17.9.2 Exercise 01

Exercise Title: Implement Cross-Attention from Scratch and Verify Shapes for Encoder Outputs and Decoder Queries

Part 1 - Why this matters

Cross-attention resembles self-attention algebraically, but its tensors come from different sequences. Queries represent target-side needs; keys and values represent source-side memory. That asymmetry is exactly where silent shape bugs occur. Equal source and target lengths can hide swapped dimensions, and a mask that broadcasts without error can still cover the wrong axis. Implementing the operation explicitly makes its data ownership visible.

Create separate projections for target queries and encoder keys and values. Split each projection into heads using named intermediate dimensions, transpose only the head and sequence axes, scale by the head width, apply a source padding mask, normalize over the source axis, mix values, concatenate heads, and apply the output projection. Return attention weights for inspection. Do not use `nn.MultiheadAttention` in the reference version.

Validate with $B = 2$, target length $T = 3$, source length $S = 5$, model width $d = 8$, and two heads. Manually compute one head for one batch item and compare it with the implementation. Mask the last two source positions of one example and prove their weights are zero. Change only decoder queries: attention weights should change while projected source keys and values remain identical. Change only encoder memory: keys and values must change. These interventions verify semantic provenance, not merely final shape.

Part 2 - Mathematical form and reasoning

With $U \in \mathbb{R}^{B\times T\times d}$ and $H \in \mathbb{R}^{B\times S\times d}$,

$$Q = UW_Q, \qquad K = HW_K, \qquad V = HW_V.$$

For h heads and $d_h = d/h$, reshape them to (B, h, T, d_h) for Q and (B, h, S, d_h) for K, V. Then

$$L_{b,r,t,s} = \frac{Q_{b,r,t,:} \cdot K_{b,r,s,:}}{\sqrt{d_h}}, \quad A_{b,r,t,:} = \operatorname{softmax}(L_{b,r,t,:} + M_{b,s}),$$

$$C_{b,r,t,:} = \sum_{s=1}^{S} A_{b,r,t,s} V_{b,r,s,:}.$$

After concatenation, C returns to (B, T, d). Softmax must use the final source axis. The mask must broadcast from (B, S) to $(B, 1, 1, S)$.

Part 3 - Hints, controls, and evidence

Assert that d is divisible by the number of heads. Use `reshape` only after ensuring the tensor layout is valid, and call `contiguous` before merging heads after a transpose. Reject batches whose source mask does not match memory length. For a fully masked row, choose and document a policy; ordinary seq2seq batches should contain at least one valid source token. Compare outputs and gradients against PyTorch's attention module after copying weights into the same convention. Evidence should contain the complete shape ledger, row-sum checks, masked-weight maximum, output parity, and gradient parity.

Part 4 - Python code skeleton

```
import math
import torch
from torch import nn

class ScratchCrossAttention(nn.Module):
    def __init__(self, model_width, number_of_heads):
        super().__init__()
        if model_width % number_of_heads != 0:
            raise ValueError("model width must divide evenly across heads")
        self.number_of_heads = number_of_heads
        self.head_width = model_width // number_of_heads
        self.query_projection = nn.Linear(model_width, model_width)
        self.key_projection = nn.Linear(model_width, model_width)
        self.value_projection = nn.Linear(model_width, model_width)
        self.output_projection = nn.Linear(model_width, model_width)

    def split_heads(self, tensor):
        batch_size, sequence_length, model_width = tensor.shape
        tensor = tensor.reshape(
            batch_size, sequence_length,
            self.number_of_heads, self.head_width
        )
        return tensor.transpose(1, 2)

    def forward(self, decoder_states, encoder_memory, source_mask):
        queries = self.split_heads(self.query_projection(decoder_states))
        keys = self.split_heads(self.key_projection(encoder_memory))
        values = self.split_heads(self.value_projection(encoder_memory))
        scores = torch.matmul(queries, keys.transpose(-2, -1))
        scores = scores / math.sqrt(self.head_width)
        visible = source_mask[:, None, None, :]
        scores = scores.masked_fill(~visible, torch.finfo(scores.dtype).min)
        weights = torch.softmax(scores.float(), dim=-1).to(scores.dtype)
        context = torch.matmul(weights, values)
        context = context.transpose(1, 2).contiguous()
        batch_size, target_length, _, _ = context.shape
        context = context.reshape(batch_size, target_length, -1)
        return self.output_projection(context), weights

def E01(decoder_states, encoder_memory, source_mask):
    layer = ScratchCrossAttention(decoder_states.size(-1), 2)
    output, weights = layer(decoder_states, encoder_memory, source_mask)
    assert output.shape == decoder_states.shape
    assert weights.shape[-2:] == (
        decoder_states.size(1), encoder_memory.size(1)
    )
    return output, weights
```

Part 5 - The Philosophy Behind the Exercise

The same matrix operation acquires different meaning from the origin of its arguments. Cross-attention teaches that tensor correctness includes provenance: who asks, what is searched, and which axis represents the available evidence. Shapes are necessary, but semantics live in the route by which tensors arrived.

17.9.3 Exercise 02

Exercise Title: Build a Tiny Seq2Seq Transformer and Validate Teacher Forcing Training Pipeline Correctly

Part 1 - Why this matters

Teacher forcing trains all target positions in parallel by feeding the known previous target tokens rather than the model's own sampled outputs. It is efficient and gives a clear next-token objective, but only if target shifting is exact. A single off-by-one error can let the current answer appear in the input, train the model to reproduce the wrong position, or misalign logits and labels while loss still decreases. This exercise builds an end-to-end reference small enough to overfit deliberately.

Create source and target embeddings, positional embeddings, an encoder, a decoder, and an output projection. A target sequence should contain beginning and end tokens. Feed `target[:, :-1]` to the decoder and compare its logits with `target[:, 1:]`. Padding labels receive an ignore index. Construct source and target masks from the exact tensors consumed by the model. Use a tiny deterministic copy or reverse dataset and train until nearly perfect token and exact-sequence accuracy. Tiny-data overfitting is a pipeline unit test, not a generalization claim.

Inspect one example explicitly. Print source IDs, full target IDs, decoder input, labels, causal mask, logits shape, and valid-token count. Confirm that the first decoder input is BOS, the first label is the first content token, and the last non-padding label is EOS. During generation, start from BOS and never supply the unknown reference continuation. This separates the training contract from the inference contract and exposes teacher-forcing leakage.

Part 2 - Mathematical form and reasoning

For a target $[\mathrm{BOS}, y_1, \ldots, y_T, \mathrm{EOS}]$, training uses

$$Y_{\text{in}} = [\mathrm{BOS}, y_1, \ldots, y_T], \qquad Y_{\text{label}} = [y_1, \ldots, y_T, \mathrm{EOS}].$$

The loss is

$$\mathcal{L} = -\frac{1}{N_{\text{valid}}} \sum_{b,t:\, Y_{b,t} \neq \mathrm{PAD}} \log p_\theta(Y_{b,t} \mid Y_{b,<t}, X_b).$$

There is one logit vector per decoder-input position and one aligned label. Both have length $T+1$ in this example. The target causal mask prevents position t from reading positions greater than t even though teacher forcing provides them elsewhere in the batch tensor.

Part 3 - Hints, controls, and evidence

Use separate source and target padding IDs if the vocabularies differ. Set dropout to zero for the first overfit test and verify every parameter receives a finite gradient. Evaluate

autoregressively rather than reporting teacher-forced accuracy alone. Create two intentional failures: remove the target shift and remove the causal mask. The first should be caught by alignment assertions; the second by a future-token intervention test. Save a known batch as a regression fixture. Evidence includes loss history, valid-token count, teacher-forced token accuracy, autoregressive exact match, and generated sequences.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class TinySeq2Seq(nn.Module):
    def __init__(self, source_vocab, target_vocab, width, heads, layers,
                 maximum_length, padding_id):
        super().__init__()
        self.source_embedding = nn.Embedding(source_vocab, width, padding_id)
        self.target_embedding = nn.Embedding(target_vocab, width, padding_id)
        self.position_embedding = nn.Embedding(maximum_length, width)
        self.transformer = nn.Transformer(
            d_model=width, nhead=heads,
            num_encoder_layers=layers, num_decoder_layers=layers,
            dim_feedforward=4 * width, dropout=0.0, batch_first=True
        )
        self.output_projection = nn.Linear(width, target_vocab)

    def add_positions(self, embedded):
        length = embedded.size(1)
        positions = torch.arange(length, device=embedded.device)
        return embedded + self.position_embedding(positions)[None, :, :]

    def forward(self, source_ids, decoder_ids, source_padding,
                target_padding):
        source = self.add_positions(self.source_embedding(source_ids))
        target = self.add_positions(self.target_embedding(decoder_ids))
        target_length = decoder_ids.size(1)
        causal_mask = nn.Transformer.generate_square_subsequent_mask(
            target_length, device=decoder_ids.device
        )
        hidden = self.transformer(
            source, target, tgt_mask=causal_mask,
            src_key_padding_mask=source_padding,
            tgt_key_padding_mask=target_padding,
            memory_key_padding_mask=source_padding,
        )
        return self.output_projection(hidden)

def E02(model, source_ids, full_target, padding_id):
    decoder_ids = full_target[:, :-1]
    labels = full_target[:, 1:]
```

```
    source_padding = source_ids.eq(padding_id)
    target_padding = decoder_ids.eq(padding_id)
    logits = model(source_ids, decoder_ids, source_padding, target_padding)
    assert logits.shape[:2] == labels.shape
    loss = nn.functional.cross_entropy(
        logits.reshape(-1, logits.size(-1)), labels.reshape(-1),
        ignore_index=padding_id
    )
    return loss, logits, labels
```

Part 5 - The Philosophy Behind the Exercise

Teacher forcing is a bargain: it exchanges inference realism for parallel, dense supervision. The bargain is valuable only when temporal meaning is protected by shifting and masking. This exercise teaches that data alignment is part of the model. An optimizer cannot repair a target that was defined one position incorrectly.

17.9.4 Exercise 03

Exercise Title: Implement Source Padding Mask and Target Causal Mask Together and Prove Both Masks Work Correctly

Part 1 - Why this matters

Seq2seq Transformers enforce two independent visibility laws. Source padding is not evidence and must be invisible to encoder self-attention and decoder cross-attention. Future target tokens are real tokens, but they are unavailable when the current token is predicted and must be hidden from decoder self-attention. Combining these masks incorrectly is dangerous because their shapes may broadcast and training loss may improve despite information leakage.

Implement masks from semantic Boolean tensors before converting them to the API convention required by a layer. Use deliberately different source and target lengths and different padding patterns for each batch row. Test source padding by replacing only padded source IDs with arbitrary alternatives; logits at valid target positions must remain unchanged. Test target causality by changing only target tokens after position t; logits through t must remain unchanged. Then modify a valid source token and confirm at least one target logit changes, proving the invariance test did not accidentally disable all conditioning.

Instrument self- and cross-attention weights if possible. For every target query, masked source columns must receive zero probability. For target self-attention, all entries above the diagonal must be zero. Distinguish a Boolean visibility mask from an additive logit mask, and document whether True means keep or block in every API call. Avoid a single variable named `mask` for all purposes; semantic names prevent convention inversion.

Part 2 - Mathematical form and reasoning

Let $P^x_{b,s} = 1$ for valid source positions and $P^y_{b,t} = 1$ for valid decoder inputs. Target causal visibility is

$$C_{t,j} = \mathbf{1}[j \leq t].$$

The decoder self-attention visibility for batch b is

$$V^{\text{self}}_{b,t,j} = P^{y}_{b,j} C_{t,j},$$

while cross-attention visibility is

$$V^{\text{cross}}_{b,t,s} = P^{x}_{b,s}.$$

An additive mask maps visible entries to zero and blocked entries to $-\infty$ before softmax. Its desired guarantee is

$$A_{b,h,t,j} = 0 \quad \text{whenever} \quad V_{b,t,j} = 0.$$

Query padding may also require output or loss masking; key masking alone does not remove predictions produced at padded target rows.

Part 3 - Hints, controls, and evidence

Create a mask-shape table before coding: source-valid (B, S), source-blocked (B, S), target-blocked (B, T), causal (T, T), cross score (B, H, T, S), and self score (B, H, T, T). Use float32 comparisons first and dropout-free eval mode. Test a batch row with no padding and another with several pads. Reject an empty source rather than allowing an all-masked softmax. Save maximum masked attention mass and maximum invariant-logit difference. An assertion should fail when you transpose the causal mask or omit the memory padding mask; this fault injection proves the test can detect the intended bug.

Part 4 - Python code skeleton

```
import torch

def causal_block_mask(target_length, device):
    row = torch.arange(target_length, device=device)[:, None]
    column = torch.arange(target_length, device=device)[None, :]
    return column > row

@torch.inference_mode()
def masking_invariance_test(model, source_ids, decoder_ids, padding_id):
    model.eval()
    source_blocked = source_ids.eq(padding_id)
    target_blocked = decoder_ids.eq(padding_id)
    target_length = decoder_ids.size(1)
    causal_blocked = causal_block_mask(target_length, decoder_ids.device)

    baseline = model(
        source_ids, decoder_ids, source_blocked,
        target_blocked, causal_blocked
    )

    padded_changed = source_ids.clone()
    replacement = torch.full_like(padded_changed, 1)
    padded_changed = torch.where(source_blocked, replacement, padded_changed)
```

```
    padding_variant = model(
        padded_changed, decoder_ids, source_blocked,
        target_blocked, causal_blocked
    )
    padding_error = (baseline - padding_variant).abs().max()

    future_changed = decoder_ids.clone()
    probe_position = 1
    future_changed[:, probe_position + 1:] = 2
    future_variant = model(
        source_ids, future_changed, source_blocked,
        target_blocked, causal_blocked
    )
    causal_error = (
        baseline[:, :probe_position + 1]
        - future_variant[:, :probe_position + 1]
    ).abs().max()

    assert padding_error.item() < 1e-5
    assert causal_error.item() < 1e-5
    return padding_error.item(), causal_error.item()

def E03(model, source_ids, decoder_ids, padding_id):
    return masking_invariance_test(model, source_ids, decoder_ids, padding_id)
```

Part 5 - The Philosophy Behind the Exercise

A mask is a law about what information is allowed to participate in a decision. Padding and the future are excluded for different reasons: one is not data, the other is data not yet available. Combining them correctly requires preserving that distinction. Reliable sequence modeling begins by treating visibility as a testable causal contract rather than a convenient tensor argument.

17.9.5 Exercise 04

Exercise Title: Train Seq2Seq Transformer on a Copy or Reverse Task and Measure Accuracy and Failure Modes

Part 1 - Why this matters

A synthetic copy or reverse task isolates the essential seq2seq pipeline. The symbols have no linguistic ambiguity, the correct output is exact, and examples can be generated at arbitrary lengths. If a small Transformer cannot solve this task, training on a real corpus will conceal rather than cure the defect. Copy tests source preservation and alignment; reversal additionally requires order- sensitive retrieval and a changing source position across decoder steps.

Generate integer sequences with reserved PAD, BOS, and EOS IDs. Split examples by seed and, more importantly, create an extrapolation set longer than training sequences. Train with teacher forcing, but evaluate with greedy autoregressive decoding from BOS until EOS or a fixed maximum. Measure valid-token accuracy, exact sequence match, EOS rate, length

error, and accuracy by source length. Teacher-forced accuracy alone can look excellent while autoregressive generation fails after its first mistake.
