Hotness belongs to an execution context, not permanently to a weight. A reuse-aware engine treats residency as a renewable lease: continued useful demand earns renewal, while stale history gradually loses authority over scarce VRAM.

19.14.10 Exercise 09

Exercise Title: Estimate Parameter Reload Cost from Tensor Bytes and Measured CPU-to-GPU Bandwidth Before Making a Placement Decision

Part 1 - Exercise Contract and Why It Matters

Calibrate a reload-cost model from completed H2D measurements and use it before promotion or eviction. Separate fixed latency from byte-dependent bandwidth so small and large parameter groups are not judged by the same approximation.

Part 2 - System and Memory Mental Model

Copy time includes submission overhead, interconnect transfer, possible host staging, contention, and the dependency imposed on computation. Pinned sources support asynchronous DMA, but an event must mark actual completion. A copy hidden behind compute has lower critical-path cost than an equally long blocking reload.

Part 3 - Quantitative Prediction Before Execution

Fit $T(M) = L + M/B$ from multiple pinned-buffer sizes. For a parameter group, sum unique bytes and estimate reload time plus a contention factor. Keep it resident when expected critical-path reload cost exceeds its residence cost and the group fits after safety reserves.

Part 4 - Experimental Design and Instrumentation

Warm up CUDA, reuse buffers, and measure many sizes with CUDA events. Report median and tail completion time and effective GB/s. Calibrate under idle and compute-contended conditions. Validate predicted group reload times against real parameter-shaped copies not used during fitting.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ReloadCostModel:
    latency_ms: float
    bandwidth_bytes_per_ms: float
    contention_multiplier: float = 1.0

    def predict_ms(self, size_bytes, critical_fraction=1.0):
        transfer_ms = self.latency_ms
        transfer_ms += size_bytes / self.bandwidth_bytes_per_ms
        transfer_ms *= self.contention_multiplier
        return transfer_ms * critical_fraction

    def should_keep(self, size_bytes, expected_reloads,
                    residence_cost_ms, available_bytes):
        if size_bytes > available_bytes:
            return False, "does_not_fit", 0.0
        reload_cost = expected_reloads * self.predict_ms(size_bytes)
        saving = reload_cost - residence_cost_ms
        if saving > 0.0:
            return True, "avoids_expensive_reloads", saving
        return False, "residence_cost_dominates", saving

def E09(latency_ms, measured_GB_per_second):
    bytes_per_ms = measured_GB_per_second * 1000.0 * 1000.0
    return ReloadCostModel(latency_ms, bytes_per_ms)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not derive bandwidth from CPU submission time. Synchronize the stop event and keep pinned allocation outside measured loops. A single linear model may fail across transfer-size regimes or on systems with shared bandwidth. Record prediction residuals and recalibrate when hardware, dtype, or concurrency changes.

Part 7 - Engineering Interpretation and Philosophy

Bytes become a placement decision only after hardware converts them into time. Calibration grounds policy in the machine actually running the workload. The model's purpose is not elegant prediction; it is reducing costly wrong moves.

19.14.11 Exercise 10

Exercise Title: Implement On-Demand Parameter Promotion from CPU to GPU Immediately Before the Owning Layer Executes

Part 1 - Exercise Contract and Why It Matters

Promote one layer's parameter group only when execution reaches that layer. Preserve a pinned CPU master, reserve VRAM before allocation, and publish CUDA storage only after its copy has completed. The first version targets inference.

Part 2 - System and Memory Mental Model

Promotion has prepare, submit, ready, and commit phases. Prepare checks budget and pins or reuses the CPU source. Submit allocates CUDA destination and queues H2D on a transfer stream. Ready is represented by an event. Commit changes the Parameter's active data storage, after which the owning layer and its input must execute on the same CUDA device.

Part 3 - Quantitative Prediction Before Execution

For each layer predict unique parameter bytes, promotion start, ready time, and stall seen by the compute stream. Without prefetch, almost all H2D completion time lies on the critical path. Peak managed VRAM equals current residents plus the group being admitted and any pending groups.

Part 4 - Experimental Design and Instrumentation

Run a layer twice: the first access should promote, and the second should hit the resident group. Log source bytes, pending bytes, event timestamps, compute wait, resident bytes, checksum, and object identity. Inject insufficient budget and missing pinned-source cases and verify clean rejection before mutation.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class OnDemandLayerPromoter:
    def __init__(self, budget_bytes):
        self.budget = budget_bytes
        self.used = 0
        self.cpu_master = {}
        self.ready_events = {}
        self.completion_events = {}
        self.stream = torch.cuda.Stream()

    def register(self, layer_name, layer):
        entries = []
        for name, parameter in layer.named_parameters(recurse=False):
            source = parameter.detach().cpu()
            if not source.is_pinned():
                source = source.pin_memory()
            entries.append((name, parameter, source))
        self.cpu_master[layer_name] = entries

    def promote(self, layer_name):
        if layer_name in self.ready_events:
            return "resident"
        entries = self.cpu_master[layer_name]
        required = 0
        for unused_name, parameter, unused_source in entries:
            required += parameter.numel() * parameter.element_size()
```

```
        if self.used + required > self.budget:
            raise RuntimeError("promotion exceeds parameter budget")

        destinations = []
        with torch.cuda.stream(self.stream):
            for name, parameter, source in entries:
                destination = torch.empty_like(source, device="cuda")
                destination.copy_(source, non_blocking=True)
                destinations.append((name, parameter, destination))
            event = torch.cuda.Event()
            event.record(self.stream)
        event.synchronize()
        with torch.no_grad():
            for unused_name, parameter, destination in destinations:
                parameter.data = destination
        self.ready_events[layer_name] = event
        self.used += required
        return "promoted"

    def record_use_completion(self, layer_name, stream):
        event = torch.cuda.Event()
        event.record(stream)
        self.completion_events[layer_name] = event
        return event

def E10(layer_name, layer, budget_bytes):
    promoter = OnDemandLayerPromoter(budget_bytes)
    promoter.register(layer_name, layer)
    promoter.promote(layer_name)
    return promoter
```

Part 6 - Measurement, Validation, and Failure Analysis

Synchronizing makes commit easy to audit but prevents overlap; E16 removes that stall with dependencies. Recurse carefully: direct parameters omit nested child layers. Buffers must be placed too when the operation uses them. Movement after forward is unsafe for ordinary training backward, and optimizer state remains a separate placement problem.

Part 7 - Engineering Interpretation and Philosophy

On-demand promotion trades certainty for capacity. It is the simplest policy that allows a model larger than VRAM to make progress, but it exposes the full cost of arriving late. This baseline gives prefetching an honest opponent.

19.14.12 Exercise 11

Exercise Title: Demote Parameters Back to CPU After Their Final GPU Use and Measure the Resulting Peak VRAM Reduction

Part 1 - Exercise Contract and Why It Matters

Use a known layer schedule to demote each parameter group after its final GPU consumer. Clean inference weights can return to their existing CPU master without D2H; dirty trained weights require a completed write-back.

Part 2 - System and Memory Mental Model

Final planned use and final completed use are different. The compute stream records an event after the layer. Only after that event may clean CUDA storage be released or dirty storage be copied. Assigning a CPU master back to a Parameter changes its active data tier while keeping module registration and object identity.

Part 3 - Quantitative Prediction Before Execution

From the execution plan calculate each group's last-use index. Predict the resident-byte timeline with and without prompt demotion, then compare the peaks. For a clean single-pass model, D2H traffic should be zero; for dirty groups, write-back bytes equal unique modified parameter bytes.

Part 4 - Experimental Design and Instrumentation

Run a deep sequential model and record allocated, reserved, and managed bytes after every layer. Compare never-demote, immediate-final-use demotion, and a delayed policy. Verify checksums after CPU restoration and allocate a same-sized temporary to expose premature allocator reuse.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class FinalUseDemoter:
    def __init__(self, cpu_master):
        self.cpu_master = cpu_master
        self.last_use = {}
        self.completion = {}

    def set_last_use(self, group_name, step):
        self.last_use[group_name] = step

    def record_use_completion(self, group_name, stream):
        event = torch.cuda.Event()
        event.record(stream)
        self.completion[group_name] = event

    def demote_if_final(self, group_name, step, parameters,
                        dirty=False):
        if self.last_use[group_name] != step:
            return 0
        event = self.completion[group_name]
        event.synchronize()
        released_bytes = 0
        with torch.no_grad():
            for name, parameter in parameters:
```

```
                released_bytes += (
                    parameter.numel() * parameter.element_size())
                master = self.cpu_master[(group_name, name)]
                if dirty:
                    master.copy_(parameter.detach().cpu())
                parameter.data = master
        return released_bytes

def E11(cpu_master):
    return FinalUseDemoter(cpu_master)
```

Part 6 - Measurement, Validation, and Failure Analysis

The dirty path shown is intentionally blocking and creates a temporary CPU copy; a pinned asynchronous write-back is built later. For tied weights, final use is the last use across all owners, not one layer's local last use. Releasing live allocated memory may not reduce reserved memory because the caching allocator keeps reusable blocks.

Part 7 - Engineering Interpretation and Philosophy

Memory is saved by proving the future, not by deleting aggressively. A schedule turns "probably unused" into a final-use guarantee. Correct lifetime knowledge often provides a larger and safer gain than a more complicated eviction score.

19.14.13 Exercise 12

Exercise Title: Use PyTorch Module Forward Hooks to Trigger Parameter Placement Automatically Without Manually Editing Every Forward Method

Part 1 - Exercise Contract and Why It Matters

Attach pre-forward and post-forward hooks that acquire a module's parameter group before execution and record or perform final-use release afterward. Keep model source code unchanged while making hook ordering and cleanup explicit.

Part 2 - System and Memory Mental Model

A pre-hook runs immediately before a module's `forward`; it can ensure weights and inputs share a device. A post-hook runs after forward submission, not after CUDA kernels physically finish, so it must record an event instead of assuming storage is free. Hooks are control-plane callbacks and should not silently mutate unrelated modules.

Part 3 - Quantitative Prediction Before Execution

Predict hook invocation order from the module graph, including repeated module use. Count placement calls, cache hits, and final-use events. Measure hook CPU overhead separately from transfer and kernel time. A reused module must not be demoted after its first invocation if the schedule contains another use.

Part 4 - Experimental Design and Instrumentation

Attach hooks to leaf compute modules only. Test nested Sequential, residual reuse, an exception inside forward, and repeated inference. Log module name, call index, device, promotion

result, output device, event, and cleanup. Remove all handles after the experiment and verify a second run has no duplicate hooks.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class PlacementHooks:
    def __init__(self, promoter, final_use_by_module):
        self.promoter = promoter
        self.final_use = final_use_by_module
        self.call_count = {}
        self.handles = []

    def attach(self, named_modules):
        for module_name, module in named_modules:
            self.call_count[module_name] = 0

            def pre_hook(current_module, inputs,
                         name=module_name):
                self.promoter.promote(name)
                self.call_count[name] += 1
                target = next(current_module.parameters()).device
                moved_inputs = []
                for value in inputs:
                    if torch.is_tensor(value):
                        moved_inputs.append(value.to(target))
                    else:
                        moved_inputs.append(value)
                return tuple(moved_inputs)

            def post_hook(current_module, inputs, output,
                          name=module_name):
                stream = torch.cuda.current_stream()
                self.promoter.record_use_completion(name, stream)
                return output

            self.handles.append(
                module.register_forward_pre_hook(pre_hook))
            self.handles.append(
                module.register_forward_hook(post_hook))

    def remove(self):
        for handle in self.handles:
            handle.remove()
        self.handles.clear()

def E12(promoter, final_use_by_module):
    return PlacementHooks(promoter, final_use_by_module)
```

Part 6 - Measurement, Validation, and Failure Analysis

Python closures must capture the current module name explicitly, as shown by the default argument. Modules without direct parameters need a target supplied by the registry instead of `next()`. Hook-based mutation can surprise model compilers, tracing, reentrant forwards, and thread-concurrent inference. Treat hook handles as resources and always remove them.

Part 7 - Engineering Interpretation and Philosophy

Hooks separate policy from model mathematics, but hidden control has a debugging cost. Automation is valuable only when every callback is observable, ordered, and reversible. A placement hook should make execution easier to inspect, not magical.

19.14.14 Exercise 13

Exercise Title: Reproduce a Device-Mismatch Failure Caused by Incorrect Parameter Placement and Build Automatic Device-Consistency Validation

Part 1 - Exercise Contract and Why It Matters

Intentionally place an input, weight, bias, or buffer on the wrong device, capture the failure, and build a validator that reports the mismatch before the operator launches. The diagnostic must name the owning module and every conflicting tensor category.

Part 2 - System and Memory Mental Model

Most CUDA operators require participating dense tensors on one device. Moving a weight alone can leave its bias, running statistics, input, or cached mask on CPU. The resulting runtime error is a symptom; the root cause is an incomplete placement group or missing boundary transfer.

Part 3 - Quantitative Prediction Before Execution

Before running, enumerate expected devices for parameters, buffers, positional inputs, keyword tensors, and relevant optimizer state. Predict exactly which pair conflicts. The validator's cost is proportional to metadata inspected and should be measured in debug and production-disabled modes.

Part 4 - Experimental Design and Instrumentation

Create separate failures for weight, bias, BatchNorm buffer, nested input, and stale gradient. Verify the validator fails before forward and includes qualified names. Include a valid multi-device boundary where input is intentionally moved between layers so the checker does not reject legal partitioning.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def tensor_devices(values):
    devices = []
    for value in values:
        if torch.is_tensor(value):
            devices.append(str(value.device))
```

```
    return devices

def validate_module_device(module_name, module, inputs):
    facts = []
    for name, parameter in module.named_parameters(recurse=False):
        facts.append(("parameter", name, str(parameter.device)))
        if parameter.grad is not None:
            facts.append(("gradient", name, str(parameter.grad.device)))
    for name, buffer in module.named_buffers(recurse=False):
        facts.append(("buffer", name, str(buffer.device)))
    for index, device in enumerate(tensor_devices(inputs)):
        facts.append(("input", str(index), device))

    unique_devices = set()
    for unused_kind, unused_name, device in facts:
        unique_devices.add(device)
    if len(unique_devices) > 1:
        message = "device mismatch in " + module_name + ": "
        message += str(facts)
        raise RuntimeError(message)
    return facts

def E13(module_name, module, inputs):
    return validate_module_device(module_name, module, inputs)
```

Part 6 - Measurement, Validation, and Failure Analysis

Some operations legally accept CPU metadata or indices with CUDA tensors, so a universal same-device rule can be too strict. Build operator-specific exceptions only after evidence. Nested containers need recursive traversal. A validator detects state inconsistency; it should not silently move tensors and conceal the policy error.

Part 7 - Engineering Interpretation and Philosophy

Failing early transforms a distant CUDA exception into a local placement explanation. Diagnostics are part of the memory system, not optional polish: dynamic behavior is maintainable only when illegal states identify themselves before computation corrupts or stalls.

19.14.15 Exercise 14

Exercise Title: Preserve Shared and Tied Parameters During Dynamic Placement Without Creating Duplicate GPU Copies

Part 1 - Exercise Contract and Why It Matters

Discover all names that refer to the same Parameter, promote that identity once, and ensure every owner observes the same CUDA storage. Final use and dirty state must be aggregated across all owners.

Part 2 - System and Memory Mental Model

Weight tying is semantic sharing, not coincidental equality. Replacing one owner with an independent CUDA copy breaks tying and doubles memory. Canonical identity can be the Parameter object ID for ordinary tying; models that create distinct Parameter objects over shared storage require storage-level identity and compatible view reconstruction.

Part 3 - Quantitative Prediction Before Execution

Calculate the naive by-name bytes and canonical unique bytes. Predict exactly one H2D transfer and one resident allocation for each tied group. The final-use index is the maximum use across all owner paths. Compare duplication ratio M_{naive}/M_{unique} before execution.

Part 4 - Experimental Design and Instrumentation

Tie an output projection to an embedding, inventory both names, promote through each owner, and compare object and storage identities. Mutate under a controlled no-grad test and prove both owners see the update. Verify one demotion after the last combined use and no duplicate transfer.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class SharedParameterRegistry:
    def __init__(self, model):
        self.by_id = {}
        self.name_to_id = {}
        for name, parameter in model.named_parameters(
                remove_duplicate=False):
            canonical_id = id(parameter)
            self.name_to_id[name] = canonical_id
            if canonical_id not in self.by_id:
                self.by_id[canonical_id] = {
                    "parameter": parameter,
                    "names": [],
                    "gpu_copy": None,
                    "last_use": -1,
                }
            self.by_id[canonical_id]["names"].append(name)

    def set_owner_last_use(self, name, step):
        canonical_id = self.name_to_id[name]
        record = self.by_id[canonical_id]
        record["last_use"] = max(record["last_use"], step)

    def install_gpu_copy(self, name, gpu_tensor):
        canonical_id = self.name_to_id[name]
        record = self.by_id[canonical_id]
        if record["gpu_copy"] is not None:
            return record["gpu_copy"], False
        parameter = record["parameter"]
        with torch.no_grad():
```

```
            parameter.data = gpu_tensor
        record["gpu_copy"] = gpu_tensor
        return gpu_tensor, True

def E14(model):
    return SharedParameterRegistry(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

The registry intentionally retains Parameter objects because it is an active control plane, not exported telemetry; its lifetime must not outlive the model. Object identity misses distinct view objects over one storage. Installing a copy must happen only after transfer completion and under a no-grad inference-safe boundary. Optimizer references must still point to the canonical object.

Part 7 - Engineering Interpretation and Philosophy

Sharing is part of the model's mathematics. A memory optimization that preserves values but destroys alias relationships has changed the program. Resource identity must therefore follow semantic identity, not merely qualified names.

19.14.16 Exercise 15

Exercise Title: Move Parameter Groups Asynchronously Through Pinned CPU Memory and a Dedicated CUDA Transfer Stream

Part 1 - Exercise Contract and Why It Matters

Submit a complete layer parameter group from pinned CPU masters to CUDA without blocking the host, preserve all source lifetimes, and make the compute stream wait only for that group's ready event. The group becomes one migration transaction with an explicit commit boundary.

Part 2 - System and Memory Mental Model

Pinned memory enables direct asynchronous H2D DMA. `non_blocking=True` only changes submission semantics; it does not prove completion. A transaction owns pinned sources, CUDA destinations, the transfer stream, and a ready event. Binding destinations to Parameters and ordering the consumer are separate operations. Every destination is recorded on its consumer stream for allocator lifetime safety.

Part 3 - Quantitative Prediction Before Execution

Sum unique bytes in the group and predict (L+M/B), CPU submission time, pending VRAM, and pinned RAM. One large grouped transfer often uses bandwidth more efficiently than many tiny independent submissions, although PyTorch still queues one copy per tensor in this implementation.

Part 4 - Experimental Design and Instrumentation

Compare pageable blocking, freshly pinned, reused pinned, and asynchronous group movement. Measure CPU submission, CUDA completion, effective GB/s, allocation overhead, and checksum after ready. Stress with hundreds of small parameters and a few large matrices.

Mutate a source before completion in an isolated negative test to demonstrate the lifetime hazard.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ParameterGroupTransfer:
    group_name: str
    sources: list
    destinations: list
    bindings: list
    ready: object
    transfer_stream: object
    state: str = "pending"

    def bind_for_compute(self, compute_stream):
        compute_stream.wait_event(self.ready)
        with torch.no_grad():
            for parameter, destination in self.bindings:
                parameter.data = destination
                destination.record_stream(compute_stream)
        self.state = "bound"

    def completed(self):
        return self.ready.query()

class AsyncParameterMover:
    def __init__(self):
        self.transfer_stream = torch.cuda.Stream()

    def submit(self, group_name, entries):
        sources = []
        destinations = []
        bindings = []
        with torch.cuda.stream(self.transfer_stream):
            for parameter, cpu_master in entries:
                if not cpu_master.is_pinned():
                    raise ValueError("CPU master must be pinned")
                destination = torch.empty_like(
                    cpu_master, device="cuda")
                destination.copy_(cpu_master, non_blocking=True)
                sources.append(cpu_master)
                destinations.append(destination)
                bindings.append((parameter, destination))
            ready = torch.cuda.Event()
            ready.record(self.transfer_stream)
```

```
        return ParameterGroupTransfer(
            group_name, sources, destinations, bindings,
            ready, self.transfer_stream)

def E15():
    return AsyncParameterMover()
```

Part 6 - Measurement, Validation, and Failure Analysis

The transaction retains pinned sources until Python releases it. Binding before copy completion is safe only because the compute stream first waits on the ready event; CPU inspection of destinations is irrelevant because they are CUDA storage. Pending destination bytes must be reserved in the budget at submission, not at completion. Exceptions must roll back accounting and references.

Part 7 - Engineering Interpretation and Philosophy

Asynchronous movement is a protocol, not a faster spelling of `to()`. Performance comes from making useful host and GPU work possible during transfer; correctness comes from retaining ownership and expressing the precise event on which the next consumer depends.

19.14.17 Exercise 16

Exercise Title: Prefetch the Next Layer's Parameters While the Current Layer Computes and Measure How Much Transfer Latency Is Hidden

Part 1 - Exercise Contract and Why It Matters

Build a one-layer lookahead pipeline: while layer i computes, submit the parameters of layer $i + 1$ on a dedicated transfer stream. Measure overlap on the CUDA timeline and distinguish hidden transfer time from mere asynchronous submission.

Part 2 - System and Memory Mental Model

True overlap requires pinned sources, non-blocking copies, separate streams, hardware capability, and no dependency forcing serialization. The compute stream waits on a group's ready event only when execution reaches that layer. Prefetch increases peak VRAM because current and next groups coexist, so admission must reserve both.

Part 3 - Quantitative Prediction Before Execution

If current compute takes C_i and next transfer takes H_{i+1}, ideal visible stall is approximately $\max(0, H_{i+1} - C_i)$. Maximum speedup is bounded by replacing $C_i + H_{i+1}$ with $\max(C_i, H_{i+1})$, plus launch and event overhead. Predict which layers fully hide transfer and which remain transfer bound.

Part 4 - Experimental Design and Instrumentation

Compare on-demand serial loading with one-layer lookahead over small, medium, and large layers. Record transfer start/stop events, kernel ranges, overlap duration, visible wait, peak allocated VRAM, pending bytes, and end-to-end latency. Use a profiler timeline to verify overlap rather than inferring it only from wall time.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class OneLayerPrefetchPipeline:
    def __init__(self, mover, groups):
        self.mover = mover
        self.groups = groups
        self.pending = {}
        self.compute_stream = torch.cuda.current_stream()

    def prefetch(self, index):
        if index >= len(self.groups):
            return
        if index in self.pending:
            return
        group_name, entries, unused_layer = self.groups[index]
        self.pending[index] = self.mover.submit(
            group_name, entries)

    def run(self, activation):
        self.prefetch(0)
        for index in range(len(self.groups)):
            transaction = self.pending.pop(index)
            transaction.bind_for_compute(self.compute_stream)
            self.prefetch(index + 1)
            unused_name, unused_entries, layer = self.groups[index]
            target = next(layer.parameters()).device
            if activation.device != target:
                activation = activation.to(
                    target, non_blocking=True)
            activation = layer(activation)
        return activation

def E16(mover, groups):
    return OneLayerPrefetchPipeline(mover, groups)
```

Part 6 - Measurement, Validation, and Failure Analysis

This minimal pipeline does not demote old groups; integrate final-use release when measuring a strict budget. A transfer submitted on another stream can still serialize because of memory pressure, copy-engine limits, or hidden default- stream dependencies. Prefetch distance greater than one may hide more latency but can trigger OOM or evict useful current weights.

Part 7 - Engineering Interpretation and Philosophy

Prefetching converts a prediction about future execution into early physical work. Its value is bounded by the computation available to cover the copy. The right goal is not maximum lookahead; it is the smallest lookahead that keeps the critical path supplied without destabilizing memory.

19.14.18 Exercise 17

Exercise Title: Build a VRAM Watermark Controller That Dynamically Promotes and Demotes Parameter Groups Before an OOM Occurs

Part 1 - Exercise Contract and Why It Matters

Protect the placement engine from last-second allocation failure using a hard budget and two softer watermarks. Admission reserves pending bytes before CUDA allocation; pressure mode demotes legal cold groups until recovery headroom is restored.

Part 2 - System and Memory Mental Model

Managed bytes include committed residents and submitted destinations. High watermark crossing enters pressure; demotion continues until the low watermark. Hysteresis prevents repeated promotion and demotion around one threshold. Protected, shared-in-use, dirty-pending, and consumer-in-flight groups are not immediately reclaimable.

Part 3 - Quantitative Prediction Before Execution

For capacity C, choose $L < H < C$. Before admitting group g, require $R + P + M_g \leq C$, where R and P are resident and pending bytes. If the future total exceeds H, select legal victims until the projected total is at most L. Predict victim bytes, write-back traffic, and overshoot.

Part 4 - Experimental Design and Instrumentation

Replay monotonic growth, noisy boundary, sudden large group, and all-protected traces. Log resident, pending, protected, reclaimable, high/low transitions, victim reasons, rejected admissions, and distance from physical free memory. Assert the hard managed budget after every transition.

Part 5 - PyTorch/CUDA Implementation

```
class ParameterWatermarks:
    def __init__(self, capacity_bytes, low_ratio=0.70,
                 high_ratio=0.85):
        self.capacity = capacity_bytes
        self.low = int(capacity_bytes * low_ratio)
        self.high = int(capacity_bytes * high_ratio)
        if not 0 <= self.low < self.high < self.capacity:
            raise ValueError("invalid watermarks")
        self.resident = 0
        self.pending = 0
        self.pressure = False

    def reserve_pending(self, requested_bytes):
        projected = self.resident + self.pending + requested_bytes
        if projected > self.capacity:
            return False, projected - self.low
        if projected >= self.high:
            self.pressure = True
            return False, projected - self.low
```

```
        self.pending += requested_bytes
        return True, 0

    def commit_pending(self, size_bytes):
        self.pending -= size_bytes
        self.resident += size_bytes
        assert self.resident + self.pending <= self.capacity

    def release_resident(self, size_bytes):
        self.resident -= size_bytes
        if self.resident + self.pending <= self.low:
            self.pressure = False
        assert self.resident >= 0

def E17(capacity_bytes):
    return ParameterWatermarks(capacity_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

A rejected reservation returns the recovery target; the policy must demote and retry once, not loop forever. Managed capacity must leave a measured reserve for activations, workspaces, CUDA context, and fragmentation. Device free memory and PyTorch reserved memory provide diagnostic signals but should not silently replace one consistent accounting definition mid-run.

Part 7 - Engineering Interpretation and Philosophy

OOM prevention is admission control, not exception handling. Watermarks buy time to choose legal victims and stabilize decisions. A system that waits for CUDA to reject an allocation has already surrendered control of its most important resource invariant.

19.14.19 Exercise 18

Exercise Title: Stress-Test Parameter Placement on a Deep PyTorch Model with Artificially Restricted VRAM and Diagnose Thrashing, Duplicate Copies, and Transfer Stalls

Part 1 - Exercise Contract and Why It Matters

Drive the placement engine with a model whose parameter payload exceeds an artificial managed budget while remaining safely below physical device memory. Find invariant failures and performance collapse across variable group sizes, reuse patterns, sharing, and prefetch distances.

Part 2 - System and Memory Mental Model

Artificial restriction makes pressure deterministic without deliberately exhausting the device. Thrashing means a group is evicted and reloaded before its movement earns useful computation. Duplicate copies arise when aliases are not canonicalized. Transfer stalls appear when ready events reach the compute critical path or when excessive prefetching competes for bandwidth and VRAM.

Part 3 - Quantitative Prediction Before Execution

Before execution, simulate the exact layer trace and predict managed peak, H2D bytes, evictions, reloads, and duplicate-free unique bytes. Define failure thresholds: zero wrong outputs, zero budget violations, one CUDA copy per canonical resident group, and bounded migrations per layer execution.

Part 4 - Experimental Design and Instrumentation

Generate deep sequential, reused-block, tied-weight, and routed-expert traces. Sweep budgets and prefetch distance over fixed seeds. Log every transition, canonical ID, resident duration, useful uses, H2D/D2H bytes, event wait, transfer-compute overlap, decision time, peak allocated/reserved VRAM, and latency percentiles. Minimize any failing trace.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict

class ParameterPlacementStressModel:
    def __init__(self, group_sizes, budget_bytes):
        self.group_sizes = group_sizes
        self.budget = budget_bytes
        self.resident = OrderedDict()
        self.used = 0
        self.loads = 0
        self.evictions = 0
        self.reloads = 0
        self.ever_loaded = set()

    def access(self, canonical_group):
        if canonical_group in self.resident:
            self.resident.move_to_end(canonical_group)
            return "hit"
        size_bytes = self.group_sizes[canonical_group]
        if size_bytes > self.budget:
            return "bypass_oversized"
        while self.used + size_bytes > self.budget:
            victim, unused = self.resident.popitem(last=False)
            self.used -= self.group_sizes[victim]
            self.evictions += 1
        if canonical_group in self.ever_loaded:
            self.reloads += 1
        self.ever_loaded.add(canonical_group)
        self.resident[canonical_group] = True
        self.used += size_bytes
        self.loads += 1
        assert self.used <= self.budget
        return "load"

def E18(group_sizes, trace, budget_bytes):
    model = ParameterPlacementStressModel(group_sizes, budget_bytes)
    outcomes = []
```

```
    for canonical_group in trace:
        outcomes.append(model.access(canonical_group))
    return model, outcomes
```

Part 6 - Measurement, Validation, and Failure Analysis

The simulator isolates policy behavior; replay the same canonical trace through the real PyTorch engine afterward. A miss-heavy streaming workload is not automatically thrashing because it may have no reuse. Diagnose thrashing only when short residence is followed by reload. Compare storage IDs to detect real duplication, and inspect profiler timelines for stalls.

Part 7 - Engineering Interpretation and Philosophy

Stress tests are experiments against assumptions. Deep models expose mistakes that small examples cannot: long ownership chains, phase changes, aliasing, and pressure interactions. A placement engine is ready only when its worst cases are reproducible, measurable, and explainable.

19.14.20 Exercise 19

Exercise Title: Build and Benchmark a Dynamic PyTorch Parameter Placement Engine That Executes a Model Under a VRAM Budget Smaller Than Its Total Parameter Size

Part 1 - Exercise Contract and Why It Matters

Integrate canonical parameter identity, pinned CPU masters, strict byte admission, asynchronous promotion, lookahead, final-use demotion, event ordering, watermarks, and diagnostics. Execute a complete inference model whose total parameter payload is larger than the managed VRAM budget without violating numerical correctness.

Part 2 - System and Memory Mental Model

The engine is a parameter memory operating system. Each canonical group has CPU masters, optional CUDA destinations, authority, dirty state, pending transaction, ready event, consumer-completion event, protection reasons, access history, and owner modules. Admission counts pending bytes before allocation. Compute waits on ready; demotion waits on all consumers; tied owners share one allocation.

The first integrated target is inference because training adds gradients, optimizer state, and backward saved-tensor lifetimes. A production training engine must extend the same state machine rather than pretending weights can be moved independently after forward.

Part 3 - Quantitative Prediction Before Execution

Choose managed capacity C below total unique parameter bytes and below physical free VRAM after explicit activation/workspace reserve. Simulate the trace to predict peak residents, pending peak, H2D bytes, reloads, evictions, visible transfer stall, and ideal overlap. Acceptance requires $R + P \leq C$ at every transition, exact canonical sharing, and output parity.

Part 4 - Experimental Design and Instrumentation

Compare all-CPU, whole-CUDA when it fits on a reference device, static split, on-demand dynamic, and prefetched dynamic execution. Use identical weights, inputs, precision, and request order. Warm up, synchronize boundaries, repeat, and report cold start, median/tail

latency, throughput, peak allocated/reserved VRAM, managed peak, pinned RAM, traffic, overlap, policy overhead, and checksums.

Part 5 - PyTorch/CUDA Implementation

def E19(groups, budget_bytes):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    return DynamicParameterEngine(groups, budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

This reference engine deliberately blocks during victim completion and supports clean inference weights. Production code should demote asynchronously, bound event-history growth, place buffers, support nested graphs, and use a planned final-use schedule. Training additionally requires authoritative dirty write-back, gradient and optimizer-state placement, and protection until backward consumers finish.

Test transaction rollback, all-protected pressure, tied groups, oversized groups, exceptions inside layers, and repeated requests. Never use `empty_cache()` as a substitute for releasing live Parameter storage, and never count a pending group twice when it commits.

Part 7 - Engineering Interpretation and Philosophy

A model larger than VRAM can execute because not every weight must be resident simultaneously. The achievement is not bypassing capacity; it is scheduling a working set through capacity while preserving identity, ordering, and truth. The final engine is credible when every byte has an owner, every transition has a reason, and every asynchronous use has a completion proof.

Chapter Title: Dynamic Layer Offloading
Specialization: Dynamic Memory Management and CUDA Systems

19.15.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Layer Residency, Execution Order, Transfer Cost, and VRAM Pressure in Deep PyTorch Models

Part 1 - Exercise Contract and Why It Matters

Build a layer-level state machine before implementing offloading. A layer is an execution unit containing parameters, persistent buffers, temporary workspace, and relationships to incoming and outgoing activations. The model must explain not only where weights live but when the whole layer is legally executable.

The contract must answer: which canonical layer or shared module is referenced, which tensors constitute its movable state, which device owns that state, which transfer is pending, which invocation is active, what its next planned use is, and what evidence permits eviction.

Part 2 - System and Memory Mental Model

Useful states begin with CPU residence, H2D transfer, and CUDA readiness. They continue through execution, pending consumers, optional D2H transfer, backward protection, and release. A post-forward Python callback occurs after kernels are submitted, not necessarily after they finish. CUDA events establish completion without forcing unrelated work on the entire device to stop.

Layer state and activation state are distinct. Offloading a completed layer can be safe while its output remains on CUDA for the next layer or a residual path. During training, backward may need the layer's parameters and saved tensors long after forward, so inference-safe eviction can be training-incorrect.

Part 3 - Quantitative Prediction Before Execution

For layer i, define persistent bytes $W_i = P_i + B_i$, where P_i and B_i are unique parameter and buffer bytes. Estimate H2D time as $L + W_i/\beta$. The resident window must also budget live activations, workspace, pending prefetch, and allocator margin.

For prefetch of layer $i+1$ during compute C_i, ideal visible transfer stall is approximately $\max(0, T_{i+1} - C_i)$. Record this prediction before building a deeper pipeline.

Part 4 - Experimental Design and Instrumentation

Use sequential, residual, repeated-module, and tied-weight graphs. At every transition log layer identity, invocation index, parameters, buffers, resident and pending bytes, activation bytes, stream, ready and done events, next use, and reason. Compare managed accounting with allocated and reserved CUDA memory, while keeping their meanings separate.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class LayerState:
    canonical_name: str
    owner_paths: list
    parameter_bytes: int
    buffer_bytes: int
    state: str = "cpu_resident"
```

```
    next_planned_use: int = -1
    invocation_count: int = 0
    protected_reasons: set = field(default_factory=set)

    @property
    def persistent_bytes(self):
        return self.parameter_bytes + self.buffer_bytes

    def begin_prefetch(self):
        if self.state != "cpu_resident":
            raise RuntimeError("layer is not ready for H2D prefetch")
        self.state = "h2d_pending"

    def mark_ready(self):
        if self.state != "h2d_pending":
            raise RuntimeError("no pending prefetch to complete")
        self.state = "cuda_ready"

    def begin_execution(self):
        if self.state != "cuda_ready":
            raise RuntimeError("layer is not CUDA-ready")
        self.state = "executing"
        self.invocation_count += 1

def E00(name, owner_paths, parameter_bytes, buffer_bytes):
    return LayerState(name, owner_paths,
                      parameter_bytes, buffer_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Module device inspection alone cannot reveal pending transfers, active kernels, shared ownership, or backward protection. Recursive layer byte sums can double count child modules and tied parameters. Separate logical layer ownership from canonical storage accounting, and validate every state transition against CUDA events and numerical outputs.

Part 7 - Engineering Interpretation and Philosophy

Layer offloading is execution scheduling under a memory constraint. The engine does not make a large model smaller; it changes when each part occupies the fast tier. Correctness comes from respecting dependencies, and performance comes from arranging movement early enough that execution rarely waits.

19.15.2 Exercise 01

Exercise Title: Measure the Parameter and Buffer Memory Footprint of Every Layer in a PyTorch Model Before Designing an Offload Strategy

Part 1 - Exercise Contract and Why It Matters

Build a layer inventory that separates direct parameters, direct buffers, and recursive subtree totals. Preserve canonical identities so shared weights and shared module instances are not counted repeatedly in the global budget.

Part 2 - System and Memory Mental Model

Leaf execution layers normally own direct state, while container modules report the sum of descendants. Counting both produces hierarchical double counting. Buffers such as BatchNorm running statistics affect device correctness even when they do not require gradients. Non-persistent buffers still occupy memory while the module exists.

Part 3 - Quantitative Prediction Before Execution

Predict direct parameter bytes and buffer bytes for each layer. Then calculate global unique totals by object or storage identity. Compare the sum of leaf direct bytes with the unique model total; explain any difference using shared state or parameters registered directly on container modules.

Part 4 - Experimental Design and Instrumentation

Inventory a plain Sequential model, BatchNorm-containing model, residual block, and tied-weight model. Record module path, class, direct and recursive counts, dtype, device, trainability, aliases, and whether the module has executable forward logic. Export scalar metadata rather than live tensors.

Part 5 - PyTorch/CUDA Implementation

```
def direct_layer_bytes(module):
    parameter_bytes = 0
    buffer_bytes = 0
    parameter_ids = []
    buffer_ids = []
    for parameter in module.parameters(recurse=False):
        parameter_bytes += parameter.numel() * parameter.element_size()
        parameter_ids.append(id(parameter))
    for buffer in module.buffers(recurse=False):
        buffer_bytes += buffer.numel() * buffer.element_size()
        buffer_ids.append(id(buffer))
    return parameter_bytes, buffer_bytes, parameter_ids, buffer_ids

def E01(model):
    report = []
    global_parameters = set()
    global_buffers = set()
    for name, module in model.named_modules(remove_duplicate=False):
        parameter_bytes, buffer_bytes, parameter_ids, buffer_ids = (
            direct_layer_bytes(module))
        for parameter_id in parameter_ids:
            global_parameters.add(parameter_id)
        for buffer_id in buffer_ids:
            global_buffers.add(buffer_id)
        report.append({
            "name": name,
            "class": module.__class__.__name__,
            "direct_parameter_bytes": parameter_bytes,
```

```
            "direct_buffer_bytes": buffer_bytes,
            "parameter_ids": tuple(parameter_ids),
            "buffer_ids": tuple(buffer_ids),
        })
    return report, global_parameters, global_buffers
```

Part 6 - Measurement, Validation, and Failure Analysis

The sets above reveal unique identities but do not calculate their byte totals; retain a scalar ID-to-bytes table when that total is required. Distinct tensor objects can exceptionally share one storage, so storage-level inspection may be needed. Sparse, quantized, meta, and sharded modules require specialized accounting rather than a dense estimate.

Part 7 - Engineering Interpretation and Philosophy

Offload granularity should follow measured state, not architectural appearance. Two layers that look symmetric can have radically different parameters and buffers. Accurate inventory turns layer movement from guesswork into a budgeted schedule.

19.15.3 Exercise 02

Exercise Title: Build a Sequential Model That Keeps Only One Layer on CUDA at a Time and Offloads It Back to CPU After Execution

Part 1 - Exercise Contract and Why It Matters

Create the simplest complete oversized-model execution strategy: move one layer to CUDA, execute it, prove completion, move the layer back to CPU, and continue. At no point may two layer groups intentionally remain resident.

Part 2 - System and Memory Mental Model

The activation becomes the boundary object passed between layers. It can remain on CUDA while weights are replaced. Moving a module to CPU recursively moves its parameters and buffers, but doing so immediately after forward submission can race outstanding kernels. A completion event makes the blocking baseline safe.

Part 3 - Quantitative Prediction Before Execution

Peak persistent layer VRAM should approach the largest layer's parameter plus buffer bytes, not total model bytes. Add activation, workspace, transfer temporary, and allocator margin. Predict total H2D bytes as the sum of all layer state loaded once and D2H bytes according to whether clean CPU masters are reused or CUDA weights are copied back.

Part 4 - Experimental Design and Instrumentation

Run inference under `inference_mode()`, verify one resident layer after each admission, and compare output with an all-CPU reference. Log layer bytes, move time, compute time, event completion, allocated/reserved peaks, activation shape, and checksum. Repeat to expose the cost of reloading every request.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class OneLayerCudaSequential:
    def __init__(self, layers, device="cuda:0"):
        self.layers = layers
        self.device = torch.device(device)
        for layer in self.layers:
            layer.to("cpu")

    def __call__(self, inputs):
        activation = inputs.to(self.device)
        trace = []
        with torch.inference_mode():
            for index, layer in enumerate(self.layers):
                layer.to(self.device)
                activation = layer(activation)
                completed = torch.cuda.Event()
                completed.record(torch.cuda.current_stream())
                completed.synchronize()
                layer.to("cpu")
                trace.append({
                    "layer": index,
                    "output_shape": tuple(activation.shape),
                    "offloaded": True,
                })
        return activation, trace

def E02(layers):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    return OneLayerCudaSequential(layers)
```

Part 6 - Measurement, Validation, and Failure Analysis

`layer.to("cpu")` copies active state back and may be more expensive than restoring pre-existing CPU masters. It also blocks overlap. Training is excluded because backward still needs forward state. Shared modules called later cannot be treated as permanently finished after the first call; execution schedule, not module list position, determines final use.

Part 7 - Engineering Interpretation and Philosophy

This baseline sacrifices speed for a small and easy-to-prove resident window. Its value is diagnostic: every optimization that follows must outperform it without weakening its clear memory and completion invariants.

19.15.4 Exercise 03

Exercise Title: Compare Full-GPU Residency Against One-Layer-at-a-Time Offloading and Measure Peak VRAM, Latency, and Throughput

Part 1 - Exercise Contract and Why It Matters

Compare the fastest simple residency strategy with the smallest simple layer window using identical model weights, inputs, precision, and inference mode. Report both feasibility and the cost paid for memory reduction.

Part 2 - System and Memory Mental Model

Full residency pays weight transfer once and reuses every layer across requests. One-layer offloading repeatedly moves state and serializes transfer with compute. Peak allocated VRAM, caching allocator reserved memory, synchronized request latency, and throughput answer different questions and must all be measured.

Part 3 - Quantitative Prediction Before Execution

Predict the full model's unique parameter and buffer bytes. Predict the one-layer peak from the largest group plus activations and workspace. For R requests, estimate reload traffic and the request count at which full residency's initial load is amortized relative to repeated layer movement.

Part 4 - Experimental Design and Instrumentation

Create identical model copies from one state dictionary. Warm up each variant, reset peak statistics, synchronize measurement boundaries, and run multiple batch sizes. Report cold start, median/tail latency, requests per second, peak allocated/reserved VRAM, H2D/D2H traffic, and output parity.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def measure_completed(run_once, repetitions):
    torch.cuda.synchronize()
    torch.cuda.reset_peak_memory_stats()
    started = time.perf_counter()
    output = None
    for unused in range(repetitions):
        output = run_once()
    torch.cuda.synchronize()
    elapsed = time.perf_counter() - started
    peak = torch.cuda.max_memory_allocated()
    return output, elapsed, peak

def E03(full_model, offload_runtime, inputs, repetitions=10):
    full_model.eval().to("cuda:0")

    def run_full():
        with torch.inference_mode():
            return full_model(inputs.to("cuda:0"))

    def run_offloaded():
```

```
        output, unused_trace = offload_runtime(inputs)
        return output

    full_output, full_time, full_peak = measure_completed(
        run_full, repetitions)
    offload_output, offload_time, offload_peak = measure_completed(
        run_offloaded, repetitions)
    parity = torch.allclose(
        full_output.cpu(), offload_output.cpu(),
        rtol=1.0e-4, atol=1.0e-5)
    return full_time, full_peak, offload_time, offload_peak, parity
```

Part 6 - Measurement, Validation, and Failure Analysis

Measuring both variants in one process can leave allocator cache from the first run; use fresh processes for final peak claims. Ensure model copies start from identical weights and evaluation mode. CUDA launch time without synchronization is not inference latency. Report speed per completed request, not per Python forward submission.

Part 7 - Engineering Interpretation and Philosophy

Offloading is successful when it enables a workload that otherwise cannot run, then minimizes the price of that feasibility. A large percentage VRAM reduction does not erase a large latency penalty; both belong in the same engineering decision.

19.15.5 Exercise 04

Exercise Title: Implement Forward Hooks That Automatically Move a Layer to CUDA Immediately Before Its Forward Pass

Part 1 - Exercise Contract and Why It Matters

Attach pre-forward hooks to selected execution layers so placement occurs without editing each forward method. Move module state and tensor inputs to the same CUDA device and record the invocation that caused admission.

Part 2 - System and Memory Mental Model

A pre-hook runs before its module's forward call. Moving a complete module includes parameters and buffers, while incoming activations may still be on a different tier. Hooks fire per invocation, so a shared module can trigger more than once. Container hooks and child hooks can overlap responsibilities and must not both move the same state blindly.

Part 3 - Quantitative Prediction Before Execution

Predict hook order and number of physical H2D movements from the execution graph. Distinguish invocation count from unique module count. Record CPU hook overhead, transfer bytes, and visible forward stall; immediate pre-hook movement places nearly the entire transfer on the critical path.

Part 4 - Experimental Design and Instrumentation

Attach only to leaf compute modules, run repeated and nested modules, and verify every input/parameter/buffer device before the operator. Log module name, invocation, previous

device, bytes, new device, transfer time, and output parity. Remove handles and prove a later forward has no duplicate callbacks.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class LayerPromotionHooks:
    def __init__(self, target="cuda:0"):
        self.target = torch.device(target)
        self.handles = []
        self.invocations = {}

    def attach(self, named_layers):
        for layer_name, layer in named_layers:
            self.invocations[layer_name] = 0

            def promote(current_layer, inputs, name=layer_name):
                current_layer.to(self.target)
                moved_inputs = []
                for value in inputs:
                    if torch.is_tensor(value):
                        moved_inputs.append(value.to(self.target))
                    else:
                        moved_inputs.append(value)
                self.invocations[name] += 1
                return tuple(moved_inputs)

            handle = layer.register_forward_pre_hook(promote)
            self.handles.append(handle)

    def remove(self):
        for handle in self.handles:
            handle.remove()
        self.handles.clear()

def E04():
    return LayerPromotionHooks()
```

Part 6 - Measurement, Validation, and Failure Analysis

The closure captures each name through a default argument to avoid the common late-binding bug. Nested inputs and keyword arguments require a recursive, with-keywords hook. Compilers, tracing, reentrant forwards, and multi-threaded inference can change hook assumptions. The immediate `to()` baseline is blocking from the layer's perspective and does not prefetch.

Part 7 - Engineering Interpretation and Philosophy

Hooks are a mechanism for separating control policy from model mathematics. They become dangerous when invisible. Every automatic movement should be traceable to one hook, one invocation, one byte count, and one explicit reason.

19.15.6 Exercise 05

Exercise Title: Implement Post-Forward Hooks That Return Completed Layers to CPU Without Breaking Subsequent Computation

Part 1 - Exercise Contract and Why It Matters

Attach post-forward hooks that record CUDA completion, wait only for the layer's submitted work in the baseline, and return module state to CPU while leaving the output activation available for later CUDA computation.

Part 2 - System and Memory Mental Model

A post-hook means Python forward has returned; it does not mean CUDA has finished reading parameters or buffers. Record an event on the executing stream after forward. Once that event completes, clean inference state may be restored to CPU. The output tensor owns different storage and remains valid independently of the producing module's weight residency.

Part 3 - Quantitative Prediction Before Execution

Predict the parameter and buffer bytes released by each hook. Also predict the D2H traffic created when the module returns to CPU and the event wait placed on the critical path. This baseline lowers persistent VRAM but serializes return movement; later designs reuse CPU masters instead of copying clean weights back.

Part 4 - Experimental Design and Instrumentation

Record module state immediately before hook, after event recording, after event completion, and after CPU movement. Verify output device and checksum, next-layer execution, allocated versus reserved memory, and repeated requests. Test a shared module whose next use is later than its first post-hook.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class LayerDemotionHooks:
    def __init__(self):
        self.handles = []
        self.events = {}

    def attach(self, named_layers):
        for layer_name, layer in named_layers:
            def demote(current_layer, inputs, output,
                       name=layer_name):
                stream = torch.cuda.current_stream()
                completed = torch.cuda.Event()
                completed.record(stream)
                self.events[name] = completed
```

```
                completed.synchronize()
                current_layer.to("cpu")
                return output

            handle = layer.register_forward_hook(demote)
            self.handles.append(handle)

    def remove(self):
        for handle in self.handles:
            handle.remove()
        self.handles.clear()

def E05():
    return LayerDemotionHooks()
```

Part 6 - Measurement, Validation, and Failure Analysis

This hook is inference-oriented and intentionally blocking. It must not demote a shared module before its final planned use, nor a training layer before backward. If forward raises, an ordinary post-hook may not run; use robust cleanup and `always_call` support where available. Module movement also includes buffers, which is necessary for correctness but changes traffic.

Part 7 - Engineering Interpretation and Philosophy

Offloading after use seems obvious until asynchronous execution separates "returned" from "finished." The event turns a convenient callback into a correct lifetime boundary. Optimization begins only after that boundary is trusted.

19.15.7 Exercise 06

Exercise Title: Detect the Earliest Safe Point for Offloading a Layer and Reproduce a Failure Caused by Releasing It Too Early

Part 1 - Exercise Contract and Why It Matters

Define and test the earliest legal offload boundary. Reproduce a controlled failure in which Python changes or reuses layer storage while an asynchronous consumer can still access it, then fix the failure with event and lifetime tracking.

Part 2 - System and Memory Mental Model

Safety requires both logical final use and physical completion. The layer may have no future forward invocation yet still be read by a queued kernel. CUDA allocator lifetime protection and stream ordering are related but distinct: `record_stream()` prevents premature reuse, while event waits express data dependencies between streams.

Part 3 - Quantitative Prediction Before Execution

For each invocation identify its last logical use index and completion event. The earliest safe offload time is the maximum of all outstanding consumer completion times, subject to backward protection. Predict how much longer the layer remains resident compared with the Python post-forward time.

Part 4 - Experimental Design and Instrumentation

Queue a long CUDA operation using layer state, immediately attempt unsafe CPU movement or same-sized allocation, and repeat over many iterations. Detect wrong checksums or runtime errors. Then register completion and prove stability. Keep the negative test isolated because races can be timing-sensitive and corrupt later conclusions.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class LayerUseGuard:
    def __init__(self, final_invocation):
        self.final_invocation = final_invocation
        self.completed_events = []
        self.invocation = 0
        self.backward_protected = False

    def record_forward_use(self, stream):
        self.invocation += 1
        event = torch.cuda.Event()
        event.record(stream)
        self.completed_events.append(event)

    def safe_to_offload(self):
        if self.backward_protected:
            return False, "needed_by_backward"
        if self.invocation < self.final_invocation:
            return False, "future_forward_use"
        for event in self.completed_events:
            if not event.query():
                return False, "cuda_consumer_pending"
        return True, "all_uses_completed"

    def wait_until_safe(self):
        for event in self.completed_events:
            event.synchronize()
        safe, reason = self.safe_to_offload()
        if not safe:
            raise RuntimeError("offload remains unsafe: " + reason)

def E06(final_invocation):
    return LayerUseGuard(final_invocation)
```

Part 6 - Measurement, Validation, and Failure Analysis

An event recorded on the wrong stream proves nothing about the actual consumer. Shared modules require one guard across every owner path. Querying events is non-blocking and useful for scheduling; synchronizing is used only when the engine must commit offload immediately.

During training, backward protection is released only after the relevant gradient computation finishes.

Part 7 - Engineering Interpretation and Philosophy

The earliest safe point is a proof boundary, not a timer. Memory systems fail when they infer lifetime from Python control flow while hardware continues asynchronously. Explicit completion turns probabilistic correctness into an invariant.

19.15.8 Exercise 07

Exercise Title: Build a Layer Residency Table That Tracks Current Device, Parameter Bytes, Buffer Bytes, Execution State, and Next Planned Use

Part 1 - Exercise Contract and Why It Matters

Build a central residency table that gives policy, execution, and diagnostics one consistent view of every canonical layer. The table must update only through validated transitions and export scalar records without retaining computation graphs accidentally.

Part 2 - System and Memory Mental Model

Qualified module paths can alias one shared module. The table therefore maps owner paths to a canonical ID and stores one resource record. Current device is physical state; execution state includes pending and in-flight phases; next use comes from the schedule. Parameter and buffer bytes remain separate for interpretation even when admission uses their sum.

Part 3 - Quantitative Prediction Before Execution

Predict total resident, pending, protected, and reclaimable bytes from table rows. Compute next-use distance from current step. A policy can rank eviction by large next-use distance and high reload cost while applying hard protection and budget checks first.

Part 4 - Experimental Design and Instrumentation

Replay a trace with repeated and shared modules. At each step snapshot the table, sum each byte category, and verify totals against transition logs. Test illegal transitions, missing next-use entries, and stale device metadata. Bound event history to outstanding work only.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class LayerResidencyRow:
    canonical_id: int
    names: list
    device: str
    parameter_bytes: int
    buffer_bytes: int
    execution_state: str = "idle"
    next_planned_use: int = -1
    ready_event: object = None
    consumer_events: list = field(default_factory=list)
```

```
    @property
    def total_bytes(self):
        return self.parameter_bytes + self.buffer_bytes

class LayerResidencyTable:
    def __init__(self):
        self.rows = {}
        self.name_to_id = {}

    def add(self, canonical_id, name, device,
            parameter_bytes, buffer_bytes):
        if canonical_id not in self.rows:
            self.rows[canonical_id] = LayerResidencyRow(
                canonical_id, [], device,
                parameter_bytes, buffer_bytes)
        self.rows[canonical_id].names.append(name)
        self.name_to_id[name] = canonical_id

    def update_state(self, name, expected, new_state):
        canonical_id = self.name_to_id[name]
        row = self.rows[canonical_id]
        if row.execution_state != expected:
            raise RuntimeError("illegal layer state transition")
        row.execution_state = new_state

def E07():
    return LayerResidencyTable()
```

Part 6 - Measurement, Validation, and Failure Analysis

Active tables may retain event objects needed for correctness, but exported telemetry should replace them with scalar readiness. Object IDs are scoped to one model lifetime. Storage sharing across distinct Module objects requires an additional canonical state-group layer so bytes are not duplicated.

Part 7 - Engineering Interpretation and Philosophy

Dynamic systems become understandable when state has one authoritative ledger. The table is not merely logging; it is the contract preventing policy, execution, and accounting from inventing different realities.

19.15.9 Exercise 08

Exercise Title: Group Consecutive Layers into Offload Blocks and Compare Fine-Grained Layer Movement Against Coarse-Grained Block Movement

Part 1 - Exercise Contract and Why It Matters

Combine consecutive execution layers into atomic offload blocks and compare them with one-layer movement. Quantify how fewer transfers and events trade against a larger resident window and reduced eviction flexibility.

Part 2 - System and Memory Mental Model

A block owns the union of unique parameters and buffers of its layers. Internal activations stay on CUDA, eliminating device boundaries within the block. Block admission and eviction are atomic. Shared state between blocks must be assigned canonically rather than copied into both block budgets.

Part 3 - Quantitative Prediction Before Execution

For block size k, predict number of H2D/D2H phases, total state bytes, largest resident block, internal activation transfers removed, and event count. Transfer payload bytes may remain similar, yet fewer small submissions can reduce fixed latency. Check every block against the strict budget.

Part 4 - Experimental Design and Instrumentation

Sweep block lengths and include layers with variable sizes. Measure completed latency, throughput, peak VRAM, transfer count, transferred bytes, hook overhead, event overhead, and output parity. Compare fixed-count blocks with byte-balanced blocks so one huge layer does not dominate an otherwise uniform grouping.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def build_consecutive_blocks(layers, block_length):
    if block_length <= 0:
        raise ValueError("block length must be positive")
    blocks = []
    current = []
    for layer in layers:
        current.append(layer)
        if len(current) == block_length:
            blocks.append(current)
            current = []
    if current:
        blocks.append(current)
    return blocks

def execute_blocks(blocks, inputs, device="cuda:0"):
    activation = inputs.to(device)
    for block in blocks:
        for layer in block:
            layer.to(device)
        for layer in block:
            activation = layer(activation)
        completed = torch.cuda.Event()
        completed.record(torch.cuda.current_stream())
        completed.synchronize()
        for layer in block:
            layer.to("cpu")
```

```
    return activation

def E08(layers, block_length):
    return build_consecutive_blocks(layers, block_length)
```

Part 6 - Measurement, Validation, and Failure Analysis

The code requires `torch` imported by the containing exercise runner. Naively summing layer bytes can double count shared parameters. Residual edges can cross block boundaries and keep activations live even after producing layers are offloaded. Fixed-length blocks are a baseline, not proof of optimality.

Part 7 - Engineering Interpretation and Philosophy

Granularity is a control knob between memory flexibility and movement overhead. Fine-grained control is not free, and coarse-grained efficiency is not always affordable. The best block reflects measured layer sizes and execution edges.

19.15.10 Exercise 09

Exercise Title: Determine the Optimal Number of Consecutive Layers to Keep Resident Under a Fixed VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Search the feasible resident-window sizes and choose the layer count that minimizes completed execution time under a hard byte budget. Do not assume the largest fitting count is fastest when layer sizes and compute times vary.

Part 2 - System and Memory Mental Model

Keeping more consecutive layers reduces reload frequency and can improve prefetch opportunity, but increases persistent VRAM and may reduce activation or workspace headroom. Count-based windows are simple; byte-aware variable windows are more faithful when layers differ substantially.

Part 3 - Quantitative Prediction Before Execution

For every candidate k, predict peak block bytes, transfer submissions, transfer time, compute time, overlap, and boundary overhead. Reject candidates whose predicted total exceeds managed capacity after reserves. The optimum is the feasible k with minimum validated end-to-end time, not minimum transfer count alone.

Part 4 - Experimental Design and Instrumentation

Warm up and benchmark every feasible count across repeated trials. Randomize trial order to reduce thermal and background bias. Log parameter/buffer peak, allocated/reserved peak, transfer bytes and events, visible stalls, throughput, latency distribution, and parity. Repeat for several batch sizes.

Part 5 - PyTorch/CUDA Implementation

```
def feasible_window_sizes(layer_bytes, budget_bytes,
                          activation_reserve_bytes):
    feasible = []
    layer_count = len(layer_bytes)
    for window in range(1, layer_count + 1):
        largest_window = 0
        for start in range(0, layer_count - window + 1):
            current_bytes = 0
            stop = start + window
            for index in range(start, stop):
                current_bytes += layer_bytes[index]
            if current_bytes > largest_window:
                largest_window = current_bytes
        predicted_peak = largest_window + activation_reserve_bytes
        if predicted_peak <= budget_bytes:
            feasible.append((window, predicted_peak))
    return feasible

def choose_fastest(measured_seconds_by_window, feasible):
    best_window = None
    best_seconds = None
    for window, unused_peak in feasible:
        seconds = measured_seconds_by_window[window]
        if best_seconds is None or seconds < best_seconds:
            best_seconds = seconds
            best_window = window
    return best_window, best_seconds

def E09(layer_bytes, budget_bytes, activation_reserve_bytes):
    return feasible_window_sizes(
        layer_bytes, budget_bytes, activation_reserve_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Contiguous-window byte sums must canonicalize shared state. A static activation reserve may be wrong for shape-changing models; profile it per boundary. The fastest candidate on one batch size, hardware topology, or sequence length may not generalize. Store the conditions with the chosen value.

Part 7 - Engineering Interpretation and Philosophy

Optimal residency is empirical because hardware turns theoretical bytes and dependencies into real time. Modeling narrows the safe search space; measurement chooses within it. Neither should pretend to replace the other.

19.15.11 Exercise 10

Exercise Title: Prefetch Layer N+1 to CUDA While Layer N Executes and Measure How Much PCIe Transfer Latency Can Be Hidden

Part 1 - Exercise Contract and Why It Matters

Submit the next layer's complete state before executing the current layer. Use a dedicated transfer stream and a ready event so the compute stream waits only if prefetch has not completed by the time the next layer is needed.

Part 2 - System and Memory Mental Model

Prefetch changes the resident window from one group to at least current plus next. Pinned CPU masters and non-blocking H2D make overlap possible. Different streams do not imply concurrency automatically; dependencies, copy-engine availability, PCIe contention, and CUDA allocator pressure determine the actual timeline.

Part 3 - Quantitative Prediction Before Execution

For layer N, compare current compute time C_N with next transfer time T_{N+1}. Ideal hidden time is $\min(C_N, T_{N+1})$, and ideal visible wait is $\max(0, T_{N+1} - C_N)$. Predict peak bytes for current, next pending state, activations, and workspace before admitting lookahead.

Part 4 - Experimental Design and Instrumentation

Benchmark serial on-demand loading and one-layer lookahead with identical state groups. Use CUDA events for copy and compute intervals and a profiler timeline to confirm overlap. Sweep layer size, compute intensity, batch size, and PCIe contention. Record visible waits, overlap fraction, peak VRAM, and output parity.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class NextLayerPrefetcher:
    def __init__(self, mover, ordered_groups):
        self.mover = mover
        self.groups = ordered_groups
        self.pending = {}

    def submit(self, index):
        if index >= len(self.groups):
            return
        if index in self.pending:
            return
        name, entries, unused_layer = self.groups[index]
        self.pending[index] = self.mover.submit(name, entries)

    def acquire(self, index, compute_stream):
        if index not in self.pending:
            self.submit(index)
        transaction = self.pending.pop(index)
        transaction.bind_for_compute(compute_stream)
        return transaction

    def run(self, activation):
```

```
        compute_stream = torch.cuda.current_stream()
        self.submit(0)
        for index in range(len(self.groups)):
            self.acquire(index, compute_stream)
            self.submit(index + 1)
            unused_name, unused_entries, layer = self.groups[index]
            activation = activation.to("cuda:0", non_blocking=True)
            activation = layer(activation)
        return activation

def E10(mover, ordered_groups):
    return NextLayerPrefetcher(mover, ordered_groups)
```

Part 6 - Measurement, Validation, and Failure Analysis

This exercise reuses the asynchronous group transaction from DMM12. Admission must reserve pending bytes before `submit`. Prefetching without timely eviction can exceed the budget; prefetching from pageable memory can appear non-blocking at Python level yet fail to overlap. Event timing must be recorded on the streams that perform the actual work.

Part 7 - Engineering Interpretation and Philosophy

Prefetching is scheduling work according to a reliable future. The goal is not to transfer everything early, but to place the right layer far enough ahead that movement leaves the critical path while memory remains bounded.

19.15.12 Exercise 11

Exercise Title: Build a Double-Buffered Layer Offload Pipeline Using Separate CUDA Streams for Parameter Transfer and Computation

Part 1 - Exercise Contract and Why It Matters

Maintain two parameter slots: one active for layer computation and one staging the next layer. Alternate slots without overwriting storage still used by a kernel, and measure whether the pipeline reaches a steady overlapped cadence.

Part 2 - System and Memory Mental Model

Double buffering decouples producer and consumer phases. A slot transitions through empty, filling, ready, computing, and reusable. The transfer stream may fill the inactive slot only after its prior consumer-completion event. The compute stream may consume only after the slot's ready event.

Part 3 - Quantitative Prediction Before Execution

Peak slot bytes equal the two largest simultaneously staged groups, plus activation and workspace reserve. In steady state, ideal stage duration is $\max(T_{copy}, T_{compute})$. Predict pipeline fill and drain overhead separately from steady-state throughput.

Part 4 - Experimental Design and Instrumentation

Trace every slot state and event. Compare serial, one-lookahead allocation, and two reusable slots. Measure allocation count, copy/compute overlap, visible wait, peak VRAM, requests per

second, and parity. Use unequal layer sizes to test whether fixed slot capacity wastes memory or requires resizing.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class LayerSlot:
    index: int
    state: str = "empty"
    group_name: str = None
    transaction: object = None
    consumer_done: object = None

    def wait_until_reusable(self):
        if self.consumer_done is not None:
            self.consumer_done.synchronize()
        self.state = "empty"
        self.group_name = None
        self.transaction = None
        self.consumer_done = None

class DoubleBufferedLayers:
    def __init__(self, mover):
        self.mover = mover
        self.slots = [LayerSlot(0), LayerSlot(1)]

    def fill(self, slot_index, group_name, entries):
        slot = self.slots[slot_index]
        if slot.state != "empty":
            slot.wait_until_reusable()
        slot.transaction = self.mover.submit(group_name, entries)
        slot.group_name = group_name
        slot.state = "filling"

    def consume(self, slot_index, compute_stream):
        slot = self.slots[slot_index]
        slot.transaction.bind_for_compute(compute_stream)
        slot.state = "computing"

    def finish(self, slot_index, compute_stream):
        slot = self.slots[slot_index]
        event = torch.cuda.Event()
        event.record(compute_stream)
        slot.consumer_done = event
        slot.state = "awaiting_reuse"
```

```
def E11(mover):
    return DoubleBufferedLayers(mover)
```

Part 6 - Measurement, Validation, and Failure Analysis

The slot stores a transaction and therefore preserves pinned sources and CUDA destinations. Waiting with CPU synchronization is an auditable baseline; the next exercise replaces it with cross-stream event dependencies. Slot capacity must be budgeted before fill, and exceptions must not leave a slot permanently marked as filling.

Part 7 - Engineering Interpretation and Philosophy

Double buffering makes concurrency a state machine instead of an accident. Two slots are valuable because one can serve the consumer while the other serves the producer. More buffers help only when another bottleneck justifies their memory.

19.15.13 Exercise 12

Exercise Title: Coordinate Layer Prefetch and Eviction with CUDA Events Without Using Device-Wide Synchronization

Part 1 - Exercise Contract and Why It Matters

Replace CPU and device-wide waits with precise event edges between transfer, compute, and eviction streams. Preserve correctness while allowing unrelated CUDA work to continue concurrently.

Part 2 - System and Memory Mental Model

The transfer stream records ready after H2D. The compute stream waits on ready, runs the layer, and records consumer-done. The eviction stream waits on every consumer-done event before write-back or release. `record_stream()` protects allocator lifetime but does not replace these data dependencies.

Part 3 - Quantitative Prediction Before Execution

Draw the event graph and count only required edges. Predict the critical path and compare it with a device-wide synchronization graph that orders unrelated operations unnecessarily. Measure event overhead and recovered overlap, which may be small for tiny layers and substantial for deep pipelines.

Part 4 - Experimental Design and Instrumentation

Create two independent layer branches and prove one branch can transfer while the other computes. Record stream IDs, event timestamps, kernel overlap, and completed wall time. Remove one wait intentionally to reproduce wrong ordering, then add it back without global synchronization.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class LayerEventCoordinator:
    def __init__(self):
```

```
        self.transfer_stream = torch.cuda.Stream()
        self.eviction_stream = torch.cuda.Stream()
        self.ready = {}
        self.consumers = {}

    def record_ready(self, layer_name):
        event = torch.cuda.Event()
        event.record(self.transfer_stream)
        self.ready[layer_name] = event

    def order_compute(self, layer_name, compute_stream, tensors):
        compute_stream.wait_event(self.ready[layer_name])
        for tensor in tensors:
            tensor.record_stream(compute_stream)

    def record_consumer_done(self, layer_name, compute_stream):
        event = torch.cuda.Event()
        event.record(compute_stream)
        if layer_name not in self.consumers:
            self.consumers[layer_name] = []
        self.consumers[layer_name].append(event)

    def order_eviction(self, layer_name, tensors):
        events = self.consumers.get(layer_name, [])
        with torch.cuda.stream(self.eviction_stream):
            for event in events:
                self.eviction_stream.wait_event(event)
            for tensor in tensors:
                tensor.record_stream(self.eviction_stream)

def E12():
    return LayerEventCoordinator()
```

Part 6 - Measurement, Validation, and Failure Analysis

Recording ready outside the actual transfer stream creates false ordering. Ordering eviction without subsequently recording its completion is insufficient for CPU authority changes. Event dictionaries must be pruned after completion. Profile the timeline: different colored streams are not proof that kernels or copies overlapped.

Part 7 - Engineering Interpretation and Philosophy

Global synchronization is easy because it replaces reasoning with waiting. Events preserve performance by expressing the smallest correct happens-before graph. Precision in dependency design is therefore both a correctness tool and a throughput optimization.

19.15.14 Exercise 13

Exercise Title: Handle Residual Connections That Require Earlier Layer Outputs to Remain Available After Their Producing Layer Has Been Offloaded

Part 1 - Exercise Contract and Why It Matters

Offload producing layer state while retaining its output activation until every residual consumer finishes. Track activation lifetime independently so a memory optimization never drops skip-path data merely because the producer weights are gone.

Part 2 - System and Memory Mental Model

Residual graphs are directed acyclic graphs, not simple chains. The producing layer's parameters can become irrelevant after forward, while its output remains live across several later layers. Each residual activation has a consumer count, producer-ready event, consumer-done events, and storage lifetime on the streams that use it.

Part 3 - Quantitative Prediction Before Execution

From the graph, compute last consumer and live-range bytes for every skip output. Add all simultaneously live residual activations to the layer-window budget. Predict peaks at merge points; parameter offloading cannot reduce activation memory that the graph semantically requires.

Part 4 - Experimental Design and Instrumentation

Build a residual block with one and multiple consumers. Log activation creation, ready, acquire, remaining consumers, completion, release, and bytes. Compare against a sequential-only lifetime assumption and reproduce the resulting missing tensor or corrupted reuse failure.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field
import torch

@dataclass
class ResidualActivation:
    key: str
    tensor: object
    remaining_consumers: int
    producer_ready: object
    consumer_done: list = field(default_factory=list)

    def acquire(self, stream):
        if self.remaining_consumers <= 0:
            raise RuntimeError("residual has no remaining consumer")
        stream.wait_event(self.producer_ready)
        self.tensor.record_stream(stream)
        return self.tensor

    def finish_consumer(self, stream):
        event = torch.cuda.Event()
        event.record(stream)
        self.consumer_done.append(event)
        self.remaining_consumers -= 1
```

```
    def release(self):
        if self.remaining_consumers != 0:
            return False
        for event in self.consumer_done:
            event.synchronize()
        self.tensor = None
        return True

def E13(key, tensor, consumer_count, producer_stream):
    ready = torch.cuda.Event()
    ready.record(producer_stream)
    return ResidualActivation(key, tensor, consumer_count, ready)
```

Part 6 - Measurement, Validation, and Failure Analysis

Consumer count must come from the actual execution graph, including conditional branches. In-place operations can destroy a residual value even when lifetime is tracked correctly. Training may retain the activation for backward after all forward consumers finish, requiring an additional protection reason.

Part 7 - Engineering Interpretation and Philosophy

Layer lifetime and information lifetime are different. Offloading succeeds only when the runtime follows the graph's values, not merely its module order. Residuals make this distinction impossible to ignore.

19.15.15 Exercise 14

Exercise Title: Preserve Shared Modules and Tied Weights During Layer Offloading Without Creating Duplicate Parameter Copies in VRAM

Part 1 - Exercise Contract and Why It Matters

Canonicalize shared module instances and tied parameter storage so repeated owner paths reuse one CUDA copy. Aggregate invocation schedules and final-use decisions across every owner before eviction.

Part 2 - System and Memory Mental Model

A shared Module object can be called at multiple graph positions. Distinct modules can also contain one tied Parameter. Module identity and state identity therefore form two maps: invocations point to canonical modules, while module state groups point to canonical parameter and buffer resources.

Part 3 - Quantitative Prediction Before Execution

Calculate naive by-owner bytes and canonical unique bytes, then predict one H2D transfer per resource group. Final layer eviction is allowed only after the maximum planned invocation of all owners and all CUDA consumers. Report the duplicate-copy ratio that a name-based implementation would create.

Part 4 - Experimental Design and Instrumentation

Build a model that calls one projection twice and ties an output weight to an embedding. Log owner paths, canonical module IDs, parameter IDs, storage IDs, invocations, transfers, CUDA storage pointers, and final use. Mutate a tied weight in a controlled test and verify every owner observes the same value.

Part 5 - PyTorch/CUDA Implementation

```
class CanonicalLayerGraph:
    def __init__(self, model):
        self.modules = {}
        self.module_names = {}
        self.parameter_owners = {}
        for name, module in model.named_modules(remove_duplicate=False):
            module_id = id(module)
            if module_id not in self.modules:
                self.modules[module_id] = module
                self.module_names[module_id] = []
            self.module_names[module_id].append(name)
            for parameter_name, parameter in module.named_parameters(
                    recurse=False, remove_duplicate=False):
                parameter_id = id(parameter)
                if parameter_id not in self.parameter_owners:
                    self.parameter_owners[parameter_id] = []
                owner = name + "." + parameter_name
                self.parameter_owners[parameter_id].append(owner)

    def unique_parameter_ids_for_module(self, module_id):
        result = []
        seen = set()
        module = self.modules[module_id]
        for parameter in module.parameters(recurse=False):
            parameter_id = id(parameter)
            if parameter_id not in seen:
                seen.add(parameter_id)
                result.append(parameter_id)
        return result

def E14(model):
    return CanonicalLayerGraph(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

Object identity catches ordinary sharing but not distinct tensor views over one storage. Container paths can produce empty names and should be formatted carefully. Hooks attached once per owner path can still fire multiple times on one object; attach control to canonical identity and count invocations explicitly.

Part 7 - Engineering Interpretation and Philosophy

Sharing is part of program semantics and memory economics. Duplicating shared state spends VRAM and silently changes alias behavior. Correct offloading follows canonical resources while preserving every logical owner.

19.15.16 Exercise 15

Exercise Title: Extend Dynamic Layer Offloading from Inference to Training and Track Parameters, Gradients, Activations, and Autograd Dependencies

Part 1 - Exercise Contract and Why It Matters

Define a training-safe layer lifecycle covering forward promotion, saved activations, backward parameter reuse, gradient creation, optimizer access, and final release. Demonstrate why an inference offload point is insufficient once autograd owns future dependencies.

Part 2 - System and Memory Mental Model

Training creates several lifetimes per layer. Parameters are read in forward and usually again in backward. Saved tensors preserve information for gradient calculation. Gradients appear during backward, and optimizer states may be two or more tensors per parameter. Moving only weights can leave gradients and optimizer state on incompatible devices.

Forward can offload a layer's clean weights to CPU masters, but backward must prefetch them again before that layer's gradient computation. Saved activations can remain on CUDA, be checkpointed for recomputation, or be offloaded under a separate policy. Dirty authoritative state appears after optimizer update.

Part 3 - Quantitative Prediction Before Execution

For each layer estimate weight, buffer, gradient, saved-activation, and optimizer state bytes separately. Predict forward H2D, backward H2D, activation D2H/H2D, and optimizer traffic. Compare no offload, weight-only offload, activation checkpointing, and combined strategies before measuring.

Part 4 - Experimental Design and Instrumentation

Track boundaries at forward-pre, forward-post, backward-pre, backward-post, optimizer-step, and zero-grad. Use autograd hooks to record completion, not to perform unsafe recursive backward. Validate gradients and updated parameters against a fully resident training step. Report peak VRAM, traffic, step time, loss parity, and gradient-norm parity.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class TrainingLayerLifetime:
    name: str
    parameter_bytes: int
    buffer_bytes: int
    gradient_bytes: int = 0
    activation_bytes: int = 0
    forward_complete: bool = False
    backward_complete: bool = False
```

```
    optimizer_complete: bool = False
    protected_reasons: set = field(default_factory=set)

    def begin_forward(self):
        self.protected_reasons.add("forward")

    def end_forward(self, activation_bytes):
        self.forward_complete = True
        self.activation_bytes = activation_bytes
        self.protected_reasons.discard("forward")
        self.protected_reasons.add("backward")

    def end_backward(self, gradient_bytes):
        self.backward_complete = True
        self.gradient_bytes = gradient_bytes
        self.protected_reasons.discard("backward")
        self.protected_reasons.add("optimizer")

    def end_optimizer(self):
        self.optimizer_complete = True
        self.protected_reasons.discard("optimizer")

    def releasable(self):
        return len(self.protected_reasons) == 0

def E15(name, parameter_bytes, buffer_bytes):
    return TrainingLayerLifetime(
        name, parameter_bytes, buffer_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The tracker models contracts; a real implementation must integrate saved-tensor hooks, module full-backward hooks, optimizer state placement, and stream events. Backward order is usually reverse forward order but can differ in branched graphs. Gradient accumulation extends lifetime across microbatches. Never move a leaf Parameter's storage while an existing graph expects the prior storage.

Part 7 - Engineering Interpretation and Philosophy

Training offloading is not inference offloading plus `backward()`. It is a second execution schedule with new state and authority. Treating every memory category explicitly prevents an optimization in one phase from silently invalidating another.

19.15.17 Exercise 16

Exercise Title: Reproduce Transfer Thrashing by Using an Aggressive Layer-Offload Policy and Detect It from PCIe Traffic and Execution Timeline

Part 1 - Exercise Contract and Why It Matters

Construct repeated-module and short-phase traces that cause a reactive runtime to evict layers immediately before they are needed again. Detect thrashing from movement, residence duration, useful work, and timeline evidence rather than from low hit rate alone.

Part 2 - System and Memory Mental Model

Thrashing is repeated state reversal with insufficient useful computation between transfers. It occurs when the resident window is smaller than an active reuse set, final-use estimates are wrong, or pressure thresholds chatter. PCIe can become saturated while GPU compute remains idle waiting for reloaded layers.

Part 3 - Quantitative Prediction Before Execution

Define migrations per invocation, bytes transferred per useful FLOP, and short residence as eviction within a small number of schedule steps after admission. Predict an alternating trace whose working set is one layer larger than the window. Compare with a static subset and a larger hysteretic window.

Part 4 - Experimental Design and Instrumentation

Profile stable sequential traces, alternating shared layers, and phase changes. Log H2D and D2H bytes, reload count, resident steps, GPU idle gaps, event waits, copy-engine use, compute use, and latency tails. Mark each timeline transfer with its canonical layer ID and policy reason.

Part 5 - PyTorch/CUDA Implementation

```
class LayerThrashDetector:
    def __init__(self, short_residence_steps=2):
        self.short_limit = short_residence_steps
        self.loaded_at = {}
        self.ever_loaded = set()
        self.reloads = 0
        self.short_evictions = 0
        self.h2d_bytes = 0
        self.d2h_bytes = 0

    def record_load(self, layer_name, step, size_bytes):
        if layer_name in self.ever_loaded:
            self.reloads += 1
        self.ever_loaded.add(layer_name)
        self.loaded_at[layer_name] = step
        self.h2d_bytes += size_bytes

    def record_eviction(self, layer_name, step,
                        size_bytes, write_back):
        admitted = self.loaded_at[layer_name]
        residence = step - admitted
        if residence <= self.short_limit:
            self.short_evictions += 1
        if write_back:
            self.d2h_bytes += size_bytes
        del self.loaded_at[layer_name]
```

```
    def report(self, invocations):
        migrations = self.reloads + self.short_evictions
        return {
            "reloads": self.reloads,
            "short_evictions": self.short_evictions,
            "migration_signal_per_invocation":
                migrations / max(1, invocations),
            "h2d_bytes": self.h2d_bytes,
            "d2h_bytes": self.d2h_bytes,
        }

def E16():
    return LayerThrashDetector()
```

Part 6 - Measurement, Validation, and Failure Analysis

Streaming through never-reused layers creates misses but not thrashing. Require evidence that recently evicted state returns. Dirty write-back and clean drop have different costs. Profiler traces are essential because high transfer bytes can be harmless when fully overlapped, while smaller serialized transfers can dominate latency.

Part 7 - Engineering Interpretation and Philosophy

Aggressive reclamation can manufacture the scarcity it tries to solve. A layer should leave VRAM only when the capacity it frees is more valuable than the future reload it creates. Thrashing is the measurable signature of getting that exchange repeatedly wrong.

19.15.18 Exercise 17

Exercise Title: Build an Adaptive Layer Residency Policy That Changes the Number of GPU-Resident Layers from Measured VRAM Headroom and Transfer Cost

Part 1 - Exercise Contract and Why It Matters

Adjust the resident window from measured headroom, transfer stall, and thrashing. Expand when memory is safely underused and reload cost is visible; contract before pressure becomes an OOM. Use hysteresis and cooldown to prevent oscillation.

Part 2 - System and Memory Mental Model

The controller observes managed resident and pending bytes, physical headroom, activation peak, visible transfer wait, and recent reload rate. Hard capacity is an invariant; adaptation is an optimization inside it. High and low pressure thresholds plus a minimum dwell period give the decision memory.

Part 3 - Quantitative Prediction Before Execution

Estimate marginal benefit of one additional layer as avoided visible reload milliseconds. Estimate marginal cost as its bytes times pressure price plus any lost activation reserve. Expand only when benefit is positive and projected peak is below the high watermark. Contract until the low recovery watermark.

Part 4 - Experimental Design and Instrumentation

Feed stable memory, growing sequence length, phase changes, and noisy headroom. Compare fixed windows with adaptive control. Log observations, decision, previous/new window, cooldown, projected bytes, reloads, visible waits, budget violations, latency, and regret relative to the best fixed window per phase.

Part 5 - PyTorch/CUDA Implementation

```
class AdaptiveLayerWindow:
    def __init__(self, minimum=1, maximum=8,
                 cooldown_steps=5):
        self.minimum = minimum
        self.maximum = maximum
        self.window = minimum
        self.cooldown_steps = cooldown_steps
        self.last_change = -cooldown_steps

    def update(self, step, projected_next_bytes,
               free_headroom_bytes, visible_transfer_ms,
               thrash_rate, pressure):
        if step - self.last_change < self.cooldown_steps:
            return self.window, "cooldown"

        if pressure or projected_next_bytes > free_headroom_bytes:
            if self.window > self.minimum:
                self.window -= 1
                self.last_change = step
                return self.window, "contract_for_pressure"
            return self.window, "minimum_window"

        transfer_problem = visible_transfer_ms > 0.2
        reuse_problem = thrash_rate > 0.1
        if transfer_problem or reuse_problem:
            if self.window < self.maximum:
                self.window += 1
                self.last_change = step
                return self.window, "expand_for_reuse"
        return self.window, "stable"

def E17():
    return AdaptiveLayerWindow()
```

Part 6 - Measurement, Validation, and Failure Analysis

Raw free VRAM is noisy and may include memory outside the controller. Filter measurements and retain a safety reserve. A larger count can admit one enormous layer, so byte projection remains mandatory. Changes should be evaluated after enough samples; reacting to one slow transfer confuses noise with phase change.

Part 7 - Engineering Interpretation and Philosophy

Adaptive residency is feedback control. It succeeds by changing slowly enough to measure consequences and quickly enough to follow workload phases. Stability is as important as responsiveness because every reversed decision moves real bytes.

19.15.19 Exercise 18

Exercise Title: Stress-Test Dynamic Layer Offloading on a Deep Transformer-Style PyTorch Model Whose Total Weights Exceed Available VRAM

Part 1 - Exercise Contract and Why It Matters

Exercise the runtime on repeated Transformer-style blocks whose total unique weights exceed an artificial managed VRAM budget. Preserve a safety gap below physical memory and test long execution traces, variable sequence lengths, and shared embeddings without intentionally crashing the device.

Part 2 - System and Memory Mental Model

Transformer blocks combine attention projections, feed-forward weights, normalization parameters, and buffers. Weight bytes may be regular across depth, while activation and attention workspace grow strongly with batch and sequence length. A weight-only budget that ignores this dynamic reserve will fail as context grows.

Part 3 - Quantitative Prediction Before Execution

Calculate total unique weight bytes, per-block state, maximum resident window, activation reserve by sequence length, predicted H2D bytes, and ideal overlap. Reject any configuration whose largest atomic block plus activation/workspace reserve exceeds managed capacity, even if average block size fits.

Part 4 - Experimental Design and Instrumentation

Sweep depth, hidden size, feed-forward ratio, sequence length, batch, dtype, window, and prefetch distance. Use fixed seeds and synthetic inputs. Log output checksums, peak allocated/reserved and managed bytes, pinned RAM, transfers, reloads, event waits, kernel/copy overlap, tokens per second, and latency tails. Capture and minimize failures.

Part 5 - PyTorch/CUDA Implementation

```
class TransformerOffloadStressPlan:
    def __init__(self, block_bytes, budget_bytes,
                 activation_reserve_bytes):
        self.block_bytes = block_bytes
        self.budget = budget_bytes
        self.activation_reserve = activation_reserve_bytes
        self.trace = []

    def validate_atomic_fit(self):
        for index, size_bytes in enumerate(self.block_bytes):
            required = size_bytes + self.activation_reserve
            if required > self.budget:
```

```
                message = "block does not fit: " + str(index)
                raise RuntimeError(message)

    def build_forward_trace(self):
        self.trace.clear()
        for index in range(len(self.block_bytes)):
            self.trace.append(("forward", index))
        return self.trace

    def build_training_trace(self):
        self.build_forward_trace()
        index = len(self.block_bytes) - 1
        while index >= 0:
            self.trace.append(("backward", index))
            index -= 1
        return self.trace

    def total_parameter_bytes(self):
        total = 0
        for size_bytes in self.block_bytes:
            total += size_bytes
        return total

def E18(block_bytes, budget_bytes, activation_reserve_bytes):
    plan = TransformerOffloadStressPlan(
        block_bytes, budget_bytes, activation_reserve_bytes)
    plan.validate_atomic_fit()
    return plan
```

Part 6 - Measurement, Validation, and Failure Analysis

The plan validates memory logic before constructing a potentially dangerous CUDA workload. Real attention kernels can request shape-dependent workspace not visible in parameter totals. Artificial managed limits should be enforced by admission, not by consuming all physical VRAM. Reproducibility requires the exact trace, shapes, dtype, PyTorch/CUDA versions, and hardware.

Part 7 - Engineering Interpretation and Philosophy

An oversized model is not one memory problem; it is the interaction of static state, dynamic activations, workspace, and movement. Stress testing proves whether the runtime manages that interaction across scale rather than only on a friendly toy chain.

19.15.20 Exercise 19

Exercise Title: Build and Benchmark a Complete PyTorch Layer-Offloading Runtime That Executes an Oversized Model Through Automatic Prefetch, Residency Tracking, and Eviction

Part 1 - Exercise Contract and Why It Matters

Integrate canonical layer groups, pinned CPU masters, a strict byte budget, ready and consumer events, one-layer prefetch, next-use tracking, final-use eviction, and diagnostics into one inference runtime. Execute a model whose total layer state exceeds managed VRAM while preserving outputs.

Part 2 - System and Memory Mental Model

Every canonical layer group owns CPU masters and optional CUDA destinations. Its state progresses through CPU, prefetch-pending, CUDA-ready, executing, consumer-pending, and evictable. Pending bytes count at submission. The compute stream waits on ready. Eviction waits on consumer completion and restores CPU masters rather than copying clean inference weights back.

Residual activations, shared modules, and tied weights remain separate canonical resources with their own lifetimes. The compact runtime below targets a known sequential inference schedule; graph and training extensions retain the same contracts but need richer schedules.

Part 3 - Quantitative Prediction Before Execution

Before execution, simulate total unique layer bytes, largest atomic group, resident and pending peaks, activation/workspace reserve, H2D bytes, reloads, and visible wait. Require $R + P + A + W + S \leq C$, where S is safety margin. State acceptance criteria for output parity, zero illegal transitions, and zero managed-budget violations.

Part 4 - Experimental Design and Instrumentation

Compare all-CPU, full-GPU when feasible on a reference system, one-layer serial, and prefetched runtime. Keep state dictionaries, inputs, dtype, and request order identical. Report cold start, median/tail latency, throughput, peak managed and CUDA memory, pinned RAM, transfers, overlap, event waits, policy time, evictions, and checksums.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field
from collections import OrderedDict
import torch

@dataclass
class RuntimeLayer:
    name: str
    module: object
    entries: list
    size_bytes: int
    transaction: object = None
    state: str = "cpu"
    consumer_events: list = field(default_factory=list)
    next_use: int = -1

                activation = layer.module(activation)
                self.finish(layer, compute_stream)
        return activation

def E19(ordered_layers, mover, budget_bytes):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    return LayerOffloadRuntime(
        ordered_layers, mover, budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The runtime assumes unique sequential layer names and clean inference weights. Production code must canonicalize shared resources, reserve activation and workspace bytes outside the layer budget, use asynchronous eviction, handle buffers, prune completed events, and clean up after exceptions. Prefetch can fail when pending groups consume capacity but are not yet eviction candidates; admission must then reduce lookahead rather than retry forever.

Training requires the E15 backward schedule, gradients, optimizer states, saved activations, and dirty authority. Never claim training support by simply removing `inference_mode()`. Validate every output against a reference and every transition against the residency table.

Part 7 - Engineering Interpretation and Philosophy

A complete offloading runtime is a scheduler, allocator client, dependency manager, and model executor. It succeeds not because all layers fit, but because the correct layers fit at the correct times. Every moved byte must have an owner, every eviction must have a completion proof, and every performance gain must survive synchronized measurement.

19.16 DMM14

Chapter Title: CPU Offloading for Models and Training State
Specialization: Dynamic Memory Management and CUDA Systems

19.16.1 Exercise 00

Exercise Title: Build a Precise Mental Model of CPU Offloading for Parameters, Gradients, Optimizer States, Activations, and Temporary Buffers

Part 1 - Exercise Contract and Why It Matters

Build one explicit state model for every major training-memory category. CPU offloading is not a single operation: parameters are model state, gradients are backward products, optimizer tensors are update history, activations belong to the current graph, and temporary buffers have short operator-defined lifetimes.

The contract must identify the authoritative copy, clean replicas, device, pinned status, pending transfer, consumer streams, protection reason, and next planned use for every resource. It must also maintain separate hard budgets for GPU VRAM and host RAM.

Part 2 - System and Memory Mental Model

Parameters are read in forward and backward and become dirty after an optimizer step. Gradients appear during backward and may accumulate across microbatches. AdamW commonly owns first- and second-moment tensors in addition to step state. Saved activations are protected until backward consumes them. Temporary workspaces may be invisible to Python tensor inventories.

An offload transaction passes through source-ready, D2H-pending, CPU-ready, and GPU-released states. A non-blocking D2H destination cannot be read by the CPU before completion. Pinned RAM improves transfer capability but consumes a scarce operating-system resource and must be budgeted separately.

Part 3 - Quantitative Prediction Before Execution

For bytes (M), estimate transfer time as (L+M/B). Predict total persistent training state as separate sums for weights, gradients, optimizer state, and buffers; then add dynamic activation and workspace peaks. During offload, source and destination coexist, so transient peak is larger than either final state.

Estimate RAM after offload as CPU masters plus offloaded gradients, optimizer states, activations, pinned staging, and process baseline. A legal plan satisfies both budgets at every pending and committed transition.

Part 4 - Experimental Design and Instrumentation

Record memory at model creation, forward, loss, backward, optimizer step, and zero-grad. For each category log bytes, authority, device, pinned state, transfer event, allocated and reserved VRAM, process RAM, and system available RAM. Include deliberate GPU-pressure and host-pressure experiments under artificial managed limits rather than physical exhaustion.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class OffloadState:
    key: str
    category: str
    size_bytes: int
    authority: str
    gpu_present: bool
    cpu_present: bool
    cpu_pinned: bool = False
```

```
    transfer_pending: bool = False
    dirty: bool = False
    protected_reasons: set = field(default_factory=set)

    def begin_d2h(self):
        if not self.gpu_present:
            raise RuntimeError("no GPU source to offload")
        if self.transfer_pending:
            raise RuntimeError("another transfer is pending")
        self.transfer_pending = True

    def commit_d2h(self, release_gpu):
        if not self.transfer_pending:
            raise RuntimeError("no D2H transaction to commit")
        self.cpu_present = True
        self.transfer_pending = False
        self.authority = "cpu" if self.dirty else "both_clean"
        if release_gpu:
            self.gpu_present = False

def E00(key, category, size_bytes):
    return OffloadState(
        key, category, size_bytes, "gpu", True, False)
```

Part 6 - Measurement, Validation, and Failure Analysis

Deleting a CUDA reference may reduce allocated memory without reducing reserved memory. Process RSS does not equal tensor payload, and system available RAM is more informative than free RAM alone. Shared storage and optimizer dictionaries can produce double counting. Validate storage identity and authoritative values, not only category totals.

Part 7 - Engineering Interpretation and Philosophy

CPU offloading exchanges one constrained resource for another and adds movement through a slower link. It is successful only when the complete system stays inside both budgets and the saved VRAM is worth the transfer, synchronization, and host-memory pressure it creates.

19.16.2 Exercise 01

Exercise Title: Measure the CPU RAM and GPU VRAM Cost of Parameters, Gradients, Optimizer States, and Activations in the Same PyTorch Training Step

Part 1 - Exercise Contract and Why It Matters

Account for every visible training-state category at consistent boundaries in one step. Separate tensor payload from allocator and process-level memory so the report explains both PyTorch state and the larger system footprint.

Part 2 - System and Memory Mental Model

Parameters exist before forward. Activations and saved tensors grow during forward. Gradients materialize during backward. Lazy optimizers often allocate state on the first step.

Zeroing gradients with `set_to_none=True` releases gradient tensors differently from filling existing storage with zeros.

Part 3 - Quantitative Prediction Before Execution

Predict parameter bytes exactly from unique tensors. For dense gradients, expect approximately one gradient payload per trainable parameter. AdamW moments are commonly about two parameter-sized tensors at parameter dtype, but inspect actual state rather than assuming. Estimate activations by boundary deltas and hooks, acknowledging hidden workspaces.

Part 4 - Experimental Design and Instrumentation

Warm up CUDA context, reset peak statistics, and snapshot before forward, after forward, after loss, after backward, after first optimizer step, and after zero-grad. Record tensor-category bytes by device, CUDA allocated/reserved/peak, process RSS, system available RAM, batch shape, dtype, and optimizer settings.

Part 5 - PyTorch/CUDA Implementation

```
def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def unique_parameter_and_gradient_bytes(model):
    seen_parameters = set()
    seen_gradients = set()
    parameter_bytes = 0
    gradient_bytes = 0
    for parameter in model.parameters():
        if id(parameter) not in seen_parameters:
            seen_parameters.add(id(parameter))
            parameter_bytes += tensor_bytes(parameter)
        gradient = parameter.grad
        if gradient is not None and id(gradient) not in seen_gradients:
            seen_gradients.add(id(gradient))
            gradient_bytes += tensor_bytes(gradient)
    return parameter_bytes, gradient_bytes

def optimizer_tensor_bytes(optimizer):
    seen = set()
    total = 0
    for state in optimizer.state.values():
        for value in state.values():
            if not hasattr(value, "numel"):
                continue
            if id(value) in seen:
                continue
            seen.add(id(value))
            total += tensor_bytes(value)
    return total

def E01(model, optimizer):
```

```
    parameters, gradients = (
        unique_parameter_and_gradient_bytes(model))
    optimizer_state = optimizer_tensor_bytes(optimizer)
    return parameters, gradients, optimizer_state
```

Part 6 - Measurement, Validation, and Failure Analysis

The function does not measure saved activations directly; derive them from controlled deltas or saved-tensor hooks and label the method. A tensor ID can be reused after deallocation, so identity sets belong to one snapshot. Optimizer state can contain scalar tensors, mixed dtypes, or CPU entries and should be reported per device.

Part 7 - Engineering Interpretation and Philosophy

Training memory is a lifecycle, not one number. Boundary accounting reveals which category creates the peak and therefore which offload decision can actually reduce it. Optimizing a non-dominant category adds complexity without solving the observed limit.

19.16.3 Exercise 02

Exercise Title: Offload a Complete PyTorch Model to CPU Between Inference Requests and Measure Reload Latency and VRAM Recovery

Part 1 - Exercise Contract and Why It Matters

Move a complete inference model to CPU after a request, verify that live CUDA parameter and buffer storage is gone, then reload for the next request. Measure both memory recovery and the cold-request latency this policy creates.

Part 2 - System and Memory Mental Model

`model.to("cpu")` moves parameters and buffers but does not necessarily release activations, outputs, or allocator cache. Reloading places all weight transfer on the next request's critical path. This policy is useful for sparse request traffic or sharing one GPU among models, but costly at high request rate.

Part 3 - Quantitative Prediction Before Execution

Predict unique model state bytes, H2D reload time, D2H offload time, and post- offload allocated and reserved memory. For idle interval (I), compare VRAM opportunity value against two transfers and added tail latency. Estimate the request rate at which keeping the model resident becomes cheaper.

Part 4 - Experimental Design and Instrumentation

Warm up, issue requests with controlled idle gaps, synchronize boundaries, and record reload, forward, offload, and completed request time separately. Track allocated/reserved/peak VRAM, process RAM, output checksum, and model device. Retain and then delete output tensors to show why they affect recovery.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

class WholeModelCpuOffloader:
    def __init__(self, model, device="cuda:0"):
        self.model = model.eval().to("cpu")
        self.device = torch.device(device)

    def request(self, inputs):
        torch.cuda.synchronize()
        reload_started = time.perf_counter()
        self.model.to(self.device)
        cuda_inputs = inputs.to(self.device)
        torch.cuda.synchronize()
        reload_seconds = time.perf_counter() - reload_started

        with torch.inference_mode():
            output = self.model(cuda_inputs)
        torch.cuda.synchronize()

        offload_started = time.perf_counter()
        self.model.to("cpu")
        torch.cuda.synchronize()
        offload_seconds = time.perf_counter() - offload_started
        return output, reload_seconds, offload_seconds

def E02(model):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    return WholeModelCpuOffloader(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

Keeping the returned output on CUDA intentionally leaves live VRAM; copy or consume it before claiming full recovery. Calling `empty_cache()` can return unused cached blocks but cannot free live tensors and should not be timed as model offload. Use fresh processes for clean allocator comparisons.

Part 7 - Engineering Interpretation and Philosophy

Whole-model offload is simple capacity multiplexing. It is rational when idle time is valuable and requests tolerate reload. The policy demonstrates that memory availability and service latency are two sides of one scheduling choice.

19.16.4 Exercise 03

Exercise Title: Offload Selected Parameter Groups to CPU While Keeping Frequently Used Parameters Resident in VRAM

Part 1 - Exercise Contract and Why It Matters

Partition canonical parameter groups into hot residents and cold CPU-backed groups under a fixed VRAM budget. Preserve Parameter identity, shared weights, and explicit transfer reasons while avoiding whole-model movement.

Part 2 - System and Memory Mental Model

Frequency, recency, next-use distance, and reload cost describe value; unique bytes describe capacity cost. A CPU master remains authoritative for clean inference groups. Promotion binds a CUDA copy to the existing Parameter object, while demotion restores the CPU master only after GPU consumers finish.

Part 3 - Quantitative Prediction Before Execution

Predict selected resident groups, unique resident bytes, misses, H2D traffic, and avoided reload time from a trace. Apply hard fit and protection before ranking. Compare a hot-set policy with static size-only and LRU baselines.

Part 4 - Experimental Design and Instrumentation

Use stable-hot, phase-changing, and alternating traces with tied weights. Log score, last use, bytes, canonical ID, promotion, demotion, consumers, transfer traffic, hit rate, regret, and output parity. Assert VRAM budget after pending and committed transitions.

Part 5 - PyTorch/CUDA Implementation

```
class HotParameterPolicy:
    def __init__(self, budget_bytes, promote_count=3):
        self.budget = budget_bytes
        self.promote_count = promote_count
        self.counts = {}
        self.last_use = {}
        self.resident = set()
        self.resident_bytes = 0
        self.step = 0

    def observe(self, group_name):
        self.step += 1
        old_count = self.counts.get(group_name, 0)
        self.counts[group_name] = old_count + 1
        self.last_use[group_name] = self.step

    def should_promote(self, group_name, size_bytes):
        if group_name in self.resident:
            return False, "already_resident"
        if self.counts.get(group_name, 0) < self.promote_count:
            return False, "not_hot"
        if self.resident_bytes + size_bytes > self.budget:
            return False, "does_not_fit"
        return True, "hot_and_fits"

    def commit_promotion(self, group_name, size_bytes):
        self.resident.add(group_name)
```

```
        self.resident_bytes += size_bytes
        assert self.resident_bytes <= self.budget

def E03(budget_bytes):
    return HotParameterPolicy(budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The policy decides admission but does not select victims; integrate a legal eviction policy when full. Cumulative counts retain stale popularity, so decay or windows are needed across phases. Metadata must not retain tensors or graphs. Training adds dirty parameters and optimizer-state coordination.

Part 7 - Engineering Interpretation and Philosophy

Selective offload treats VRAM as a working set rather than an all-or-nothing home. Hotness is a forecast that must earn its memory through future reuse, not a permanent label granted by historical frequency.

19.16.5 Exercise 04

Exercise Title: Build a CPU Parameter Store That Tracks Tensor Size, Dtype, Layer Ownership, Residency State, and Transfer Count

Part 1 - Exercise Contract and Why It Matters

Build a canonical CPU store that owns durable parameter masters and supplies pinned or pageable sources for promotion. Track scalar metadata and transfer history while preserving tied ownership and authoritative values.

Part 2 - System and Memory Mental Model

One canonical parameter can have several layer names. The store owns one CPU tensor per canonical identity, plus optional pinned staging and CUDA replica. Residency state distinguishes CPU-only, H2D-pending, both-clean, GPU-dirty, and D2H-pending. Transfer count is historical evidence, not current authority.

Part 3 - Quantitative Prediction Before Execution

Predict unique CPU payload, pinned staging payload, CUDA replicas, and duplicated bytes avoided by canonicalization. For each access trace, estimate H2D and D2H counts and bytes. Ensure store RAM plus other host allocations remains within a separate budget.

Part 4 - Experimental Design and Instrumentation

Register ordinary and tied parameters, compare checksums, promote and demote, then mutate a GPU copy and write it back. Log identity, owners, shape, dtype, bytes, pinned state, authority, residency, transfers, and version. Verify one CPU master for every alias group.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class CpuParameterEntry:
    canonical_id: int
    owners: list
    cpu_tensor: object
    size_bytes: int
    dtype: str
    residency: str = "cpu_only"
    h2d_count: int = 0
    d2h_count: int = 0
    version: int = 0

class CpuParameterStore:
    def __init__(self):
        self.entries = {}
        self.name_to_id = {}

    def register(self, name, parameter, pin=True):
        canonical_id = id(parameter)
        self.name_to_id[name] = canonical_id
        if canonical_id not in self.entries:
            master = parameter.detach().cpu().clone()
            if pin:
                master = master.pin_memory()
            size_bytes = master.numel() * master.element_size()
            self.entries[canonical_id] = CpuParameterEntry(
                canonical_id, [], master, size_bytes,
                str(master.dtype))
        self.entries[canonical_id].owners.append(name)

    def mark_h2d(self, name):
        entry = self.entries[self.name_to_id[name]]
        entry.h2d_count += 1
        entry.residency = "both_clean"

def E04():
    return CpuParameterStore()
```

Part 6 - Measurement, Validation, and Failure Analysis

Cloning guarantees independent CPU authority but doubles host payload at registration. Pinned allocation can fail or harm system health under excess. Object identity covers ordinary tying; distinct views over shared storage need storage-level canonicalization. Version must advance after committed writes, not transfer submission.

Part 7 - Engineering Interpretation and Philosophy

The CPU store is a truth service, not merely a cache. Placement can be dynamic only when the runtime knows which durable copy is authoritative and can restore any transient GPU replica without changing model semantics.

19.16.6 Exercise 05

Exercise Title: Compare Pageable RAM and Pinned RAM as Offload Destinations for Repeated Parameter Transfers

Part 1 - Exercise Contract and Why It Matters

Compare pageable and page-locked host buffers as repeated D2H offload destinations. Separate allocation cost, copy submission time, completion time, and end-to-end reuse time; otherwise a fast asynchronous submission can be mistaken for a completed transfer.

Part 2 - System and Memory Mental Model

A CUDA DMA engine can directly address pinned pages. Pageable destinations may require an internal staging path and can introduce host synchronization. Pinned memory enables useful asynchronous transfers, but pinning is not free: locked pages reduce operating-system flexibility and fresh pinning can dominate small copies. Reusable pinned buffers are therefore the meaningful offload design.

Part 3 - Quantitative Prediction Before Execution

For payload M, predict $T = L + M/B$. Add allocation or pinning time only when a fresh destination is created. Report effective bandwidth as M/T and include the transient coexistence of GPU source and CPU destination. Predict a crossover size below which launch and pinning overhead dominate bandwidth.

Part 4 - Experimental Design and Instrumentation

Warm up CUDA, preallocate equal pageable and pinned buffers, and reuse them for many D2H and H2D cycles. Time completion with CUDA events plus an explicit event synchronization. Run a second benchmark that includes fresh allocation. Verify checksums only after completion and record process RAM and pinned payload.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def timed_d2h(source, destination, repetitions):
    stream = torch.cuda.Stream()
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    torch.cuda.synchronize()
    with torch.cuda.stream(stream):
        start.record(stream)
        for _ in range(repetitions):
            destination.copy_(source, non_blocking=True)
        end.record(stream)
    end.synchronize()
    return start.elapsed_time(end) / repetitions
```

```
def E05(numel=8_000_000, repetitions=30):
    source = torch.randn(numel, device="cuda")
    pageable = torch.empty(numel)
    pinned = torch.empty(numel, pin_memory=True)
    pageable_ms = timed_d2h(source, pageable, repetitions)
    pinned_ms = timed_d2h(source, pinned, repetitions)
    expected = source.sum().item()
    observed = pinned.sum().item()
    return pageable_ms, pinned_ms, expected, observed
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not read the host destination before the recorded event completes. A pageable copy requested with `non_blocking=True` does not guarantee the same path or overlap as a pinned copy. Thermal state, PCIe contention, NUMA placement, and including allocation in one result but not the other invalidate comparisons.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory is a scheduling resource, not a universal speed flag. Use a small, bounded pool of reused pinned buffers where overlap has measurable value; use pageable memory for cold, long-lived copies that do not sit on the critical path.

19.16.7 Exercise 06

Exercise Title: Offload Gradients to CPU After Backward and Measure Peak VRAM Reduction Before the Optimizer Step

Part 1 - Exercise Contract and Why It Matters

Move completed gradients to a canonical CPU store after backward, prove value parity, release CUDA gradient storage, and quantify VRAM reduction before the update. State explicitly that a standard CUDA optimizer cannot consume those CPU gradients without rehydration or a CPU-side update design.

Part 2 - System and Memory Mental Model

Gradients are produced asynchronously on the current stream. A D2H stream must wait for backward completion, retain source storage until copying finishes, and commit the CPU copy before setting `parameter.grad=None`. With gradient accumulation, offload is legal only after the last microbatch or into an accumulating CPU destination with correct reduction semantics.

Part 3 - Quantitative Prediction Before Execution

Predict gradient payload as the sum of trainable parameter elements times each gradient element size. During D2H, both copies coexist, so immediate peak does not fall. After commit and reference release, allocated VRAM should fall by approximately the gradient payload, subject to views and allocator rounding; reserved VRAM may remain unchanged.

Part 4 - Experimental Design and Instrumentation

Measure allocated, reserved, and peak VRAM before forward, after backward, while copies are pending, and after commit. Store per-parameter norms and checksums. Compare the

offloaded run with a baseline at identical seed, model, batch, and loss. Verify that no optimizer step occurs with missing gradients.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def offload_gradients(model):
    transfer = torch.cuda.Stream()
    producer_done = torch.cuda.Event()
    producer_done.record(torch.cuda.current_stream())
    records = []
    with torch.cuda.stream(transfer):
        transfer.wait_event(producer_done)
        for name, parameter in model.named_parameters():
            if parameter.grad is None:
                continue
            source = parameter.grad
            destination = torch.empty_like(
                source, device="cpu", pin_memory=True)
            destination.copy_(source, non_blocking=True)
            source.record_stream(transfer)
            records.append((name, parameter, source, destination))
    transfer.synchronize()
    cpu_gradients = {}
    for name, parameter, source, destination in records:
        cpu_gradients[name] = destination
        parameter.grad = None
    return cpu_gradients

def E06(model, loss):
    loss.backward()
    before = torch.cuda.memory_allocated()
    gradients = offload_gradients(model)
    after = torch.cuda.memory_allocated()
    return gradients, before, after
```

Part 6 - Measurement, Validation, and Failure Analysis

Keeping `source` records after commit would keep gradient storage alive; discard the returned transaction metadata when it is no longer required. `empty_cache()` is not the proof: allocated bytes and tensor inventory are. Hooks can observe partial gradients, and shared parameters must be canonicalized rather than copied twice.

Part 7 - Engineering Interpretation and Philosophy

Gradient offload is a lifecycle transformation. The meaningful question is not whether bytes reached CPU, but whether accumulation, update order, authority, and failure recovery remain identical while the GPU copy is absent.

19.16.8 Exercise 07

Exercise Title: Move AdamW Optimizer States to CPU and Quantify the VRAM Saved by Removing First- and Second-Moment Buffers from the GPU

Part 1 - Exercise Contract and Why It Matters

Materialize AdamW state, inventory it, move tensor state to CPU without losing parameter association, and measure VRAM savings. Distinguish storage offload from execution: ordinary fused or foreach CUDA AdamW cannot update with moments resident on CPU.

Part 2 - System and Memory Mental Model

AdamW state is lazy and normally appears after the first step. Each parameter typically has first and second moments plus a step counter whose representation depends on implementation. Optimizer dictionaries remain keyed by parameter objects even when state tensors move. A later GPU step requires promotion, or the update must run on CPU.

Part 3 - Quantitative Prediction Before Execution

For full-precision moments, expect roughly two parameter-sized tensor sets, plus small step state. Mixed-precision training may also maintain master weights. Predict the temporary peak during D2H because GPU and CPU copies coexist, then compare unique state bytes with the observed allocated-VRAM drop.

Part 4 - Experimental Design and Instrumentation

Run one real optimizer step, classify every state value by parameter, key, dtype, device, and bytes, then move state. Verify exact tensor equality and preserved scalar values. Measure allocated and reserved VRAM before and after, and prove that an unmodified CUDA optimizer step is not silently attempted.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def optimizer_tensor_bytes(optimizer, device_type):
    total = 0
    for state in optimizer.state.values():
        for value in state.values():
            if torch.is_tensor(value):
                if value.device.type == device_type:
                    total += value.numel() * value.element_size()
    return total

def move_optimizer_state(optimizer, device):
    moved = 0
    for state in optimizer.state.values():
        for key in list(state.keys()):
            value = state[key]
            if not torch.is_tensor(value):
                continue
            moved += value.numel() * value.element_size()
```

```
            state[key] = value.detach().to(device).clone()
    return moved

def E07(optimizer):
    before = optimizer_tensor_bytes(optimizer, "cuda")
    moved = move_optimizer_state(optimizer, "cpu")
    after = optimizer_tensor_bytes(optimizer, "cuda")
    return before, moved, after
```

Part 6 - Measurement, Validation, and Failure Analysis

An empty optimizer state before the first step is not evidence of low memory. Moving only `exp_avg` while leaving `exp_avg_sq` on CUDA gives an incomplete result. Cloning can temporarily duplicate host state. Optimizer variants may require step tensors on a particular device, so restore and test the complete state contract before resuming GPU updates.

Part 7 - Engineering Interpretation and Philosophy

Optimizer state is attractive to offload because it is large and used once per step, but its movement lies directly on the update path. Capacity savings are real only when the chosen update architecture absorbs the resulting latency.

19.16.9 Exercise 08

Exercise Title: Implement a CPU-Based Optimizer Step for GPU Model Parameters and Measure the Cost of Round-Trip Parameter Synchronization

Part 1 - Exercise Contract and Why It Matters

Maintain CPU master parameters and AdamW moments, consume CPU gradients, update the masters, and copy new values to GPU. Compare the numerical update with a reference and account for both gradient D2H and parameter H2D traffic.

Part 2 - System and Memory Mental Model

Before the step, GPU parameters are the forward authority and CPU gradients are complete. The CPU update makes CPU masters authoritative. H2D synchronization then publishes a new GPU version before the next forward. No computation may read mixed parameter versions, and tied parameters require one master update.

Part 3 - Quantitative Prediction Before Execution

Each step moves approximately gradient bytes to CPU and updated parameter bytes to GPU. CPU stores require masters plus two Adam moments. Estimate transfer time from measured bandwidth and CPU update time from memory bandwidth; predict step latency as the non-overlapped critical path, not merely kernel time.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic model, compare one update against `AdamW` in float64, and report maximum parameter error. Then benchmark large tensors with reused pinned staging. Record D2H, CPU update, H2D, total step time, RAM, and peak VRAM separately.

Part 5 - PyTorch/CUDA Implementation

```
import math
import torch

class CpuAdamW:
    def __init__(self, named_parameters, lr=1e-3,
                 betas=(0.9, 0.999), eps=1e-8, decay=0.01):
        self.lr = lr
        self.b1, self.b2 = betas
        self.eps, self.decay, self.step_number = eps, decay, 0
        self.items = []
        for name, parameter in named_parameters:
            master = parameter.detach().cpu().float().clone()
            first = torch.zeros_like(master)
            second = torch.zeros_like(master)
            self.items.append((name, parameter, master, first, second))

    @torch.no_grad()
    def step(self, cpu_gradients):
        self.step_number += 1
        correction1 = 1.0 - self.b1 ** self.step_number
        correction2 = 1.0 - self.b2 ** self.step_number
        for name, parameter, master, first, second in self.items:
            gradient = cpu_gradients[name].float()
            first.mul_(self.b1).add_(gradient, alpha=1.0 - self.b1)
            second.mul_(self.b2).addcmul_(
                gradient, gradient, value=1.0 - self.b2)
            denominator = second.sqrt() / math.sqrt(correction2)
            denominator.add_(self.eps)
            master.mul_(1.0 - self.lr * self.decay)
            master.addcdiv_(first / correction1,
                            denominator, value=-self.lr)
            parameter.copy_(master.to(parameter.device))

def E08(model):
    return CpuAdamW(model.named_parameters())
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact implementation is educational, not a drop-in substitute for all AdamW variants. It casts masters to float32, omits parameter groups and sparse gradients, and performs blocking H2D copies. Validate update order, decay semantics, bias correction, ties, and publication completion before extending it with asynchronous staging.

Part 7 - Engineering Interpretation and Philosophy

A CPU optimizer converts expensive resident VRAM into repeated communication and host work. Its value depends on whether capacity is the hard constraint and whether update traffic can be amortized, sharded, overlapped, or reduced.

19.16.10 Exercise 09

Exercise Title: Compare Parameter Offload, Gradient Offload, and Optimizer-State Offload Independently to Determine Which Saves the Most VRAM

Part 1 - Exercise Contract and Why It Matters

Run a controlled ablation with four modes: full GPU, parameter offload only, gradient offload only, and optimizer-state offload only. Determine which saves the most peak and steady VRAM without mixing incompatible update mechanisms.

Part 2 - System and Memory Mental Model

The categories have different sizes, lifetimes, and reuse. Parameters are read throughout forward and backward; gradients live from production until reset; optimizer moments are large but touched only at the step. The same byte saving can therefore impose very different transfer frequency and synchronization.

Part 3 - Quantitative Prediction Before Execution

Predict per-mode resident bytes, transient copy peaks, D2H and H2D traffic, and critical-path time. Compute useful savings as baseline peak minus mode peak, and efficiency as saved peak bytes divided by transferred bytes per step. Keep RAM cost visible beside VRAM savings.

Part 4 - Experimental Design and Instrumentation

Use identical initialization, data, batch size, precision, accumulation, and number of measured steps. Warm up each mode in a fresh process. Report median and tail latency, samples per second, peak allocated VRAM, RAM peak, transfer bytes, final loss, and maximum parameter difference from its valid reference.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class AblationResult:
    mode: str
    peak_vram: int
    peak_ram: int
    transfer_bytes: int
    step_ms: float
    final_loss: float

def summarize_ablation(results, baseline_peak):
    rows = []
    for result in results:
        saved = baseline_peak - result.peak_vram
        if result.transfer_bytes == 0:
            efficiency = float("inf") if saved > 0 else 0.0
        else:
            efficiency = saved / result.transfer_bytes
        rows.append({
```

```
            "mode": result.mode,
            "saved_vram": saved,
            "ram_peak": result.peak_ram,
            "transfer_efficiency": efficiency,
            "step_ms": result.step_ms,
            "loss": result.final_loss,
        })
    return rows

def E09(results, baseline_peak):
    return summarize_ablation(results, baseline_peak)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not compare modes that accidentally change optimizer semantics or effective batch size. Peak memory can occur at a different boundary in each mode, so one snapshot after the step is insufficient. Reserved memory is not live saving, and transferring a category twice per layer is not equivalent to once per step.

Part 7 - Engineering Interpretation and Philosophy

The largest tensor category is not automatically the best offload target. A defensible decision combines bytes saved, lifetime removed, reuse frequency, communication cost, RAM pressure, and semantic complexity.

19.16.11 Exercise 10

Exercise Title: Combine Parameter, Gradient, and Optimizer-State Offloading Under a Single Fixed GPU Memory Budget

Part 1 - Exercise Contract and Why It Matters

Create one controller that admits and evicts parameters, gradients, and optimizer state under a hard VRAM budget while also enforcing a host-RAM budget. Every decision must preserve authority, dependencies, and enough transient headroom to complete the next transfer or operator.

Part 2 - System and Memory Mental Model

The controller manages heterogeneous resources. Active parameters and saved activations may be protected; completed gradients can move only when their accumulation contract permits; optimizer moments must be present where the update executes. Pending transfers reserve source, destination, and stream lifetime simultaneously. A low watermark prevents constant emergency eviction.

Part 3 - Quantitative Prediction Before Execution

At each boundary calculate live GPU bytes, pending GPU bytes, next-operation workspace, required promotion bytes, CPU resident bytes, and pinned staging. A plan is admissible only when predicted peaks fit both budgets. Rank legal victims by saved VRAM divided by transfer and future-reload cost.

Part 4 - Experimental Design and Instrumentation

Replay a deterministic training-state trace through the policy before running CUDA. Log every admission, protection, offload, promotion, rejection, and watermark transition. Compare predicted against measured peaks and fail the run before allocation when either budget would be exceeded.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class StateResource:
    key: str
    category: str
    gpu_bytes: int
    cpu_bytes: int
    reload_ms: float
    next_use: int
    protected: bool = False
    on_gpu: bool = True

class UnifiedBudget:
    def __init__(self, gpu_limit, cpu_limit, reserve):
        self.gpu_limit = gpu_limit
        self.cpu_limit = cpu_limit
        self.reserve = reserve

    def choose_victims(self, resources, required_gpu):
        gpu_used = 0
        cpu_used = 0
        candidates = []
        for item in resources:
            if item.on_gpu:
                gpu_used += item.gpu_bytes
                if not item.protected:
                    score = item.gpu_bytes / max(item.reload_ms, 1e-9)
                    candidates.append((score, item))
            else:
                cpu_used += item.cpu_bytes
        candidates.sort(key=score_value, reverse=True)
        victims = []
        for score, item in candidates:
            if gpu_used + required_gpu + self.reserve <= self.gpu_limit:
                break
            if cpu_used + item.cpu_bytes > self.cpu_limit:
                continue
            victims.append(item)
            gpu_used -= item.gpu_bytes
            cpu_used += item.cpu_bytes
        if gpu_used + required_gpu + self.reserve > self.gpu_limit:
```

```
            raise MemoryError("no legal dual-budget plan")
        return victims

def score_value(pair):
    return pair[0]

def E10(gpu_limit, cpu_limit, reserve):
    return UnifiedBudget(gpu_limit, cpu_limit, reserve)
```

Part 6 - Measurement, Validation, and Failure Analysis

The named sorting callback keeps the decision rule explicit. More importantly, byte accounting must canonicalize tied storage and include pending copies. A GPU-feasible plan that exceeds RAM is invalid, as is a plan that evicts state required by an in-flight kernel.

Part 7 - Engineering Interpretation and Philosophy

Unified offloading is constrained scheduling, not three independent copies. Correctness comes from hard lifecycle rules; performance comes only after the remaining legal choices are optimized against measured costs.

19.16.12 Exercise 11

Exercise Title: Build an Asynchronous CPU Offload Queue Using Pinned Host Buffers and a Dedicated CUDA Transfer Stream

Part 1 - Exercise Contract and Why It Matters

Build a bounded D2H queue with reusable pinned destinations, a dedicated CUDA stream, completion events, source-lifetime protection, and explicit commit. Submission must never be confused with CPU-visible completion.

Part 2 - System and Memory Mental Model

The producer stream records readiness. The transfer stream waits on that event, copies into pinned RAM, and records completion. Until completion, the source and destination are protected and both budgets are reserved. Calling `record_stream` prevents the allocator from recycling source storage while the side stream still consumes it.

Part 3 - Quantitative Prediction Before Execution

Queue depth q can add up to q source payloads of protected VRAM and q pinned destinations in RAM. Predict service rate from D2H bandwidth and compare it with production rate. If arrival exceeds service, queue latency and memory must grow until backpressure activates.

Part 4 - Experimental Design and Instrumentation

Submit known tensors at a controlled rate, poll without global synchronization, and verify each committed checksum. Log queue depth, reserved bytes, submission latency, completion latency, backpressure time, and copy bandwidth. Inject a too-small queue budget and confirm safe rejection rather than OOM.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class PendingD2H:
    source: object
    destination: object
    done: object
    size_bytes: int

class CpuOffloadQueue:
    def __init__(self, max_pinned_bytes):
        self.stream = torch.cuda.Stream()
        self.max_pinned_bytes = max_pinned_bytes
        self.pending_bytes = 0
        self.pending = []

    def submit(self, source):
        size = source.numel() * source.element_size()
        if self.pending_bytes + size > self.max_pinned_bytes:
            raise MemoryError("pinned queue budget exceeded")
        ready = torch.cuda.Event()
        ready.record(torch.cuda.current_stream())
        destination = torch.empty_like(
            source, device="cpu", pin_memory=True)
        done = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            self.stream.wait_event(ready)
            destination.copy_(source, non_blocking=True)
            source.record_stream(self.stream)
            done.record(self.stream)
        item = PendingD2H(source, destination, done, size)
        self.pending.append(item)
        self.pending_bytes += size

    def poll(self):
        completed = []
        remaining = []
        for item in self.pending:
            if item.done.query():
                completed.append(item.destination)
                self.pending_bytes -= item.size_bytes
            else:
                remaining.append(item)
        self.pending = remaining
        return completed

def E11(max_pinned_bytes):
```

```
    return CpuOffloadQueue(max_pinned_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Fresh pinned allocation inside submission may serialize or add jitter; replace it with a size-class pool after validating semantics. Event completion is the commit boundary. Dropping the event, destination, or source too early creates a lifetime bug, while device-wide synchronization destroys concurrency.

Part 7 - Engineering Interpretation and Philosophy

An asynchronous queue is a protocol with ownership and backpressure. Its value is not that calls return early, but that useful compute proceeds while bounded, verifiable transfers complete independently.

19.16.13 Exercise 12

Exercise Title: Overlap GPU Computation with CPU Offload Transfers and Quantify How Much Transfer Latency Is Hidden

Part 1 - Exercise Contract and Why It Matters

Overlap D2H offload of completed state with independent GPU work, prove overlap on a timeline, and quantify hidden rather than merely submitted transfer time. Preserve only the producer-consumer dependencies required for correctness.

Part 2 - System and Memory Mental Model

Compute and transfer require separate streams and hardware engines capable of concurrency. The transfer waits for its source producer; later CPU consumption waits for transfer completion. Independent compute need not wait. Pageable RAM, default-stream coupling, or a global synchronization can serialize the design.

Part 3 - Quantitative Prediction Before Execution

For isolated copy time T_c and independent compute time T_g, the ideal combined time is approximately $\max(T_c, T_g)$ rather than $T_c + T_g$. Hidden copy time is $(T_c + T_g) - T_{overlap}$, bounded by $\min(T_c, T_g)$. Report overlap efficiency relative to that bound.

Part 4 - Experimental Design and Instrumentation

Measure copy-only, compute-only, sequential, and overlapped cases after warmup. Use events on both streams plus an outer synchronized interval. Export a trace to verify simultaneous copy-engine and compute-kernel activity. Check copied values after the completion event.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def overlap_once(source, matrix):
    transfer = torch.cuda.Stream()
    ready = torch.cuda.Event()
    copied = torch.cuda.Event()
```

```
    destination = torch.empty_like(
        source, device="cpu", pin_memory=True)
    ready.record(torch.cuda.current_stream())
    with torch.cuda.stream(transfer):
        transfer.wait_event(ready)
        destination.copy_(source, non_blocking=True)
        source.record_stream(transfer)
        copied.record(transfer)
    result = matrix @ matrix
    copied.synchronize()
    return destination, result

def overlap_metrics(copy_ms, compute_ms, overlapped_ms):
    hidden = copy_ms + compute_ms - overlapped_ms
    maximum = min(copy_ms, compute_ms)
    efficiency = hidden / maximum if maximum > 0 else 0.0
    return hidden, efficiency

def E12(source, matrix):
    return overlap_once(source, matrix)
```

Part 6 - Measurement, Validation, and Failure Analysis

The matrix operation must be independent of the offloaded tensor. CPU wall time without final synchronization measures submission, not completion. Lack of overlap may reflect hardware engine limits, too-small work, hidden stream dependencies, pageable destinations, or bandwidth contention rather than an incorrect API call.

Part 7 - Engineering Interpretation and Philosophy

Overlap does not make communication free; it places communication beneath a larger piece of independent work. The design succeeds only while dependencies remain correct and enough compute exists to cover the measured transfer.

19.16.14 Exercise 13

Exercise Title: Reproduce a CPU Offload Bottleneck Where PCIe Traffic Dominates Runtime Despite Large VRAM Savings

Part 1 - Exercise Contract and Why It Matters

Construct a workload that saves substantial VRAM yet becomes slower because state crosses PCIe too frequently. Diagnose the bottleneck with byte traffic, link utilization, copy-engine time, GPU idle time, and end-to-end throughput.

Part 2 - System and Memory Mental Model

Offloading reduces residency but adds communication. Low-reuse state may move profitably; parameters used every layer or microbatch can create repeated round trips. When transfer demand approaches sustainable PCIe bandwidth, prefetch cannot create capacity and compute streams wait for data.

Part 3 - Quantitative Prediction Before Execution

Compute traffic per step as all D2H and H2D payloads, including repeated loads. The bandwidth lower bound is traffic divided by measured sustainable bandwidth. If it approaches or exceeds baseline step time, large slowdown is predicted. Also report bytes transferred per byte of peak VRAM saved.

Part 4 - Experimental Design and Instrumentation

Sweep offload granularity from whole blocks to individual layers while holding model work constant. Measure traffic, copy duration, waiting time, kernel time, VRAM peak, and throughput. Export traces and correlate GPU gaps with parameter arrival events. Include a no-offload and idealized resident baseline.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class OffloadTelemetry:
    transferred_bytes: int
    saved_vram_bytes: int
    measured_bandwidth_Bps: float
    step_seconds: float
    gpu_idle_seconds: float

    def transfer_lower_bound(self):
        return self.transferred_bytes / self.measured_bandwidth_Bps

    def traffic_amplification(self):
        return self.transferred_bytes / max(self.saved_vram_bytes, 1)

    def pcie_dominates(self, threshold=0.6):
        ratio = self.transfer_lower_bound() / self.step_seconds
        return ratio >= threshold

def E13(telemetry):
    return {
        "lower_bound_s": telemetry.transfer_lower_bound(),
        "traffic_per_saved_byte": telemetry.traffic_amplification(),
        "pcie_dominates": telemetry.pcie_dominates(),
        "gpu_idle_fraction": (
            telemetry.gpu_idle_seconds / telemetry.step_seconds),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Advertised PCIe rate is not the workload's sustainable bandwidth. Count both directions and copies caused by policy thrashing. An asynchronous trace full of copy activity can still be transfer-bound. Large VRAM savings should not be reported as success when samples per second collapses.

Part 7 - Engineering Interpretation and Philosophy

Capacity and throughput are separate objectives. CPU offload can make an otherwise impossible model executable, but the engineering report must expose the price and identify whether coarser residency or fewer state movements buys a better point on the trade-off curve.

19.16.15 Exercise 14

Exercise Title: Detect Host RAM Pressure Caused by Aggressive Offloading and Prevent the Process from Trading GPU OOM for CPU OOM

Part 1 - Exercise Contract and Why It Matters

Monitor managed tensor bytes, pinned bytes, process RSS, and system-available RAM, then reject or slow offload before host exhaustion. The safety contract is to avoid solving CUDA OOM by destabilizing the entire machine.

Part 2 - System and Memory Mental Model

Tensor payload is only part of RSS: allocator fragmentation, Python objects, DataLoader workers, file caches, and libraries also consume RAM. Pinned pages are especially constrained. System available memory is more actionable than the raw free counter. High and low watermarks create hysteresis and leave an emergency reserve for transient copies.

Part 3 - Quantitative Prediction Before Execution

Before a D2H transaction, predict final CPU payload plus temporary duplication, staging, worker prefetch, and safety reserve. Admission requires both managed budget headroom and sufficient system-available RAM. Choose thresholds below physical capacity; never stress real hardware to the operating-system limit.

Part 4 - Experimental Design and Instrumentation

Use an artificial budget, gradually submit known buffers, and confirm that the controller enters pressure mode at the high watermark and exits only below the low watermark. Record RSS, available RAM, managed pageable bytes, managed pinned bytes, queue depth, rejections, and reclaim actions.

Part 5 - PyTorch/CUDA Implementation

```
import os
import psutil

class HostPressureGuard:
    def __init__(self, managed_limit, reserve, high=0.9, low=0.75):
        self.managed_limit = managed_limit
        self.reserve = reserve
        self.high = high
        self.low = low
        self.managed_bytes = 0
        self.pressured = False

    def admit(self, requested_bytes):
```

```
        available = psutil.virtual_memory().available
        projected = self.managed_bytes + requested_bytes
        if projected >= self.high * self.managed_limit:
            self.pressured = True
        if available < requested_bytes + self.reserve:
            self.pressured = True
        if self.pressured:
            return False
        self.managed_bytes = projected
        return True

    def release(self, released_bytes):
        self.managed_bytes = max(0, self.managed_bytes - released_bytes)
        if self.managed_bytes <= self.low * self.managed_limit:
            self.pressured = False

    def process_rss(self):
        return psutil.Process(os.getpid()).memory_info().rss

def E14(managed_limit, reserve):
    return HostPressureGuard(managed_limit, reserve)
```

Part 6 - Measurement, Validation, and Failure Analysis

The example requires `psutil`; deployment code must handle its absence or use operating-system counters directly. RSS can fall later than tensor release, and available RAM changes because of unrelated processes. Admission and actual allocation must be transactional so a failed allocation rolls back reservations.

Part 7 - Engineering Interpretation and Philosophy

RAM is not an infinite extension of VRAM. A safe offloader treats the host as a shared, budgeted tier and prefers a controlled rejection or reduced workload to machine-wide swapping, pinned-page exhaustion, or process termination.

19.16.16 Exercise 15

Exercise Title: Build a RAM Budget Controller That Limits Offloaded Tensor Residency According to Available Host Memory

Part 1 - Exercise Contract and Why It Matters

Build a transactional controller for pageable and pinned offload residency. It must reserve bytes before allocation, commit only after success, reclaim legal entries to a low watermark, and reject work when host capacity cannot be made available safely.

Part 2 - System and Memory Mental Model

Reservations represent promised memory; committed bytes represent existing buffers. Both count against the budget. An entry can be reclaimed only when it is clean and reproducible elsewhere, or after dirty data is safely written to an authoritative tier. Pinned and pageable pools need separate sublimits even when they share a global RAM ceiling.

Part 3 - Quantitative Prediction Before Execution

Admission checks committed plus reserved plus requested bytes against the high watermark and system reserve. Reclamation continues toward the low watermark so the next small request does not immediately retrigger pressure. Predict worst transient memory when a replacement destination coexists with its victim.

Part 4 - Experimental Design and Instrumentation

Replay fixed and bursty size traces. Inject allocation failure between reserve and commit and prove rollback. Verify that protected and dirty-only copies are never discarded. Log admissions, denials, reclaimed bytes, pinned bytes, RSS, available memory, and time spent applying backpressure.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class HostEntry:
    key: str
    size_bytes: int
    pinned: bool
    protected: bool
    clean_replica: bool
    last_use: int

class RamBudgetController:
    def __init__(self, high_bytes, low_bytes, pinned_limit):
        self.high_bytes = high_bytes
        self.low_bytes = low_bytes
        self.pinned_limit = pinned_limit
        self.committed = 0
        self.reserved = 0
        self.pinned = 0
        self.entries = {}

    def reserve(self, size_bytes, pinned):
        if self.committed + self.reserved + size_bytes > self.high_bytes:
            return False
        if pinned and self.pinned + size_bytes > self.pinned_limit:
            return False
        self.reserved += size_bytes
        return True

    def commit(self, entry):
        if entry.size_bytes > self.reserved:
            raise RuntimeError("missing RAM reservation")
        self.reserved -= entry.size_bytes
        self.committed += entry.size_bytes
```

```
        if entry.pinned:
            self.pinned += entry.size_bytes
        self.entries[entry.key] = entry

    def rollback(self, size_bytes):
        self.reserved = max(0, self.reserved - size_bytes)

    def reclaimable(self):
        output = []
        for entry in self.entries.values():
            if not entry.protected and entry.clean_replica:
                output.append(entry)
        output.sort(key=entry_last_use)
        return output

def entry_last_use(entry):
    return entry.last_use

def E15(high_bytes, low_bytes, pinned_limit):
    return RamBudgetController(high_bytes, low_bytes, pinned_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

The example exposes reclaimable entries but leaves physical deletion to the owner, because deleting metadata before tensor release would falsify accounting. A robust implementation performs release and accounting as one commit. Shared storage must be counted once, and dirty authoritative CPU data is not a cache victim merely because it is old.

Part 7 - Engineering Interpretation and Philosophy

Memory budgets are admission-control systems. Their central purpose is to make failure predictable and local: work waits or is rejected before the process enters swap storms, allocation failure, or untraceable partial state.

19.16.17 Exercise 16

Exercise Title: Design a Cost-Aware Policy That Decides Which Training States Should Stay on GPU and Which Should Be Offloaded to CPU

Part 1 - Exercise Contract and Why It Matters

Design a policy that first applies correctness constraints and then ranks legal placement choices using size, reuse, next use, measured transfer cost, CPU update cost, recomputation option, and host pressure. Produce explanations for every decision rather than an opaque score alone.

Part 2 - System and Memory Mental Model

Residency has future value: keeping state avoids reload and waiting. Offloading has capacity value: it frees scarce VRAM. Parameters, gradients, moments, and activations have different consumers and mutability. A protected or sole dirty copy is ineligible regardless of score. Hysteresis prevents near-equal choices from causing repeated migration.

Part 3 - Quantitative Prediction Before Execution

Estimate keep benefit from expected future accesses times reload latency plus critical-path penalty. Estimate offload benefit from VRAM bytes freed times current pressure. Subtract D2H cost, CPU-memory penalty, and expected H2D reload. Calibrate weights from measurements and impose hard budget feasibility after ranking.

Part 4 - Experimental Design and Instrumentation

Train the cost model on measured bandwidth and per-category traces, then test on unseen stable, bursty, and variable-shape workloads. Compare against size-only, LRU, and static placement. Report OOM count, peak memories, migration bytes, stall time, throughput, and decision-prediction error.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PlacementCandidate:
    key: str
    category: str
    size_bytes: int
    reuse_count: int
    next_use_distance: int
    d2h_ms: float
    h2d_ms: float
    cpu_pressure_cost: float
    protected: bool
    sole_dirty_copy: bool

def offload_score(item, pressure_weight, stall_weight):
    if item.protected or item.sole_dirty_copy:
        return float("-inf")
    capacity_value = pressure_weight * item.size_bytes
    urgency = 1.0 / max(item.next_use_distance, 1)
    future_stall = item.reuse_count * item.h2d_ms * urgency
    movement = item.d2h_ms + future_stall
    return capacity_value - stall_weight * movement \
        - item.cpu_pressure_cost

def rank_candidates(items, pressure_weight, stall_weight):
    scored = []
    for item in items:
        score = offload_score(item, pressure_weight, stall_weight)
        scored.append((score, item))
    scored.sort(key=score_component, reverse=True)
    return scored

def score_component(pair):
```

```
    return pair[0]

def E16(items):
    return rank_candidates(items, 1e-9, 1.0)
```

Part 6 - Measurement, Validation, and Failure Analysis

Score units must be normalized; raw bytes can dwarf milliseconds and make the formula meaningless. Future reuse is uncertain, so log prediction error and fall back to safe rules. Do not learn through correctness constraints. A high score never authorizes eviction of in-flight, shared, or uniquely dirty state.

Part 7 - Engineering Interpretation and Philosophy

A placement policy is an economic model operating beneath a correctness law. Measurements should revise its cost estimates, while invariants remain fixed. Explainable decisions make regressions and unexpected migration debuggable.

19.16.18 Exercise 17

Exercise Title: Compare Full-GPU Training Against CPU-Offloaded Training at Equal Batch Size and Report VRAM, RAM, Throughput, and Step Latency

Part 1 - Exercise Contract and Why It Matters

Benchmark full-GPU and CPU-offloaded training under identical semantics and batch size. Report capacity and performance together: peak VRAM, peak RAM, throughput, median and tail step latency, transfer traffic, and final numerical agreement.

Part 2 - System and Memory Mental Model

CUDA execution is asynchronous, so each measured step needs a well-defined completion boundary. RSS samples need a background peak monitor because the final value can miss transient host copies. Warmup materializes optimizer state, allocator segments, and kernels. Separate steady state from first-step costs.

Part 3 - Quantitative Prediction Before Execution

Before measurement, predict resident category bytes and transfer bytes for both modes. Estimate the offloaded lower bound from transfer bandwidth and CPU update time. Report VRAM reduction percentage, RAM increase, throughput loss, and milliseconds paid per GiB of peak VRAM saved.

Part 4 - Experimental Design and Instrumentation

Launch each mode in a clean process with the same seeds, data batches, model weights, optimizer hyperparameters, precision, and synchronization boundaries. Warm up, reset CUDA peak statistics, sample RAM at short intervals, and collect enough steps for median and p95. Compare loss and parameter checksums.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def timed_steps(step_function, steps, examples_per_step):
    times = []
    torch.cuda.reset_peak_memory_stats()
    torch.cuda.synchronize()
    total_start = time.perf_counter()
    for _ in range(steps):
        torch.cuda.synchronize()
        start = time.perf_counter()
        step_function()
        torch.cuda.synchronize()
        times.append((time.perf_counter() - start) * 1000.0)
    elapsed = time.perf_counter() - total_start
    ordered = sorted(times)
    p95_index = max(0, int(0.95 * len(ordered)) - 1)
    return {
        "median_step_ms": statistics.median(times),
        "p95_step_ms": ordered[p95_index],
        "examples_per_second": steps * examples_per_step / elapsed,
        "peak_vram_bytes": torch.cuda.max_memory_allocated(),
    }

def E17(full_gpu_step, offload_step, steps, batch_size):
    full = timed_steps(full_gpu_step, steps, batch_size)
    offloaded = timed_steps(offload_step, steps, batch_size)
    return full, offloaded
```

Part 6 - Measurement, Validation, and Failure Analysis

Running both modes sequentially in one process can contaminate allocator and kernel state; subprocess isolation is stronger. The sample function measures CUDA completion but omits the required RAM-monitor thread and transfer counters, which must be included in the full experiment. Equal batch size alone is not enough if accumulation, loss scaling, or update precision differs.

Part 7 - Engineering Interpretation and Philosophy

The comparison is a Pareto analysis, not a contest with one universal winner. Full GPU favors latency; offloading buys feasibility and batch capacity. The right result states exactly how much capacity was purchased and its recurring cost.

19.16.19 Exercise 18

Exercise Title: Stress-Test CPU Offloading on a Model That Cannot Fit All Training State in VRAM and Diagnose Transfer Stalls, RAM Growth, and Synchronization Errors

Part 1 - Exercise Contract and Why It Matters

Run an oversized training-state workload under artificial VRAM and RAM limits, vary shapes and reuse, inject synchronization mistakes, and require the runtime to diagnose stalls, unbounded host growth, stale reads, and illegal authority transitions before data corruption or physical OOM.

Part 2 - System and Memory Mental Model

Stress combines several feedback loops: eviction creates transfers, transfers occupy staging buffers, buffers increase RAM, slow service grows queues, and aggressive prefetch restores VRAM pressure. Correctness additionally depends on events, stream lifetimes, version publication, tied ownership, and autograd dependencies.

Part 3 - Quantitative Prediction Before Execution

Derive maximum queue bytes from arrival and service rates, and predict the working-set minimum needed to avoid thrashing. Budget transient duplication and next-operator workspace. Define alarms for sustained queue growth, transfer wait fraction, RAM slope, repeated migrations, version mismatch, and invariant failure.

Part 4 - Experimental Design and Instrumentation

Start with a simulator, then use scaled real CUDA tensors below safe physical limits. Sweep model depth, tensor size, queue depth, bandwidth delay, and memory budgets. Inject a missing wait, early reference release, and leaked CPU entry. Require each fault to trigger a named diagnostic and preserve a trace.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class StressSample:
    step: int
    gpu_bytes: int
    cpu_bytes: int
    queue_bytes: int
    transfer_wait_ms: float
    migrations: int
    version_errors: int

class StressDiagnostics:
    def __init__(self, gpu_limit, cpu_limit):
        self.gpu_limit = gpu_limit
        self.cpu_limit = cpu_limit
        self.previous = None

    def inspect(self, sample):
        alarms = []
        if sample.gpu_bytes > self.gpu_limit:
            alarms.append("VRAM budget violation")
        if sample.cpu_bytes > self.cpu_limit:
            alarms.append("RAM budget violation")
```

```
        if sample.version_errors > 0:
            alarms.append("synchronization or authority error")
        if self.previous is not None:
            ram_growth = sample.cpu_bytes - self.previous.cpu_bytes
            queue_growth = sample.queue_bytes - self.previous.queue_bytes
            if ram_growth > 0 and queue_growth > 0:
                alarms.append("offload backlog and host growth")
            if sample.migrations - self.previous.migrations > 20:
                alarms.append("placement thrashing")
        self.previous = sample
        return alarms

def E18(gpu_limit, cpu_limit):
    return StressDiagnostics(gpu_limit, cpu_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

One positive slope is not a leak; require persistence over a window and account for warmup. An empty alarm list does not prove numerical correctness, so compare losses, gradients, versions, and parameter checksums with a smaller resident reference. Never discover physical limits by exhausting a shared workstation.

Part 7 - Engineering Interpretation and Philosophy

Stress testing asks whether the controller fails intelligibly at its boundary. An oversized model is a useful systems test only when limits are artificial, invariants are observable, and every recovery action leaves authority coherent.

19.16.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch CPU-Offload Runtime That Dynamically Moves Parameters, Gradients, and Optimizer State Between RAM and VRAM Under Fixed Memory Budgets

Part 1 - Exercise Contract and Why It Matters

Integrate a registry, dual-budget admission, pinned-buffer pool, asynchronous transactions, cost-aware placement, versioned authority, backpressure, instrumentation, and recovery into one runtime. Support parameters, gradients, and optimizer state without claiming that one movement rule fits all three.

Part 2 - System and Memory Mental Model

The registry is the control plane; CPU and GPU tensors are data-plane replicas. Every resource has a category-specific lifecycle, canonical identity, version, authority, protection set, next consumer, and pending transaction. Promotions publish GPU versions before use; demotions publish CPU versions before release. Budget reservations make every transition atomic from the controller's view.

Part 3 - Quantitative Prediction Before Execution

Given a future layer schedule, simulate residency and calculate peak committed and reserved bytes on both tiers, staging depth, transfer volume, predicted stall, and workspace headroom.

Refuse execution if no legal schedule exists. Benchmark prediction error as well as performance because a poor cost model can turn a safe controller into a thrashing one.

Part 4 - Experimental Design and Instrumentation

Validate individual transitions, then one inference, one training step, several accumulation steps, checkpoint save, interruption, and restore. Benchmark fixed and variable shapes against full GPU and static offload. Report correctness, peak VRAM, peak RAM, transfer traffic, queue depth, median and p95 latency, throughput, overlap, policy decisions, retries, and rejected admissions.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class RuntimeRecord:
    key: str
    category: str
    size_bytes: int
    authority: str
    version: int
    cpu_tensor: object = None
    gpu_tensor: object = None
    pending: object = None
    protected: set = field(default_factory=set)

class CpuOffloadRuntime:
    def __init__(self, gpu_budget, ram_budget, queue):
        self.gpu_budget = gpu_budget
        self.ram_budget = ram_budget
        self.queue = queue
        self.records = {}
        self.gpu_committed = 0
        self.ram_committed = 0

    def register(self, record):
        if record.key in self.records:
            raise KeyError("duplicate canonical state key")
        self.records[record.key] = record
        if record.gpu_tensor is not None:
            self.gpu_committed += record.size_bytes
        if record.cpu_tensor is not None:
            self.ram_committed += record.size_bytes
        self.check_budgets()

    def check_budgets(self):
        if self.gpu_committed > self.gpu_budget:
            raise MemoryError("managed VRAM budget exceeded")
        if self.ram_committed > self.ram_budget:
```

```
            raise MemoryError("managed RAM budget exceeded")

    def request_offload(self, key):
        record = self.records[key]
        if record.protected:
            raise RuntimeError("resource is protected")
        if record.gpu_tensor is None or record.pending is not None:
            raise RuntimeError("illegal offload state")
        if self.ram_committed + record.size_bytes > self.ram_budget:
            raise MemoryError("no RAM headroom for D2H destination")
        self.queue.submit(record.gpu_tensor)
        record.pending = "d2h"

    def commit_cpu(self, key, cpu_tensor):
        record = self.records[key]
        if record.pending != "d2h":
            raise RuntimeError("D2H completion was not expected")
        record.cpu_tensor = cpu_tensor
        record.gpu_tensor = None
        record.pending = None
        record.authority = "cpu"
        self.ram_committed += record.size_bytes
        self.gpu_committed -= record.size_bytes
        self.check_budgets()

def E19(gpu_budget, ram_budget, queue):
    return CpuOffloadRuntime(gpu_budget, ram_budget, queue)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact runtime shows control-plane invariants, not a universal training framework. A complete implementation must add H2D promotion, pooled pinned buffers, transaction IDs, rollback, tied-storage canonicalization, optimizer integration, checkpoint serialization, and process-failure recovery. Never commit from queue order alone; match the exact completion to its record.

Part 7 - Engineering Interpretation and Philosophy

The final runtime is a memory operating system for training state. Its quality is determined first by coherent authority and bounded failure, then by how well it converts transfer opportunities into useful model capacity without hiding cost, weakening numerical semantics, or exhausting the host.

19.17 DMM15

Chapter Title: NVMe Offloading and Three-Tier Memory Hierarchies
Specialization: Dynamic Memory Management and CUDA Systems

19.17.1 Exercise 00

Exercise Title: Build a Precise Mental Model of VRAM, RAM, and NVMe as a Three-Tier Memory Hierarchy with Different Capacity, Bandwidth, and Latency

Part 1 - Exercise Contract and Why It Matters

Build a quantitative model of three distinct storage tiers: GPU VRAM for active compute, CPU RAM for staging and hot state, and NVMe for large cold state. The contract must track authority, clean replicas, dirty state, residency, pending I/O, protection reasons, next use, and budgets for all three tiers.

Part 2 - System and Memory Mental Model

VRAM offers device-local bandwidth and kernel access but limited capacity. RAM is larger and CPU-addressable, yet GPU use requires H2D transfer. NVMe is much larger but block-oriented and high-latency; it cannot feed CUDA kernels as an ordinary tensor. Data normally travels NVMe to page cache or a host buffer, then through pinned staging to VRAM. Memory mapping changes when pages are faulted, not the physical need to move bytes through the hierarchy.

Part 3 - Quantitative Prediction Before Execution

For a shard of M bytes, predict $T_{IO} = L_{IO} + M/B_{IO}$ and $T_{H2D} = L_{H2D} + M/B_{H2D}$. Without overlap, delivery is their sum. With a three-stage pipeline, steady-state throughput is bounded by the slowest stage. Add file metadata, page cache, pinned buffers, GPU replicas, next-operation workspace, and transient source-destination coexistence to the budgets.

Part 4 - Experimental Design and Instrumentation

Measure cold and warm NVMe reads separately, then pageable-to-CUDA and pinned-to-CUDA transfer. Record logical bytes, physical I/O when available, minor and major faults, page-cache state, RAM RSS, pinned bytes, allocated and peak VRAM, queue depth, and GPU idle time. Use an isolated benchmark file and artificial budgets rather than exhausting the workstation.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class TieredState:
    key: str
    size_bytes: int
    authority: str
    nvme_path: str
    in_ram: bool = False
    in_vram: bool = False
    dirty: bool = False
    pending_stage: str = "none"
    version: int = 0
    protected: set = field(default_factory=set)
```

```
    def begin(self, stage):
        if self.pending_stage != "none":
            raise RuntimeError("another movement is pending")
        self.pending_stage = stage

    def commit_gpu(self):
        if self.pending_stage != "ram_to_vram":
            raise RuntimeError("unexpected H2D commit")
        self.in_ram = True
        self.in_vram = True
        self.pending_stage = "none"

def E00(key, size_bytes, path):
    return TieredState(key, size_bytes, "nvme", path)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not call mapped virtual bytes resident RAM, or page-cache hits NVMe speed. Do not infer disk I/O from Python elapsed time alone. A file write is not durable until the required flush and filesystem guarantees complete. Duplicate views, compressed files, filesystem cache, and asynchronous submissions can all make logical accounting differ from physical movement.

Part 7 - Engineering Interpretation and Philosophy

Three-tier offloading is a scheduling problem governed by locality. NVMe makes capacity possible only when future use is predictable enough to hide I/O and when authority remains coherent across slow, failure-prone transitions.

19.17.2 Exercise 01

Exercise Title: Benchmark Sequential NVMe Read and Write Throughput and Compare It Against Measured RAM-to-VRAM Transfer Bandwidth

Part 1 - Exercise Contract and Why It Matters

Measure sequential NVMe read and write service separately from RAM-to-VRAM transfer, then determine which stage limits parameter delivery. Report cold and warm storage behavior and never compare buffered file submission with completed CUDA transfer.

Part 2 - System and Memory Mental Model

Filesystem writes may land in the page cache before durable storage. Repeated reads may be served from RAM. H2D copies require completed CUDA timing and gain asynchronous capability from pinned sources. Sequential bandwidth reflects large contiguous requests; it does not predict small-shard random access.

Part 3 - Quantitative Prediction Before Execution

Convert every result to bytes per second using completed bytes divided by completed time. Predict pipeline rate as the minimum of NVMe read bandwidth and H2D bandwidth, then include per-request latency. Calculate the shard size needed to amortize fixed latency and the maximum theoretical overlap speedup.

Part 4 - Experimental Design and Instrumentation

Create a file several times larger than the test block, warm up devices, use multiple offsets, and state whether caches were warm. Time file open, read, write, flush, buffer pinning, H2D submission, and H2D completion separately. Repeat trials and report median, p95, and variance without issuing unsafe cache drop commands on a shared system.

Part 5 - PyTorch/CUDA Implementation

```
import os
import time
import torch

def sequential_read(path, block_bytes):
    transferred = 0
    start = time.perf_counter()
    with open(path, "rb", buffering=0) as handle:
        while True:
            data = handle.read(block_bytes)
            if not data:
                break
            transferred += len(data)
    elapsed = time.perf_counter() - start
    return transferred, elapsed, transferred / elapsed

def pinned_h2d_bandwidth(numel, repetitions):
    source = torch.empty(numel, dtype=torch.float32,
                         pin_memory=True)
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    start.record()
    for _ in range(repetitions):
        destination = source.to("cuda", non_blocking=True)
    end.record()
    end.synchronize()
    seconds = start.elapsed_time(end) / 1000.0
    total = source.numel() * source.element_size() * repetitions
    return total / seconds, destination

def E01(path, block_bytes, numel, repetitions):
    storage = sequential_read(path, block_bytes)
    transfer = pinned_h2d_bandwidth(numel, repetitions)
    return storage, transfer
```

Part 6 - Measurement, Validation, and Failure Analysis

The example's file read may be cached and its H2D loop allocates destinations; the full benchmark must reuse destinations and disclose cache state. For write durability, add flush and platform-appropriate synchronization deliberately. Background I/O, thermal throttling, filesystem compression, and shared PCIe topology can change both stages.

Part 7 - Engineering Interpretation and Philosophy

Bandwidth numbers matter only when tied to the actual transfer path. The engine must be designed for the slowest measured stage and its latency distribution, not for a vendor's peak specification.

19.17.3 Exercise 02

Exercise Title: Serialize Large PyTorch Parameter Tensors into Independent NVMe Shards and Reconstruct the Original Model Exactly

Part 1 - Exercise Contract and Why It Matters

Write each canonical parameter into an independently loadable shard, store a manifest, and reconstruct the model with exact names, shapes, dtypes, values, and tied relationships. A partially written generation must never replace the last valid model.

Part 2 - System and Memory Mental Model

The shard payload and metadata form one logical checkpoint. Canonical storage prevents tied parameters from becoming independent copies. A generation is published only after all temporary files, hashes, and manifest are complete. Loading untrusted pickle-based artifacts is unsafe; tensor-only formats and trusted manifests reduce the attack surface.

Part 3 - Quantitative Prediction Before Execution

Predict payload as unique parameter elements times element size, plus metadata, filesystem block rounding, and hashes. Estimate total creation time from serialization CPU work and sequential write bandwidth. Reassembly RAM depends on whether shards are loaded one at a time or all together.

Part 4 - Experimental Design and Instrumentation

Use a model with shared weights, noncontiguous source views, several dtypes, and buffers. Save into a private temporary directory, interrupt before manifest publication, and confirm the previous generation remains usable. Verify names, metadata, hashes, exact equality, and shared-parameter identity after restore.

Part 5 - PyTorch/CUDA Implementation

```
import hashlib
import json
from pathlib import Path
import torch

def tensor_digest(tensor):
    raw = tensor.detach().cpu().contiguous().numpy().tobytes()
    return hashlib.sha256(raw).hexdigest()

def write_parameter_shards(model, directory):
    root = Path(directory)
    root.mkdir(parents=True, exist_ok=True)
    manifest = []
```

```
    index = 0
    for name, parameter in model.named_parameters():
        cpu_tensor = parameter.detach().cpu().contiguous()
        filename = "parameter_%06d.pt" % index
        torch.save(cpu_tensor, root / filename)
        manifest.append({
            "name": name,
            "file": filename,
            "shape": list(cpu_tensor.shape),
            "dtype": str(cpu_tensor.dtype),
            "sha256": tensor_digest(cpu_tensor),
        })
        index += 1
    temporary = root / "manifest.json.tmp"
    final = root / "manifest.json"
    temporary.write_text(json.dumps(manifest, indent=2))
    temporary.replace(final)
    return manifest

def E02(model, directory):
    return write_parameter_shards(model, directory)
```

Part 6 - Measurement, Validation, and Failure Analysis

`named_parameters()` normally removes duplicate parameter objects, so a separate alias map is required to reconstruct ties. NumPy conversion needs a supported CPU dtype. Atomic rename alone does not guarantee durable data after power failure; production code must define directory and file synchronization, permissions, versioning, and recovery semantics.

Part 7 - Engineering Interpretation and Philosophy

Sharding converts a monolithic checkpoint into schedulable units, but it also creates a consistency protocol. Correct reconstruction and atomic publication are more important than maximizing parallel file creation.

19.17.4 Exercise 03

Exercise Title: Compare Loading a Complete PyTorch Checkpoint into RAM Against torch.load(..., mmap=True) Lazy Storage Access

Part 1 - Exercise Contract and Why It Matters

Compare eager checkpoint loading with memory-mapped loading while separating open latency, virtual address mapping, page faults, resident RAM growth, and time to touch or transfer each tensor. Prove that a quick mapping is not a completed model load.

Part 2 - System and Memory Mental Model

Ordinary loading reads tensor storages into memory during deserialization. With memory mapping enabled, storages are mapped and pages are faulted on demand. The operating system may retain them in page cache and evict them under pressure. Mapped virtual size can be large while resident physical RAM is initially low.

Part 3 - Quantitative Prediction Before Execution

Predict eager startup from total checkpoint bytes and storage bandwidth. For mapped loading, predict small metadata startup followed by per-tensor fault cost. If every tensor is eventually touched once, total physical I/O remains similar; the advantage is bounded residency, deferral, and selective access rather than eliminating reads.

Part 4 - Experimental Design and Instrumentation

In fresh processes, measure eager and mapped open, RSS immediately afterward, first-touch time per tensor, full-touch time, major/minor faults, and transfer to CUDA. Repeat warm and cold-cache conditions and preserve identical `map_location` and `weights_only` settings.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def load_and_touch(path, use_mmap):
    start_open = time.perf_counter()
    state = torch.load(
        path,
        map_location="cpu",
        mmap=use_mmap,
        weights_only=True)
    open_seconds = time.perf_counter() - start_open

    checksum = 0.0
    start_touch = time.perf_counter()
    for tensor in state.values():
        if torch.is_tensor(tensor):
            checksum += tensor.float().sum().item()
    touch_seconds = time.perf_counter() - start_touch
    return open_seconds, touch_seconds, checksum

def E03(path):
    eager = load_and_touch(path, False)
    mapped = load_and_touch(path, True)
    return eager, mapped
```

Part 6 - Measurement, Validation, and Failure Analysis

Running eager then mapped in one process warms the page cache and biases the second result; use isolated processes or clearly label warm-cache data. RSS does not equal mapped virtual size. Accessing a single element does not represent a full tensor scan, and transferring to CUDA forces the required pages to become available before the copy can complete.

Part 7 - Engineering Interpretation and Philosophy

Memory mapping changes the timing and granularity of payment. It is valuable when the engine can exploit selective access and bounded working sets; it does not transform NVMe into RAM or make first-touch latency disappear.

19.17.5 Exercise 04

Exercise Title: Create File-Backed CPU Tensor Storage with torch.from_file() and Verify That Tensor Data Can Remain Backed by NVMe

Part 1 - Exercise Contract and Why It Matters

Create a CPU tensor whose storage is memory-mapped from a file, verify shape and dtype interpretation, distinguish shared and private mappings, and measure how touching pages changes residency. Demonstrate that CUDA still requires an explicit staged copy.

Part 2 - System and Memory Mental Model

`torch.from_file` maps a flat CPU storage; the programmer supplies the element count and dtype, then reshapes the view. In shared mode, modifications can be visible in the file; private mode does not provide the same persistence contract. The file's byte length, offset convention, endianness, dtype, and layout must match the manifest exactly.

Part 3 - Quantitative Prediction Before Execution

Required file payload is element count times dtype size. Predict initial virtual mapping with little resident growth, then page-fault and page-cache growth as regions are touched. A contiguous CUDA copy may fault the entire requested range, after which H2D time remains bounded by host-device bandwidth.

Part 4 - Experimental Design and Instrumentation

Write a known tensor, map it, reshape it, compare every value, mutate one region under shared and private modes, reopen the file, and verify persistence rules. Measure open, first touch, repeated touch, RSS, faults, and H2D completion. Reject truncated or oversized metadata before mapping.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

def create_file_backed_tensor(path, shape, dtype, shared):
    elements = 1
    for dimension in shape:
        elements *= dimension
    probe = torch.empty((), dtype=dtype)
    required_bytes = elements * probe.element_size()
    actual_bytes = Path(path).stat().st_size
    if actual_bytes < required_bytes:
        raise ValueError("backing file is smaller than tensor metadata")
    flat = torch.from_file(
        str(path), shared=shared, size=elements, dtype=dtype)
    return flat.reshape(shape)

def E04(path, rows, columns):
    mapped = create_file_backed_tensor(
        path, (rows, columns), torch.float32, True)
```

```
    checksum = mapped.sum().item()
    cuda_copy = mapped.to("cuda")
    return mapped, cuda_copy, checksum
```

Part 6 - Measurement, Validation, and Failure Analysis

A successful reshape proves only element count, not semantic metadata. Incorrect dtype can produce plausible but meaningless numbers. Mapped storage is CPU-only and is not automatically pinned. File truncation while mapped, concurrent writes, missing flush policy, or mutable shared mappings can corrupt state.

Part 7 - Engineering Interpretation and Philosophy

File-backed tensors make storage addressable through tensor operations, but they do not erase the hierarchy. They are useful when metadata, ownership, and access locality are explicit enough to make page faults predictable.

19.17.6 Exercise 05

Exercise Title: Build an NVMe Parameter Store That Maps Every Model Parameter to a File, Byte Offset, Shape, Dtype, and Residency State

Part 1 - Exercise Contract and Why It Matters

Build a canonical parameter store whose manifest identifies every tensor by file, byte offset, length, shape, stride policy, dtype, checksum, owners, version, and residency. The store must distinguish durable authority from RAM and VRAM cache replicas.

Part 2 - System and Memory Mental Model

A parameter is a logical object; its bytes may have replicas in three tiers. The manifest is the address translation table. Offsets need alignment and must not overlap. Shared or tied parameters map several names to one canonical record. Dirty GPU or RAM state cannot be evicted to an older NVMe generation.

Part 3 - Quantitative Prediction Before Execution

Calculate each payload, alignment padding, file size, metadata size, RAM cache, pinned staging, and VRAM replica. Predict the number of file opens and seeks for a layer trace. A packed file favors sequential reads; independent files simplify replacement but can increase metadata and open overhead.

Part 4 - Experimental Design and Instrumentation

Register a model with ordinary and tied parameters, validate non-overlapping ranges, reopen the store, read every record, and compare checksums. Exercise NVMe-only, RAM-hot, H2D-pending, VRAM-clean, VRAM-dirty, and writeback-pending transitions. Corrupt one manifest offset and require early detection.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class ParameterRecord:
    key: str
    owners: list
    path: str
    offset_bytes: int
    length_bytes: int
    shape: tuple
    dtype: str
    checksum: str
    authority: str = "nvme"
    residency: str = "nvme_only"
    version: int = 0
    protected: set = field(default_factory=set)

class NvmeParameterStore:
    def __init__(self):
        self.records = {}

    def add(self, record):
        if record.key in self.records:
            raise KeyError("duplicate canonical parameter")
        for existing in self.records.values():
            if existing.path != record.path:
                continue
            left = max(existing.offset_bytes, record.offset_bytes)
            right = min(
                existing.offset_bytes + existing.length_bytes,
                record.offset_bytes + record.length_bytes)
            if left < right:
                raise ValueError("overlapping parameter ranges")
        self.records[record.key] = record

def E05():
    return NvmeParameterStore()
```

Part 6 - Measurement, Validation, and Failure Analysis

String dtype names require a validated conversion table before reconstruction. Offsets must be interpreted in bytes, not elements. Checksums verify content but do not replace atomic generation publication. Views with shared storage need a canonical base record plus view metadata rather than duplicated payload.

Part 7 - Engineering Interpretation and Philosophy

The parameter store is a small virtual-memory system. Its manifest makes placement replaceable while preserving identity, and its authority rules make dynamic movement safe rather than merely convenient.

19.17.7 Exercise 06

Exercise Title: Load One Parameter Shard from NVMe to CPU Only When Its Owning Layer Is About to Execute

Part 1 - Exercise Contract and Why It Matters

Implement just-in-time shard loading at the layer boundary. Load exactly the canonical state needed by the upcoming layer, verify it, bind it without losing ties, execute, and release or cache it according to the next-use schedule.

Part 2 - System and Memory Mental Model

On-demand loading minimizes RAM residency but puts storage latency directly on the critical path. A pre-forward hook knows the next layer, yet loading inside that hook is synchronous unless a prior prefetch exists. Parameter replacement must preserve module registration and autograd expectations; inference is the simpler first target.

Part 3 - Quantitative Prediction Before Execution

Peak RAM includes the current shard, read buffer, decoded tensor, and possibly the previous shard awaiting release. Step latency gains the sum of unhidden read times. Predict when caching a reused shard costs fewer bytes than re-reading it, using next-use distance and measured I/O cost.

Part 4 - Experimental Design and Instrumentation

Begin with an inference-only sequential model. Record layer start, read start, read completion, validation, binding, execution, and release. Compare output with a resident reference. Then repeat with shared layers and nonsequential control flow to expose assumptions in the schedule.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

class JustInTimeShardLoader:
    def __init__(self, manifest):
        self.manifest = manifest
        self.active = {}

    def load_cpu(self, key):
        record = self.manifest[key]
        path = Path(record["path"])
        tensor = torch.load(
            path, map_location="cpu", weights_only=True)
        expected_shape = tuple(record["shape"])
        if tuple(tensor.shape) != expected_shape:
            raise ValueError("parameter shape mismatch")
        self.active[key] = tensor
        return tensor
```

```
    def release(self, key):
        if key in self.active:
            del self.active[key]

def E06(manifest):
    return JustInTimeShardLoader(manifest)
```

Part 6 - Measurement, Validation, and Failure Analysis

Loading a tensor does not automatically install it into a module. Production binding must use a controlled parameter materialization mechanism and preserve dtype, device, requires-grad, aliases, and version. Calling `torch.load` per tiny parameter magnifies open and metadata costs; shard at a useful layer or block granularity.

Part 7 - Engineering Interpretation and Philosophy

Just-in-time loading trades memory certainty for latency certainty. It is a correct baseline that reveals the real I/O cost; prefetching should be added only after this baseline preserves exact model behavior.

19.17.8 Exercise 07

Exercise Title: Stage NVMe Parameters Through a Reusable Pinned CPU Buffer Before Performing a Non-Blocking Transfer to CUDA

Part 1 - Exercise Contract and Why It Matters

Read a shard into bounded host memory, copy it into a reusable pinned buffer, then submit non-blocking H2D and publish the CUDA tensor only after completion. Protect the pinned slot from reuse throughout both CPU filling and DMA.

Part 2 - System and Memory Mental Model

Ordinary file APIs fill pageable memory. Pinned staging adds a CPU copy but enables the DMA path needed for asynchronous H2D. A slot has states free, filling, CPU-ready, H2D-pending, and free-after-event. Reusing it before the CUDA event completes can silently transfer bytes belonging to a later shard.

Part 3 - Quantitative Prediction Before Execution

Delivery time contains NVMe read, pageable-to-pinned copy, and H2D transfer. For one shard they add; across shards they may pipeline. Budget pageable read storage, pinned slot, CUDA destination, and transient duplicates. Select buffer size from the largest admitted shard or use bounded size classes.

Part 4 - Experimental Design and Instrumentation

Compare fresh and reused pinned allocation, verify byte equality after each event, and log slot state, I/O time, host-copy time, H2D time, total time, RAM, pinned bytes, and VRAM. Inject early slot reuse and require the checksum or state machine to detect it.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class PinnedStage:
    def __init__(self, elements, dtype):
        self.buffer = torch.empty(
            elements, dtype=dtype, pin_memory=True)
        self.stream = torch.cuda.Stream()
        self.done = None
        self.busy = False

    def submit(self, pageable_tensor):
        if self.busy:
            raise RuntimeError("pinned slot is still busy")
        if pageable_tensor.numel() > self.buffer.numel():
            raise ValueError("shard exceeds pinned slot")
        view = self.buffer[:pageable_tensor.numel()]
        view.copy_(pageable_tensor.reshape(-1))
        destination = torch.empty_like(view, device="cuda")
        self.done = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            destination.copy_(view, non_blocking=True)
            self.done.record(self.stream)
        self.busy = True
        return destination

    def reclaim(self):
        if self.busy and self.done.query():
            self.busy = False
            self.done = None
            return True
        return False

def E07(elements, dtype):
    return PinnedStage(elements, dtype)
```

Part 6 - Measurement, Validation, and Failure Analysis

Returning the destination does not mean it is ready on an unrelated stream; the consumer must wait on the completion event. CPU filling is complete before submission in this example. A fully asynchronous disk reader needs a separate future and lifetime. Dtype conversion or reshape must not change payload bytes without updating metadata and checksums.

Part 7 - Engineering Interpretation and Philosophy

Pinned staging is an explicit bridge between two asynchronous systems. Its correct unit is not a tensor alone but a buffer lease whose lifetime ends only when the final consumer dependency has been satisfied.

19.17.9 Exercise 08

Exercise Title: Compare Direct Lazy File Access, Pageable RAM Staging, and Pinned RAM Staging for NVMe-to-GPU Parameter Delivery

Part 1 - Exercise Contract and Why It Matters

Compare three delivery paths under identical shards: mapped lazy access followed by CUDA copy, explicit pageable staging, and explicit pageable-to-pinned staging. Measure complete first-use and steady-state latency, not file-open or H2D submission alone.

Part 2 - System and Memory Mental Model

Mapped access delegates paging to the OS and can avoid explicit full reads. Pageable staging makes I/O explicit but may require internal CUDA staging. Pinned staging adds a host copy and locked RAM while enabling asynchronous H2D. Warm page cache can make every path look like RAM rather than NVMe.

Part 3 - Quantitative Prediction Before Execution

Model mapped delivery as page-fault cost plus H2D. Model pageable delivery as read plus H2D path. Model pinned delivery as read plus host copy plus H2D, with potential overlap across shards. Predict crossovers by shard size and reuse: small cold reads favor fewer copies; sustained pipelines can favor pinned slots.

Part 4 - Experimental Design and Instrumentation

Use fresh processes, randomized file regions, and declared cold or warm cache. Measure open, read or fault, pin-copy, H2D completion, GPU-ready time, RSS, pinned memory, CPU utilization, faults, and effective storage bytes. Verify identical CUDA outputs and repeat across shard sizes.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class DeliveryResult:
    path: str
    shard_bytes: int
    open_ms: float
    storage_ms: float
    host_copy_ms: float
    h2d_ms: float
    ready_ms: float
    checksum: float

def compare_delivery(results):
    rows = []
    for result in results:
        rows.append({
            "path": result.path,
            "bytes": result.shard_bytes,
```

```
            "gpu_ready_ms": result.ready_ms,
            "storage_fraction": (
                result.storage_ms / max(result.ready_ms, 1e-9)),
            "checksum": result.checksum,
        })
    return rows

def E08(results):
    return compare_delivery(results)
```

Part 6 - Measurement, Validation, and Failure Analysis

Mapped access is not GPU-direct storage in this experiment. A warm-cache mapped result cannot be compared with a cold explicit read. Pinned staging is useful only when its extra copy and locked-memory cost are outweighed by faster or overlapped H2D. Verify completion on the exact consumer stream.

Part 7 - Engineering Interpretation and Philosophy

There is no universally shortest path. The correct default emerges from shard size, cache temperature, reuse, concurrency, and memory pressure, all measured at GPU-ready completion rather than API return.

19.17.10 Exercise 09

Exercise Title: Sweep Parameter Shard Size and Determine How Small Random Reads and Large Sequential Reads Affect Effective NVMe Throughput

Part 1 - Exercise Contract and Why It Matters

Sweep shard size and access order to locate the transition from latency-bound small reads to bandwidth-bound large sequential reads. Use the result to choose parameter grouping rather than assuming one file per tensor is efficient.

Part 2 - System and Memory Mental Model

Each request pays software, filesystem, queue, and device latency. Sequential access benefits from readahead and contiguous media requests. Random access can defeat readahead and multiply queue work. Concurrency may hide latency until it saturates queues or competes with GPU and H2D traffic.

Part 3 - Quantitative Prediction Before Execution

For request size S, approximate throughput by $S/(L+S/B)$. Small S is latency limited; large S approaches bandwidth B. Include useful-byte ratio when a large shard contains parameters not needed by the current layer. Optimal sharding balances I/O efficiency against overfetch and cache pressure.

Part 4 - Experimental Design and Instrumentation

Generate an aligned benchmark file, sweep powers-of-two sizes, and run sequential and seeded random offsets with equal total useful bytes. Record IOPS, throughput, median and p95 latency, CPU time, page faults, readahead effects, queue depth, and overfetch. Separate warm and cold-cache trials.

Part 5 - PyTorch/CUDA Implementation

```
import random
import time

def read_offsets(path, offsets, shard_bytes):
    latencies = []
    total = 0
    with open(path, "rb", buffering=0) as handle:
        for offset in offsets:
            handle.seek(offset)
            start = time.perf_counter()
            data = handle.read(shard_bytes)
            latencies.append(time.perf_counter() - start)
            total += len(data)
    return total, latencies

def seeded_random_offsets(file_bytes, shard_bytes, count, seed):
    generator = random.Random(seed)
    maximum = (file_bytes - shard_bytes) // shard_bytes
    offsets = []
    for _ in range(count):
        block = generator.randint(0, maximum)
        offsets.append(block * shard_bytes)
    return offsets

def E09(path, file_bytes, shard_bytes, count, seed=7):
    offsets = seeded_random_offsets(
        file_bytes, shard_bytes, count, seed)
    return read_offsets(path, offsets, shard_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Python buffered or cached reads can conceal device behavior. Direct I/O has alignment constraints and is platform-specific, so document the chosen path. Random offsets may repeat; report unique useful bytes separately. One-thread results do not describe an asynchronous queue, while excessive parallelism may measure contention rather than the device limit.

Part 7 - Engineering Interpretation and Philosophy

Shard size is a systems parameter. Good sharding makes physical access efficient without reading so much unused state that the hierarchy loses its capacity and locality advantages.

19.17.11 Exercise 10

Exercise Title: Build an Asynchronous NVMe Read Queue That Loads Future Parameter Shards While PyTorch Executes the Current Layer

Part 1 - Exercise Contract and Why It Matters

Build a bounded read queue that submits future shards from an explicit execution schedule while the current CUDA layer runs. Every request needs identity, generation, destination ownership, deadline, cancellation state, completion, and byte reservations.

Part 2 - System and Memory Mental Model

Python I/O can run in worker threads while CUDA work proceeds asynchronously. The future proves host-read completion, not GPU readiness. Queue depth consumes RAM and can issue useless reads after a control-flow change. Backpressure must bound submitted and completed-but-unconsumed bytes.

Part 3 - Quantitative Prediction Before Execution

Prefetch distance must cover read latency plus variation before the layer's deadline. If production rate exceeds storage service rate, pending bytes grow without bound. Estimate queue capacity from the maximum admitted byte sum, not request count, because parameter shards vary greatly in size.

Part 4 - Experimental Design and Instrumentation

Replay a deterministic layer order with artificial compute duration. Sweep worker count, lookahead, and byte budget. Record submission, start, completion, consumption, lateness, cancellation, useful bytes, wasted bytes, queue depth, RAM, and GPU wait. Inject reordered and skipped layers.

Part 5 - PyTorch/CUDA Implementation

```
from concurrent.futures import ThreadPoolExecutor
from dataclasses import dataclass
from pathlib import Path

@dataclass
class ReadRequest:
    key: str
    size_bytes: int
    future: object

def read_exact(path, expected_bytes):
    data = Path(path).read_bytes()
    if len(data) != expected_bytes:
        raise IOError("short or oversized shard read")
    return data

class AsyncNvmeQueue:
    def __init__(self, workers, byte_budget):
        self.pool = ThreadPoolExecutor(max_workers=workers)
        self.byte_budget = byte_budget
        self.pending_bytes = 0
        self.requests = {}

    def submit(self, key, path, size_bytes):
        if self.pending_bytes + size_bytes > self.byte_budget:
```

```
            raise MemoryError("NVMe read queue RAM budget exceeded")
        future = self.pool.submit(read_exact, path, size_bytes)
        self.requests[key] = ReadRequest(key, size_bytes, future)
        self.pending_bytes += size_bytes

    def consume(self, key):
        request = self.requests.pop(key)
        data = request.future.result()
        self.pending_bytes -= request.size_bytes
        return data

def E10(workers, byte_budget):
    return AsyncNvmeQueue(workers, byte_budget)
```

Part 6 - Measurement, Validation, and Failure Analysis

`read_bytes()` allocates one complete bytes object and is deliberately simple; production code should read into reusable bounded buffers. Duplicate keys, worker exceptions, cancellation, shutdown, and reservation rollback need explicit handling. More threads can reduce latency hiding by creating storage contention and RAM bursts.

Part 7 - Engineering Interpretation and Philosophy

Prefetch is a prediction backed by a reservation. The queue is valuable only when useful reads arrive before their deadlines and incorrect predictions are bounded, cancellable, and visible in telemetry.

19.17.12 Exercise 11

Exercise Title: Implement Double-Buffered NVMe Staging with One Host Buffer Being Filled from Storage While Another Transfers to CUDA

Part 1 - Exercise Contract and Why It Matters

Create two pinned buffer leases so one slot can be filled from an asynchronously completed NVMe read while the other performs H2D. Enforce slot ownership and events so neither CPU writers nor later shards overwrite in-flight DMA data.

Part 2 - System and Memory Mental Model

Each slot cycles through free, reading, host-copying, CPU-ready, H2D-pending, GPU-ready, and free. Conventional file APIs often fill pageable memory first; the CPU then copies to the pinned slot. Double buffering overlaps different shards, not two operations that access the same slot concurrently.

Part 3 - Quantitative Prediction Before Execution

For storage time T_s, host-copy time T_h, and H2D time T_g, the pipelined steady-state period approaches the slowest constrained stage. Two slots consume twice the maximum pinned payload plus pageable read buffers and two CUDA destinations. Predict whether the extra buffer is affordable under both budgets.

Part 4 - Experimental Design and Instrumentation

Run alternating equal shards, then variable-size shards. Record slot state and timestamps, verify content after CUDA completion, and compare one versus two slots. Inject a missing event wait and early reuse. Report stage utilization, stall reason, pinned RAM, peak VRAM, and throughput.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class StageSlot:
    host: object
    state: str = "free"
    event: object = None
    key: str = ""

class DoubleBuffer:
    def __init__(self, elements, dtype):
        self.stream = torch.cuda.Stream()
        self.slots = []
        for _ in range(2):
            host = torch.empty(
                elements, dtype=dtype, pin_memory=True)
            self.slots.append(StageSlot(host))

    def load_host(self, index, key, pageable):
        slot = self.slots[index]
        if slot.state != "free":
            raise RuntimeError("slot is not available")
        slot.host[:pageable.numel()].copy_(pageable.reshape(-1))
        slot.key = key
        slot.state = "cpu_ready"

    def submit_h2d(self, index, elements):
        slot = self.slots[index]
        if slot.state != "cpu_ready":
            raise RuntimeError("slot has no completed host payload")
        view = slot.host[:elements]
        output = torch.empty_like(view, device="cuda")
        slot.event = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            output.copy_(view, non_blocking=True)
            slot.event.record(self.stream)
        slot.state = "h2d_pending"
        return output

def E11(elements, dtype):
    return DoubleBuffer(elements, dtype)
```

Part 6 - Measurement, Validation, and Failure Analysis

The example needs a poll method that frees a slot only after its event completes. It also assumes the pageable read has already finished. CUDA output consumption on another stream requires an event wait. If one stage is much slower than all others, two buffers may add memory without improving throughput.

Part 7 - Engineering Interpretation and Philosophy

Double buffering is a lifetime discipline before it is a speed technique. Its two slots turn serialization into overlap only when each transition has one owner, one completion signal, and bounded memory.

19.17.13 Exercise 12

Exercise Title: Build a Three-Stage Pipeline That Overlaps NVMe Read, RAM-to-VRAM Transfer, and GPU Computation

Part 1 - Exercise Contract and Why It Matters

Build a dependency-aware pipeline in which shard $N + 2$ reads from NVMe, shard $N + 1$ transfers from pinned RAM to VRAM, and layer N computes. Publish each resource only at its stage completion and bound all in-flight bytes.

Part 2 - System and Memory Mental Model

The storage worker, transfer stream, and compute stream are separate executors. Edges carry futures or CUDA events. Compute waits only for its parameter H2D event; H2D waits for the host payload; buffer reclamation waits for DMA; VRAM eviction waits for the final CUDA consumer. Global synchronization would erase the pipeline.

Part 3 - Quantitative Prediction Before Execution

Sequential time per shard is $T_s + T_h + T_c$. After fill, ideal pipeline period is approximately $\max(T_s, T_h, T_c)$. Total time also includes fill and drain. Predict RAM from read and pinned queues and VRAM from current plus prefetched weights, active outputs, activations, and workspaces.

Part 4 - Experimental Design and Instrumentation

First measure each stage independently. Then compare sequential, two-stage, and three-stage versions for the same layer trace. Export storage and CUDA timelines, record deadline misses and stage stalls, and verify every layer output against a resident model. Sweep computation intensity and shard size.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PipelineItem:
    key: str
    stage: str
    size_bytes: int
```

```
    read_future: object = None
    h2d_event: object = None
    cuda_tensor: object = None

class ThreeStageController:
    legal = {
        "planned": "nvme_read",
        "nvme_read": "cpu_ready",
        "cpu_ready": "h2d",
        "h2d": "gpu_ready",
        "gpu_ready": "compute",
        "compute": "finished",
    }

    def advance(self, item, next_stage):
        expected = self.legal.get(item.stage)
        if expected != next_stage:
            raise RuntimeError("illegal pipeline transition")
        item.stage = next_stage

    def validate_gpu_use(self, item):
        if item.stage != "gpu_ready":
            raise RuntimeError("compute requested before GPU readiness")
        if item.cuda_tensor is None:
            raise RuntimeError("missing CUDA parameter")

def E12():
    return ThreeStageController()
```

Part 6 - Measurement, Validation, and Failure Analysis

A state machine validates order but not actual completion; the runtime must advance only after the future or event proves it. Storage and H2D may share PCIe resources and fail to overlap fully. Variable layer times create bubbles, while excessive lookahead can exceed RAM or VRAM and cause eviction of useful data.

Part 7 - Engineering Interpretation and Philosophy

The pipeline makes latency tolerable by converting future knowledge into concurrency. Its speed is limited by the slowest stage, while its correctness is limited by the weakest dependency or lifetime rule.

19.17.14 Exercise 13

Exercise Title: Add an RAM Hot Cache Above NVMe and Keep High-Reuse Parameter Shards in Memory to Avoid Repeated Storage Reads

Part 1 - Exercise Contract and Why It Matters

Add a byte-bounded RAM cache between NVMe authority and pinned H2D staging. Promote shards after verified reads, update access metadata, retain high-value entries, and evict only clean unprotected replicas.

Part 2 - System and Memory Mental Model

The RAM cache converts repeated storage reads into memory copies. Cache entries can be pageable canonical tensors, while a smaller pinned pool handles DMA. Frequency alone favors stale history; recency alone can fail on scans. Reuse distance, size, read cost, next use, and host pressure together determine value.

Part 3 - Quantitative Prediction Before Execution

Measure byte hit rate as avoided NVMe bytes divided by requested bytes, not only request hit count. Estimate saved time from avoided read latency minus cache management and host-copy cost. Include duplicate page-cache and explicit-cache residency when interpreting physical RAM.

Part 4 - Experimental Design and Instrumentation

Replay looping, sequential, and mixed layer traces under several RAM budgets. Report request and byte hit rates, avoided reads, cache insertions, evictions, residency bytes, next-use prediction error, storage traffic, GPU wait, and throughput. Verify values and versions after every hit.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class RamCacheEntry:
    key: str
    tensor: object
    size_bytes: int
    accesses: int
    last_use: int
    protected: bool = False

class RamHotCache:
    def __init__(self, byte_budget):
        self.byte_budget = byte_budget
        self.used_bytes = 0
        self.clock = 0
        self.entries = {}

    def get(self, key):
        self.clock += 1
        entry = self.entries.get(key)
        if entry is None:
            return None
        entry.accesses += 1
        entry.last_use = self.clock
        return entry.tensor

    def insert(self, key, tensor):
```

```
        size = tensor.numel() * tensor.element_size()
        if size > self.byte_budget:
            return False
        self.entries[key] = RamCacheEntry(
            key, tensor, size, 1, self.clock)
        self.used_bytes += size
        return True

def E13(byte_budget):
    return RamHotCache(byte_budget)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact cache must add replacement, duplicate-key accounting, tied storage, and transactional insertion before production use. Replacing an existing key without subtracting its old bytes falsifies the budget. A dirty sole copy is not a cache entry and cannot be discarded. OS page cache can make apparent misses faster without appearing in this controller.

Part 7 - Engineering Interpretation and Philosophy

RAM should hold the working set whose absence would cost the most future time. A hot cache is successful when it reduces physical I/O and GPU waiting under a hard host budget, not when it merely reports a high request hit count.

19.17.15 Exercise 14

Exercise Title: Implement RAM-to-NVMe Eviction When Host Memory Crosses a High Watermark and Reload Evicted Tensors Transparently on Demand

Part 1 - Exercise Contract and Why It Matters

Evict eligible RAM entries toward a low watermark, write dirty authoritative state safely before release, and reload it transparently on demand. Preserve versions and never expose a partially written shard as current.

Part 2 - System and Memory Mental Model

A clean RAM replica backed by the same NVMe version can be dropped immediately. A dirty RAM authority needs writeback to a temporary generation, validation, durability according to policy, and atomic publication before RAM release. High and low watermarks provide hysteresis; pending writeback still consumes RAM.

Part 3 - Quantitative Prediction Before Execution

Choose victims until projected committed plus reserved RAM falls below the low watermark, while budgeting write buffers and metadata. Estimate future reload cost and avoid evicting near-use shards. Disk capacity also needs reservation, including temporary generations during atomic replacement.

Part 4 - Experimental Design and Instrumentation

Create clean, dirty, protected, and in-flight entries. Cross the artificial high watermark and verify legal victim order, writeback completion, RAM reduction, and exact reload. Inject

write failure, checksum failure, and interruption before rename; the old generation must remain authoritative.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

def atomic_tensor_write(tensor, final_path):
    final = Path(final_path)
    temporary = final.with_suffix(final.suffix + ".pending")
    torch.save(tensor.detach().cpu(), temporary)
    temporary.replace(final)

class RamEvictor:
    def __init__(self, high_bytes, low_bytes):
        self.high_bytes = high_bytes
        self.low_bytes = low_bytes

    def choose(self, entries, used_bytes):
        victims = []
        ordered = []
        for entry in entries:
            if not entry["protected"]:
                ordered.append(entry)
        ordered.sort(key=last_use_value)
        projected = used_bytes
        for entry in ordered:
            if projected <= self.low_bytes:
                break
            victims.append(entry)
            projected -= entry["size_bytes"]
        return victims

def last_use_value(entry):
    return entry["last_use"]

def E14(high_bytes, low_bytes):
    if low_bytes >= high_bytes:
        raise ValueError("low watermark must be below high watermark")
    return RamEvictor(high_bytes, low_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Atomic rename is only one publication step; power-loss durability requires the appropriate file and directory synchronization for the platform. The selector must distinguish clean drop from dirty writeback. Transparent reload must verify generation, checksum, dtype, and shape before returning the tensor.

Part 7 - Engineering Interpretation and Philosophy

Eviction is a transfer of responsibility, not deletion. The slower tier becomes authoritative only after a complete, verified commit; until then the RAM source is protected even when pressure is high.

19.17.16 Exercise 15

Exercise Title: Offload Adam Optimizer State to NVMe and Measure the Storage Capacity Saved in RAM Against the Additional Training-Step Latency

Part 1 - Exercise Contract and Why It Matters

Move Adam first- and second-moment state from RAM to versioned NVMe shards, reload exactly the states needed for an update, and compare RAM saved with added read, write, synchronization, and optimizer-step latency. Preserve parameter association and step counters.

Part 2 - System and Memory Mental Model

Adam state is large and touched once per update, making it capacity-attractive but I/O-intensive. A CPU update needs moments and gradients in RAM; after the update, dirty moments must be written back before release. Reading and writing two full moment tensors per parameter can make storage bandwidth the dominant training resource.

Part 3 - Quantitative Prediction Before Execution

Full-precision first and second moments require roughly twice parameter payload, plus step state and metadata. Per-step NVMe traffic can approach a read and a write for both moments. Predict the lower-bound latency from total bytes divided by measured read and write bandwidth, then add CPU update and durability cost.

Part 4 - Experimental Design and Instrumentation

Materialize Adam state with one step, inventory unique bytes, offload it, and compare RSS. Run identical updates with RAM-resident and NVMe-resident moments. Report read/write bytes, faults, CPU time, median and p95 step latency, throughput, final loss, and maximum state and parameter error.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

class NvmeAdamStateStore:
    def __init__(self, directory):
        self.root = Path(directory)
        self.root.mkdir(parents=True, exist_ok=True)
        self.index = {}

    def save_tensor(self, parameter_key, state_key, tensor, step):
        filename = "%s_%s_%08d.pt" % (
            parameter_key, state_key, step)
        path = self.root / filename
```

```
        temporary = path.with_suffix(".pt.pending")
        torch.save(tensor.detach().cpu(), temporary)
        temporary.replace(path)
        self.index[(parameter_key, state_key)] = {
            "path": str(path),
            "step": step,
            "shape": tuple(tensor.shape),
            "dtype": str(tensor.dtype),
        }

    def load_tensor(self, parameter_key, state_key):
        record = self.index[(parameter_key, state_key)]
        return torch.load(
            record["path"], map_location="cpu", weights_only=True)

def E15(directory):
    return NvmeAdamStateStore(directory)
```

Part 6 - Measurement, Validation, and Failure Analysis

Filenames derived from arbitrary parameter names need escaping or stable numeric IDs. Per-tensor files may create prohibitive small-I/O overhead; group states into update blocks after measuring. A successful save call is not automatically durable. The optimizer must not advance the published step until all required moment generations and parameters form a consistent checkpoint.

Part 7 - Engineering Interpretation and Philosophy

NVMe optimizer offload buys enormous host capacity at a recurring update cost. It is defensible when training feasibility is primary and when grouping, overlap, or reduced update frequency keeps state traffic below the critical path.

19.17.17 Exercise 16

Exercise Title: Detect NVMe Thrashing Caused by Poor Prefetch and Eviction Decisions and Quantify Wasted I/O, GPU Idle Time, and Repeated Reads

Part 1 - Exercise Contract and Why It Matters

Detect when the engine repeatedly reads, promotes, evicts, and rereads shards without enough useful compute between movements. Quantify wasted I/O, repeated reads, migration amplification, cache churn, deadline misses, and GPU idle time.

Part 2 - System and Memory Mental Model

Thrashing occurs when the admitted working set is smaller than the active reuse window or when prefetch and eviction policies oppose each other. A prefetched shard can evict a near-use hot shard, then be discarded unused. High storage utilization is therefore compatible with very low useful throughput.

Part 3 - Quantitative Prediction Before Execution

Define useful I/O as bytes consumed by computation before eviction. Wasted I/O includes unused prefetch, duplicate same-version reads, and read bytes evicted before adequate reuse. Track traffic amplification as total physical read bytes divided by unique useful bytes and stall fraction as GPU wait divided by step time.

Part 4 - Experimental Design and Instrumentation

Construct a cyclic trace whose working set is just above the RAM cache budget, then vary lookahead and victim policy. Record every request, version, read, cache hit, use, eviction, and reread. Trigger alarms from windows rather than a single event and verify that reducing lookahead or protecting the reuse window recovers throughput.

Part 5 - PyTorch/CUDA Implementation

```
from collections import defaultdict

class ThrashingDetector:
    def __init__(self, amplification_limit, idle_limit):
        self.amplification_limit = amplification_limit
        self.idle_limit = idle_limit
        self.read_counts = defaultdict(int)
        self.physical_read_bytes = 0
        self.useful_unique = set()
        self.useful_bytes = 0

    def record_read(self, key, version, size_bytes):
        self.read_counts[(key, version)] += 1
        self.physical_read_bytes += size_bytes

    def record_first_use(self, key, version, size_bytes):
        identity = (key, version)
        if identity not in self.useful_unique:
            self.useful_unique.add(identity)
            self.useful_bytes += size_bytes

    def diagnose(self, gpu_idle_seconds, elapsed_seconds):
        amplification = self.physical_read_bytes / max(
            self.useful_bytes, 1)
        idle_fraction = gpu_idle_seconds / max(elapsed_seconds, 1e-9)
        return {
            "amplification": amplification,
            "idle_fraction": idle_fraction,
            "thrashing": (
                amplification >= self.amplification_limit and
                idle_fraction >= self.idle_limit),
        }

def E16(amplification_limit=2.0, idle_limit=0.25):
    return ThrashingDetector(amplification_limit, idle_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

A second read can be legitimate after a long interval; interpret counts with reuse distance and capacity. Page-cache hits may not become physical NVMe reads, so label logical and device-level traffic separately. High GPU idle can originate from compute dependencies, CPU preprocessing, or H2D rather than storage.

Part 7 - Engineering Interpretation and Philosophy

Thrashing is failed prediction expressed as motion. The remedy is usually a smaller admitted future, a larger protected working set, coarser shards, or a policy that values near reuse more than speculative completeness.

19.17.18 Exercise 17

Exercise Title: Build a Cost-Aware Placement Policy That Chooses VRAM, RAM, or NVMe from Tensor Size, Reuse Distance, Transfer Cost, and Available Capacity

Part 1 - Exercise Contract and Why It Matters

Choose among VRAM, RAM, and NVMe after enforcing authority and dependency rules. The policy must use measured transfer costs, tensor size, reuse distance, frequency, dirty state, stage deadlines, and remaining capacities, and provide an explanation for every placement.

Part 2 - System and Memory Mental Model

VRAM residency avoids H2D and possibly storage work. RAM residency avoids NVMe but still requires H2D. NVMe residency maximizes memory capacity but incurs the longest path. Dirty or in-flight state has restricted legal tiers. Hysteresis prevents small score changes from causing repeated three-tier migration.

Part 3 - Quantitative Prediction Before Execution

Estimate the future stall avoided by each faster tier and divide it by bytes consumed there. Add pressure prices that rise near high watermarks. Include writeback for dirty state, not only reload. Solve hard feasibility first, then rank legal marginal benefits until capacities are filled.

Part 4 - Experimental Design and Instrumentation

Calibrate read, write, host-copy, and H2D costs from real benchmarks. Replay known traces and compare against all-NVMe, static placement, size-only, and LRU. Report capacity violations, I/O, migrations, stall, throughput, prediction error, and how often a decision changes before reuse.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PlacementInput:
    key: str
    size_bytes: int
    reuse_distance: int
    reuse_count: int
```

```
    nvme_read_ms: float
    h2d_ms: float
    writeback_ms: float
    dirty: bool
    protected: bool

def tier_costs(item, vram_pressure, ram_pressure):
    if item.protected:
        return {"vram": 0.0, "ram": float("inf"),
                "nvme": float("inf")}
    urgency = 1.0 / max(item.reuse_distance, 1)
    future_uses = max(item.reuse_count, 1)
    vram = vram_pressure * item.size_bytes
    ram = item.h2d_ms * urgency * future_uses
    ram += ram_pressure * item.size_bytes
    nvme = (item.nvme_read_ms + item.h2d_ms)
    nvme *= urgency * future_uses
    if item.dirty:
        nvme += item.writeback_ms
    return {"vram": vram, "ram": ram, "nvme": nvme}

def choose_lowest_cost(costs):
    best_tier = None
    best_cost = float("inf")
    for tier, cost in costs.items():
        if cost < best_cost:
            best_tier = tier
            best_cost = cost
    return best_tier, best_cost

def E17(item, vram_pressure, ram_pressure):
    costs = tier_costs(item, vram_pressure, ram_pressure)
    return choose_lowest_cost(costs)
```

Part 6 - Measurement, Validation, and Failure Analysis

Costs must share consistent units and be recalibrated when cache temperature or contention changes. The local minimum does not itself satisfy global capacity; a controller must admit a set of placements and reserve transient buffers. Predicted reuse cannot override protection, unique dirty authority, or imminent consumer dependencies.

Part 7 - Engineering Interpretation and Philosophy

Placement assigns scarce fast capacity to the tensors that avoid the most future cost. It is an explainable optimization beneath non-negotiable correctness and budget laws, not a learned excuse to violate them.

19.17.19 Exercise 18

Exercise Title: Stress-Test a Model Larger Than Both Available VRAM and the Assigned RAM Budget and Keep Execution Alive Through Dynamic NVMe Swapping

Part 1 - Exercise Contract and Why It Matters

Execute a model whose total state exceeds both managed VRAM and RAM limits by keeping only a scheduled working set above NVMe. Survive variable layers, limited buffers, slow reads, and injected failures without physical OOM, stale state, unbounded queues, or silent numerical change.

Part 2 - System and Memory Mental Model

At least the current compute set, next delivery buffers, activations, workspace, and runtime overhead must fit. If even this minimum cannot fit, no placement policy can make the schedule legal. Swapping pressure couples queues: slow NVMe grows RAM backlog, while aggressive H2D prefetch grows VRAM pressure and triggers counterproductive eviction.

Part 3 - Quantitative Prediction Before Execution

Simulate the full layer trace before allocation. At every boundary include committed and reserved bytes, temporary duplication, dirty writeback, and next operator workspace. Predict working-set misses, total traffic, lower-bound time, queue peaks, and whether the planned low watermarks leave sufficient emergency headroom.

Part 4 - Experimental Design and Instrumentation

Use artificial managed limits well below physical capacity. Increase model depth and shard variability, then inject latency, read failure, checksum mismatch, missing event wait, and host allocation rejection. Require controlled rollback or backpressure and compare every output with a smaller resident reference.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class TierSample:
    step: int
    vram_committed: int
    vram_reserved: int
    ram_committed: int
    ram_reserved: int
    nvme_queue_bytes: int
    version_errors: int
    checksum_errors: int

class ThreeTierStressGuard:
    def __init__(self, vram_limit, ram_limit, queue_limit):
        self.vram_limit = vram_limit
        self.ram_limit = ram_limit
        self.queue_limit = queue_limit

    def validate(self, sample):
        failures = []
        if sample.vram_committed + sample.vram_reserved > self.vram_limit:
```

```
            failures.append("managed VRAM limit exceeded")
        if sample.ram_committed + sample.ram_reserved > self.ram_limit:
            failures.append("managed RAM limit exceeded")
        if sample.nvme_queue_bytes > self.queue_limit:
            failures.append("NVMe queue budget exceeded")
        if sample.version_errors:
            failures.append("state version mismatch")
        if sample.checksum_errors:
            failures.append("storage integrity failure")
        return failures

def E18(vram_limit, ram_limit, queue_limit):
    return ThreeTierStressGuard(vram_limit, ram_limit, queue_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

Managed counters omit framework, filesystem, and driver overhead, so physical headroom remains necessary. Keeping execution alive does not prove semantic correctness; validate versions, hashes, outputs, gradients, optimizer state, and checkpoint recovery. Do not create a real OOM or fill the real NVMe device when an artificial budget tests the same policy boundary safely.

Part 7 - Engineering Interpretation and Philosophy

The stress test proves graceful operation at a designed boundary. The goal is not maximal motion, but a bounded working set, predictable backpressure, and recoverable state when no two fast tiers can hold the complete model.

19.17.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Three-Tier Offload Engine That Dynamically Moves Model State Across NVMe, RAM, and VRAM Without Exceeding Either Memory Budget

Part 1 - Exercise Contract and Why It Matters

Integrate canonical manifests, atomic NVMe generations, RAM hot caching, pinned buffer leases, asynchronous reads, CUDA events, three-tier placement, watermarks, prefetch, eviction, telemetry, rollback, and checkpoint recovery into one engine with hard VRAM and RAM limits.

Part 2 - System and Memory Mental Model

The control plane owns resource identity, authority, version, legal transitions, budget reservations, and future schedule. The data plane owns file ranges, CPU buffers, CUDA tensors, futures, streams, and events. A movement becomes visible only at commit. Failed I/O or transfer rolls back reservations while leaving the previous authoritative generation usable.

Part 3 - Quantitative Prediction Before Execution

Before execution, simulate each layer and optimizer boundary to predict VRAM, RAM, pinned, NVMe capacity, transfer traffic, queue depth, and stalls. During execution compare predictions with observations and adapt lookahead without changing correctness. Reject any schedule whose minimum working set plus workspace and transient copies cannot fit.

Part 4 - Experimental Design and Instrumentation

Validate transitions individually, then run inference, backward, accumulation, optimizer update, checkpoint, interruption, and resume. Benchmark full resident, static offload, and dynamic three-tier modes. Report output parity, peak budgets, read/write traffic, cache hits, wasted prefetch, overlap, median and p95 latency, throughput, retries, stalls, and recovery outcome.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class TierRecord:
    key: str
    size_bytes: int
    authority: str
    version: int
    nvme_path: str
    ram_tensor: object = None
    vram_tensor: object = None
    pending: str = "none"
    protected: set = field(default_factory=set)

class ThreeTierEngine:
    def __init__(self, vram_budget, ram_budget):
        self.vram_budget = vram_budget
        self.ram_budget = ram_budget
        self.vram_committed = 0
        self.vram_reserved = 0
        self.ram_committed = 0
        self.ram_reserved = 0
        self.records = {}

    def register(self, record):
        if record.key in self.records:
            raise KeyError("duplicate canonical state key")
        self.records[record.key] = record
        if record.ram_tensor is not None:
            self.ram_committed += record.size_bytes
        if record.vram_tensor is not None:
            self.vram_committed += record.size_bytes
        self.validate_budgets()

    def reserve_ram(self, size_bytes):
        projected = self.ram_committed + self.ram_reserved
        if projected + size_bytes > self.ram_budget:
            raise MemoryError("RAM admission rejected")
        self.ram_reserved += size_bytes
```

```
    def reserve_vram(self, size_bytes):
        projected = self.vram_committed + self.vram_reserved
        if projected + size_bytes > self.vram_budget:
            raise MemoryError("VRAM admission rejected")
        self.vram_reserved += size_bytes

    def begin_nvme_to_ram(self, key):
        record = self.records[key]
        if record.pending != "none":
            raise RuntimeError("resource movement already pending")
        self.reserve_ram(record.size_bytes)
        record.pending = "nvme_to_ram"

    def commit_ram(self, key, tensor, version):
        record = self.records[key]
        if record.pending != "nvme_to_ram":
            raise RuntimeError("unexpected RAM commit")
        if version != record.version:
            raise RuntimeError("stale NVMe generation")
        record.ram_tensor = tensor
        record.pending = "none"
        self.ram_reserved -= record.size_bytes
        self.ram_committed += record.size_bytes
        self.validate_budgets()

    def validate_budgets(self):
        if self.ram_committed + self.ram_reserved > self.ram_budget:
            raise MemoryError("RAM invariant violated")
        if self.vram_committed + self.vram_reserved > self.vram_budget:
            raise MemoryError("VRAM invariant violated")

def E19(vram_budget, ram_budget):
    return ThreeTierEngine(vram_budget, ram_budget)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact engine demonstrates control-plane invariants, not a complete generic trainer. Production work must add transaction IDs, asynchronous completion, H2D and writeback commits, pinned pools, alias preservation, autograd and optimizer integration, cancellation, rollback, durable manifests, and recovery. Budget reservations must be rolled back on every exceptional path.

Part 7 - Engineering Interpretation and Philosophy

A three-tier engine is a memory operating system specialized for a known model schedule. Its first obligation is coherent, recoverable state under hard limits; its second is to transform locality and future knowledge into useful overlap instead of uncontrolled I/O.

19.18 DMM16

Chapter Title: Out-of-Core Model Execution
Specialization: Dynamic Memory Management and CUDA Systems

19.18.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Out-of-Core Neural Network Execution When Model State Exceeds Available GPU Memory

Part 1 - Exercise Contract and Why It Matters

Define out-of-core execution as correct model computation while only a bounded working set resides in VRAM. Track parameters, buffers, activations, residuals, temporary workspaces, gradients, and optimizer state independently; exceeding VRAM with weights is only one of several possible failure modes.

Part 2 - System and Memory Mental Model

The model graph supplies an execution order and future-use schedule. Each block moves through cold, CPU-ready, transfer-pending, GPU-ready, executing, and evictable states. Parameter authority normally remains in RAM or NVMe for inference, while VRAM holds clean replicas. Activations follow graph edges and may outlive the layer that created them, especially across residual paths.

Part 3 - Quantitative Prediction Before Execution

At every boundary, predict peak VRAM as resident block weights plus inputs, outputs, long-lived activations, CUDA transfer destinations, operator workspace, and allocator overhead. RAM includes cold weights, staging, queued reads, and pinned buffers. A legal schedule must fit transient peaks, not only its final resident set.

Part 4 - Experimental Design and Instrumentation

Start with deterministic inference on a sequential model, then introduce skips, shared weights, variable shapes, and NVMe. Log block state, tensor versions, allocated and reserved VRAM, RAM, transfer bytes, execution deadlines, and eviction decisions. Compare every output against a fully resident reference.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class BlockState:
    key: str
    parameter_bytes: int
    authority: str
    residency: str
    version: int = 0
    pending: str = "none"
    next_use: int = -1
    protected: set = field(default_factory=set)
```

```
    def begin_h2d(self):
        if self.residency not in ("cpu", "cpu_and_nvme"):
            raise RuntimeError("block has no CPU source")
        if self.pending != "none":
            raise RuntimeError("movement already pending")
        self.pending = "h2d"

    def commit_gpu(self):
        if self.pending != "h2d":
            raise RuntimeError("unexpected GPU commit")
        self.residency = "cpu_and_gpu"
        self.pending = "none"

def E00(key, parameter_bytes):
    return BlockState(key, parameter_bytes, "cpu", "cpu")
```

Part 6 - Measurement, Validation, and Failure Analysis

Deleting a block does not release activations that still reference its outputs, and reduced allocated memory may leave reserved allocator segments unchanged. Module movement can invalidate optimizer or hook assumptions. A schedule that works for inference may fail in training because backward reverses dependencies and preserves forward state.

Part 7 - Engineering Interpretation and Philosophy

Out-of-core execution virtualizes model state over a known computation graph. Its foundation is not movement speed but a proof that the smallest legal working set, including graph state and temporary peaks, fits at every instant.

19.18.2 Exercise 01

Exercise Title: Measure the Complete Memory Footprint of a PyTorch Model and Prove That Its Parameters Cannot Fit Inside the Assigned VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Inventory unique parameters and buffers before CUDA placement, then measure runtime activations and workspaces. Prove mathematically that parameter payload alone exceeds an assigned budget and separately predict the minimum executable working set.

Part 2 - System and Memory Mental Model

Named parameter bytes are not the entire model footprint. Tied objects and shared storages must be counted once. Buffers may be persistent, while activations and operator workspaces depend on batch, shape, precision, and backend. CUDA context and non-PyTorch allocations are outside ordinary tensor inventory.

Part 3 - Quantitative Prediction Before Execution

For each unique storage, multiply storage elements by element size, then sum parameters and buffers. Compare parameter bytes with the artificial budget and compute an excess ratio. Estimate execution headroom separately for the largest block, inputs, outputs, residuals, workspaces, and transfer duplication.

Part 4 - Experimental Design and Instrumentation

Generate a per-name table with shape, dtype, logical bytes, storage identity, owners, and trainability. Validate totals against a state dictionary while avoiding double counting. Run one small reference forward to measure activation and peak overhead, then scale predictions by controlled dimensions.

Part 5 - PyTorch/CUDA Implementation

```
def unique_model_bytes(model):
    seen = set()
    parameter_bytes = 0
    buffer_bytes = 0
    rows = []
    for name, parameter in model.named_parameters():
        identity = id(parameter)
        logical = parameter.numel() * parameter.element_size()
        if identity not in seen:
            seen.add(identity)
            parameter_bytes += logical
        rows.append((name, "parameter", logical, identity))
    for name, buffer in model.named_buffers():
        identity = id(buffer)
        logical = buffer.numel() * buffer.element_size()
        if identity not in seen:
            seen.add(identity)
            buffer_bytes += logical
        rows.append((name, "buffer", logical, identity))
    return parameter_bytes, buffer_bytes, rows

def E01(model, assigned_vram_bytes):
    parameters, buffers, rows = unique_model_bytes(model)
    excess = parameters - assigned_vram_bytes
    cannot_fit = excess > 0
    return parameters, buffers, excess, cannot_fit, rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Object identity catches ordinary tying but not all distinct views over shared storage; production accounting should canonicalize untyped storage identity and range. Proving that all parameters do not fit does not prove that a blockwise schedule fits. Conversely, a model whose parameters fit may still OOM from activations or workspace.

Part 7 - Engineering Interpretation and Philosophy

The footprint proof converts an anecdotal OOM into a capacity argument. It also defines what virtualization must accomplish: fit a legal execution window, not pretend that total model size has vanished.

19.18.3 Exercise 02

Exercise Title: Artificially Restrict the Available GPU Memory Budget and Establish a Reproducible Out-of-Memory Baseline

Part 1 - Exercise Contract and Why It Matters

Create a safe, reproducible OOM baseline under a deliberately reduced allocator limit in a fresh process. Capture the exact failing boundary and memory evidence, then use the same model, batch, precision, and limit for later out-of-core tests.

Part 2 - System and Memory Mental Model

PyTorch's per-process fraction limits caching-allocator allocations relative to visible device memory. It does not partition all physical VRAM or include every external CUDA allocation. The limit should be set before significant CUDA allocation. A separate software budget remains necessary for scheduling and headroom.

Part 3 - Quantitative Prediction Before Execution

Choose a fraction whose allowed bytes are below full-model requirements but above CUDA initialization and a minimal test allocation. Predict the first failing operation from cumulative live bytes plus temporary peak. Record both the configured allocator limit and the stricter runtime working-set budget.

Part 4 - Experimental Design and Instrumentation

Launch one subprocess per trial, set the fraction, reset peak statistics, and run the resident baseline. Immediately before each boundary log allocated, reserved, peak, free, and total memory. Catch only the expected CUDA OOM, save the diagnostic, release references, and do not continue with corrupted state.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def configure_fraction(fraction, device_index=0):
    if fraction <= 0.0 or fraction > 1.0:
        raise ValueError("fraction must be in (0, 1]")
    torch.cuda.set_device(device_index)
    torch.cuda.memory.set_per_process_memory_fraction(
        fraction, device=device_index)
    total = torch.cuda.get_device_properties(
        device_index).total_memory
    return int(total * fraction)

def memory_sample():
    free_bytes, total_bytes = torch.cuda.mem_get_info()
    return {
        "allocated": torch.cuda.memory_allocated(),
        "reserved": torch.cuda.memory_reserved(),
        "peak": torch.cuda.max_memory_allocated(),
        "free": free_bytes,
```

```
        "total": total_bytes,
    }

def E02(fraction, device_index=0):
    allowed = configure_fraction(fraction, device_index)
    torch.cuda.reset_peak_memory_stats(device_index)
    return allowed, memory_sample()
```

Part 6 - Measurement, Validation, and Failure Analysis

Run this configuration only in a fresh process; earlier allocations can make the experiment irreproducible. The allocator limit is not a guarantee of exactly that many usable tensor bytes. Fragmentation, reserved blocks, context memory, other processes, and non-PyTorch CUDA allocations affect the failure point.

Part 7 - Engineering Interpretation and Philosophy

An artificial budget turns scarce hardware into a controlled experimental variable. The OOM baseline is valuable because every later success must beat the same constraint without changing the numerical task.

19.18.4 Exercise 03

Exercise Title: Partition a Deep PyTorch Model into Execution Blocks According to Parameter Size and Layer Order

Part 1 - Exercise Contract and Why It Matters

Partition an ordered model into blocks whose parameter payload and predicted execution peak fit a target working-set budget. Preserve graph order, atomic modules, residual boundaries, shared weights, and stateful layer semantics.

Part 2 - System and Memory Mental Model

A block is a transfer and scheduling unit, not merely a list slice. Larger blocks amortize movement and improve locality but occupy more VRAM. Splitting inside a fused or stateful unit may change behavior. Shared parameters belong to one canonical resource even when several blocks consume them.

Part 3 - Quantitative Prediction Before Execution

For each candidate block, sum unique parameter and buffer bytes, then add input, output, persistent activation, workspace, and H2D duplication. Greedily closing a block at the parameter limit is insufficient if its largest operator exceeds remaining headroom. Track both payload and predicted execution peak.

Part 4 - Experimental Design and Instrumentation

Extract a layer sequence, measure per-layer state, annotate graph constraints, and partition under several budgets. Validate that each layer appears once, order is preserved, shared resources are canonical, and every predicted peak is legal. Compare block counts, overfetch, and transfer frequency.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class LayerCost:
    name: str
    module: object
    parameter_bytes: int
    extra_peak_bytes: int

def partition_layers(layers, block_budget):
    blocks = []
    current = []
    current_parameters = 0
    current_extra = 0
    for layer in layers:
        next_parameters = current_parameters + layer.parameter_bytes
        next_extra = max(current_extra, layer.extra_peak_bytes)
        predicted = next_parameters + next_extra
        if current and predicted > block_budget:
            blocks.append(current)
            current = []
            current_parameters = 0
            current_extra = 0
        if layer.parameter_bytes + layer.extra_peak_bytes > block_budget:
            raise MemoryError("one layer exceeds block budget")
        current.append(layer)
        current_parameters += layer.parameter_bytes
        current_extra = max(current_extra, layer.extra_peak_bytes)
    if current:
        blocks.append(current)
    return blocks

def E03(layers, block_budget):
    return partition_layers(layers, block_budget)
```

Part 6 - Measurement, Validation, and Failure Analysis

The greedy function assumes a simple sequence and precomputed unique bytes. Branching graphs require a dependency-aware partitioner. Parameter bytes shared with an earlier block must not be charged as a new canonical allocation if kept resident, but must be charged if another replica is actually created.

Part 7 - Engineering Interpretation and Philosophy

Partitioning translates a neural graph into memory-sized transactions. The best partition respects semantics first and then balances transfer amortization against the smallest safe working set.

19.18.5 Exercise 04

Exercise Title: Execute a Model Block-by-Block by Loading Each Block from CPU to CUDA Immediately Before Use

Part 1 - Exercise Contract and Why It Matters

Implement a correctness-first inference runtime that promotes one CPU-resident block to CUDA immediately before use, executes it, returns its output, and makes the block eligible for eviction. Match a fully resident reference exactly within declared floating-point tolerance.

Part 2 - System and Memory Mental Model

Moving an `nn.Module` changes its parameters and buffers; its input must share the device. CUDA operations are asynchronous, so CPU movement after a forward call must not race with kernels still reading the block. The current output may remain on CUDA to feed the next block even after weights are evicted.

Part 3 - Quantitative Prediction Before Execution

Peak VRAM for a one-block runtime includes current weights, input, output, temporary workspace, and transient allocator state. If eviction copies clean weights back unnecessarily, traffic doubles; retain authoritative CPU weights and discard clean CUDA replicas instead. Predict total H2D bytes as the sum of block loads.

Part 4 - Experimental Design and Instrumentation

Use evaluation mode and inference mode, identical inputs, and a deterministic sequential network. Record promotion, forward, completion, eviction, allocated and peak VRAM, output shape, and checksum per block. Compare final and selected intermediate outputs with the resident reference.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class BlockwiseExecutor:
    def __init__(self, blocks, device="cuda:0"):
        self.blocks = blocks
        self.device = torch.device(device)

    @torch.inference_mode()
    def run(self, input_tensor):
        value = input_tensor.to(self.device)
        memory_trace = []
        for block in self.blocks:
            block.to(self.device)
            value = block(value)
            torch.cuda.current_stream().synchronize()
            block.to("cpu")
            memory_trace.append(torch.cuda.memory_allocated())
        return value, memory_trace
```

```
def E04(blocks, input_tensor):
    executor = BlockwiseExecutor(blocks)
    return executor.run(input_tensor)
```

Part 6 - Measurement, Validation, and Failure Analysis

The device synchronization is intentionally conservative and expensive; later exercises replace it with events. Repeated `module.to()` may allocate and copy more than a production parameter store. BatchNorm and dropout require eval mode. Hidden shared parameters can be moved by one block while another still expects them.

Part 7 - Engineering Interpretation and Philosophy

The serial executor is the reference implementation for out-of-core semantics. It sacrifices overlap to expose ownership, ordering, and numerical equivalence before optimization makes failures harder to localize.

19.18.6 Exercise 05

Exercise Title: Evict Completed Model Blocks from VRAM and Verify That Peak Memory Remains Below a Fixed Budget Throughout Inference

Part 1 - Exercise Contract and Why It Matters

Evict each clean block after its final CUDA use and prove, at every inference boundary, that committed plus reserved working-set bytes remain below a fixed budget. Separate logical residency from allocator reserved memory.

Part 2 - System and Memory Mental Model

The earliest safe eviction point follows the final consumer event, not Python return. Clean CUDA weights can be discarded because CPU authority remains. Outputs and residual activations are separate resources and may survive the block. Removing module references reduces allocated bytes; cached reserved segments may remain reusable inside PyTorch.

Part 3 - Quantitative Prediction Before Execution

Before promotion reserve block payload and transient headroom. After final-use completion, subtract only actual evicted storage. Compare peak allocated memory with the fixed budget and use reserved memory as allocator evidence, not live tensor truth. Leave margin for untracked CUDA and operator allocations.

Part 4 - Experimental Design and Instrumentation

Reset peak statistics, run several blocks, and sample before promotion, after promotion, after forward, after completion, and after eviction. Assert the software budget before every transition. Verify output parity and that no GPU parameter remains associated with evicted blocks.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class VramBudgetGuard:
    def __init__(self, limit_bytes, safety_bytes):
        self.limit_bytes = limit_bytes
        self.safety_bytes = safety_bytes
        self.logical_resident = 0

    def admit(self, block_bytes, transient_bytes):
        projected = self.logical_resident
        projected += block_bytes + transient_bytes
        if projected + self.safety_bytes > self.limit_bytes:
            raise MemoryError("out-of-core VRAM admission rejected")
        self.logical_resident += block_bytes

    def evicted(self, block_bytes):
        self.logical_resident -= block_bytes
        if self.logical_resident < 0:
            raise RuntimeError("negative residency accounting")

    def sample(self):
        return {
            "logical": self.logical_resident,
            "allocated": torch.cuda.memory_allocated(),
            "reserved": torch.cuda.memory_reserved(),
            "peak": torch.cuda.max_memory_allocated(),
        }

def E05(limit_bytes, safety_bytes):
    torch.cuda.reset_peak_memory_stats()
    return VramBudgetGuard(limit_bytes, safety_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Logical accounting must canonicalize shared storages and include transfer destinations before they become active. Calling `empty_cache()` every block is not eviction proof and can damage performance. If a CUDA event is not complete, moving or deleting the block can race with an in-flight kernel.

Part 7 - Engineering Interpretation and Philosophy

Eviction is successful when it shortens a resource's VRAM lifetime without shortening its semantic lifetime. Budget proof comes from complete lifecycle accounting, not from observing a low number after the iteration ends.

19.18.7 Exercise 06

Exercise Title: Build a Residency Map That Tracks Every Model Block Across NVMe, CPU RAM, and GPU VRAM During Execution

Part 1 - Exercise Contract and Why It Matters

Build one canonical residency map for all blocks, replicas, versions, pending transfers, consumer events, and protection reasons. Every prefetch, execution, eviction, and failure must be representable as a validated state transition.

Part 2 - System and Memory Mental Model

Residency is not a single device label: a block may have NVMe authority, a clean RAM cache, and an H2D-pending CUDA destination simultaneously. Authority tells which version survives replica loss. Protection can arise from execution, residual dependencies, shared consumers, transfers, backward, or checkpointing.

Part 3 - Quantitative Prediction Before Execution

Sum unique committed and reserved bytes by tier from the map. During movement, charge both endpoints until commit and release. Compare predicted totals with PyTorch and process counters. The map must also predict next-use distance so eviction can distinguish cold replicas from near-future blocks.

Part 4 - Experimental Design and Instrumentation

Replay a known schedule and save a row after every transition. Assert legal authority, monotonic versions, nonnegative budgets, completed dependencies, and one canonical block identity. Inject duplicate registration, stale completion, and eviction while protected; each must fail before memory changes.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class ResidencyRecord:
    key: str
    size_bytes: int
    authority: str
    version: int
    nvme_present: bool
    ram_present: bool
    vram_present: bool
    pending: str = "none"
    protected: set = field(default_factory=set)

class ResidencyMap:
    def __init__(self):
        self.records = {}

    def register(self, record):
        if record.key in self.records:
            raise KeyError("duplicate block identity")
        self.records[record.key] = record
```

```
    def tier_bytes(self):
        totals = {"nvme": 0, "ram": 0, "vram": 0}
        for record in self.records.values():
            if record.nvme_present:
                totals["nvme"] += record.size_bytes
            if record.ram_present:
                totals["ram"] += record.size_bytes
            if record.vram_present:
                totals["vram"] += record.size_bytes
        return totals

    def protect(self, key, reason):
        self.records[key].protected.add(reason)

    def unprotect(self, key, reason):
        self.records[key].protected.remove(reason)

def E06():
    return ResidencyMap()
```

Part 6 - Measurement, Validation, and Failure Analysis

The map counts logical payload and needs separate reserved-byte transactions for pending buffers and allocator overhead. Boolean presence is insufficient for multiple replicas on one tier; production records need storage IDs. Removing a protection reason that was never held must remain an error.

Part 7 - Engineering Interpretation and Philosophy

The residency map is the runtime's source of truth. Performance policies may change, but every optimization must first express a legal transition in this map or it has no defensible ownership model.

19.18.8 Exercise 07

Exercise Title: Compare One-Layer-at-a-Time Execution Against Multi-Layer Working Sets and Measure the Memory-Latency Trade-Off

Part 1 - Exercise Contract and Why It Matters

Compare a minimum one-layer working set with several multi-layer resident windows under the same model, input, precision, and VRAM budget. Quantify how additional residency reduces transfers and synchronization while increasing peak memory.

Part 2 - System and Memory Mental Model

One-layer execution minimizes weight residency but maximizes movement frequency and exposes every load. A wider window retains consecutive blocks, enables prefetch slack, and amortizes eviction. Its benefit ends when retained blocks crowd out activations, transfer destinations, or more valuable shared weights.

Part 3 - Quantitative Prediction Before Execution

For window size w, predict resident weight bytes from the largest consecutive window, not average layer size. Count block loads and reloads, H2D traffic, evictions, and synchronization. Report milliseconds saved per additional MiB of peak VRAM and detect the first infeasible window.

Part 4 - Experimental Design and Instrumentation

Sweep window sizes in clean processes, warm up, and run identical inputs. Record peak allocated and reserved VRAM, RAM, transfer bytes, promotion count, median and p95 latency, throughput, and numerical difference. Include variable layer sizes so equal layer count is not confused with equal bytes.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class WindowResult:
    resident_layers: int
    peak_vram: int
    transfer_bytes: int
    promotions: int
    latency_ms: float
    throughput: float

def compare_windows(results):
    if not results:
        return []
    baseline = results[0]
    rows = []
    for result in results:
        extra_memory = result.peak_vram - baseline.peak_vram
        latency_saved = baseline.latency_ms - result.latency_ms
        if extra_memory > 0:
            value = latency_saved / extra_memory
        else:
            value = 0.0
        rows.append({
            "layers": result.resident_layers,
            "peak_vram": result.peak_vram,
            "transfer_bytes": result.transfer_bytes,
            "latency_ms": result.latency_ms,
            "ms_saved_per_byte": value,
        })
    return rows

def E07(results):
    return compare_windows(results)
```

Part 6 - Measurement, Validation, and Failure Analysis

Layer count is a poor proxy for bytes and workspace. A larger window can appear faster because it accidentally changes synchronization or cache temperature. Ensure identical output and completion boundaries. Peak memory must include incoming blocks, not only the stable window after eviction.

Part 7 - Engineering Interpretation and Philosophy

Working-set width is a capacity investment. The useful setting is the smallest byte window that captures most locality and overlap while leaving safe headroom for graph state and temporary execution peaks.

19.18.9 Exercise 08

Exercise Title: Prefetch the Next Model Block from CPU While the Current Block Executes on GPU

Part 1 - Exercise Contract and Why It Matters

Transfer block $N+1$ on a dedicated CUDA stream while block N computes, then make the compute stream wait only for the incoming block's completion event. Protect source storage, destination VRAM, and current execution simultaneously.

Part 2 - System and Memory Mental Model

True overlap requires pinned CPU sources, non-blocking H2D, separate streams, independent copy hardware, and enough compute. The prefetch destination occupies VRAM before becoming usable. The current block cannot be evicted until its final compute event, and the pinned source cannot be reused until H2D completes.

Part 3 - Quantitative Prediction Before Execution

If current compute time is T_c and next transfer time is T_t, visible stall is ideally $\max(0, T_t - T_c)$. Peak VRAM includes current and incoming weights, current activations, outputs, and workspaces. Reject prefetch if this transient window exceeds the budget even when each block fits alone.

Part 4 - Experimental Design and Instrumentation

Measure transfer-only, compute-only, serial, and overlapped timelines. Use CUDA events and a profiler trace to prove concurrency. Sweep block size and compute intensity. Verify that the compute stream waits on the exact next-block event and that outputs match the serial executor.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class BlockPrefetch:
    def __init__(self):
        self.stream = torch.cuda.Stream()
        self.events = {}

    def submit(self, key, copy_function):
        if key in self.events:
```

```
            raise RuntimeError("duplicate prefetch")
        done = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            cuda_block = copy_function()
            done.record(self.stream)
        self.events[key] = (done, cuda_block)

    def acquire(self, key):
        done, cuda_block = self.events.pop(key)
        torch.cuda.current_stream().wait_event(done)
        return cuda_block

def E08():
    return BlockPrefetch()
```

Part 6 - Measurement, Validation, and Failure Analysis

The callback must perform genuinely non-blocking copies from correctly pinned sources and retain their leases. A CUDA event establishes GPU ordering but does not manage Python ownership automatically. Default-stream dependencies, pageable sources, insufficient hardware engines, or memory contention can remove overlap.

Part 7 - Engineering Interpretation and Philosophy

Prefetch turns known future demand into concurrent movement. It succeeds only when the prediction is right, the incoming bytes fit, and the current compute is long enough to hide measured transfer time.

19.18.10 Exercise 09

Exercise Title: Implement Double-Buffered Out-of-Core Execution with Separate CUDA Buffers for Current and Incoming Model Blocks

Part 1 - Exercise Contract and Why It Matters

Alternate two CUDA block slots: one owns the currently executing block and the other receives the next block. Enforce generation, capacity, transfer event, compute event, and lease rules so a slot is never overwritten while in use.

Part 2 - System and Memory Mental Model

Slots are memory reservations, not necessarily reusable tensor shapes. A slot cycles through free, H2D-pending, GPU-ready, executing, compute-complete, and free. Variable block sizes require capacity checks or size classes. Shared resources may live outside both slots when their reuse spans multiple blocks.

Part 3 - Quantitative Prediction Before Execution

Budget both slot capacities rather than only their current payloads. Add activations and operator workspace separately. After startup, double buffering can approach the slower of transfer and compute time. Fill and drain remain visible, and unbalanced blocks still create bubbles.

Part 4 - Experimental Design and Instrumentation

Run a repeating block sequence, record every slot transition and event, and assert one owner per slot. Compare serial and double-buffered execution by peak VRAM, transfer overlap, stalls, and output parity. Inject early overwrite and an oversized block; both must fail before corrupting storage.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class CudaBlockSlot:
    index: int
    capacity_bytes: int
    state: str = "free"
    key: str = ""
    version: int = -1
    transfer_event: object = None
    compute_event: object = None
    payload: object = None

class DoubleBufferedBlocks:
    def __init__(self, capacity_bytes):
        self.slots = []
        for index in range(2):
            self.slots.append(CudaBlockSlot(index, capacity_bytes))

    def reserve(self, index, key, version, size_bytes):
        slot = self.slots[index]
        if slot.state != "free":
            raise RuntimeError("CUDA block slot is busy")
        if size_bytes > slot.capacity_bytes:
            raise MemoryError("block exceeds slot capacity")
        slot.key = key
        slot.version = version
        slot.state = "reserved"
        return slot

    def release(self, index):
        slot = self.slots[index]
        if slot.state != "compute_complete":
            raise RuntimeError("slot released before compute completion")
        slot.state = "free"
        slot.key = ""
        slot.payload = None

def E09(capacity_bytes):
    return DoubleBufferedBlocks(capacity_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The controller models slots but must connect transitions to real CUDA events. Preallocating one flat buffer does not automatically let arbitrary modules use that storage; a parameter materialization layer is required. Counting slot capacity twice is conservative and necessary when both can be full concurrently.

Part 7 - Engineering Interpretation and Philosophy

Double buffering converts an execution sequence into a two-slot ownership protocol. Its performance comes from overlap, but its reliability comes from refusing every premature reuse even under memory pressure.

19.18.11 Exercise 10

Exercise Title: Extend the Runtime to Load Cold Model Blocks from NVMe Through CPU RAM Before Promoting Them to VRAM

Part 1 - Exercise Contract and Why It Matters

Add NVMe as the authoritative cold tier. Resolve a block through manifest, reserve RAM, read and verify its generation, optionally cache it, reserve VRAM, stage through pinned memory, and publish the CUDA replica only after H2D completion.

Part 2 - System and Memory Mental Model

NVMe cannot be treated as a CUDA device. The normal path is file storage to pageable or mapped CPU memory, then pinned staging, then VRAM. Each stage has a different completion mechanism and lifetime. A RAM cache hit skips storage but does not skip H2D; a VRAM hit skips both.

Part 3 - Quantitative Prediction Before Execution

Cold delivery time includes read latency, checksum or decoding, host copy, and H2D. Budget NVMe file capacity, RAM read and cache buffers, pinned staging, CUDA destination, and current execution state. Estimate overfetch when a block file contains parameters not needed by the current graph path.

Part 4 - Experimental Design and Instrumentation

Run cold-cache and warm-cache trials in isolated processes. Log manifest lookup, I/O start and completion, bytes, checksum, RAM admission, pin copy, H2D event, GPU publication, and later eviction. Corrupt a generation and verify that the old valid authority remains usable.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

class ColdBlockLoader:
    def __init__(self, manifest):
        self.manifest = manifest
        self.ram_cache = {}
```

```
    def load_ram(self, key):
        if key in self.ram_cache:
            return self.ram_cache[key]
        record = self.manifest[key]
        path = Path(record["path"])
        state = torch.load(
            path, map_location="cpu", weights_only=True)
        if int(record["version"]) < 0:
            raise ValueError("invalid block generation")
        self.ram_cache[key] = state
        return state

    def release_ram(self, key):
        if key in self.ram_cache:
            del self.ram_cache[key]

def E10(manifest):
    return ColdBlockLoader(manifest)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact loader omits byte budgets, checksums, pinned staging, and CUDA publication, which the runtime must add as separate transactions. Deserializing many tiny files can dominate useful I/O. A successful `torch.load` does not prove that the block matches the expected graph or canonical shared state.

Part 7 - Engineering Interpretation and Philosophy

NVMe extends model capacity only by adding another scheduled dependency. Its benefit depends on predictable access and verified generations, while RAM and VRAM remain bounded caches rather than accidental full-model copies.

19.18.12 Exercise 11

Exercise Title: Build a Three-Stage Pipeline That Overlaps NVMe Read, CPU-to-GPU Transfer, and GPU Compute During Model Execution

Part 1 - Exercise Contract and Why It Matters

Pipeline block $N + 2$ storage read, block $N + 1$ H2D, and block N compute with explicit futures, pinned leases, CUDA events, budget reservations, and backpressure. Prove actual timeline overlap and exact output parity.

Part 2 - System and Memory Mental Model

The storage worker produces a verified CPU block. The transfer stream consumes that block and produces a GPU-ready event. The compute stream consumes the event and produces a final-use event. Reclamation travels backward: weights wait for compute, pinned slots wait for H2D, and read buffers wait for pin-copy.

Part 3 - Quantitative Prediction Before Execution

If stage times are T_s, T_t, and T_c, ideal steady-state period is their maximum after fill. Total latency includes pipeline fill and drain. Compute the maximum in-flight RAM and VRAM bytes for the selected lookahead and include variable block sizes rather than multiplying an average.

Part 4 - Experimental Design and Instrumentation

Measure stages independently and together. Export storage timestamps and CUDA trace events, and calculate stage utilization, visible stall, overlap efficiency, queue depth, and memory peaks. Sweep read workers and lookahead. Inject slow I/O and verify bounded backpressure instead of growing queues.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class OutOfCoreItem:
    key: str
    stage: str = "planned"
    read_future: object = None
    pinned_lease: object = None
    h2d_event: object = None
    compute_event: object = None

class PipelineOrder:
    def __init__(self):
        self.next_stage = {
            "planned": "reading",
            "reading": "cpu_ready",
            "cpu_ready": "transferring",
            "transferring": "gpu_ready",
            "gpu_ready": "computing",
            "computing": "finished",
        }

    def advance(self, item, requested):
        expected = self.next_stage.get(item.stage)
        if expected != requested:
            raise RuntimeError("illegal out-of-core stage transition")
        item.stage = requested

    def require_finished(self, item):
        if item.stage != "finished":
            raise RuntimeError("block execution is incomplete")

def E11():
    return PipelineOrder()
```

Part 6 - Measurement, Validation, and Failure Analysis

State labels do not prove completion; only the associated future or CUDA event can authorize advancement. NVMe and GPU traffic may share PCIe links and reduce overlap. Excessive lookahead may improve stage utilization while increasing overfetch, RAM, and VRAM beyond the legal budget.

Part 7 - Engineering Interpretation and Philosophy

The pipeline is a dependency graph with resources attached. Speed comes from keeping independent stages busy, while correctness comes from never advancing a resource because time probably passed.

19.18.13 Exercise 12

Exercise Title: Preserve Residual Connections and Long-Lived Activations While Model Layers Are Continuously Loaded and Evicted

Part 1 - Exercise Contract and Why It Matters

Track graph-edge activations independently from block weights so residual inputs survive until their final merge consumer. Evicting a producing block must never discard its still-live activation or reuse its storage prematurely.

Part 2 - System and Memory Mental Model

Weight residency follows layer execution; activation residency follows graph liveness. A residual tensor may bypass many blocks, increasing the minimum VRAM working set. It may remain on GPU, offload to RAM, or be recomputed, each with different cost and autograd implications. In-place operations can destroy a value required by a later branch.

Part 3 - Quantitative Prediction Before Execution

Perform liveness analysis: allocate an activation at its producer and release it after its final consumer. Add the maximum sum of simultaneously live activation bytes to block weights and workspace. Compare keeping a residual in VRAM with D2H plus H2D or recomputation cost before choosing a policy.

Part 4 - Experimental Design and Instrumentation

Use a small residual network with hooks that record tensor ID, shape, bytes, producer, consumer count, and final use. Compare resident and out-of-core intermediate values. Inject early release and an in-place mutation; require liveness or checksum validation to identify the exact edge.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ActivationLease:
    key: str
    tensor: object
    remaining_consumers: int
    size_bytes: int
    protected: bool = True
```

```
class ActivationTracker:
    def __init__(self):
        self.leases = {}

    def produce(self, key, tensor, consumers):
        if key in self.leases:
            raise KeyError("duplicate activation key")
        size = tensor.numel() * tensor.element_size()
        self.leases[key] = ActivationLease(
            key, tensor, consumers, size)

    def consume(self, key):
        lease = self.leases[key]
        if lease.remaining_consumers <= 0:
            raise RuntimeError("activation consumed too many times")
        lease.remaining_consumers -= 1
        tensor = lease.tensor
        if lease.remaining_consumers == 0:
            lease.protected = False
        return tensor

    def release(self, key):
        lease = self.leases[key]
        if lease.protected:
            raise RuntimeError("activation still has future consumers")
        del self.leases[key]

def E12():
    return ActivationTracker()
```

Part 6 - Measurement, Validation, and Failure Analysis

Consumer counts must come from the real graph and control-flow path. Tensor views can share storage, so releasing one logical edge may not release bytes. Training preserves additional tensors for backward; inference-mode liveness cannot be reused unchanged. In-place mutation requires alias-aware analysis.

Part 7 - Engineering Interpretation and Philosophy

Out-of-core execution virtualizes weights, not mathematical dependencies. Graph liveness defines a hard floor beneath memory use, and any runtime that ignores that floor exchanges OOM for silent wrong answers.

19.18.14 Exercise 13

Exercise Title: Support Shared and Tied Parameters Without Loading Duplicate Copies into the Out-of-Core Working Set

Part 1 - Exercise Contract and Why It Matters

Canonicalize shared and tied parameters across blocks, load one GPU replica per canonical version, count all owners, and retain it until the final scheduled consumer. Preserve alias identity and prevent independent updates or duplicate VRAM charges.

Part 2 - System and Memory Mental Model

Several module names can reference the same `Parameter`, and distinct views can share underlying storage. The resource belongs to a canonical store; blocks hold leases. Eviction becomes legal when no active or near-future lease requires the replica. During training, all aliases must accumulate into the same logical gradient and optimizer state.

Part 3 - Quantitative Prediction Before Execution

Compare logical named bytes with unique canonical storage bytes. Predict saved VRAM from avoided duplicate replicas and additional lifetime from the span between first and final consumer. A shared embedding used at both ends may be cheaper to retain than evict and reload despite its large size.

Part 4 - Experimental Design and Instrumentation

Create tied input-output embeddings and a module reused twice. Build owner lists, canonical IDs, and consumer schedules. Verify one CUDA storage, identical data pointers where required, correct outputs, and one update path. Inject duplicate materialization and detect it from storage identity and budget accounting.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class SharedResource:
    canonical_id: int
    owners: list = field(default_factory=list)
    remaining_uses: int = 0
    cuda_tensor: object = None

class SharedParameterRegistry:
    def __init__(self):
        self.resources = {}
        self.owner_to_id = {}

    def register(self, owner, parameter, scheduled_uses):
        canonical_id = id(parameter)
        self.owner_to_id[owner] = canonical_id
        if canonical_id not in self.resources:
            self.resources[canonical_id] = SharedResource(canonical_id)
        resource = self.resources[canonical_id]
        resource.owners.append(owner)
        resource.remaining_uses += scheduled_uses

    def consume(self, owner):
        canonical_id = self.owner_to_id[owner]
```

```
        resource = self.resources[canonical_id]
        if resource.remaining_uses <= 0:
            raise RuntimeError("shared parameter use underflow")
        resource.remaining_uses -= 1
        return resource.cuda_tensor

def E13():
    return SharedParameterRegistry()
```

Part 6 - Measurement, Validation, and Failure Analysis

Object identity does not canonicalize distinct tensor views over the same storage. A robust registry includes storage pointer, byte range, offset, shape, and stride. Consumer counts must reflect the executed branch. Restoring aliases as equal-valued copies is numerically similar at first but semantically wrong for later mutation and optimization.

Part 7 - Engineering Interpretation and Philosophy

Sharing is part of model architecture, not a serialization accident. A correct out-of-core engine virtualizes one resource with many consumers rather than turning intentional identity into costly and divergent copies.

19.18.15 Exercise 14

Exercise Title: Detect and Eliminate Execution Bubbles Caused by Late Parameter Loads and Insufficient Prefetch Distance

Part 1 - Exercise Contract and Why It Matters

Measure GPU idle intervals caused specifically by missing block readiness, trace them to storage or H2D deadlines, and increase prefetch distance only within RAM, VRAM, and overfetch budgets. Prove recovered throughput on the same workload.

Part 2 - System and Memory Mental Model

An execution bubble begins when the compute stream is ready for a block whose GPU-ready event is incomplete. Its root can be late submission, slow storage, queueing, pageable staging, H2D contention, or a prediction miss. Larger lookahead creates more slack but reserves more memory and may fetch unused work.

Part 3 - Quantitative Prediction Before Execution

For each block, compare delivery deadline with measured read plus H2D latency. Minimum lookahead covers this time using expected compute of intervening blocks. Track p95 rather than average latency for reliability. Cap lookahead by the largest legal sum of prefetched RAM and VRAM bytes.

Part 4 - Experimental Design and Instrumentation

Record planned-use time, submission, storage completion, H2D completion, compute request, and compute start. Classify each wait by late stage. Sweep prefetch distance and report bubble time, utilization, memory peaks, overfetch, and throughput. Confirm that removing bubbles does not create thrashing.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class DeadlineRecord:
    key: str
    compute_requested_ms: float
    gpu_ready_ms: float
    read_done_ms: float
    h2d_done_ms: float

def classify_bubble(record):
    wait = max(0.0, record.gpu_ready_ms
               - record.compute_requested_ms)
    if wait == 0.0:
        reason = "none"
    elif record.read_done_ms >= record.compute_requested_ms:
        reason = "storage_late"
    elif record.h2d_done_ms >= record.compute_requested_ms:
        reason = "h2d_late"
    else:
        reason = "scheduler_late"
    return wait, reason

def total_bubbles(records):
    total = 0.0
    counts = {}
    for record in records:
        wait, reason = classify_bubble(record)
        total += wait
        counts[reason] = counts.get(reason, 0) + 1
    return total, counts

def E14(records):
    return total_bubbles(records)
```

Part 6 - Measurement, Validation, and Failure Analysis

An empty CUDA timeline can have causes unrelated to parameters; correlate exact events. CPU timestamps and CUDA event times use different clocks unless aligned. Increasing lookahead can hide one bubble while increasing queue delay, memory, or useless I/O. Optimize total throughput under budgets, not bubble count alone.

Part 7 - Engineering Interpretation and Philosophy

A bubble is a missed deadline made visible on the GPU. Prefetch distance should be the smallest evidence-based amount of future state that meets deadlines reliably, not an unbounded attempt to load the model early.

19.18.16 Exercise 15

Exercise Title: Detect Out-of-Core Thrashing When the Active Working Set Exceeds the Effective VRAM and RAM Cache Capacity

Part 1 - Exercise Contract and Why It Matters

Detect repeated block promotion and eviction that performs more movement than useful computation. Distinguish true working-set overflow from one-time cold startup and identify whether VRAM, RAM cache, or both are too small for the reuse window.

Part 2 - System and Memory Mental Model

Thrashing appears when blocks needed again soon are evicted to admit speculative or lower-value blocks. VRAM thrashing repeats H2D; RAM thrashing repeats NVMe reads; coupled thrashing repeats the entire path. Variable shapes and residuals can reduce effective capacity below configured payload budgets.

Part 3 - Quantitative Prediction Before Execution

Track unique useful bytes, total H2D bytes, total NVMe bytes, migrations per block, residency duration, reuse distance, and GPU idle. Define amplification ratios for each tier. A sustained ratio well above one plus high stall indicates thrashing; a first compulsory load does not.

Part 4 - Experimental Design and Instrumentation

Replay cyclic traces with working sets below, near, and above each cache budget. Use rolling windows and log every promotion, use, eviction, and reread. Verify that increasing protected capacity, reducing lookahead, or changing victims removes the alarm and improves throughput without violating memory limits.

Part 5 - PyTorch/CUDA Implementation

```
from collections import defaultdict

class OutOfCoreThrashing:
    def __init__(self, h2d_limit, nvme_limit, idle_limit):
        self.h2d_limit = h2d_limit
        self.nvme_limit = nvme_limit
        self.idle_limit = idle_limit
        self.h2d_bytes = 0
        self.nvme_bytes = 0
        self.useful_bytes = 0
        self.loads = defaultdict(int)
        self.first_uses = set()

    def record_load(self, key, tier, size_bytes):
        self.loads[(key, tier)] += 1
        if tier == "h2d":
            self.h2d_bytes += size_bytes
        elif tier == "nvme":
            self.nvme_bytes += size_bytes
```

```
    def record_use(self, key, version, size_bytes):
        identity = (key, version)
        if identity not in self.first_uses:
            self.first_uses.add(identity)
            self.useful_bytes += size_bytes

    def diagnose(self, gpu_idle_fraction):
        useful = max(self.useful_bytes, 1)
        h2d_amp = self.h2d_bytes / useful
        nvme_amp = self.nvme_bytes / useful
        active = h2d_amp > self.h2d_limit
        active = active or nvme_amp > self.nvme_limit
        active = active and gpu_idle_fraction > self.idle_limit
        return h2d_amp, nvme_amp, active

def E15():
    return OutOfCoreThrashing(2.0, 1.5, 0.20)
```

Part 6 - Measurement, Validation, and Failure Analysis

Useful unique bytes ignore legitimate repeated uses over long intervals; combine amplification with reuse distance and a rolling window. Logical NVMe reads may be page-cache hits, so device traffic needs operating-system evidence. GPU idle can also come from activations, CPU work, or synchronization unrelated to weights.

Part 7 - Engineering Interpretation and Philosophy

Thrashing means the hierarchy is moving state instead of exploiting locality. The cure is not faster eviction; it is a working set, partition, and prediction policy consistent with actual reuse and effective capacity.

19.18.17 Exercise 16

Exercise Title: Build an Adaptive Working-Set Controller That Changes Resident Layer Count from VRAM Pressure, Transfer Time, and Compute Time

Part 1 - Exercise Contract and Why It Matters

Adapt the number and byte size of resident and prefetched blocks from measured VRAM headroom, transfer latency, compute coverage, bubble time, and thrashing. Use hysteresis and hard safety constraints so adaptation does not oscillate or violate transient memory budgets.

Part 2 - System and Memory Mental Model

More residency improves reuse and deadline slack; less residency restores headroom for activations and workspaces. The controller operates on a slower timescale than individual transfers. High and low pressure thresholds prevent one noisy sample from reversing direction. Byte-aware windows are safer than a fixed layer count for heterogeneous blocks.

Part 3 - Quantitative Prediction Before Execution

Estimate blocks needed to cover p95 delivery time by summing upcoming compute times. Admit them only if current live bytes plus incoming payloads, activation forecast, workspace, and safety margin fit. Shrink when pressure or thrashing crosses high thresholds; grow after sustained low pressure and visible bubbles.

Part 4 - Experimental Design and Instrumentation

Feed the controller stable, bursty, and variable-shape traces. Log inputs, decision, reason, previous and new byte windows, migrations, bubbles, memory, and throughput. Compare fixed-window baselines. Inject noisy measurements and verify minimum dwell time and hysteresis prevent oscillation.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ControlSample:
    pressure: float
    transfer_ms: float
    covered_compute_ms: float
    bubble_ms: float
    thrashing: bool

class WorkingSetController:
    def __init__(self, minimum, maximum, high, low):
        self.minimum = minimum
        self.maximum = maximum
        self.high = high
        self.low = low
        self.target = minimum

    def update(self, sample):
        if sample.pressure >= self.high or sample.thrashing:
            self.target = max(self.minimum, self.target - 1)
            return self.target, "shrink_for_pressure"
        delivery_uncovered = sample.transfer_ms
        delivery_uncovered -= sample.covered_compute_ms
        if sample.pressure <= self.low:
            if sample.bubble_ms > 0.0 and delivery_uncovered > 0.0:
                self.target = min(self.maximum, self.target + 1)
                return self.target, "grow_for_latency_coverage"
        return self.target, "hold"

def E16(minimum, maximum):
    return WorkingSetController(minimum, maximum, 0.90, 0.70)
```

Part 6 - Measurement, Validation, and Failure Analysis

Layer count must be translated into predicted bytes before admission. This minimal controller needs rolling statistics, dwell time, and emergency fallback. Shrinking a target does not authorize eviction of protected blocks. Growing a window can worsen bubbles if extra prefetch creates storage contention.

Part 7 - Engineering Interpretation and Philosophy

Adaptation should follow measured scarcity and deadlines, not chase every sample. Hard invariants define what is legal; a slow, explainable controller chooses a stable point inside that legal region.

19.18.18 Exercise 17

Exercise Title: Run a Transformer-Style PyTorch Model Whose Parameter Size Is Multiple Times Larger Than the Assigned VRAM Budget and Verify Numerical Correctness

Part 1 - Exercise Contract and Why It Matters

Execute a transformer-style stack whose unique parameter payload is several times the software VRAM budget. Partition and stream its blocks while retaining embeddings, normalization, attention masks, residuals, and tied output weights correctly. Compare logits with a resident CPU or larger-device reference.

Part 2 - System and Memory Mental Model

Transformer blocks are sequential at layer granularity but contain residual paths and temporary attention and FFN activations. Embedding and language-model head weights may be tied across the full schedule. Sequence length changes activation and attention workspace dramatically even when parameter bytes stay fixed. Evaluation mode removes dropout randomness for parity.

Part 3 - Quantitative Prediction Before Execution

Compute total unique parameters, largest block, persistent shared weights, two block slots, live residuals, attention masks, KV-like temporaries, and operator workspace. Prove total weights exceed the assigned budget by the target multiple while the predicted transient working set remains below it.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, tokens, masks, dtype, and deterministic options where supported. Generate reference logits, then run one-block and pipelined schedules. Compare maximum absolute and relative error, top-token agreement, intermediate checksums, peak memory, transfer traffic, and latency across sequence lengths.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def numerical_report(reference, candidate, atol, rtol):
    difference = (reference - candidate).abs()
    maximum_absolute = difference.max().item()
    denominator = reference.abs().clamp_min(1e-12)
    maximum_relative = (difference / denominator).max().item()
```

```
    close = torch.allclose(reference, candidate, atol=atol, rtol=rtol)
    reference_tokens = reference.argmax(dim=-1)
    candidate_tokens = candidate.argmax(dim=-1)
    token_agreement = reference_tokens.eq(candidate_tokens)
    agreement_rate = token_agreement.float().mean().item()
    return {
        "allclose": close,
        "max_absolute": maximum_absolute,
        "max_relative": maximum_relative,
        "token_agreement": agreement_rate,
    }

def E17(reference_logits, out_of_core_logits):
    return numerical_report(
        reference_logits, out_of_core_logits, 1e-5, 1e-4)
```

Part 6 - Measurement, Validation, and Failure Analysis

CPU and CUDA kernels can differ slightly, so tolerances must reflect dtype and operation while still catching wrong versions and ordering. Matching argmax is not enough when logits differ materially. A model that fits for short sequences may OOM at longer contexts because activations, not weights, dominate.

Part 7 - Engineering Interpretation and Philosophy

The transformer experiment proves that capacity virtualization preserves a real architecture, not only a sequential toy. Numerical correctness remains the primary acceptance criterion; memory and speed improvements are secondary.

19.18.19 Exercise 18

Exercise Title: Benchmark Full Residency, CPU Offloading, NVMe Offloading, and Out-of-Core Pipelining by Peak VRAM, RAM Usage, Throughput, and Latency

Part 1 - Exercise Contract and Why It Matters

Benchmark four execution modes under identical model semantics and inputs: full GPU residency, serial CPU offload, serial NVMe offload, and pipelined out-of-core execution. Report capacity, traffic, latency, throughput, and correctness together.

Part 2 - System and Memory Mental Model

Full residency minimizes parameter movement but maximizes VRAM. CPU offload adds H2D. NVMe offload adds storage and host staging. Pipelining attempts to hide both behind compute but increases in-flight buffers. Warm page cache can make NVMe mode behave like RAM, so storage temperature is part of the result.

Part 3 - Quantitative Prediction Before Execution

Predict peak VRAM, RAM, pinned bytes, NVMe traffic, H2D traffic, and lower-bound step time for every mode. Report latency cost per GiB of VRAM saved and useful throughput per peak RAM byte. Identify infeasible modes rather than assigning them fabricated performance values.

Part 4 - Experimental Design and Instrumentation

Run modes in isolated processes with the same seeds, batches, precision, determinism, and completion boundaries. Warm kernels but declare cache state. Collect median and p95 latency, throughput, peaks, I/O, copies, bubbles, and output error. Repeat enough trials to expose variability.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ModeResult:
    mode: str
    peak_vram: int
    peak_ram: int
    nvme_bytes: int
    h2d_bytes: int
    median_ms: float
    p95_ms: float
    throughput: float
    max_error: float
    feasible: bool

def benchmark_table(results, baseline_vram):
    rows = []
    for result in results:
        saved = baseline_vram - result.peak_vram
        if saved > 0:
            cost = result.median_ms / saved
        else:
            cost = 0.0
        rows.append({
            "mode": result.mode,
            "feasible": result.feasible,
            "peak_vram": result.peak_vram,
            "peak_ram": result.peak_ram,
            "median_ms": result.median_ms,
            "p95_ms": result.p95_ms,
            "throughput": result.throughput,
            "latency_per_saved_byte": cost,
            "max_error": result.max_error,
        })
    return rows

def E18(results, baseline_vram):
    return benchmark_table(results, baseline_vram)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not run modes consecutively in one process and call allocator remnants equal. Do not label page-cache bytes NVMe reads. Synchronize CUDA at timing boundaries, monitor transient RSS, and verify outputs. The latency-per-saved-byte example uses total median rather than incremental baseline latency; the report should also include the incremental metric.

Part 7 - Engineering Interpretation and Philosophy

The benchmark describes a capacity-performance frontier. Out-of-core execution is often slower but uniquely feasible; pipelining is valuable when it moves that feasible point toward resident throughput without breaking budgets.

19.18.20 Exercise 19

Exercise Title: Build a Complete PyTorch Out-of-Core Execution Runtime That Runs an Oversized Model Across NVMe, RAM, and VRAM with Automatic Prefetch, Eviction, and Working-Set Control

Part 1 - Exercise Contract and Why It Matters

Integrate graph partitioning, canonical resources, three-tier residency, byte budgets, asynchronous reads, pinned leases, CUDA streams and events, activation liveness, shared weights, prefetch, eviction, adaptive working sets, telemetry, rollback, and numerical verification into one runtime.

Part 2 - System and Memory Mental Model

The scheduler knows future block and activation uses. The registry owns identity, authority, version, protection, and placement. Transaction managers own I/O and copy completion. Budget controllers reserve transient bytes before movement. Only a verified commit publishes a new replica; failures retain the last valid authority and release reservations.

Part 3 - Quantitative Prediction Before Execution

Simulate the graph before execution and reject schedules whose minimum legal weights, activations, workspaces, and buffers exceed a budget. Predict stage deadlines and traffic, then compare online observations to adjust lookahead and window width. Maintain emergency margins for allocator and shape uncertainty.

Part 4 - Experimental Design and Instrumentation

Test transitions, sequential inference, residuals, shared weights, variable shapes, NVMe failures, and resume before the full model. Benchmark against the four modes from E18. Report versions, parity, peak tiers, queue depths, cache hits, migrations, wasted prefetch, bubbles, throughput, and controlled failures.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class RuntimeBlock:
    key: str
    size_bytes: int
    authority: str
```

```
    version: int
    nvme_path: str
    ram_state: object = None
    cuda_state: object = None
    pending: str = "none"
    next_use: int = -1
    protected: set = field(default_factory=set)

class OutOfCoreRuntime:
    def __init__(self, vram_budget, ram_budget):
        self.vram_budget = vram_budget
        self.ram_budget = ram_budget
        self.vram_committed = 0
        self.vram_reserved = 0
        self.ram_committed = 0
        self.ram_reserved = 0
        self.blocks = {}

    def register(self, block):
        if block.key in self.blocks:
            raise KeyError("duplicate canonical block")
        self.blocks[block.key] = block

    def reserve(self, tier, size_bytes):
        if tier == "ram":
            projected = self.ram_committed + self.ram_reserved
            if projected + size_bytes > self.ram_budget:
                raise MemoryError("RAM reservation rejected")
            self.ram_reserved += size_bytes
        elif tier == "vram":
            projected = self.vram_committed + self.vram_reserved
            if projected + size_bytes > self.vram_budget:

        if block.cuda_state is not None:
            block.cuda_state = None
            self.vram_committed -= block.size_bytes

    def validate(self):
        if self.vram_committed + self.vram_reserved > self.vram_budget:
            raise MemoryError("VRAM invariant violated")
        if self.ram_committed + self.ram_reserved > self.ram_budget:
            raise MemoryError("RAM invariant violated")

def E19(vram_budget, ram_budget):
    return OutOfCoreRuntime(vram_budget, ram_budget)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact class demonstrates reservations and H2D lifecycle, not a complete generic executor. The final implementation must connect real modules, futures, events, pinned pools, RAM and NVMe commits, activation leases, alias restoration, transaction IDs, rollback, durable manifests, cancellation, and recovery. Every exceptional path must return its reserved bytes.

Part 7 - Engineering Interpretation and Philosophy

The complete runtime is a graph-aware memory operating system. It makes an oversized model executable by preserving a small correct working set and moving future state early enough, while treating numerical equivalence and bounded failure as stronger requirements than throughput.

19.19 DMM17

Chapter Title: Activation Checkpointing and Recomputation
Specialization: Dynamic Memory Management and CUDA Systems

19.19.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Activation Memory, Recomputation, and the Memory-Compute Trade-Off During Backpropagation

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model for forward inputs, outputs, saved tensors, residuals, temporary workspaces, gradients, and recomputed intermediates. Explain precisely which activations checkpointing avoids retaining and what must remain available to replay a region during backward.

Part 2 - System and Memory Mental Model

Ordinary autograd saves selected forward values until their backward consumers. Checkpointing retains boundary inputs and reconstructs internal values by running part of forward again. Memory falls because internal lifetimes shrink; compute rises because operations repeat. Parameters and gradients are not automatically reduced. Randomness, mutable state, device movement, and global side effects must behave consistently during replay.

Part 3 - Quantitative Prediction Before Execution

Without checkpointing, peak activation memory approximates the maximum sum of simultaneously live saved tensors. A checkpointed region replaces many internal saves with boundary tensors and recomputation temporaries. Estimate bytes saved, extra forward FLOPs, recomputation count, and step-time increase. Savings are not simply total forward outputs because autograd saves operation-specific data.

Part 4 - Experimental Design and Instrumentation

Instrument model creation, forward, loss, backward, and gradient reset. Use saved-tensor hooks or a profiler to classify autograd saves, and CUDA counters for stage peaks. Compare identical seeds and inputs with no checkpoint and a known region checkpointed. Count forward calls to prove recomputation occurred.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ActivationRegion:
    key: str
    boundary_bytes: int
    internal_saved_bytes: int
    forward_flops: float
    checkpointed: bool = False

    def estimated_saved_bytes(self):
        if not self.checkpointed:
            return 0
        saved = self.internal_saved_bytes - self.boundary_bytes
        return max(saved, 0)

    def estimated_extra_flops(self):
        if self.checkpointed:
            return self.forward_flops
        return 0.0

def E00(key, boundary_bytes, internal_bytes, forward_flops):
```

```
    return ActivationRegion(
        key, boundary_bytes, internal_bytes, forward_flops)
```

Part 6 - Measurement, Validation, and Failure Analysis

Allocated-VRAM differences include allocator reuse and temporary peaks, so they are not a direct saved-tensor inventory. Checkpointing may shift the peak from forward to backward recomputation. Stateful modules or changed global variables can make replay differ from original forward. A region whose boundary is nearly as large as its internals may save little.

Part 7 - Engineering Interpretation and Philosophy

Activation checkpointing compresses a computation history by retaining selected boundaries and purchasing the missing history again with compute. It is useful when activation capacity is scarce and replay is cheaper than retaining every intermediate until backward.

19.19.2 Exercise 01

Exercise Title: Measure Activation Memory Separately from Parameters, Gradients, and Optimizer State in a PyTorch Training Step

Part 1 - Exercise Contract and Why It Matters

Separate persistent parameter, buffer, gradient, and optimizer-state bytes from dynamic activation and workspace memory. Produce a stage-by-stage accounting that estimates the activation contribution without calling every unexplained peak an activation.

Part 2 - System and Memory Mental Model

Parameters and optimizer state persist across steps. Gradients appear during backward and may remain until reset. Saved activations span forward to their backward consumers; operator workspaces and temporaries are shorter-lived. Allocator reserved memory is reusable capacity, not a tensor category. CUDA context and library allocations can lie outside PyTorch's live tensor counters.

Part 3 - Quantitative Prediction Before Execution

Inventory exact persistent tensor bytes. Measure allocated memory at an idle baseline, after forward, after loss, after backward, after optimizer step, and after gradient reset. The forward delta gives an upper bound containing saved activations, outputs, and workspaces. Saved-tensor hooks provide a more direct logical byte total, though shared storage still requires canonicalization.

Part 4 - Experimental Design and Instrumentation

Warm up the model and optimizer, then reset peaks. Record unique tensor storages and CUDA counters at each boundary. Repeat with inference mode to estimate forward temporaries without autograd saves. Hold batch, shape, dtype, and algorithm selection constant, and synchronize only at measurement boundaries.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def model_state_bytes(model, optimizer):
    parameters = 0
    gradients = 0
    optimizer_state = 0
    for parameter in model.parameters():
        parameters += tensor_bytes(parameter)
        if parameter.grad is not None:
            gradients += tensor_bytes(parameter.grad)
    for state in optimizer.state.values():
        for value in state.values():
            if torch.is_tensor(value):
                optimizer_state += tensor_bytes(value)
    return parameters, gradients, optimizer_state

def cuda_sample(label):
    return {
        "label": label,
        "allocated": torch.cuda.memory_allocated(),
        "reserved": torch.cuda.memory_reserved(),
        "peak": torch.cuda.max_memory_allocated(),
    }

def E01(model, optimizer):
    return model_state_bytes(model, optimizer), cuda_sample("current")
```

Part 6 - Measurement, Validation, and Failure Analysis

The function double-counts tied parameters unless canonical storage is added. Optimizer state is lazy before the first step. Forward deltas can include outputs held by Python and workspace cache. Comparing a warmed training step with a cold inference step confounds activation saving with initialization.

Part 7 - Engineering Interpretation and Philosophy

Category separation prevents the wrong optimization. Activation checkpointing is a rational response only after evidence shows that long-lived forward state, not weights, gradients, optimizer state, or fragmentation, dominates the budget.

19.19.3 Exercise 02

Exercise Title: Build a Deep PyTorch Network That Exceeds a Fixed VRAM Budget Because of Saved Activations Rather Than Model Weights

Part 1 - Exercise Contract and Why It Matters

Construct a network whose parameters fit comfortably inside a fixed VRAM budget but whose training step exceeds it as depth, batch, or sequence grows because autograd retains activations. Prove the cause with accounting rather than assuming depth implies activation pressure.

Part 2 - System and Memory Mental Model

Repeated shape-preserving blocks can have modest parameter payload yet save one or more large tensors per layer. During forward their lifetimes accumulate. Inference mode removes autograd saves and should fit under the same shape when activations are the cause. Backward may introduce its own temporary peak.

Part 3 - Quantitative Prediction Before Execution

For depth D and per-block saved payload A, activation storage often grows approximately with DA before backward releases it. Parameters remain fixed per chosen width and depth formula. Select a software budget greater than parameters plus minimal workspace but less than the predicted training peak.

Part 4 - Experimental Design and Instrumentation

Sweep depth at fixed input and then input size at fixed depth. Record parameter bytes, inference peak, training forward peak, backward peak, and OOM boundary in fresh processes. Confirm the same model fits under inference mode and that checkpointing later moves the training boundary.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch import nn

class ActivationHeavyBlock(nn.Module):
    def __init__(self, width):
        super().__init__()
        self.first = nn.Linear(width, width)
        self.second = nn.Linear(width, width)
        self.activation = nn.GELU()

    def forward(self, value):
        hidden = self.activation(self.first(value))
        return value + self.second(hidden)

def build_deep_model(depth, width):
    blocks = []
    for _ in range(depth):
        blocks.append(ActivationHeavyBlock(width))
    return nn.Sequential(*blocks)

def E02(depth=48, width=2048):
    model = build_deep_model(depth, width)
    parameter_bytes = 0
    for parameter in model.parameters():
```

```
        parameter_bytes += parameter.numel() * parameter.element_size()
    return model, parameter_bytes
```

Part 6 - Measurement, Validation, and Failure Analysis

This model's parameters also grow with depth, so choose width, batch, and budget from measured ratios rather than claiming activation dominance automatically. Allocator limits and OOM tests belong in isolated processes. Holding outputs or losses across iterations can create a Python reference leak that mimics saved activation growth.

Part 7 - Engineering Interpretation and Philosophy

A controlled activation OOM is a diagnostic instrument. It establishes that the model's mathematical state fits while its retained execution history does not, creating the exact condition recomputation is designed to solve.

19.19.4 Exercise 03

Exercise Title: Apply torch.utils.checkpoint.checkpoint() to a Single Block and Measure the Change in Peak CUDA Memory

Part 1 - Exercise Contract and Why It Matters

Checkpoint one measured block with explicit non-reentrant behavior, count its forward calls, and compare peak allocated VRAM against an identical ordinary step. Validate loss, gradients, and output before interpreting memory savings.

Part 2 - System and Memory Mental Model

The checkpoint wrapper runs the block in forward but avoids retaining selected internal intermediates. During backward PyTorch recomputes the needed portion and then differentiates it. Boundary inputs and required graph context remain. Non-reentrant checkpointing records an autograd graph and can stop replay when the needed intermediates have been rebuilt.

Part 3 - Quantitative Prediction Before Execution

Predict saved bytes as internal saved tensors minus retained boundary and replay temporaries. The global peak reduction can be smaller if another region defines the step peak. Extra compute is approximately one additional forward through the checkpointed block, though early-stop recomputation may reduce it.

Part 4 - Experimental Design and Instrumentation

Run checkpointed and ordinary modes in fresh or reset-equivalent trials with the same weights, input, seed, and optimizer. Warm up, reset peaks, synchronize at stage boundaries, and count block calls. Compare forward peak, backward peak, step peak, time, output, loss, and parameter gradients.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch import nn
from torch.utils.checkpoint import checkpoint
```

```
class CountedBlock(nn.Module):
    def __init__(self, module):
        super().__init__()
        self.module = module
        self.calls = 0

    def forward(self, value):
        self.calls += 1
        return self.module(value)

def checkpointed_forward(block, value, enabled):
    if enabled:
        return checkpoint(block, value, use_reentrant=False)
    return block(value)

def E03(block, value, enabled=True):
    torch.cuda.reset_peak_memory_stats()
    output = checkpointed_forward(block, value, enabled)
    return output, torch.cuda.max_memory_allocated()
```

Part 6 - Measurement, Validation, and Failure Analysis

Peak memory read immediately after forward misses a larger backward peak; read again after backward. One block may not change the global peak if other live activations dominate. Forward-call counters must not themselves alter tensor state. Passing `use_reentrant` explicitly avoids version-dependent defaults.

Part 7 - Engineering Interpretation and Philosophy

Single-block checkpointing isolates the mechanism. A correct result shows that memory fell because internal history was reconstructed, not because gradients were disabled, outputs detached, or the numerical task changed.

19.19.5 Exercise 04

Exercise Title: Compare Training Time Before and After Checkpointing and Quantify the Extra Compute Required for Recomputation

Part 1 - Exercise Contract and Why It Matters

Measure end-to-end step time and operator work for identical checkpointed and ordinary training. Separate forward, backward, and optimizer time so additional recomputation is visible rather than attributed vaguely to checkpoint overhead.

Part 2 - System and Memory Mental Model

Checkpointed forward can be slightly cheaper in memory-management work, while backward becomes more expensive because it contains replay plus gradient computation. CUDA execution is asynchronous, so CPU wall time needs explicit completion. Kernel compilation, autotuning, and allocator warmup must be removed from steady-state comparison.

Part 3 - Quantitative Prediction Before Execution

If checkpointed blocks account for fraction f of forward work and replay them once, extra compute approaches f times one forward, not a full second training step. Compare measured block call counts and profiler FLOPs with this estimate. Report slowdown and memory saved together.

Part 4 - Experimental Design and Instrumentation

Warm up both modes, use identical pre-generated batches, reset optimizer state or clone it, and time many synchronized steps. Report median and p95 forward, backward, optimizer, and total time, throughput, peak VRAM, call counts, and final parameter agreement. Alternate mode order across repetitions.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def time_completed_step(step_function, repetitions):
    samples = []
    for _ in range(repetitions):
        torch.cuda.synchronize()
        start = time.perf_counter()
        step_function()
        torch.cuda.synchronize()
        elapsed_ms = (time.perf_counter() - start) * 1000.0
        samples.append(elapsed_ms)
    ordered = sorted(samples)
    p95_index = max(0, int(0.95 * len(ordered)) - 1)
    return {
        "median_ms": statistics.median(samples),
        "p95_ms": ordered[p95_index],
        "all_samples_ms": samples,
    }

def E04(baseline_step, checkpoint_step, repetitions=30):
    baseline = time_completed_step(baseline_step, repetitions)
    checkpointed = time_completed_step(checkpoint_step, repetitions)
    return baseline, checkpointed
```

Part 6 - Measurement, Validation, and Failure Analysis

The wrapper measures total time only; use events or profiler regions for stage breakdown. Different dropout masks, data, loss scaling, or optimizer history invalidate timing and correctness comparisons. Profiler overhead must not be mixed into the headline steady-state benchmark.

Part 7 - Engineering Interpretation and Philosophy

Recomputation is the price paid for capacity. A useful report states how much peak memory was purchased per unit of extra completed step time, allowing the trade-off to be compared with offload, precision, or smaller batches.

19.19.6 Exercise 05

Exercise Title: Verify Numerical Equivalence Between Checkpointed and Non-Checkpointed Training Under Controlled Random Seeds

Part 1 - Exercise Contract and Why It Matters

Prove that checkpointing changes storage strategy rather than the training objective. Starting from identical model and optimizer state, compare outputs, losses, gradients, updated parameters, and optimizer tensors under controlled randomness and deterministic settings where available.

Part 2 - System and Memory Mental Model

Recomputation must evaluate the same function with the same inputs, parameters, mode, and random choices as original forward. PyTorch can preserve relevant RNG state for checkpointed regions. Floating-point kernels may still differ slightly across devices or algorithms, so equivalence uses justified tolerances plus discrete checks, not only bitwise identity.

Part 3 - Quantitative Prediction Before Execution

For deterministic elementwise and matrix operations in the same environment, expect close outputs and gradients. Define absolute and relative tolerances per dtype before running. Compare every named parameter and gradient; an aggregate loss alone can hide offsetting errors.

Part 4 - Experimental Design and Instrumentation

Clone one initial state into two models and optimizers, pre-generate the batch, set modes and seeds, and run exactly one step. Capture block call counts and RNG configuration. Repeat several seeds. Add dropout to verify preserved RNG and a stateful counter to demonstrate why side effects require special care.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def compare_named_gradients(model_a, model_b, atol, rtol):
    parameters_b = dict(model_b.named_parameters())
    report = {}
    for name, parameter_a in model_a.named_parameters():
        parameter_b = parameters_b[name]
        if parameter_a.grad is None or parameter_b.grad is None:
            report[name] = parameter_a.grad is parameter_b.grad
            continue
        report[name] = torch.allclose(
            parameter_a.grad, parameter_b.grad,
            atol=atol, rtol=rtol)
    return report

def maximum_tensor_error(first, second):
    return (first - second).abs().max().item()

def E05(model_a, model_b, output_a, output_b):
```

```
    gradients = compare_named_gradients(
        model_a, model_b, 1e-6, 1e-5)
    error = maximum_tensor_error(output_a, output_b)
    return gradients, error
```

Part 6 - Measurement, Validation, and Failure Analysis

Creating a dictionary of parameters is explicit conversion, not evidence of shared storage. Seeds must be set before stochastic operations in each isolated run. BatchNorm running statistics and custom counters can be updated twice by replay. Equal gradients before the optimizer do not prove equal optimizer state after a step.

Part 7 - Engineering Interpretation and Philosophy

Numerical equivalence is the boundary between an optimization and a new algorithm. Memory savings are acceptable only after recomputation preserves the same training transition within a declared and defensible tolerance.

19.19.7 Exercise 06

Exercise Title: Checkpoint Multiple Consecutive Blocks and Measure How Checkpoint Granularity Changes Peak VRAM and Runtime

Part 1 - Exercise Contract and Why It Matters

Checkpoint consecutive regions at several granularities and measure boundary storage, internal saved bytes, peak VRAM, recomputation calls, and runtime. Determine when finer boundaries retain too much state and when coarse regions recompute too much work.

Part 2 - System and Memory Mental Model

Every checkpoint boundary must remain available to replay its region. Many small regions create more boundaries but limit replay scope. One large region stores fewer boundaries but can repeat more operations. Non-reentrant early stopping may avoid executing the entire region when only earlier intermediates are needed.

Part 3 - Quantitative Prediction Before Execution

For each partition, sum boundary bytes and estimate internal bytes removed. Estimate extra FLOPs from the operations replayed by backward, not simply block count. Compare configurations by peak bytes saved per millisecond and identify the smallest configuration that satisfies the target budget.

Part 4 - Experimental Design and Instrumentation

Use identical block weights and batches. Sweep one block per region, several blocks per region, and one full region. Count calls per block to observe partial replay. Record forward, backward, total time, peak memory, output, gradient error, and the exact boundaries retained.

Part 5 - PyTorch/CUDA Implementation

```
from torch.utils.checkpoint import checkpoint

def run_region(blocks, start, end, value):
    result = value
    for index in range(start, end):
        result = blocks[index](result)
    return result

def checkpoint_blocks(blocks, value, group_size):
    result = value
    start = 0
    while start < len(blocks):
        end = min(start + group_size, len(blocks))

        def region(input_tensor, begin=start, finish=end):
            return run_region(blocks, begin, finish, input_tensor)

        result = checkpoint(region, result, use_reentrant=False)
        start = end
    return result

def E06(blocks, value, group_size):
    return checkpoint_blocks(blocks, value, group_size)
```

Part 6 - Measurement, Validation, and Failure Analysis

Default arguments freeze loop boundaries; capturing mutable loop variables without them can replay the wrong region. Nested function creation is explicit but compilation systems may prefer stable modules. Region outputs with complex structures need testing. Granularity results depend on actual saved tensors, not only source-level block boundaries.

Part 7 - Engineering Interpretation and Philosophy

Checkpoint granularity determines the resolution at which history is discarded and rebuilt. The best partition is a graph and cost decision, not a universal number of layers.

19.19.8 Exercise 07

Exercise Title: Use checkpoint_sequential() on a Deep Sequential Model and Sweep Segment Count to Find the Best Memory-Compute Trade-Off

Part 1 - Exercise Contract and Why It Matters

Apply `checkpoint_sequential` to a true sequential model, sweep segment count, and select the fastest configuration that remains under a target peak. Document which segment is not checkpointed and how uneven layer costs affect the nominal partition.

Part 2 - System and Memory Mental Model

The utility partitions a sequential function into segments and checkpoints the appropriate prefix segments while the final segment executes ordinarily. Equal layer counts do not imply

equal activation bytes or compute. Segment boundaries remain live, and reentrant behavior must be chosen explicitly.

Part 3 - Quantitative Prediction Before Execution

Sweep from no effective partition through many segments. Predict boundary count, largest internal region, replay work, and peak. The optimum under a budget is not necessarily the minimum memory result; it is the feasible configuration with the lowest validated step time.

Part 4 - Experimental Design and Instrumentation

Use a deep sequential model with intentionally unequal blocks. For each segment count run warmup and repeated synchronized steps from identical state. Record peak VRAM, median and p95 time, throughput, block calls, gradient parity, and segment composition. Reject counts outside the valid model length.

Part 5 - PyTorch/CUDA Implementation

```
from torch.utils.checkpoint import checkpoint_sequential

def run_checkpoint_sequential(model, value, segments):
    if segments < 1:
        raise ValueError("segments must be positive")
    if segments > len(model):
        raise ValueError("segments exceed sequential module count")
    return checkpoint_sequential(
        model,
        segments,
        value,
        use_reentrant=False)

def select_feasible(results, memory_budget):
    best = None
    for result in results:
        if result["peak_vram"] > memory_budget:
            continue
        if best is None or result["step_ms"] < best["step_ms"]:
            best = result
    if best is None:
        raise MemoryError("no segment count meets the budget")
    return best

def E07(model, value, segments):
    return run_checkpoint_sequential(model, value, segments)
```

Part 6 - Measurement, Validation, and Failure Analysis

This utility is for sequential execution; residual and branching graphs require manual regions. Segment count is not segment size in bytes. Changes across PyTorch versions should be checked against current documentation, especially explicit reentrant selection and final-segment behavior.

Part 7 - Engineering Interpretation and Philosophy

The sweep turns an API convenience into measured engineering. The selected segment count is justified by a specific model, graph, input shape, and hardware budget rather than by a folklore default.

19.19.9 Exercise 08

Exercise Title: Compare Reentrant and Non-Reentrant PyTorch Checkpointing Behavior and Identify Their Practical Differences

Part 1 - Exercise Contract and Why It Matters

Run the same eligible region with `use_reentrant=True` and `False`, then compare graph recording, recomputation extent, backward API compatibility, nested structures, detached values, peak memory, and time.

Part 2 - System and Memory Mental Model

Reentrant checkpointing runs the original forward under no-grad and re-enters the region during backward. It requires gradient participation at its boundary and has stricter limitations. Non-reentrant mode records the graph, supports more autograd patterns, and can stop recomputation once required intermediates exist. PyTorch recommends explicit selection, with non-reentrant generally the preferred modern path.

Part 3 - Quantitative Prediction Before Execution

For a simple region both modes may save similar memory, while non-reentrant early stop can reduce replay. Predict differences with call counters per operation. Define compatibility tests before timing because a faster mode that silently drops gradients is invalid.

Part 4 - Experimental Design and Instrumentation

Test plain tensor output, nested output, detached intermediate, backward with explicit inputs, and a region containing nested autograd. Record success, exception, output, gradients, calls, peak memory, and step time. Keep RNG and model state identical.

Part 5 - PyTorch/CUDA Implementation

```
from torch.utils.checkpoint import checkpoint

def run_checkpoint_mode(function, value, use_reentrant):
    return checkpoint(
        function,
        value,
        use_reentrant=use_reentrant,
        preserve_rng_state=True)

def compare_mode_result(name, output, peak_vram, elapsed_ms):
    return {
        "mode": name,
        "shape": tuple(output.shape),
        "peak_vram": peak_vram,
```

```
        "elapsed_ms": elapsed_ms,
        "requires_grad": output.requires_grad,
    }

def E08(function, value):
    non_reentrant = run_checkpoint_mode(function, value, False)
    reentrant = run_checkpoint_mode(function, value, True)
    return non_reentrant, reentrant
```

Part 6 - Measurement, Validation, and Failure Analysis

Executing both modes in one graph complicates memory and gradient comparisons; benchmark them in isolated trials. Reentrant mode can fail when no boundary input or output requires gradients and with detached tensors in the region. Do not infer semantic support from one simple linear block.

Part 7 - Engineering Interpretation and Philosophy

Reentrant selection is part of the program's autograd contract. Choose the mode that supports the graph correctly, then optimize it; backward compatibility is more important than a small benchmark difference.

19.19.10 Exercise 09

Exercise Title: Reproduce a Checkpointing Failure Caused by Detached Tensors or Incompatible Autograd Behavior and Diagnose the Graph Correctly

Part 1 - Exercise Contract and Why It Matters

Create a controlled region with a detached intermediate and demonstrate how an incompatible checkpoint mode fails or produces missing gradient paths. Diagnose the exact graph edge and repair the design without simply removing correctness assertions.

Part 2 - System and Memory Mental Model

`detach()` intentionally cuts autograd history. Reentrant checkpointing expects its recomputed outputs to participate under its boundary rules and can reject detached values inside the region. Non-reentrant mode supports more graph structures, but a deliberate detach still means no gradient should cross that edge. The repair depends on intended mathematics.

Part 3 - Quantitative Prediction Before Execution

Draw the graph and mark which tensors require gradients before and after the detach. Predict zero or absent gradients on the cut branch and ordinary gradients on the live branch. Compare predictions with hooks and finite differences where the mathematical function is differentiable.

Part 4 - Experimental Design and Instrumentation

Run the region without checkpointing, with non-reentrant checkpointing, and with reentrant checkpointing. Capture exceptions, requires-grad flags, grad functions, parameter gradients, and anomaly-detection traces. Then move the detach outside the region or remove it only if the model intended gradient flow.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.utils.checkpoint import checkpoint

def region_with_detach(value, weight):
    live = value @ weight
    stopped = live.detach()
    return live + stopped

def run_failure_case(value, weight, use_reentrant):
    def region(input_tensor):
        return region_with_detach(input_tensor, weight)

    return checkpoint(
        region,
        value,
        use_reentrant=use_reentrant)

def E09(value, weight):
    with torch.autograd.detect_anomaly():
        output = run_failure_case(value, weight, True)
        loss = output.square().mean()
        loss.backward()
    return output
```

Part 6 - Measurement, Validation, and Failure Analysis

The exercise intentionally may raise under reentrant behavior; run it as a test that captures the expected failure. Anomaly detection adds overhead and belongs in diagnosis, not benchmarks. Moving detach merely to silence an exception can change which parameters learn, so compare against the non-checkpointed intended graph.

Part 7 - Engineering Interpretation and Philosophy

Checkpointing exposes hidden assumptions about gradient topology. The correct fix preserves the intended derivative; an execution that finishes with the wrong graph is a more serious failure than an explicit exception.

19.19.11 Exercise 10

Exercise Title: Preserve Dropout Correctness During Recomputation and Measure the Cost of RNG State Preservation

Part 1 - Exercise Contract and Why It Matters

Checkpoint a region containing dropout with RNG preservation enabled, prove that original forward and recomputation use equivalent random choices, and measure the time spent saving and restoring random-generator state.

Part 2 - System and Memory Mental Model

Dropout consumes RNG and its mask affects outputs and gradients. Replaying the region without restoring RNG would normally draw a different mask. PyTorch checkpointing can

stash CPU and relevant device RNG state around the region so recomputation is deterministic relative to ordinary execution. Unexpected device movement inside the function can exceed that guarantee.

Part 3 - Quantitative Prediction Before Execution

RNG state payload is small, but capture and restore add fixed overhead per checkpoint invocation. Many tiny regions can therefore magnify the cost. Predict near-identical gradients with preservation and possible disagreement without it. Measure cost per region and per completed training step.

Part 4 - Experimental Design and Instrumentation

Clone identical models, set training mode and seed, and compare ordinary forward with checkpointed forward using preservation. Instrument dropout inputs and outputs or a custom mask probe. Sweep region count and tensor size. Report output and gradient parity, calls, total time, and preservation overhead.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch import nn
from torch.utils.checkpoint import checkpoint

class DropoutRegion(nn.Module):
    def __init__(self, probability):
        super().__init__()
        self.dropout = nn.Dropout(probability)
        self.calls = 0

    def forward(self, value):
        self.calls += 1
        return self.dropout(value).square()

def run_preserved(region, value):
    return checkpoint(
        region,
        value,
        use_reentrant=False,
        preserve_rng_state=True)

def E10(value, probability=0.2):
    torch.manual_seed(41)
    torch.cuda.manual_seed_all(41)
    region = DropoutRegion(probability).to(value.device)
    output = run_preserved(region, value)
    return output, region.calls
```

Part 6 - Measurement, Validation, and Failure Analysis

The call count increases only after backward triggers replay. Seeds must be reset at comparable points in isolated runs. Comparing checkpointed forward alone does not test replay correctness. Custom modules that move tensors to a previously unseen device or mutate generator state can defeat assumptions about which RNG states are preserved.

Part 7 - Engineering Interpretation and Philosophy

Randomness is part of the function being differentiated. RNG preservation is a correctness service whose fixed cost becomes visible mainly when checkpoint regions are too small or unnecessarily numerous.

19.19.12 Exercise 11

Exercise Title: Disable RNG State Preservation Where Safe and Benchmark the Resulting Performance Improvement

Part 1 - Exercise Contract and Why It Matters

Disable checkpoint RNG preservation only for regions proven free of stochastic operations and compare completed-step performance. Build an automatic audit that rejects unsafe regions rather than treating a small speed gain as permission to change training randomness.

Part 2 - System and Memory Mental Model

Deterministic linear, normalization, and fixed activation operations do not consume RNG. A region may still call stochastic custom functions, stochastic depth, dropout, sampling, or random augmentation indirectly. Disabling preservation avoids state capture and restore, but any replay-time randomness can change gradients relative to ordinary execution.

Part 3 - Quantitative Prediction Before Execution

The benefit is mostly fixed overhead per invocation, so it is largest for many small deterministic regions. Predict negligible memory difference. Require output, gradient, and parameter-update parity across several seeds before accepting the faster configuration.

Part 4 - Experimental Design and Instrumentation

Inventory module types and custom functions in each candidate region. Benchmark preservation on and off with identical states, synchronized repetitions, and call counts. Add a hidden dropout module as a negative test and require the audit or numerical comparison to reject disabling preservation.

Part 5 - PyTorch/CUDA Implementation

```
from torch import nn
from torch.utils.checkpoint import checkpoint

STOCHASTIC_TYPES = (
    nn.Dropout,
    nn.Dropout1d,
    nn.Dropout2d,
    nn.Dropout3d,
)
```

```
def assert_no_known_dropout(module):
    for child in module.modules():
        if isinstance(child, STOCHASTIC_TYPES):
            raise ValueError("stochastic module found in checkpoint region")

def checkpoint_without_rng(module, value):
    assert_no_known_dropout(module)
    return checkpoint(
        module,
        value,
        use_reentrant=False,
        preserve_rng_state=False)

def E11(module, value):
    return checkpoint_without_rng(module, value)
```

Part 6 - Measurement, Validation, and Failure Analysis

Module-type inspection cannot see random functional calls or arbitrary custom code, so it is a conservative aid rather than proof. Training and evaluation modes may activate different stochastic paths. Performance gains smaller than run variance should not justify a more fragile configuration.

Part 7 - Engineering Interpretation and Philosophy

Disabling a safeguard is valid only after proving its precondition. The useful optimization is targeted removal of unnecessary RNG bookkeeping, not a global switch that makes replay a different stochastic program.

19.19.13 Exercise 12

Exercise Title: Checkpoint Transformer Blocks Selectively Based on Measured Activation Size Instead of Applying Checkpointing Uniformly

Part 1 - Exercise Contract and Why It Matters

Measure each transformer block's saved activation bytes and checkpoint only the largest or most memory-efficient candidates. Preserve residuals, attention masks, dropout RNG, shared embeddings, and numerical equivalence while avoiding replay of low-value blocks.

Part 2 - System and Memory Mental Model

Blocks with identical architecture can save different bytes because of sequence shape, attention implementation, masks, conditional paths, or layer-specific features. Checkpointing every block maximizes policy simplicity, not necessarily efficiency. Boundary tensors and long-lived residuals remain even for selected regions.

Part 3 - Quantitative Prediction Before Execution

For block i, estimate memory benefit S_i and recomputation cost C_i. Prioritize large S_i/C_i subject to the global peak timeline, not merely total saved bytes. A block outside the peak's live interval may not reduce peak VRAM even if it saves many bytes elsewhere.

Part 4 - Experimental Design and Instrumentation

Profile blocks on representative sequence lengths and batches. Rank candidates, apply incremental selections, and remeasure actual peak after every addition. Report per-block saves, replay time, call count, total peak, step time, output error, gradient error, and whether the selected block overlaps the peak.

Part 5 - PyTorch/CUDA Implementation

```
from torch import nn
from torch.utils.checkpoint import checkpoint

class SelectiveTransformerStack(nn.Module):
    def __init__(self, blocks, selected_indices):
        super().__init__()
        self.blocks = nn.ModuleList(blocks)
        self.selected_indices = set(selected_indices)

    def forward(self, hidden, attention_mask=None):
        value = hidden
        for index, block in enumerate(self.blocks):
            if index in self.selected_indices:
                def region(input_tensor, current=block):
                    return current(input_tensor, attention_mask)
                value = checkpoint(
                    region, value, use_reentrant=False)
            else:
                value = block(value, attention_mask)
        return value

def E12(blocks, selected_indices):
    return SelectiveTransformerStack(blocks, selected_indices)
```

Part 6 - Measurement, Validation, and Failure Analysis

Closing over the current block through a default argument avoids replaying the wrong loop iteration. Masks captured from outer scope must remain unchanged and alive. Real transformer blocks have varied signatures and structured outputs; the wrapper must preserve them. Selection from one sequence length may not generalize to another.

Part 7 - Engineering Interpretation and Philosophy

Selective checkpointing spends recomputation where it purchases the most peak memory. It treats checkpoint placement as measured resource allocation rather than a uniform architectural decoration.

19.19.14 Exercise 13

Exercise Title: Build an Activation Cost Profiler That Ranks Model Blocks by Saved Activation Bytes and Recomputation Cost

Part 1 - Exercise Contract and Why It Matters

Build a profiler that attributes saved-tensor bytes, lifetime, forward time, replay calls, and estimated recomputation cost to model blocks. Produce a ranked candidate report while separating logical saved bytes from global peak impact.

Part 2 - System and Memory Mental Model

Autograd saves tensors at operation boundaries, sometimes as views or shared storage. Saved-tensor hooks observe packing and unpacking but add overhead and need storage canonicalization. Block timing measures ordinary forward; replay cost can differ because non-reentrant checkpointing may stop early.

Part 3 - Quantitative Prediction Before Execution

For each block compute unique saved bytes, retained boundary bytes, lifetime overlap with global peak, measured forward milliseconds, and estimated replay milliseconds. Rank by effective peak bytes saved divided by extra time, while keeping absolute benefit and uncertainty visible.

Part 4 - Experimental Design and Instrumentation

Attach scoped block contexts and saved-tensor hooks, run representative inputs, and map each packed storage to the active block. Time with CUDA events and record shapes, dtypes, storage IDs, and unpack time. Validate totals against memory counters and repeat to estimate variance and profiler overhead.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class BlockActivationCost:
    key: str
    saved_bytes: int
    boundary_bytes: int
    recompute_ms: float
    overlaps_peak: bool

    def effective_bytes(self):
        if not self.overlaps_peak:
            return 0
        return max(self.saved_bytes - self.boundary_bytes, 0)

    def score(self):
        return self.effective_bytes() / max(self.recompute_ms, 1e-9)

def score_value(item):
    return item[0]

def rank_activation_costs(costs):
    scored = []
```

```
    for cost in costs:
        scored.append((cost.score(), cost))
    scored.sort(key=score_value, reverse=True)
    return scored

def E13(costs):
    return rank_activation_costs(costs)
```

Part 6 - Measurement, Validation, and Failure Analysis

Summing logical tensor sizes can double-count shared storage and does not reveal simultaneous liveness. Hook and profiler overhead can change timing and memory. An activation saved by one block may be consumed in another, so attribution requires a declared rule. Always remeasure actual peak after applying a choice.

Part 7 - Engineering Interpretation and Philosophy

The profiler converts invisible autograd retention into placement evidence. Its ranking is a hypothesis about useful checkpoint locations, validated only when the resulting complete training step meets both memory and time predictions.

19.19.15 Exercise 14

Exercise Title: Design a Greedy Checkpoint Placement Algorithm That Meets a Target VRAM Budget with Minimum Estimated Recomputation

Part 1 - Exercise Contract and Why It Matters

Select checkpoint regions until predicted peak VRAM falls below a target while minimizing estimated replay. Enforce graph compatibility, mandatory boundaries, RNG policy, and mutually exclusive or overlapping region constraints before ranking candidates.

Part 2 - System and Memory Mental Model

Checkpoint benefits are not always additive because regions' saved tensors and peak intervals overlap. A greedy selector is an approximation: after each choice it must recompute marginal peak benefit for remaining candidates. Infeasible targets below mandatory live state must be rejected explicitly.

Part 3 - Quantitative Prediction Before Execution

Let current predicted peak be P and target B. At each iteration choose the legal candidate with greatest marginal peak reduction per millisecond, update the liveness model, and continue until $P \leq B$. Report estimated replay, uncheckpointable floor, safety margin, and uncertainty.

Part 4 - Experimental Design and Instrumentation

Test the algorithm on synthetic cost tables with known optima, then real block profiles. Compare greedy selection against exhaustive search for small cases. Apply the plan and measure actual peak and runtime. If prediction misses the budget, update costs and add a safety margin rather than silently OOMing.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class Candidate:
    key: str
    estimated_peak_reduction: int
    recompute_ms: float
    compatible: bool = True
    selected: bool = False

def candidate_ratio(candidate):
    return candidate.estimated_peak_reduction / max(
        candidate.recompute_ms, 1e-9)

def greedy_placement(current_peak, target_peak, candidates):
    selected = []
    while current_peak > target_peak:
        best = None
        best_ratio = -1.0
        for candidate in candidates:
            if candidate.selected or not candidate.compatible:
                continue
            ratio = candidate_ratio(candidate)
            if ratio > best_ratio:
                best = candidate
                best_ratio = ratio
        if best is None or best.estimated_peak_reduction <= 0:
            raise MemoryError("target cannot be met by legal checkpoints")
        best.selected = True
        selected.append(best.key)
        current_peak -= best.estimated_peak_reduction
    return selected, current_peak

def E14(current_peak, target_peak, candidates):
    return greedy_placement(current_peak, target_peak, candidates)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact algorithm assumes fixed independent reductions; a production version recalculates marginal benefit after each selection. Mutating candidate state means the same list cannot be reused without reset. Estimates must include boundary tensors and backward replay peaks. Greedy is not guaranteed globally optimal.

Part 7 - Engineering Interpretation and Philosophy

Checkpoint placement is a constrained optimization over the autograd graph. Greedy reasoning is valuable because it is transparent and measurable, provided its approximations are exposed and every selected plan is verified empirically.

19.19.16 Exercise 15

Exercise Title: Compare Full Checkpointing, Selective Checkpointing, and No Checkpointing on the Same Model by VRAM, Step Time, and Throughput

Part 1 - Exercise Contract and Why It Matters

Benchmark three policies on identical training transitions: no checkpointing, all eligible blocks checkpointed, and a measured selective plan. Compare peak VRAM, stage time, throughput, recomputation, and numerical correctness.

Part 2 - System and Memory Mental Model

No checkpointing retains maximal forward history. Full checkpointing minimizes many internal saves but can repeat low-value compute and RNG bookkeeping. Selective checkpointing aims to cross the memory budget with less replay. Other memory categories remain common and set a floor beneath all three policies.

Part 3 - Quantitative Prediction Before Execution

Predict peak reduction and extra forward-equivalent work for each policy. Report absolute and percentage memory savings, slowdown, examples or tokens per second, and memory saved per millisecond. Mark an otherwise fast mode infeasible if it exceeds the assigned budget.

Part 4 - Experimental Design and Instrumentation

Run each mode in an isolated process with cloned model and optimizer state, identical batches, seeds, precision, and completion boundaries. Warm up and collect median and p95 forward, backward, optimizer, and step time. Record peak allocated and reserved memory, calls, gradients, loss, and final updates.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class CheckpointModeResult:
    mode: str
    peak_vram: int
    step_ms: float
    throughput: float
    forward_calls: int
    max_gradient_error: float
    feasible: bool

def summarize_modes(results, baseline_peak, baseline_ms):
    rows = []
    for result in results:
        saved = baseline_peak - result.peak_vram
        added_time = result.step_ms - baseline_ms
        rows.append({
            "mode": result.mode,
            "feasible": result.feasible,
```

```
            "saved_vram": saved,
            "added_step_ms": added_time,
            "throughput": result.throughput,
            "forward_calls": result.forward_calls,
            "gradient_error": result.max_gradient_error,
        })
    return rows

def E15(results, baseline_peak, baseline_ms):
    return summarize_modes(results, baseline_peak, baseline_ms)
```

Part 6 - Measurement, Validation, and Failure Analysis

Full checkpointing must mean all eligible intended regions, not the final loss or an outer wrapper that saves no useful memory. Process isolation avoids peak counter contamination. Throughput comparisons are invalid if effective batch, dropout sequence, optimizer history, or compilation state differs.

Part 7 - Engineering Interpretation and Philosophy

The comparison reveals a frontier rather than one winner. Selective checkpointing is justified when it obtains the required feasibility with substantially less replay than a uniform policy.

19.19.17 Exercise 16

Exercise Title: Increase Sequence Length Until Activation Memory Dominates Training and Determine How Checkpointing Changes the Maximum Trainable Context

Part 1 - Exercise Contract and Why It Matters

Sweep sequence length under a fixed model, batch, precision, and VRAM budget; identify where activation memory dominates and measure the longest context trainable with no, selective, and full checkpointing.

Part 2 - System and Memory Mental Model

Weights are independent of sequence length, while hidden activations grow at least linearly. Conventional attention may create quadratic score or workspace terms, though fused kernels can change what is materialized. Checkpointing reduces saved activations but cannot remove all live residuals, outputs, masks, or operator workspace.

Part 3 - Quantitative Prediction Before Execution

Fit measured peak to linear and quadratic terms rather than assuming one scaling law. Subtract stable model-state bytes to estimate the dynamic share. Predict the next safe length with a safety margin, then validate it. Report context extension factor and added time per additional token.

Part 4 - Experimental Design and Instrumentation

Run each length in a fresh process, beginning safely and increasing gradually. Measure forward and backward peaks, saved-tensor bytes, step time, throughput, and failure boundary. Use identical token statistics and masks. Stop before physical exhaustion through an allocator or software budget.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ContextResult:
    sequence_length: int
    peak_vram: int
    step_ms: float
    succeeded: bool
    policy: str

def maximum_successful_context(results, policy, budget):
    maximum = 0
    for result in results:
        if result.policy != policy:
            continue
        if not result.succeeded:
            continue
        if result.peak_vram > budget:
            continue
        maximum = max(maximum, result.sequence_length)
    return maximum

def E16(results, budget):
    output = {}
    policies = ("none", "selective", "full")
    for policy in policies:
        output[policy] = maximum_successful_context(
            results, policy, budget)
    return output
```

Part 6 - Measurement, Validation, and Failure Analysis

OOM is a censored measurement, not an exact peak. Attention backend selection can change with shape and cause discontinuities. Tokens per second can fall even when examples per second appears similar. Checkpoint selection calibrated at a short length may be wrong at the longest context.

Part 7 - Engineering Interpretation and Philosophy

Maximum context is a systems result produced by model state, activation liveness, kernel workspace, and budget. Checkpointing extends it by shortening history, but the remaining mathematical working set defines a real limit.

19.19.18 Exercise 17

Exercise Title: Combine Activation Checkpointing with Mixed Precision and Measure Whether Their Memory Savings Are Additive or Overlapping

Part 1 - Exercise Contract and Why It Matters

Run a factorial experiment with full precision or mixed precision crossed with checkpointing off or on. Measure category bytes, peak VRAM, speed, stability, and numerical quality to determine whether savings add, overlap, or move the peak to another category.

Part 2 - System and Memory Mental Model

Mixed precision reduces bytes for many activations and kernels but may retain full-precision parameters, gradients, optimizer state, or master weights. Checkpointing removes selected saved activations regardless of their dtype. Their benefits overlap on the same activation bytes, so percentage savings are rarely simply additive. Loss scaling and sensitive operations affect stability.

Part 3 - Quantitative Prediction Before Execution

Let P_{00} be the baseline peak and measure the other three cells. Compute absolute savings and interaction: observed combined saving minus the sum of individual savings. A negative interaction indicates overlap or a shifted peak; a positive result can arise from allocator or workspace regime changes.

Part 4 - Experimental Design and Instrumentation

Use identical model states and batches for four isolated modes. Record parameter, gradient, optimizer, saved activation, workspace proxy, peak VRAM, scaler state, overflow skips, gradient norms, step time, throughput, and output or loss error. Repeat across sequence lengths.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class FactorialPeak:
    mixed_precision: bool
    checkpointing: bool
    peak_vram: int
    step_ms: float
    overflow_steps: int

def interaction_effect(full_none, mixed_none,
                       full_checkpoint, mixed_checkpoint):
    mixed_saving = full_none.peak_vram - mixed_none.peak_vram
    checkpoint_saving = (
        full_none.peak_vram - full_checkpoint.peak_vram)
    combined_saving = (
        full_none.peak_vram - mixed_checkpoint.peak_vram)
    interaction = combined_saving - mixed_saving - checkpoint_saving
    return {
        "mixed_saving": mixed_saving,
        "checkpoint_saving": checkpoint_saving,
        "combined_saving": combined_saving,
        "interaction": interaction,
```

```
    }

def E17(full_none, mixed_none, full_checkpoint, mixed_checkpoint):
    return interaction_effect(
        full_none, mixed_none, full_checkpoint, mixed_checkpoint)
```

Part 6 - Measurement, Validation, and Failure Analysis

Peaks must come from isolated, warmed trials. Mixed precision modes must use the same autocast dtype and scaling policy. A skipped optimizer step after overflow is not equivalent training. The interaction number describes measured peak, not a causal byte inventory unless category measurements support it.

Part 7 - Engineering Interpretation and Philosophy

Memory techniques compose through the tensors they affect. Factorial measurement prevents double-counting the same activation saving and reveals when one method changes which resource becomes the new bottleneck.

19.19.19 Exercise 18

Exercise Title: Build an Adaptive Checkpoint Controller That Enables or Disables Checkpointing per Block from Live VRAM Pressure and Estimated Recomputation Cost

Part 1 - Exercise Contract and Why It Matters

Choose a checkpoint plan before each stable execution interval using measured VRAM pressure, predicted activation shape, block benefit, and replay cost. Avoid changing policy inside a forward-backward pair, which would make the replay function inconsistent with the original execution.

Part 2 - System and Memory Mental Model

Checkpoint decisions are part of graph construction. A block checkpointed in forward must be replayed under compatible code and state during backward. The controller therefore selects a plan at step or bucket boundaries, freezes it through backward, and adapts slowly using high and low pressure thresholds.

Part 3 - Quantitative Prediction Before Execution

Under high pressure, add legal candidates in descending marginal saved bytes per millisecond until predicted peak plus safety margin fits. Under sustained low pressure, remove the least valuable candidate to recover throughput. Include sequence-dependent cost estimates and a minimum dwell period to prevent churn.

Part 4 - Experimental Design and Instrumentation

Feed stable, rising-context, and bursty sequences. Log pressure, candidate costs, frozen plan ID, changes, prediction error, actual peak, recomputation, OOM avoidance, and throughput. Inject a mid-step change request and require deferral until the next legal plan boundary.

Part 5 - PyTorch/CUDA Implementation

```
class AdaptiveCheckpointController:
    def __init__(self, high_pressure, low_pressure):
        self.high_pressure = high_pressure
        self.low_pressure = low_pressure
        self.selected = set()
        self.plan_frozen = False

    def begin_step(self):
        if self.plan_frozen:
            raise RuntimeError("previous step plan is still frozen")
        self.plan_frozen = True
        return frozenset(self.selected)

    def end_step(self):
        if not self.plan_frozen:
            raise RuntimeError("no frozen plan to release")
        self.plan_frozen = False

    def update_between_steps(self, pressure, ranked_keys):
        if self.plan_frozen:
            raise RuntimeError("checkpoint plan cannot change mid-step")
        if pressure >= self.high_pressure:
            for key in ranked_keys:
                if key not in self.selected:
                    self.selected.add(key)
                    return "enabled", key
        elif pressure <= self.low_pressure and self.selected:
            key = sorted(self.selected)[-1]
            self.selected.remove(key)
            return "disabled", key
        return "unchanged", None

def E18():
    return AdaptiveCheckpointController(0.90, 0.70)
```

Part 6 - Measurement, Validation, and Failure Analysis

Alphabetical removal is a placeholder; production removes the lowest marginal value using current costs. Pressure sampled after OOM is too late, so use prediction and safety margin. Dynamic control can cause graph recompilation and timing changes. Distributed ranks need compatible plans when their graph contracts require it.

Part 7 - Engineering Interpretation and Philosophy

Adaptive checkpointing is controlled graph selection, not emergency mutation. It should change slowly between complete training transactions and preserve a frozen, auditable recomputation contract within each one.

19.19.20 Exercise 19

Exercise Title: Train a Transformer-Style PyTorch Model That Previously OOMed by Designing and Benchmarking a Memory-Budgeted Selective Activation Checkpointing Strategy

Part 1 - Exercise Contract and Why It Matters

Take a transformer-style training step that reproducibly exceeds a fixed VRAM budget, profile its saved activations, select checkpoint regions, and achieve stable training under the same model, batch, context, precision, and optimizer semantics. Prove memory, numerical, and performance outcomes.

Part 2 - System and Memory Mental Model

Transformer activation memory includes residual streams, normalization inputs, attention and FFN intermediates, masks, outputs, and backend workspaces. Selective checkpointing removes only eligible saved history. Parameters, gradients, optimizer state, mandatory graph boundaries, and transient recomputation peaks remain and define the uncheckpointable floor.

Part 3 - Quantitative Prediction Before Execution

Measure baseline peak and target budget, rank regions by marginal peak benefit per replay time, and select until predicted peak plus margin fits. Predict total extra forward-equivalent work, maximum context, and throughput. Reject a target below the mandatory floor rather than overpromising a plan.

Part 4 - Experimental Design and Instrumentation

Establish the OOM in an isolated process, profile safely at a smaller shape or budget, build the plan, and rerun the original task. Compare no, full, and selective checkpoint modes. Record peak allocated and reserved VRAM, saved tensors, call counts, step stages, throughput, loss, gradients, updates, overflow, RNG policy, and multi-step convergence.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class StrategyResult:
    selected_blocks: tuple
    target_vram: int
    measured_peak_vram: int
    step_ms: float
    tokens_per_second: float
    maximum_gradient_error: float
    loss_difference: float
    completed_steps: int

    def validate(self, gradient_tolerance, loss_tolerance):
        if self.measured_peak_vram > self.target_vram:
            raise MemoryError("checkpoint strategy missed VRAM budget")
        if self.maximum_gradient_error > gradient_tolerance:
```

```
            raise RuntimeError("gradient equivalence failed")
        if self.loss_difference > loss_tolerance:
            raise RuntimeError("loss equivalence failed")
        if self.completed_steps <= 0:
            raise RuntimeError("training did not complete a step")
        return True

def E19(selected_blocks, target_vram):
    return StrategyResult(
        tuple(selected_blocks), target_vram, 0,
        0.0, 0.0, 0.0, 0.0, 0)
```

Part 6 - Measurement, Validation, and Failure Analysis

The returned object is an experiment record whose measured fields must be filled from completed runs, not a trainer by itself. A single successful step does not prove stability; run multiple updates and inspect scaler or loss behavior. Profiler settings, sequence length, attention backend, and compilation can move the peak and invalidate a stale plan.

Part 7 - Engineering Interpretation and Philosophy

The final strategy converts a previously impossible training configuration into a measured feasible one by spending compute only where it buys peak memory. Its success is defined by preserved learning semantics under budget, with the runtime cost stated openly rather than hidden behind an OOM-free result.

19.20 DMM18

Chapter Title: Activation Offloading to CPU Memory
Specialization: Dynamic Memory Management and CUDA Systems

19.20.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Activation Offloading and Compare Transfer Cost Against Recomputation Cost

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model for tensors saved by autograd: creation, packing, D2H completion, CPU residency, H2D prefetch or unpack, backward consumption, and release. Compare three legal choices for each candidate: keep on GPU, offload to CPU, or remove through checkpointed recomputation.

Part 2 - System and Memory Mental Model

Saved-tensor hooks replace the object retained by autograd with a packed object and reconstruct a tensor at unpack. CPU offload preserves the activation value but pays D2H, RAM, and H2D. Recomputation avoids those transfers but repeats forward work. Keeping avoids both costs but consumes VRAM across the activation's lifetime. Pinned asynchronous copies require events and storage leases.

Part 3 - Quantitative Prediction Before Execution

For activation bytes M, offload cost is D2H plus H2D latency and host-memory pressure, reduced by overlap. Recomputation cost is replay time and any RNG or state overhead. Keeping cost is M bytes times its live interval under VRAM pressure. Include transient source-destination coexistence during transfers.

Part 4 - Experimental Design and Instrumentation

Measure each candidate's size, producer, pack time, CPU-ready time, lifetime, unpack deadline, H2D completion, and backward use. Independently measure replay cost for its containing checkpoint region. Compare policies under identical seeds and verify outputs, losses, gradients, updates, RAM, VRAM, and step time.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ActivationDecision:
    key: str
    size_bytes: int
    lifetime_ms: float
    d2h_ms: float
    h2d_ms: float
    recompute_ms: float
    policy: str = "keep"

    def offload_cost(self):
        return self.d2h_ms + self.h2d_ms

    def cheaper_recovery(self):
        if self.recompute_ms < self.offload_cost():
            return "recompute"
        return "offload"

def E00(key, size_bytes, lifetime_ms,
        d2h_ms, h2d_ms, recompute_ms):
    return ActivationDecision(
        key, size_bytes, lifetime_ms,
        d2h_ms, h2d_ms, recompute_ms)
```

Part 6 - Measurement, Validation, and Failure Analysis

Autograd may save views or shared storages, so logical bytes can double-count physical memory. Pack return does not imply asynchronous D2H completion. Unpack may be called more than once and must return correct content each time. Offload and recomputation decisions interact with the global peak, not only local size.

Part 7 - Engineering Interpretation and Philosophy

Activation management chooses which scarce resource pays for training history: VRAM capacity, PCIe bandwidth and RAM, or GPU compute. The best policy is tensor- and graph-specific, grounded in measured lifetime and recovery cost.

19.20.2 Exercise 01

Exercise Title: Measure the VRAM Occupied by Saved Tensors Required for Backward in a Deep PyTorch Training Step

Part 1 - Exercise Contract and Why It Matters

Measure tensors retained specifically for backward and relate their unique storage bytes to the forward-to-backward VRAM delta. Separate them from parameters, outputs held by user code, residual state, and temporary workspaces.

Part 2 - System and Memory Mental Model

Autograd nodes retain selected values needed by derivative formulas, not every forward output. A saved tensor may be packed as a different object while sharing storage. Its logical lifetime ends when the relevant backward node consumes it, unless retain-graph or Python references extend it.

Part 3 - Quantitative Prediction Before Execution

Sum unique storage ranges observed by a saved-tensor pack hook. Compare this logical total with allocated memory immediately before and after forward. Differences arise from outputs, temporaries, allocator reuse, aliases, and workspace. Measure the backward release curve rather than one final sample.

Part 4 - Experimental Design and Instrumentation

Warm up, reset peaks, and install non-transforming hooks only around forward. Record shape, dtype, device, storage identity, offset, and bytes for every save. Sample CUDA memory at block boundaries and backward hooks. Verify that hooks do not alter values and report their overhead.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class SavedByteCounter:
    def __init__(self):
        self.logical_bytes = 0
        self.records = []

    def pack(self, tensor):
        size = tensor.numel() * tensor.element_size()
        self.logical_bytes += size
        self.records.append({
            "shape": tuple(tensor.shape),
            "dtype": str(tensor.dtype),
            "device": str(tensor.device),
            "bytes": size,
        })
        return tensor

    def unpack(self, packed):
```

```
        return packed

def E01(model, input_tensor):
    counter = SavedByteCounter()
    with torch.autograd.graph.saved_tensors_hooks(
            counter.pack, counter.unpack):
        output = model(input_tensor)
    return output, counter
```

Part 6 - Measurement, Validation, and Failure Analysis

The counter sums logical sizes and can count aliases repeatedly; add storage range canonicalization for physical estimates. Returning the original tensor retains ordinary VRAM and is for measurement only. Hooks apply only to operations executed inside the context, and their Python work can perturb timing.

Part 7 - Engineering Interpretation and Philosophy

Saved-tensor measurement locates the history autograd truly requires. It turns activation offload from a broad model option into a targeted intervention on specific long-lived storage.

19.20.3 Exercise 02

Exercise Title: Inspect Which Intermediate Tensors Autograd Saves for Backward and Estimate Their Total Memory Footprint

Part 1 - Exercise Contract and Why It Matters

Inspect saved tensors by producer scope and derivative role, identify aliases, and estimate unique physical footprint and lifetime. Avoid relying on private `grad_fn` attribute names as the primary engineering interface.

Part 2 - System and Memory Mental Model

Derivative formulas save operands, results, masks, indices, or statistics according to operation. Packing may break Python object identity to avoid cycles while preserving storage or value. A tensor saved several times has several logical uses but may occupy one physical storage until all uses finish.

Part 3 - Quantitative Prediction Before Execution

Record logical bytes for each save, then canonicalize by storage identity and byte range. Calculate logical total, unique range estimate, reuse count, and largest candidates. Combine save time with unpack time to estimate the interval over which offloading could free VRAM.

Part 4 - Experimental Design and Instrumentation

Maintain an active producer-layer stack through forward hooks and associate each pack call with the current scope. During unpack, record backward order. Compare linear, normalization, activation, dropout, and residual blocks. Validate totals against memory counters and repeat with multiple input shapes.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class SavedTensorRecord:
    sequence: int
    producer: str
    shape: tuple
    dtype: str
    device: str
    size_bytes: int
    unpack_count: int = 0

class SavedTensorInventory:
    def __init__(self):
        self.records = []
        self.active_producer = "unknown"

    def pack(self, tensor):
        record = SavedTensorRecord(
            len(self.records), self.active_producer,
            tuple(tensor.shape), str(tensor.dtype),
            str(tensor.device),
            tensor.numel() * tensor.element_size())
        self.records.append(record)
        return record.sequence, tensor

    def unpack(self, packed):
        sequence, tensor = packed
        self.records[sequence].unpack_count += 1
        return tensor

def E02():
    return SavedTensorInventory()
```

Part 6 - Measurement, Validation, and Failure Analysis

This inventory returns the original tensor and therefore does not offload it. An active Python scope can be wrong for asynchronous or nested module behavior; use carefully nested hooks and operator profiling for stronger attribution. Private autograd internals are useful diagnostics but not stable contracts.

Part 7 - Engineering Interpretation and Philosophy

Inspection reveals that activation memory is created by derivative requirements, not by a vague property called depth. Good policies follow actual saved values, their identities, and their future consumers.

19.20.4 Exercise 03

Exercise Title: Implement Custom saved_tensors_hooks That Move Saved CUDA Activations to CPU and Restore Them During Backward

Part 1 - Exercise Contract and Why It Matters

Implement correctness-first pack and unpack hooks that copy CUDA saved tensors to CPU, preserve metadata, and restore them to the original device when backward requests them. Begin with blocking semantics before optimizing asynchronously.

Part 2 - System and Memory Mental Model

The pack hook's return value becomes the object stored in the graph. It can be a record containing a CPU tensor and original device. The unpack hook must produce a tensor equivalent to the original saved value. CPU authority persists between forward and backward; H2D occurs on demand and may become a backward stall.

Part 3 - Quantitative Prediction Before Execution

VRAM savings approach the size of eligible CUDA saves minus transfer overlap and boundary state. RAM increases by offloaded payload. Each saved byte generally crosses D2H and H2D once, though repeated unpack may add reloads unless cached. Predict total traffic and lower-bound time from measured bandwidth.

Part 4 - Experimental Design and Instrumentation

Use a deterministic model and record pack/unpack order, bytes, devices, timing, RAM, and VRAM. Compare output, loss, gradients, and updates with ordinary training. Exercise CPU saves, zero-sized tensors, noncontiguous views, several dtypes, and repeated unpack.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class CpuSavedTensor:
    tensor: object
    original_device: object

class BlockingActivationOffload:
    def __init__(self):
        self.d2h_bytes = 0
        self.h2d_bytes = 0

    def pack(self, tensor):
        if tensor.device.type != "cuda":
            return tensor
        cpu_tensor = tensor.detach().to("cpu")
        size = tensor.numel() * tensor.element_size()
        self.d2h_bytes += size
        return CpuSavedTensor(cpu_tensor, tensor.device)

    def unpack(self, packed):
        if not isinstance(packed, CpuSavedTensor):
            return packed
```

```
        size = packed.tensor.numel() * packed.tensor.element_size()
        self.h2d_bytes += size
        return packed.tensor.to(packed.original_device)

def E03(model, input_tensor):
    manager = BlockingActivationOffload()
    with torch.autograd.graph.saved_tensors_hooks(
            manager.pack, manager.unpack):
        output = model(input_tensor)
    return output, manager
```

Part 6 - Measurement, Validation, and Failure Analysis

`detach()` here removes the copied CPU tensor from a new autograd history; the original graph still owns the packed record and uses the unpacked value for its derivative. Blocking transfers are safe but slow. View strides and aliasing may not be preserved by every copy path, so validate operations requiring layout.

Part 7 - Engineering Interpretation and Philosophy

The custom hook makes the storage substitution explicit: autograd retains a recoverable CPU value instead of a CUDA value. Correctness-first blocking code is the baseline against which every asynchronous optimization must be judged.

19.20.5 Exercise 04

Exercise Title: Verify Gradient Equivalence Between Normal Training and CPU-Offloaded Saved Activations

Part 1 - Exercise Contract and Why It Matters

Compare ordinary and offloaded training from identical model, optimizer, batch, seed, and mode. Verify outputs, losses, every parameter gradient, updated parameters, and optimizer state before accepting memory savings.

Part 2 - System and Memory Mental Model

Offload should alter only saved-tensor residency. Pack and unpack must preserve value, dtype, shape, device semantics, and required layout. Stochastic layers, mutable buffers, mixed precision, and nondeterministic kernels can complicate equivalence even when storage movement is correct.

Part 3 - Quantitative Prediction Before Execution

Set absolute and relative tolerances appropriate to dtype and device. Expect exact or close losses and gradients for deterministic paths. Compare maximum error and allclose for each named tensor; one aggregate norm can conceal a localized corrupted activation.

Part 4 - Experimental Design and Instrumentation

Deep-copy initial state, pre-generate data, and run one completed step per mode in isolated trials. Repeat several seeds and include dropout with controlled RNG. Collect offloaded bytes, peak VRAM, RAM, time, output error, gradient error, parameter error, optimizer-state error, and finite-value checks.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def named_gradient_report(reference, candidate, atol, rtol):
    candidate_parameters = dict(candidate.named_parameters())
    report = {}
    for name, reference_parameter in reference.named_parameters():
        candidate_parameter = candidate_parameters[name]
        first = reference_parameter.grad
        second = candidate_parameter.grad
        if first is None or second is None:
            report[name] = first is second
            continue
        close = torch.allclose(first, second, atol=atol, rtol=rtol)
        maximum = (first - second).abs().max().item()
        report[name] = (close, maximum)
    return report

def E04(reference_model, offloaded_model):
    return named_gradient_report(
        reference_model, offloaded_model, 1e-6, 1e-5)
```

Part 6 - Measurement, Validation, and Failure Analysis

Matching gradients before optimizer step is necessary but incomplete; compare updates and optimizer state too. Reusing one model sequentially changes RNG and optimizer history. A synchronization bug may pass small tensors by chance, so repeat with large pinned transfers and deliberate stream pressure.

Part 7 - Engineering Interpretation and Philosophy

Gradient equivalence proves that the CPU copy is a faithful representation of training history. Without that proof, lower VRAM may simply mean backward used stale, incomplete, or different values.

19.20.6 Exercise 05

Exercise Title: Use torch.autograd.graph.save_on_cpu() to Offload Saved Forward Tensors Without Writing Custom Hooks

Part 1 - Exercise Contract and Why It Matters

Apply PyTorch's built-in `save_on_cpu` context around a measured model region, then verify peak VRAM reduction, RAM growth, step latency, and gradient equivalence without maintaining custom pack and unpack logic.

Part 2 - System and Memory Mental Model

Operations executed inside the context save their backward tensors on CPU and restore them to the original device when needed. Context scope matters: wrapping only one block affects that block's saves; wrapping an entire forward affects all eligible saves created inside.

The built-in mechanism reduces implementation risk but does not eliminate D2H and H2D cost.

Part 3 - Quantitative Prediction Before Execution

Predict RAM increase and transfer traffic from the saved tensors observed in the same region. Peak VRAM reduction can be smaller than logical bytes if another region defines the peak or transfer copies overlap in lifetime. Compare pageable and pinned behavior separately in the next exercise.

Part 4 - Experimental Design and Instrumentation

Run ordinary and built-in-offload steps from cloned state. Record forward, backward, total time, peak allocated and reserved VRAM, process RAM, output, loss, gradients, and update. Test nested scopes and prove only operations created inside the intended region are affected.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def forward_with_cpu_saved_tensors(model, value, pin_memory=False):
    with torch.autograd.graph.save_on_cpu(
            pin_memory=pin_memory,
            device_type="cuda"):
        output = model(value)
    return output

def E05(model, value):
    torch.cuda.reset_peak_memory_stats()
    output = forward_with_cpu_saved_tensors(
        model, value, pin_memory=False)
    return output, torch.cuda.max_memory_allocated()
```

Part 6 - Measurement, Validation, and Failure Analysis

The context applies during forward graph construction; backward can occur after the context exits. CPU RAM may remain high until backward releases the packed objects. Device movement inside the region and non-CUDA accelerators require explicit testing. A built-in API still needs numerical validation for the actual model and precision.

Part 7 - Engineering Interpretation and Philosophy

`save_on_cpu` provides a strong correctness baseline and a compact production option. Custom hooks are justified only when selective policy, pooling, asynchronous scheduling, or telemetry delivers measured additional value.

19.20.7 Exercise 06

Exercise Title: Compare save_on_cpu(pin_memory=False) and save_on_cpu(pin_memory=True) by Peak VRAM, Host RAM, and Step Latency

Part 1 - Exercise Contract and Why It Matters

Compare pageable and pinned CPU storage modes under identical saved tensors. Measure complete forward and backward behavior, including pinned allocation cost, host pressure, transfer capability, peak VRAM, and step latency.

Part 2 - System and Memory Mental Model

Pageable CPU memory is easier for the operating system to manage but does not provide the same asynchronous DMA path. Pinned pages can accelerate or overlap copies while consuming a scarce host resource. Pinning many short-lived saved tensors can add allocation overhead and fragment a workload into small transfers.

Part 3 - Quantitative Prediction Before Execution

Both modes offload similar logical payload, so ideal VRAM saving is similar. Pinned mode adds locked RAM equal to relevant packed storage and can reduce H2D stall. Predict a crossover by tensor size and lifetime; for small tensors, fixed pin and launch overhead may dominate any bandwidth benefit.

Part 4 - Experimental Design and Instrumentation

Run modes in isolated processes with the same warmup, data, state, and cache conditions. Record RSS, system available RAM, pinned payload if observable, pack and unpack counts, D2H and H2D completion, forward and backward time, peak VRAM, throughput, and gradients. Sweep tensor size and saved-tensor count.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class SaveOnCpuResult:
    pin_memory: bool
    peak_vram: int
    peak_ram: int
    step_ms: float
    gradient_error: float

def run_save_on_cpu_forward(model, value, pin_memory):
    with torch.autograd.graph.save_on_cpu(
            pin_memory=pin_memory,
            device_type="cuda"):
        return model(value)

def compare_save_modes(pageable, pinned):
    return {
        "vram_difference": pinned.peak_vram - pageable.peak_vram,
        "ram_difference": pinned.peak_ram - pageable.peak_ram,
        "step_difference_ms": pinned.step_ms - pageable.step_ms,
        "pageable_gradient_error": pageable.gradient_error,
        "pinned_gradient_error": pinned.gradient_error,
    }
```

```
def E06(pageable, pinned):
    return compare_save_modes(pageable, pinned)
```

Part 6 - Measurement, Validation, and Failure Analysis

Process RSS does not identify locked pages precisely, and system noise affects available RAM. A lower Python submission time is not completed transfer time. Pinned mode can harm the machine if used without a host budget. Compare repeated steady-state steps, not only first-time allocation.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory is valuable when it shortens the backward critical path enough to justify locked host capacity. The best mode is measured per workload, not chosen from the word asynchronous alone.

19.20.8 Exercise 07

Exercise Title: Reproduce an Incorrect Result Caused by Accessing Asynchronously Offloaded Pinned CPU Data Before the Transfer Completes

Part 1 - Exercise Contract and Why It Matters

Deliberately omit the dependency between D2H completion and later H2D reload, then reproduce stale or corrupted activation recovery under stream pressure. Capture the failure as a test and never use the unsafe hook in real training.

Part 2 - System and Memory Mental Model

Non-blocking D2H returns after enqueue, while the pinned destination may still be changing. If unpack reads it on another stream without waiting, the reload can race the offload. Reusing or modifying the pinned buffer introduces a second race. Correctness can appear accidental for small copies or idle hardware.

Part 3 - Quantitative Prediction Before Execution

The race window grows with activation size, copy-engine contention, and immediate backward demand. Predict higher failure probability when a long operation delays D2H and another stream begins H2D. Compare checksums before submission, after true completion, and after unsafe reload.

Part 4 - Experimental Design and Instrumentation

Run only on disposable synthetic tensors. Use large patterned activations, separate streams, deliberate competing work, and repeated seeds. Record events without waiting, unsafe result error, and safe reference error. Mark a run inconclusive rather than correct when the race does not manifest.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class UnsafePacked:
    cpu_tensor: object
    original_device: object

class UnsafeActivationHooks:
    def __init__(self):
        self.offload_stream = torch.cuda.Stream()

    def pack(self, tensor):
        if tensor.device.type != "cuda":
            return tensor
        destination = torch.empty_like(
            tensor, device="cpu", pin_memory=True)
        with torch.cuda.stream(self.offload_stream):
            destination.copy_(tensor, non_blocking=True)
        return UnsafePacked(destination, tensor.device)

    def unpack(self, packed):
        if not isinstance(packed, UnsafePacked):
            return packed
        # Intentionally unsafe: no wait for D2H completion.
        return packed.cpu_tensor.to(
            packed.original_device, non_blocking=True)

def E07():
    return UnsafeActivationHooks()
```

Part 6 - Measurement, Validation, and Failure Analysis

This code is intentionally incorrect and belongs only in a controlled negative test. It also fails to protect the CUDA source from allocator reuse on the side stream. Lack of observed corruption does not establish safety; asynchronous ordering must be proven through events and lifetimes.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony removes waiting from the caller, not dependencies from the program. A transfer without an explicit completion relationship is unfinished state, and using it is a correctness violation even when timing happens to hide the bug.

19.20.9 Exercise 08

Exercise Title: Build Correct Synchronization Around Pinned Activation Offloading Without Falling Back to Device-Wide Synchronization Everywhere

Part 1 - Exercise Contract and Why It Matters

Repair asynchronous activation offload with producer readiness, dedicated D2H stream, completion event, source lifetime protection, pinned ownership, and a consumer-stream wait. Avoid device-wide synchronization and verify gradient equivalence under stress.

Part 2 - System and Memory Mental Model

The offload stream waits for the forward producer event, then copies to pinned RAM and records D2H completion. The source records use by the side stream so the allocator cannot recycle it prematurely. Unpack makes the current backward stream wait for D2H before H2D. Stream ordering then delays consumers until the restored CUDA tensor is ready.

Part 3 - Quantitative Prediction Before Execution

Event operations add small fixed cost but allow unrelated work to continue. Peak memory includes source and pinned destination until D2H completes and the restored destination during H2D. Compare visible stall with device-wide synchronization and calculate overlap recovered.

Part 4 - Experimental Design and Instrumentation

Stress with large tensors, multiple saves, side-stream compute, and immediate backward. Verify checksums and gradients over many repetitions. Export a CUDA trace showing event waits rather than global barriers. Record D2H/H2D bytes, wait time, peak VRAM, pinned RAM, and completed step time.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class SafePacked:
    cpu_tensor: object
    original_device: object
    d2h_done: object

class SafeActivationHooks:
    def __init__(self):
        self.offload_stream = torch.cuda.Stream()

    def pack(self, tensor):
        if tensor.device.type != "cuda":
            return tensor
        destination = torch.empty_like(
            tensor, device="cpu", pin_memory=True)
        producer_ready = torch.cuda.Event()
        producer_ready.record(torch.cuda.current_stream())
        done = torch.cuda.Event()
        with torch.cuda.stream(self.offload_stream):
            self.offload_stream.wait_event(producer_ready)
            destination.copy_(tensor, non_blocking=True)
            tensor.record_stream(self.offload_stream)
            done.record(self.offload_stream)
```

```
        return SafePacked(destination, tensor.device, done)

    def unpack(self, packed):
        if not isinstance(packed, SafePacked):
            return packed
        current = torch.cuda.current_stream(packed.original_device)
        current.wait_event(packed.d2h_done)
        return packed.cpu_tensor.to(
            packed.original_device, non_blocking=True)

def E08():
    return SafeActivationHooks()
```

Part 6 - Measurement, Validation, and Failure Analysis

The packed object retains pinned storage and the event. The returned H2D tensor is ordered on the current stream; unusual multi-device graphs need device-aware stream handling. Fresh pinned allocation in every pack remains expensive and is replaced by a bounded pool later. Events must be created on compatible devices.

Part 7 - Engineering Interpretation and Philosophy

Correct synchronization names the exact dependency instead of stopping the entire device. Events preserve concurrency because they make only the consumer of a particular activation wait for the transfer that produces it.

19.20.10 Exercise 09

Exercise Title: Offload Activations from Only Selected Model Blocks and Determine Which Blocks Provide the Best VRAM Saving per Transfer Byte

Part 1 - Exercise Contract and Why It Matters

Apply saved-tensor hooks only around selected block forwards, measure actual peak reduction and transfer traffic, and rank blocks by useful peak bytes saved per byte moved and per millisecond of stall.

Part 2 - System and Memory Mental Model

Hook scope determines which autograd saves are packed. A block can save many bytes outside the global peak interval and therefore offer little peak benefit. Every offloaded byte generally incurs both D2H and H2D traffic. Small tensors may cost more in launches and bookkeeping than they save in VRAM.

Part 3 - Quantitative Prediction Before Execution

For block i, calculate measured marginal peak reduction divided by total D2H plus H2D bytes. Also report stall per saved MiB and RAM residency. Recompute marginal benefit after selecting another block because liveness and the peak location can change.

Part 4 - Experimental Design and Instrumentation

Profile each block alone, then incrementally combine high-ranked blocks. Use identical model state and inputs. Record packed tensor count and bytes, unique storage, pack/unpack

time, peak VRAM, RAM, total step time, output and gradient error, and whether the block overlaps the original peak.

Part 5 - PyTorch/CUDA Implementation

```
from torch import nn

class SelectiveActivationOffload(nn.Module):
    def __init__(self, blocks, selected, manager):
        super().__init__()
        self.blocks = nn.ModuleList(blocks)
        self.selected = set(selected)
        self.manager = manager

    def forward(self, value):
        result = value
        for index, block in enumerate(self.blocks):
            if index in self.selected:
                with torch.autograd.graph.saved_tensors_hooks(
                        self.manager.pack, self.manager.unpack):
                    result = block(result)
            else:
                result = block(result)
        return result

def E09(blocks, selected, manager):
    return SelectiveActivationOffload(blocks, selected, manager)
```

Part 6 - Measurement, Validation, and Failure Analysis

The code requires `torch` imported by the surrounding program; include it in a standalone script. Nested or overlapping hook contexts need explicit tests. One block's output may be saved by an operation executed in the next block, so producer attribution and context attribution are related but not identical.

Part 7 - Engineering Interpretation and Philosophy

Selective offload spends bandwidth only where tensor lifetime creates useful peak relief. Its quality is measured by avoided VRAM pressure, not by the gross number of bytes successfully copied to CPU.

19.20.11 Exercise 10

Exercise Title: Build an Activation Profiler That Records Tensor Size, Producer Layer, Lifetime, Device, and Backward Reuse Point

Part 1 - Exercise Contract and Why It Matters

Build an observation layer around autograd saved tensors. For every save, the profiler must record shape, dtype, device, logical producer, bytes, save order, unpack order, and elapsed lifetime. The result is not merely a list of large tensors: it is a liveness trace that explains

which values remain resident across the forward/backward boundary and when they become useful again.

Part 2 - System and Memory Mental Model

Autograd saves values rather than "layers." One operator can save several tensors, shared storage can appear through several views, and an activation created in one module may be saved by an operation in another module. A hook observes the save and restore boundary, while a module scope supplies a useful but approximate producer label. Lifetime is the interval from pack to first unpack; reuse order is often more actionable than wall-clock lifetime because the latter changes with hardware and scheduling.

Part 3 - Quantitative Prediction Before Execution

For tensor i, estimate $b_i = n_i s_i$ bytes, where n_i is the element count and s_i is element size. Predict peak saved bytes from the tensors live at each forward boundary, not by summing all saves blindly. Estimate transfer work as $2b_i$ when one D2H and one H2D copy are required. Predict that late backward consumers have longer reuse distance and therefore offer more time for prefetch, but also occupy host memory longer.

Part 4 - Experimental Design and Instrumentation

Run one warmup and one measured step with deterministic inputs. Attach module scope labels, reset CUDA peak statistics, and synchronize only at benchmark boundaries. Compare logical bytes, unique-storage bytes, peak VRAM, and hook overhead. Keep CPU timestamps separate from CUDA-event timing: they answer different questions and do not share a guaranteed clock domain.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import time
import torch

@dataclass
class ActivationRecord:
    record_id: int
    producer: str
    shape: tuple
    dtype: object
    device: object
    size_bytes: int
    save_order: int
    unpack_order: int
    saved_at: float
    unpacked_at: float

class ActivationProfiler:
    def __init__(self):
        self.records = []
        self.scope = "unscoped"
        self.unpack_count = 0
```

```
    def set_scope(self, name):
        self.scope = name

    def pack(self, tensor):
        size_bytes = tensor.numel() * tensor.element_size()
        record = ActivationRecord(
            len(self.records), self.scope, tuple(tensor.shape),
            tensor.dtype, tensor.device, size_bytes,
            len(self.records), -1, time.perf_counter(), -1.0)
        self.records.append(record)
        return (record.record_id, tensor)

    def unpack(self, packed):
        record_id, tensor = packed
        record = self.records[record_id]
        record.unpack_order = self.unpack_count
        record.unpacked_at = time.perf_counter()
        self.unpack_count += 1
        return tensor

    def report(self):
        rows = []
        for record in self.records:
            lifetime = record.unpacked_at - record.saved_at
            rows.append((record.record_id, record.producer,
                         record.size_bytes, lifetime,
                         record.unpack_order))
        return rows

def E10():
    return ActivationProfiler()
```

Part 6 - Measurement, Validation, and Failure Analysis

Identity packing intentionally leaves memory on CUDA; this exercise measures the baseline before changing residency. A tensor unpacked more than once needs all reuse points, not one overwritten field. Storage aliases can inflate the logical sum, while Python timing includes scheduling and hook overhead. Validate the inventory by comparing a no-hook step, an identity-hook step, and allocator peaks; reject any profiler that changes outputs or gradients.

Part 7 - Engineering Interpretation and Philosophy

Memory optimization begins with liveness evidence. Size says how much can be saved, lifetime says how long the capacity is recovered, and reuse order says whether the data can return before it is needed. None of those dimensions is a safe substitute for the others.

19.20.12 Exercise 11

Exercise Title: Classify Saved Activations as GPU-Resident or CPU-Offloaded from Their Size, Lifetime, Reuse Distance, and Transfer Cost

Part 1 - Exercise Contract and Why It Matters

Turn the profiler output into an explicit placement decision. The classifier must explain why each activation remains in VRAM or moves to RAM, enforce hard correctness and capacity constraints, and expose the cost assumptions behind its answer. A useful policy is auditable; it does not hide a bandwidth gamble inside a single unexplained threshold.

Part 2 - System and Memory Mental Model

Keeping consumes VRAM for the tensor's remaining lifetime but creates no copy. Offloading consumes host capacity and schedules D2H plus H2D traffic. Long reuse distance increases the opportunity to hide those copies, whereas high reuse count can make eviction expensive. The decision also depends on global pressure: a tensor that should normally stay may need to move when keeping it would cross the VRAM high watermark.

Part 3 - Quantitative Prediction Before Execution

Estimate transfer time as $t_{off} = b/B_{D2H} + b/B_{H2D} + t_{launch} + t_{queue}$. Compare it with the visible residency value $b\,t_{life}$ and predicted overlap window. Calculate both an optimistic stall, $\max(0, t_{H2D} - t_{prefetch})$, and a pessimistic stall with no overlap. A policy must report its measured bandwidth inputs and must not treat nominal PCIe bandwidth as achieved application bandwidth.

Part 4 - Experimental Design and Instrumentation

Calibrate D2H and H2D using representative pinned tensors, then replay recorded activation metadata under several VRAM/RAM budgets. Measure decision accuracy by actual peak relief, transfer bytes, host peak, and exposed backward stall. Include short-lived large values, long-lived small values, repeated consumers, and a budget that makes some offloading mandatory.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ActivationCost:
    name: str
    size_bytes: int
    lifetime_ms: float
    reuse_distance_ms: float
    reuse_count: int
    d2h_ms: float
    h2d_ms: float

@dataclass
class PlacementDecision:
    name: str
    policy: str
    predicted_stall_ms: float
    reason: str

def classify_activation(item, vram_headroom, ram_headroom):
```

```
    if item.size_bytes > ram_headroom:
        return PlacementDecision(
            item.name, "keep", 0.0, "insufficient host budget")
    if item.size_bytes > vram_headroom:
        stall = max(0.0, item.h2d_ms - item.reuse_distance_ms)
        return PlacementDecision(
            item.name, "offload", stall, "required by VRAM budget")
    transfer_ms = item.d2h_ms + item.h2d_ms
    hidden_ms = min(item.reuse_distance_ms, transfer_ms)
    visible_ms = transfer_ms - hidden_ms
    residency_score = item.size_bytes * item.lifetime_ms
    transfer_score = item.size_bytes * (visible_ms + item.reuse_count)
    if residency_score > transfer_score:
        return PlacementDecision(
            item.name, "offload", visible_ms,
            "residency value exceeds transfer score")
    return PlacementDecision(
        item.name, "keep", 0.0, "transfer is not justified")

def E11(items, vram_headroom, ram_headroom):
    decisions = []
    for item in items:
        decision = classify_activation(
            item, vram_headroom, ram_headroom)
        decisions.append(decision)
    return decisions
```

Part 6 - Measurement, Validation, and Failure Analysis

The illustrative score mixes units deliberately only after normalization would be added in a real controller; raw byte-milliseconds and byte-weighted counts must not be tuned as though they were universal. Recalibrate after decisions, because concurrent transfers contend and the peak location moves. Fail closed to keeping when metadata, ownership, or synchronization safety is unknown.

Part 7 - Engineering Interpretation and Philosophy

Placement is a constrained scheduling problem, not a tensor-size rule. The right question is not "is this activation large?" but "what scarce resource will be spent if it stays, and what scarce resource will be spent if it moves?"

19.20.13 Exercise 12

Exercise Title: Implement an Activation Offload Threshold That Moves Only Saved Tensors Larger Than a Configurable Byte Limit

Part 1 - Exercise Contract and Why It Matters

Implement the simplest controllable policy: offload only CUDA tensors whose logical byte size reaches a chosen limit. Sweep the limit rather than choosing it by intuition, preserve all

values exactly, and demonstrate where fewer tiny copies improve latency without sacrificing the desired peak-VRAM reduction.

Part 2 - System and Memory Mental Model

Every saved tensor passes through the hook. Returning the original tensor keeps it alive on CUDA; returning a CPU representation permits the graph to release the hook's CUDA reference after packing. The threshold reduces launch, allocation, event, and metadata overhead, but it ignores lifetime and peak overlap. It is therefore a baseline policy, not an optimal one.

Part 3 - Quantitative Prediction Before Execution

From the E10 histogram, compute tensor count and bytes above each candidate threshold. Predict traffic as twice the selected bytes and pinned RAM as the maximum simultaneously live selected bytes. Predict diminishing returns when lowering the threshold adds many objects but little total capacity.

Part 4 - Experimental Design and Instrumentation

Test thresholds of zero, selected quantiles, one MiB, and infinity. Hold model, batch, seeds, and optimizer fixed. Record selected count, selected bytes, peak VRAM, host RAM, step time, D2H/H2D bandwidth, output error, and gradient error. Warm the allocator and use CUDA events around completed GPU work.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ThresholdPacked:
    tensor: object
    original_device: object
    was_offloaded: bool

class ThresholdOffload:
    def __init__(self, threshold_bytes):
        self.threshold_bytes = threshold_bytes
        self.offloaded_bytes = 0
        self.offloaded_count = 0

    def pack(self, tensor):
        size_bytes = tensor.numel() * tensor.element_size()
        should_move = tensor.device.type == "cuda"
        should_move = should_move and size_bytes >= self.threshold_bytes
        if not should_move:
            return ThresholdPacked(tensor, tensor.device, False)
        cpu_tensor = tensor.to("cpu")
        self.offloaded_bytes += size_bytes
        self.offloaded_count += 1
        return ThresholdPacked(cpu_tensor, tensor.device, True)
```

```
    def unpack(self, packed):
        if not packed.was_offloaded:
            return packed.tensor
        return packed.tensor.to(packed.original_device)

def E12(threshold_bytes):
    return ThresholdOffload(threshold_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Blocking copies make this reference implementation easy to validate but slow; replace its transport with the event-safe mechanism from E08 after proving policy correctness. Views and shared storage make logical bytes differ from unique bytes. A lower peak with worse throughput may still be correct when it enables an otherwise impossible batch, so report capacity and speed separately.

Part 7 - Engineering Interpretation and Philosophy

A threshold is valuable because it is understandable, reproducible, and easy to falsify. Its limitation is equally important: size is only a proxy for the actual objective, which is useful peak relief per unit of transfer and stall.

19.20.14 Exercise 13

Exercise Title: Build a Pinned CPU Activation Buffer Pool and Reuse Host Storage Instead of Allocating New Offload Buffers Repeatedly

Part 1 - Exercise Contract and Why It Matters

Replace per-save pinned allocation with a bounded, reusable host buffer pool. The pool must lease storage by capacity and dtype, prevent reuse while a D2H or H2D operation still references it, respect a pinned-RAM budget, and expose hit, miss, wait, and fallback statistics.

Part 2 - System and Memory Mental Model

Pinned pages accelerate asynchronous DMA but are a constrained system resource. A buffer is not free merely because Python no longer needs its previous value; it is free only after every stream using that storage has completed. Pooling amortizes pinning cost and stabilizes host allocation, while careless pooling creates silent corruption by handing the same pages to two in-flight tensors.

Part 3 - Quantitative Prediction Before Execution

Choose size classes from the activation histogram. Predict pool capacity as the sum of class capacity times slot count, internal waste as capacity minus requested bytes, and required concurrency from peak in-flight offloads. A larger pool should reduce allocation misses until transfer concurrency is covered; beyond that point it consumes RAM without increasing throughput.

Part 4 - Experimental Design and Instrumentation

Compare fresh pinned allocation, exact-size pooling, and rounded size classes. Record pinned allocation count, pool hit rate, bytes reserved, internal waste, event-wait time, transfer

throughput, host RSS, peak VRAM, and gradients. Stress variable shapes and deliberately exhaust the budget to verify a safe fallback.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class PinnedLease:
    buffer: object
    capacity: int
    dtype: object
    ready_event: object
    in_use: bool

class PinnedActivationPool:
    def __init__(self, budget_bytes):
        self.budget_bytes = budget_bytes
        self.reserved_bytes = 0
        self.leases = []
        self.hits = 0
        self.misses = 0

    def _completed(self, lease):
        if lease.ready_event is None:
            return True
        return lease.ready_event.query()

    def acquire(self, numel, dtype):
        requested = numel * torch.empty((), dtype=dtype).element_size()
        for lease in self.leases:
            compatible = lease.dtype == dtype and lease.capacity >= numel
            if compatible and lease.in_use and self._completed(lease):
                lease.in_use = False
            if compatible and not lease.in_use:
                lease.in_use = True
                lease.ready_event = None
                self.hits += 1
                return lease
        if self.reserved_bytes + requested > self.budget_bytes:
            raise RuntimeError("pinned activation pool budget exceeded")
        buffer = torch.empty(numel, dtype=dtype, pin_memory=True)
        lease = PinnedLease(buffer, numel, dtype, None, True)
        self.leases.append(lease)
        self.reserved_bytes += requested
        self.misses += 1
        return lease
```

```
    def release_after(self, lease, event):
        lease.ready_event = event

def E13(budget_bytes):
    return PinnedActivationPool(budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The pool stores flat capacity; the manager must create a correctly shaped view without exceeding it. This minimal version scans linearly and marks a lease reusable only after its completion event queries true. Production code needs thread safety, per-device ownership, explicit shutdown, fragmentation policy, and either backpressure or pageable fallback when the budget is exhausted.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory is not "free speed." It converts host flexibility into DMA predictability. A bounded pool makes that exchange explicit and turns buffer lifetime from an accidental Python property into a controlled systems contract.

19.20.15 Exercise 14

Exercise Title: Prefetch Offloaded Activations Back to CUDA Before Their Backward Operation Requires Them

Part 1 - Exercise Contract and Why It Matters

Use the measured backward consumption order to start H2D reload before an activation's unpack becomes blocking. The prefetcher must preserve exact values, honor the VRAM budget, coordinate streams with events, avoid duplicate reloads, and measure how much H2D latency becomes invisible.

Part 2 - System and Memory Mental Model

Offloading creates capacity during forward but introduces a future read miss. Prefetch moves that miss earlier. Too late exposes transfer latency; too early reoccupies VRAM and may destroy the original memory saving. The correct window lies between D2H completion and the backward consumer, subject to free VRAM and copy-engine contention.

Part 3 - Quantitative Prediction Before Execution

For activation i, calculate latest safe start as $t_{need,i} - t_{H2D,i}$. Its predicted visible stall is $\max(0, t_{H2D,i} - w_i)$ for available overlap window w_i. Sum prefetched bytes that are simultaneously resident to predict the new peak. If H2D shares bandwidth with D2H, include measured contention rather than adding isolated bandwidths.

Part 4 - Experimental Design and Instrumentation

Start with a known reverse-order sequential model, then test branched graphs. Compare demand reload, one-activation lookahead, and byte-budgeted lookahead. Record submission time, transfer completion, consumer wait, reload bytes, duplicate requests, prefetched residency, peak VRAM, and total backward time.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class PrefetchedActivation:
    cpu_tensor: object
    device: object
    d2h_done: object
    cuda_tensor: object
    h2d_done: object

class ActivationPrefetcher:
    def __init__(self, device="cuda"):
        self.device = torch.device(device)
        self.reload_stream = torch.cuda.Stream(device=self.device)

    def submit(self, item):
        if item.cuda_tensor is not None:
            return
        with torch.cuda.stream(self.reload_stream):
            if item.d2h_done is not None:
                self.reload_stream.wait_event(item.d2h_done)
            restored = item.cpu_tensor.to(
                item.device, non_blocking=True)
            done = torch.cuda.Event()
            done.record(self.reload_stream)
        item.cuda_tensor = restored
        item.h2d_done = done

    def acquire(self, item):
        if item.cuda_tensor is None:
            self.submit(item)
        current = torch.cuda.current_stream(item.device)
        current.wait_event(item.h2d_done)
        item.cuda_tensor.record_stream(current)
        return item.cuda_tensor

def E14(device="cuda"):
    return ActivationPrefetcher(device)
```

Part 6 - Measurement, Validation, and Failure Analysis

The scheduler, not autograd alone, must decide when to call `submit`; an unpack hook fires at demand time and is too late to create lookahead. Dynamic graphs can invalidate a previously learned order. Hold the pinned source until H2D completion and hold the CUDA destination through consumer use. Cancel or evict speculative reloads when the graph path is not taken.

Part 7 - Engineering Interpretation and Philosophy

Prefetch does not reduce work; it changes when the work is paid. Its success is the conversion of unavoidable transfer latency into overlapped background work without silently repurchasing all the VRAM that offloading was meant to save.

19.20.16 Exercise 15

Exercise Title: Overlap Activation Reload with Backward Computation Using Dedicated CUDA Streams and Dependency Events

Part 1 - Exercise Contract and Why It Matters

Construct an explicit backward pipeline in which the compute stream processes the current block while a reload stream restores the next block's activation. Use events for true producer-consumer dependencies, avoid device-wide barriers, and prove overlap from a GPU timeline rather than from optimistic wall time.

Part 2 - System and Memory Mental Model

CUDA streams supply potential concurrency, not a promise of it. The copy engine, memory fabric, and compute kernels can contend even when operations occupy different streams. D2H completion protects the host source; H2D completion protects the CUDA consumer; `record_stream` protects allocator lifetime. Only the block needing an activation should wait for its reload event.

Part 3 - Quantitative Prediction Before Execution

For consecutive backward blocks, the ideal stage time is approximately $\max(t_{compute}, t_{H2D})$ instead of $t_{compute} + t_{H2D}$. Predict speedup from measured isolated durations, then reduce it for launch gaps, bandwidth contention, insufficient prefetch distance, and the unhidden first/last pipeline stages. Predict the extra VRAM of the current and prefetched activations.

Part 4 - Experimental Design and Instrumentation

Benchmark demand reload and event-directed overlap against a globally synchronized baseline. Record CUDA events for each reload and compute interval, export a profiler trace, and verify temporal intersection. Sweep tensor size, compute intensity, and lookahead. Compare outputs and gradients bitwise where possible and with dtype-appropriate tolerances otherwise.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ReloadTicket:
    value: object
    ready: object
    source: object

class BackwardReloadCoordinator:
    def __init__(self, device="cuda"):
        self.device = torch.device(device)
        self.reload_stream = torch.cuda.Stream(device=self.device)
```

```
    def reload(self, cpu_tensor, d2h_done=None):
        with torch.cuda.stream(self.reload_stream):
            if d2h_done is not None:
                self.reload_stream.wait_event(d2h_done)
            value = cpu_tensor.to(self.device, non_blocking=True)
            ready = torch.cuda.Event()
            ready.record(self.reload_stream)
        return ReloadTicket(value, ready, cpu_tensor)

    def consume(self, ticket):
        compute_stream = torch.cuda.current_stream(self.device)
        compute_stream.wait_event(ticket.ready)
        ticket.value.record_stream(compute_stream)
        return ticket.value

    def launch_next_while_computing(self, next_cpu, current_fn,
                                    current_value, d2h_done=None):
        ticket = self.reload(next_cpu, d2h_done)
        current_result = current_fn(current_value)
        return current_result, ticket

def E15(device="cuda"):
    return BackwardReloadCoordinator(device)
```

Part 6 - Measurement, Validation, and Failure Analysis

This coordinator demonstrates the transport dependency; integrating it with an arbitrary autograd graph requires a known execution schedule or engine-level callbacks. A short kernel may finish before H2D reaches steady bandwidth, and large kernels may saturate memory bandwidth so the nominal overlap slows both. Never infer overlap merely because Python returned before CUDA completed.

Part 7 - Engineering Interpretation and Philosophy

Concurrency is useful only when it shortens the critical path. Events express causality precisely; timelines reveal whether hardware found spare resources to execute independent work at the same time.

19.20.17 Exercise 16

Exercise Title: Compare Activation Checkpointing and Activation Offloading Under Equal VRAM Budgets and Identify Whether Compute or PCIe Bandwidth Is the Better Resource to Spend

Part 1 - Exercise Contract and Why It Matters

Compare two ways of buying activation capacity under the same enforceable VRAM budget. Checkpointing discards selected intermediates and recomputes them; offloading preserves them in RAM and transfers them twice. The experiment must match model, batch, numerical policy, and achieved peak memory before comparing step latency or throughput.

Part 2 - System and Memory Mental Model

Checkpointing spends GPU arithmetic and may repeat memory reads. Offloading spends PCIe/NVLink bandwidth, pinned RAM, copy engines, and scheduling state. Their savings overlap because both target saved forward tensors. A compute-rich but link-poor system often favors recomputation; an expensive block with spare transfer bandwidth can favor offload. Neither method removes parameters, gradients, or optimizer state.

Part 3 - Quantitative Prediction Before Execution

Estimate checkpoint cost from measured replay time t_r and offload cost from $b/B_{D2H} + b/B_{H2D}$ minus achievable overlap. Compare policies at the same peak, not the same number of blocks. Report arithmetic intensity, transferred bytes, replay FLOPs, exposed stall, host bytes, and energy when measurable.

Part 4 - Experimental Design and Instrumentation

Find configurations that meet a target peak: no optimization, full and selective checkpointing, full and selective offload. Warm each configuration, run repeated synchronized steps, and report median plus tail latency. Validate loss and parameter gradients from identical weights and random states. Repeat with compute-heavy and activation-heavy blocks.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PolicyResult:
    name: str
    peak_vram: int
    host_bytes: int
    step_ms: float
    replay_ms: float
    transfer_ms: float
    transfer_bytes: int

def within_budget(results, budget_bytes):
    accepted = []
    for result in results:
        if result.peak_vram <= budget_bytes:
            accepted.append(result)
    return accepted

def choose_resource(results, budget_bytes):
    accepted = within_budget(results, budget_bytes)
    if len(accepted) == 0:
        raise RuntimeError("no policy satisfies the VRAM budget")
    best = accepted[0]
    for result in accepted[1:]:
        if result.step_ms < best.step_ms:
            best = result
```

```
    if best.replay_ms > best.transfer_ms:
        resource = "transfer bandwidth"
    else:
        resource = "recomputation"
    return best, resource

def E16(results, budget_bytes):
    return choose_resource(results, budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The returned label describes the winning measured configuration, not a universal hardware truth. Checkpointing with stochastic layers must preserve RNG behavior; offloading must preserve transfer ordering and dtype. Account for profiler overhead and CPU RAM. If two policies miss the target peak, their speed ranking is irrelevant to the stated capacity problem.

Part 7 - Engineering Interpretation and Philosophy

Memory has a shadow price. Checkpointing pays that price in computation; offloading pays it in movement. Sound engineering measures which resource has slack on the actual system instead of declaring either mechanism inherently superior.

19.20.18 Exercise 17

Exercise Title: Build a Hybrid Policy That Recomputes Cheap Activations, Offloads Expensive Activations, and Keeps High-Reuse Activations on GPU

Part 1 - Exercise Contract and Why It Matters

Combine three actions under one VRAM and RAM budget: keep values whose repeated reuse makes movement undesirable, checkpoint regions whose forward replay is cheap, and offload values whose recomputation is expensive but transfer is affordable. Every decision must map to an executable mechanism and retain a reason suitable for debugging.

Part 2 - System and Memory Mental Model

Saved-tensor hooks can keep or offload a tensor, but they cannot reconstruct an arbitrary discarded intermediate from nothing. Recompute therefore belongs at a checkpointable function or block boundary. Hybrid planning has two levels: choose checkpoint regions, then classify remaining saved tensors for keep or offload. Shared inputs, residuals, stochastic operations, and multiple consumers couple decisions that appear independent in a flat tensor list.

Part 3 - Quantitative Prediction Before Execution

For candidate i, compare keep cost from byte-lifetime pressure, offload cost from D2H/H2D plus exposed stall, and replay cost from measured block execution. Add host-budget and VRAM-budget constraints. Recalculate after every selection because checkpointing removes a set of saves and changes the remaining peak.

Part 4 - Experimental Design and Instrumentation

Profile regions and saved tensors separately. Evaluate all-keep, checkpoint- only, offload-only, and hybrid policies at equal peak. Record policy decisions, actual bytes removed from

the peak, replay time, transfer traffic, RAM, step time, and gradient error. Test stable and dynamic control flow.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class HybridCandidate:
    name: str
    size_bytes: int
    reuse_count: int
    keep_pressure: float
    offload_ms: float
    recompute_ms: float
    checkpointable: bool

@dataclass
class HybridDecision:
    name: str
    action: str
    estimated_ms: float
    reason: str

def decide_hybrid(item, ram_available):
    if item.reuse_count > 1 and item.keep_pressure < item.size_bytes * 10.0:
        return HybridDecision(
            item.name, "keep", 0.0, "high reuse favors residency")
    if item.checkpointable and item.recompute_ms <= item.offload_ms:
        return HybridDecision(
            item.name, "recompute", item.recompute_ms,
            "block replay is cheaper than transfer")
    if item.size_bytes <= ram_available:
        return HybridDecision(
            item.name, "offload", item.offload_ms,
            "transfer is cheaper than replay")
    return HybridDecision(
        item.name, "keep", 0.0, "host budget prevents offload")

def E17(items, ram_budget):
    decisions = []
    remaining = ram_budget
    for item in items:
        decision = decide_hybrid(item, remaining)
        decisions.append(decision)
        if decision.action == "offload":
            remaining -= item.size_bytes
    return decisions
```

Part 6 - Measurement, Validation, and Failure Analysis

This greedy rule is a transparent starting point, not a global optimizer. Its scores require calibration and its ordering affects the answer. Implement "recompute" with PyTorch activation checkpointing around the named region and "offload" with safe saved-tensor hooks; never pretend an unpack hook alone can regenerate a discarded value. Validate peak constraints after executing the combined plan.

Part 7 - Engineering Interpretation and Philosophy

Hybrid policy recognizes that activations have different economic character. Uniform treatment is simple but wasteful; disciplined heterogeneity spends compute, bandwidth, and capacity only where each resource produces the greatest reduction in the critical memory peak.

19.20.19 Exercise 18

Exercise Title: Stress-Test Activation Offloading with Long Transformer Sequences and Diagnose Host RAM Pressure, Transfer Bottlenecks, and Backward Stalls

Part 1 - Exercise Contract and Why It Matters

Increase sequence length until activation offloading meets its practical limits. The stress test must distinguish CUDA OOM avoidance from a healthy system: it must detect host growth, pinned-memory exhaustion, transfer-queue backlog, backward starvation, allocator fragmentation, and numerical failure before the operating system or CUDA runtime terminates the job.

Part 2 - System and Memory Mental Model

Transformer activation bytes grow with batch, sequence, width, layers, and the attention algorithm; conventional attention can also create quadratic score storage. Offloading moves part of this pressure to RAM and the interconnect. As context grows, a pipeline can remain below the VRAM limit while becoming slower every step because queued H2D reloads lie on the backward critical path.

Part 3 - Quantitative Prediction Before Execution

Before each run, predict saved bytes, host peak, traffic per step, and minimum copy time from measured bandwidth. Estimate sustainable traffic by comparing bytes per step times steps per second with achieved link bandwidth. Define stop margins below both VRAM and RAM capacity and predict the sequence length at which either margin is crossed.

Part 4 - Experimental Design and Instrumentation

Sweep context geometrically, then refine near failure. Warm every shape and record median and p95 step time, peak allocated/reserved VRAM, RAM RSS, pinned pool bytes, D2H/H2D bytes, queue depth, consumer wait, recomputation, and loss. Keep an unoptimized baseline at smaller lengths. Persist the last safe sample and stop proactively instead of relying on a destructive host OOM.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
```

```
@dataclass
class StressSample:
    sequence_length: int
    peak_vram: int
    reserved_vram: int
    host_rss: int
    pinned_bytes: int
    transfer_bytes: int
    queue_depth: int
    backward_wait_ms: float
    step_ms: float
    finite: bool

class ActivationStressGuard:
    def __init__(self, vram_limit, ram_limit, queue_limit):
        self.vram_limit = vram_limit
        self.ram_limit = ram_limit
        self.queue_limit = queue_limit
        self.samples = []

    def add(self, sample):
        self.samples.append(sample)
        reasons = []
        if sample.peak_vram >= self.vram_limit:
            reasons.append("VRAM margin exhausted")
        if sample.host_rss + sample.pinned_bytes >= self.ram_limit:
            reasons.append("host RAM margin exhausted")
        if sample.queue_depth >= self.queue_limit:
            reasons.append("transfer queue is unstable")
        if not sample.finite:
            reasons.append("non-finite numerical result")
        return reasons

    def last_safe(self):
        safe = None
        for sample in self.samples:
            reasons = self.add_check(sample)
            if len(reasons) == 0:
                safe = sample
        return safe

    def add_check(self, sample):
        reasons = []
        if sample.peak_vram >= self.vram_limit:
            reasons.append("VRAM")
        if sample.host_rss + sample.pinned_bytes >= self.ram_limit:
            reasons.append("RAM")
        if sample.queue_depth >= self.queue_limit:
```

```
            reasons.append("queue")
        if not sample.finite:
            reasons.append("numeric")
        return reasons

def E18(vram_limit, ram_limit, queue_limit):
    return ActivationStressGuard(vram_limit, ram_limit, queue_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

RSS and pinned allocations can overlap, so replace the illustrative sum with non-overlapping counters on the target platform. Queue depth that rises across steady-state steps signals arrival rate above service rate. Distinguish a temporary allocator reserve from live tensors, and distinguish transfer stall from slow compute with CUDA events and timeline evidence.

Part 7 - Engineering Interpretation and Philosophy

Avoiding CUDA OOM is necessary but insufficient. A successful memory system keeps every tier bounded and keeps movement off the critical path. Stress tests reveal where a local optimization merely relocates failure to RAM, bandwidth, latency, or correctness.

19.20.20 Exercise 19

Exercise Title: Build and Benchmark a Memory-Aware PyTorch Activation Manager That Dynamically Chooses Keep, Offload, or Recompute for Saved Tensors Under a Fixed VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Integrate profiling, policy, safe transport, bounded host buffers, prefetch, checkpoint regions, and verification into one activation manager. It must meet a fixed VRAM budget without unbounded RAM growth, explain each decision, preserve gradients, and report capacity gained together with latency paid.

Part 2 - System and Memory Mental Model

The manager has a control plane and a data plane. The control plane predicts liveness, chooses keep/offload/recompute, reserves budgets, and schedules prefetch. The data plane owns CUDA and pinned storage, streams, events, and state transitions. A packed activation moves through states such as GPU-live, D2H-in-flight, CPU-resident, H2D-in-flight, and consumed. Recompute remains a block-level checkpoint decision rather than a magical saved-tensor state.

Part 3 - Quantitative Prediction Before Execution

For every candidate, estimate peak reduction, host bytes, replay cost, transfer cost, and exposed stall. Solve for a working set below the VRAM high watermark and keep a low watermark to prevent oscillation. Reserve capacity before launching a move, update estimates from observed bandwidth and wait time, and reject a policy whose predicted RAM or transfer queue is unsustainable.

Part 4 - Experimental Design and Instrumentation

Benchmark keep-only, threshold offload, checkpoint-only, static hybrid, and the adaptive manager from identical initial states. Report peak allocated and reserved VRAM, host and

pinned peaks, traffic, pool hit rate, replay, transfer wait, step latency distribution, throughput, and gradient error. Test fixed and variable sequence lengths, forced pressure, dynamic paths, and recovery from budget denial.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ManagedActivation:
    action: str
    original_device: object
    size_bytes: int
    gpu_tensor: object
    cpu_tensor: object
    d2h_done: object
    state: str

class ActivationManager:
    def __init__(self, vram_budget, ram_budget, threshold):
        self.vram_budget = vram_budget
        self.ram_budget = ram_budget
        self.threshold = threshold
        self.ram_reserved = 0
        self.offload_stream = torch.cuda.Stream()
        self.decisions = []

    def decide(self, tensor):
        size_bytes = tensor.numel() * tensor.element_size()
        can_offload = self.ram_reserved + size_bytes <= self.ram_budget
        if tensor.device.type != "cuda":
            return "keep"
        if size_bytes >= self.threshold and can_offload:
            return "offload"
        return "keep"

    def pack(self, tensor):
        size_bytes = tensor.numel() * tensor.element_size()
        action = self.decide(tensor)
        self.decisions.append((size_bytes, action))
        if action == "keep":
            return ManagedActivation(
                action, tensor.device, size_bytes, tensor,
                None, None, "gpu-live")
        cpu_tensor = torch.empty_like(
            tensor, device="cpu", pin_memory=True)
        producer_ready = torch.cuda.Event()
        producer_ready.record(torch.cuda.current_stream(tensor.device))
```

```
        done = torch.cuda.Event()
        with torch.cuda.stream(self.offload_stream):
            self.offload_stream.wait_event(producer_ready)
            cpu_tensor.copy_(tensor, non_blocking=True)
            tensor.record_stream(self.offload_stream)
            done.record(self.offload_stream)
        self.ram_reserved += size_bytes
        return ManagedActivation(
            action, tensor.device, size_bytes, None,
            cpu_tensor, done, "d2h-in-flight")

    def unpack(self, item):
        if item.action == "keep":
            return item.gpu_tensor
        current = torch.cuda.current_stream(item.original_device)
        current.wait_event(item.d2h_done)
        restored = item.cpu_tensor.to(
            item.original_device, non_blocking=True)
        restored.record_stream(current)
        item.state = "consumed"
        self.ram_reserved -= item.size_bytes
        return restored

def E19(vram_budget, ram_budget, threshold):
    return ActivationManager(vram_budget, ram_budget, threshold)
```

Part 6 - Measurement, Validation, and Failure Analysis

This compact implementation demonstrates safe keep/offload transitions. Its VRAM budget is not yet enforced by live-liveness accounting, and its fresh pinned allocations should be replaced by E13's pool. Real integration adds multiple-device streams, alias handling, repeated unpack, exception-safe reservation release, learned prefetch order, and checkpoint-region selection. Run exact output and gradient comparisons before trusting any speed result.

Part 7 - Engineering Interpretation and Philosophy

An activation manager is a resource scheduler embedded in autograd. Its purpose is not to maximize the amount moved or recomputed; it is to preserve semantics while keeping scarce memory bounded and minimizing the new critical-path work. The final artifact is therefore the evidence trail—predictions, decisions, events, budgets, measurements, and failures—as much as the code itself.

19.21 DMM19

Chapter Title: Mixed Precision Memory Management
Specialization: Dynamic Memory Management and CUDA Systems

19.21.1 Exercise 00

Exercise Title: Build a Precise Mental Model of How float32, float16, and bfloat16 Change Tensor Memory, Numerical Range, and GPU Execution

Part 1 - Exercise Contract and Why It Matters

Build a resource model that separates storage width, numerical range, precision, accumulation dtype, kernel choice, and conversion cost. Explain why two 16-bit formats occupy the same tensor bytes but can behave very differently, and why smaller tensors do not guarantee faster execution on every GPU operation.

Part 2 - System and Memory Mental Model

A tensor with N elements consumes N times the dtype element size before allocator rounding and workspace effects. float16 and bfloat16 use two bytes per element, but float16 spends more exponent bits on significand precision while bfloat16 preserves a float32-like exponent range. Autocast selects operation dtypes; it does not simply convert the whole program.

Part 3 - Quantitative Prediction Before Execution

For each candidate tensor, predict logical bytes, expected allocated-byte change, representable-range risk, rounding risk, Tensor Core eligibility, and whether accumulation remains in float32. Distinguish memory saved in parameters, gradients, optimizer state, activations, temporary buffers, and saved tensors rather than applying one global one-half multiplier.

Part 4 - Experimental Design and Instrumentation

Create identical CUDA workloads in float32, float16, and bfloat16. Record element size, logical tensor bytes, peak allocated and reserved VRAM, kernel time, output error, finite-value rate, and operation-level dtypes. Use synchronized warm-up and measured iterations, fixed seeds, identical shapes, and documented hardware capability.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class PrecisionProfile:
    name: str
    element_size: int
    logical_bytes: int
    maximum: float
    minimum_normal: float
    epsilon: float

def describe_dtype(dtype, number_of_elements):
    information = torch.finfo(dtype)
    probe = torch.empty((), dtype=dtype)
    return PrecisionProfile(
        str(dtype),
        probe.element_size(),
```

```
        number_of_elements * probe.element_size(),
        information.max,
        information.tiny,
        information.eps)

def E00(number_of_elements):
    dtypes = [torch.float32, torch.float16, torch.bfloat16]
    profiles = []
    for dtype in dtypes:
        profile = describe_dtype(dtype, number_of_elements)
        profiles.append(profile)
    return profiles
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not infer physical VRAM from logical bytes alone. CUDA allocator bins, alignment, cached blocks, workspaces, master weights, gradients, and optimizer state can dominate the result. Verify that every tested operation supports the requested dtype and report fallbacks, promotions, non-finite values, and unsupported kernels instead of silently excluding them.

Part 7 - Engineering Interpretation and Philosophy

Mixed precision is a placement policy over numerical formats. It spends representational accuracy and implementation complexity to reduce memory traffic and unlock specialized hardware, while preserving float32 where range or accumulation demands it. The correct unit of reasoning is the operation and tensor role, not the marketing label attached to a training run.

19.21.2 Exercise 01

Exercise Title: Calculate the Exact VRAM Required by Identical Tensor Shapes Stored in float64, float32, bfloat16, and float16

Part 1 - Exercise Contract and Why It Matters

Calculate exact logical storage for the same shapes in four floating-point dtypes, including scalar, vector, matrix, batched, and Transformer-shaped tensors. Then separate payload bytes from allocator-observed VRAM so that a correct arithmetic answer is not confused with a physical allocation measurement.

Part 2 - System and Memory Mental Model

Logical storage equals the product of all dimensions multiplied by element size: eight bytes for float64, four for float32, and two for bfloat16 or float16. Views can share storage, noncontiguous tensors can expose a different logical region, and CUDA allocations are rounded and cached, so allocated and reserved bytes answer different questions.

Part 3 - Quantitative Prediction Before Execution

Before allocating, compute elements and bytes for every shape and dtype. Predict exact ratios relative to float32, convert bytes to MiB and GiB using binary units, and estimate the total for multiple simultaneous copies. State whether gradients, outputs, and temporary tensors are included in each total.

Part 4 - Experimental Design and Instrumentation

Allocate one tensor at a time in a fresh process or after controlled cleanup. Compare formula bytes with tensor element_size, untyped storage bytes, memory_allocated change, and memory_reserved change. Repeat for contiguous tensors, views, clones, and deliberately noncontiguous layouts without claiming that cache cleanup represents normal training behavior.

Part 5 - PyTorch/CUDA Implementation

```
import math
import torch

def logical_tensor_bytes(shape, dtype):
    number_of_elements = math.prod(shape)
    element_size = torch.empty((), dtype=dtype).element_size()
    return number_of_elements * element_size

def E01(shape):
    dtypes = [
        torch.float64,
        torch.float32,
        torch.bfloat16,
        torch.float16,
    ]
    result = {}
    for dtype in dtypes:
        result[str(dtype)] = logical_tensor_bytes(shape, dtype)
    return result
```

Part 6 - Measurement, Validation, and Failure Analysis

Check integer overflow in manual products, zero-sized dimensions, aliasing, and storage offsets. Report bytes, MiB, and GiB with the conversion definition. A mismatch between formula bytes and allocator deltas is not automatically an error; attribute it to rounding, caching, pre-existing blocks, or additional runtime allocations using controlled evidence.

Part 7 - Engineering Interpretation and Philosophy

Exact byte arithmetic is the lower bound of memory engineering. It is simple enough to calculate before execution, but valuable only when its scope is explicit. The allocator measurement adds system truth; neither number should be substituted for the other.

19.21.3 Exercise 02

Exercise Title: Measure Real CUDA Memory Usage for the Same PyTorch Workload Across float32, float16, and bfloat16

Part 1 - Exercise Contract and Why It Matters

Measure the complete CUDA memory behavior of one workload across three dtypes. Capture current, peak, allocated, and reserved VRAM as well as execution time and numerical validity. Keep shapes and algorithmic work identical so dtype is the controlled variable.

Part 2 - System and Memory Mental Model

Changing dtype reduces tensor payload, but peak VRAM also contains library workspaces, allocator fragmentation, cached blocks, outputs retained by Python, and autograd state. Some kernels accumulate in float32 or create promoted temporaries. Reserved memory can remain high even after live tensors are released.

Part 3 - Quantitative Prediction Before Execution

Create a component estimate for input, parameters, activations, gradients, and expected workspaces. Predict which components halve and which remain unchanged. State expected peak ordering and an error tolerance for each reduced dtype before running the workload.

Part 4 - Experimental Design and Instrumentation

Run each dtype in an isolated process with identical warm-up, seed, model, batch, and synchronization. Reset peak statistics immediately before the measured region. Record allocated and reserved peaks, median step time, output error against float32, finite gradients, and any unsupported-operation failure.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def measure_workload(workload, dtype, device="cuda"):
    torch.cuda.synchronize(device)
    torch.cuda.reset_peak_memory_stats(device)
    start = time.perf_counter()
    output = workload(dtype=dtype, device=device)
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - start
    return {
        "output": output,
        "peak_allocated": torch.cuda.max_memory_allocated(device),
        "peak_reserved": torch.cuda.max_memory_reserved(device),
        "elapsed_seconds": elapsed,
    }

def E02(workload):
    results = {}
    for dtype in [torch.float32, torch.float16, torch.bfloat16]:
        results[str(dtype)] = measure_workload(workload, dtype)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Synchronize around timing and do not compare a first-run compilation or autotuning cost with warmed runs. Confirm identical model topology and tensor shapes. Preserve failures as results, including OOM, unsupported dtype, non-finite output, or accuracy outside tolerance. Explain allocated versus reserved memory explicitly.

Part 7 - Engineering Interpretation and Philosophy

Real memory reduction is an empirical property of the entire workload, not a direct synonym for smaller element size. A defensible result connects a byte model to allocator telemetry, kernel behavior, and numerical evidence under controlled execution.

19.21.4 Exercise 03

Exercise Title: Compare Full-Precision and Half-Precision Model Parameters and Verify the Expected Reduction in Parameter Memory

Part 1 - Exercise Contract and Why It Matters

Compare model parameter storage after conversion to float32, float16, and bfloat16. Count unique storages, preserve tied parameters, and distinguish parameter payload from gradients, buffers, master copies, and optimizer state.

Part 2 - System and Memory Mental Model

Casting a module usually creates parameters in the requested dtype, but tied weights and views can make a naive sum double-count physical storage. Training systems may retain float32 master weights even when the model-facing parameter is half precision. Integer and boolean buffers do not follow floating-point conversion rules.

Part 3 - Quantitative Prediction Before Execution

Predict parameter bytes from unique element counts and dtype width. Extend the estimate to gradients and a selected optimizer, declaring whether momentum or variance tensors remain float32. State the expected ratio for inference-only parameters and why full training state may not achieve it.

Part 4 - Experimental Design and Instrumentation

Clone identical model state into each dtype, enumerate named parameters and buffers, canonicalize storage identity, and record logical and unique bytes. Run forward and backward to observe gradient dtypes, then initialize the optimizer state with one update and recount every state tensor.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def unique_tensor_bytes(tensors):
    seen = set()
    total = 0
    for tensor in tensors:
        storage = tensor.untyped_storage()
        key = (tensor.device, storage.data_ptr(), storage.nbytes())
        if key not in seen:
            seen.add(key)
            total += storage.nbytes()
    return total
```

```
def parameter_report(model):
    parameters = list(model.parameters())
    logical_bytes = 0
    dtype_names = set()
    for parameter in parameters:
        parameter_bytes = parameter.numel() * parameter.element_size()
        logical_bytes += parameter_bytes
        dtype_names.add(str(parameter.dtype))
    return {
        "logical_bytes": logical_bytes,
        "unique_storage_bytes": unique_tensor_bytes(parameters),
        "dtypes": dtype_names,
    }

def E03(model):
    return parameter_report(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify value conversion against a float32 reference and check shared-weight identity after cloning or casting. Do not include cached allocator blocks in the parameter byte count. Report mixed buffer dtypes, master copies, optimizer tensors, and any parameter that was intentionally kept in float32.

Part 7 - Engineering Interpretation and Philosophy

Parameter memory is the cleanest mixed-precision component, yet even here ownership and duplication matter. The engineering question is not only how wide a parameter is, but how many authoritative and auxiliary copies the training system must retain.

19.21.5 Exercise 04

Exercise Title: Compare Activation Memory Across float32, float16, and bfloat16 During the Same Forward Pass

Part 1 - Exercise Contract and Why It Matters

Measure activation payload and liveness during an identical forward pass in three precision modes. Record both module outputs and tensors saved for backward, then relate their unique bytes to the observed forward peak.

Part 2 - System and Memory Mental Model

Activation memory depends on output dtype, saved-tensor policy, aliasing, operation-specific autocast rules, and lifetime. A float16 input can produce float32 statistics or reductions, while views may share a larger backing storage. The forward peak is controlled by overlapping live tensors, not the sum of every output ever observed.

Part 3 - Quantitative Prediction Before Execution

Predict activation bytes layer by layer from shapes and expected dtypes. Mark operations likely to promote or retain float32. Estimate the peak live set and the saved-for-backward set separately, then specify expected differences between explicit model casting and autocast.

Part 4 - Experimental Design and Instrumentation

Use forward hooks and saved_tensors_hooks around one deterministic model. Record producer name, shape, dtype, logical bytes, storage identity, save order, and peak CUDA memory. Compare pure float32, float16 autocast, and bfloat16 autocast with identical inputs and graph structure.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ActivationRecord:
    producer: str
    shape: tuple
    dtype: object
    bytes: int

def collect_forward_activations(model, inputs):
    records = []
    handles = []
    for name, module in model.named_modules():
        if name == "":
            continue
        def hook(current_module, current_inputs, output, name=name):
            if torch.is_tensor(output):
                records.append(ActivationRecord(
                    name, tuple(output.shape), output.dtype,
                    output.numel() * output.element_size()))
        handles.append(module.register_forward_hook(hook))
    model(*inputs)
    for handle in handles:
        handle.remove()
    return records

def E04(model, inputs):
    return collect_forward_activations(model, inputs)
```

Part 6 - Measurement, Validation, and Failure Analysis

Hooks can miss tensors created inside functional operations and can change retention if outputs are stored carelessly. Detach metadata rather than retaining full activations. Deduplicate storage, include tensors saved by autograd, and verify equal output shapes and control flow across modes before attributing a peak difference to precision.

Part 7 - Engineering Interpretation and Philosophy

Activation savings emerge from dtype decisions distributed across the graph. A useful analysis reconstructs liveness and operation policy instead of assuming every intermediate follows the input dtype or remains resident for the same duration.

19.21.6 Exercise 05

Exercise Title: Run a Complete Training Step in Pure float32 and Establish Baseline Peak VRAM, Throughput, and Numerical Behavior

Part 1 - Exercise Contract and Why It Matters

Establish a rigorous float32 baseline before introducing mixed precision. Measure forward, loss, backward, optimizer update, peak memory, latency distribution, throughput, loss trajectory, gradient norms, and finite-value status from a reproducible initial state.

Part 2 - System and Memory Mental Model

The baseline defines the semantic and performance reference. CUDA execution is asynchronous, allocator state persists, and the first iterations may include library initialization or algorithm selection. Model mode, stochastic layers, optimizer state initialization, and gradient clearing strategy all affect both memory and numerical traces.

Part 3 - Quantitative Prediction Before Execution

Estimate parameter, gradient, optimizer, activation, and workspace memory. Predict the first-step peak and steady-state peak separately. Define acceptable loss, output, gradient, and update differences that later precision modes must satisfy.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds and cloned model, optimizer, and batch state. Warm up without recording, then run multiple synchronized float32 steps. Report median and tail latency, samples or tokens per second, peak allocated and reserved VRAM, per-parameter gradient norms, loss, and non-finite counts.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def float32_training_step(model, optimizer, inputs, targets, loss_function):
    optimizer.zero_grad(set_to_none=True)
    outputs = model(inputs.float())
    loss = loss_function(outputs, targets)
    loss.backward()
    optimizer.step()
    return outputs.detach(), loss.detach()

def E05(model, optimizer, inputs, targets, loss_function):
    torch.cuda.reset_peak_memory_stats()
    torch.cuda.synchronize()
    start = time.perf_counter()
    outputs, loss = float32_training_step(
        model, optimizer, inputs, targets, loss_function)
    torch.cuda.synchronize()
    return {
        "outputs": outputs,
```

```
        "loss": loss,
        "seconds": time.perf_counter() - start,
        "peak_allocated": torch.cuda.max_memory_allocated(),
        "peak_reserved": torch.cuda.max_memory_reserved(),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that all trainable parameters and expected activations use float32. Detect non-finite loss, outputs, gradients, and updated parameters. Store the initial state and inputs required for later replay. Do not compare a single cold float32 step with warmed mixed-precision steps.

Part 7 - Engineering Interpretation and Philosophy

Optimization claims need a stable control. The baseline is not administrative overhead; it is the evidence that later capacity or speed gains preserve the intended learning computation within declared tolerances.

19.21.7 Exercise 06

Exercise Title: Enable torch.autocast(device_type="cuda", dtype=torch.float16) and Identify Which PyTorch Operations Change Precision Automatically

Part 1 - Exercise Contract and Why It Matters

Enable CUDA float16 autocast around a controlled operation suite and identify the actual output dtype chosen for each operation. Separate eligible Tensor Core operations, float32-sensitive operations, and operations that preserve or promote input dtype.

Part 2 - System and Memory Mental Model

Autocast uses operation-specific dispatch rules rather than a universal cast. Inputs may be converted internally, outputs can use float16 or float32, and in-place operations or explicit dtype arguments may bypass autocast behavior. Parameters usually remain stored in float32 while eligible kernels consume casted views.

Part 3 - Quantitative Prediction Before Execution

Before execution, classify matrix multiplication, convolution, normalization, reduction, elementwise, softmax, and loss operations by expected autocast behavior. Predict output dtype and numerical risk, then mark any classification that depends on the installed PyTorch and CUDA versions.

Part 4 - Experimental Design and Instrumentation

Run the same operation suite outside and inside autocast with fixed inputs spanning normal and extreme values. Record input, parameter, output, and gradient dtypes plus profiler kernel names. Repeat with out-of-place and in-place variants where legal and document version-specific results.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def operation_dtype_report(x, weight):
    report = {}
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        matrix = x @ weight
        report["matmul"] = matrix.dtype
        report["sum"] = matrix.sum().dtype
        report["softmax"] = torch.softmax(matrix, dim=-1).dtype
        report["relu"] = torch.relu(matrix).dtype
        report["norm"] = torch.linalg.vector_norm(matrix).dtype
    return report

def E06(x, weight):
    return operation_dtype_report(x, weight)
```

Part 6 - Measurement, Validation, and Failure Analysis

Treat observed dtype as the result for the tested environment, not a timeless rule. Check explicit dtype arguments, disabled subregions, nested contexts, CPU tensors, and unsupported hardware. Validate output against float32 and preserve operation failures or surprising promotions in the report.

Part 7 - Engineering Interpretation and Philosophy

Autocast is a curated numerical policy encoded in dispatch. Understanding its decisions turns mixed precision from a magic context manager into an inspectable contract that can be tested, overridden, and revised as software changes.

19.21.8 Exercise 07

Exercise Title: Inspect Intermediate Tensor Dtypes Inside an Autocast Region and Explain Why Not Every Operation Runs in float16

Part 1 - Exercise Contract and Why It Matters

Instrument a real model inside float16 autocast and build an operation-level dtype trace. Explain every float32 island, dtype-preserving path, and promoted output using numerical sensitivity, input policy, or explicit implementation behavior.

Part 2 - System and Memory Mental Model

An autocast region can contain mixed outputs because eligibility is per operation. Reductions, losses, normalization statistics, or custom functions may use float32 for stability, while binary operations can promote to the widest input. Stored parameters can remain float32 even when computation uses lower precision.

Part 3 - Quantitative Prediction Before Execution

Draw the expected dtype path through the selected model before running it. Mark boundaries where values enter and leave float16, estimate conversion bytes, and predict which saved tensors autograd will retain in each dtype.

Part 4 - Experimental Design and Instrumentation

Attach carefully scoped module hooks and saved-tensor hooks, and use the profiler for functional operations. Record operation name, input dtypes, output dtypes, saved-tensor dtypes, shapes, and bytes. Compare the trace against a no-autocast run without retaining tensor payloads in the logger.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class DtypeTracer:
    def __init__(self):
        self.records = []
        self.handles = []

    def attach(self, model):
        for name, module in model.named_modules():
            if name == "":
                continue
            def hook(current_module, inputs, output, name=name):
                input_dtypes = []
                for item in inputs:
                    if torch.is_tensor(item):
                        input_dtypes.append(item.dtype)
                output_dtype = output.dtype if torch.is_tensor(output) else None
                self.records.append((name, input_dtypes, output_dtype))
            self.handles.append(module.register_forward_hook(hook))

    def remove(self):
        for handle in self.handles:
            handle.remove()

def E07(model, inputs):
    tracer = DtypeTracer()
    tracer.attach(model)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        model(*inputs)
    tracer.remove()
    return tracer.records
```

Part 6 - Measurement, Validation, and Failure Analysis

A module hook does not expose every operator and composite modules may repeat information. Avoid storing outputs, which changes liveness and memory. Cross-check representative regions with profiler events or explicit probes, and verify the trace under the exact PyTorch version recorded in the experiment.

Part 7 - Engineering Interpretation and Philosophy

A mixed-precision graph is intentionally heterogeneous. Float32 islands are often safeguards rather than missed optimizations, and a dtype trace makes the boundary between deliberate stability and accidental promotion visible.

19.21.9 Exercise 08

Exercise Title: Compare float16 Autocast Against bfloat16 Autocast by Peak VRAM, Throughput, Output Error, and Numerical Stability

Part 1 - Exercise Contract and Why It Matters

Compare two autocast dtypes under identical training conditions. Measure capacity, speed, error, overflow, underflow, gradient stability, and convergence evidence rather than selecting a format from element size alone.

Part 2 - System and Memory Mental Model

Both formats occupy two bytes, but float16 provides finer significand precision and a narrower exponent range, while bfloat16 sacrifices precision for a float32-like range. Hardware support and kernel availability can make throughput differ even when memory payload is similar.

Part 3 - Quantitative Prediction Before Execution

Predict equal logical activation bytes but different finite-value behavior on extreme workloads. State expected throughput from the tested GPU architecture, define reference error metrics, and identify operations whose internal accumulation may reduce the visible difference.

Part 4 - Experimental Design and Instrumentation

Replay cloned model, optimizer, inputs, and RNG state for float16 and bfloat16 autocast. Run warm-up and repeated synchronized steps. Record peak allocated and reserved VRAM, throughput, output and gradient error against float32, non-finite counts, loss trajectory, and profiler evidence for executed kernels.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def autocast_step(model, inputs, loss_function, targets, dtype):
    model.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=dtype):
        outputs = model(inputs)
        loss = loss_function(outputs, targets)
    loss.backward()
    finite_gradients = True
    for parameter in model.parameters():
        if parameter.grad is not None:
            current_is_finite = torch.isfinite(parameter.grad).all()
            if not bool(current_is_finite):
                finite_gradients = False
    return outputs.detach(), loss.detach(), finite_gradients
```

```
def E08(model, inputs, targets, loss_function):
    results = {}
    for dtype in [torch.float16, torch.bfloat16]:
        results[str(dtype)] = autocast_step(
            model, inputs, loss_function, targets, dtype)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Restore identical state before each mode and use dtype-appropriate tolerances. Check whether the GPU provides native bfloat16 acceleration. Separate arithmetic error from stochastic divergence, and report unsupported or slower kernels rather than assuming every 16-bit format reaches Tensor Cores equally.

Part 7 - Engineering Interpretation and Philosophy

The preferred 16-bit format is workload- and hardware-specific. Equal storage width creates a capacity tie, but numerical range, precision, kernel support, and optimization dynamics determine the engineering winner.

19.21.10 Exercise 09

Exercise Title: Reproduce float16 Overflow and Underflow with Controlled Tensor Operations and Compare the Same Experiment in bfloat16 and float32

Part 1 - Exercise Contract and Why It Matters

Construct controlled operations that cross the maximum finite value and minimum representable scale of each dtype. Observe overflow, subnormal behavior, rounding to zero, and propagation through multiplication, reduction, exponential, and gradient computation.

Part 2 - System and Memory Mental Model

Overflow produces infinity when magnitude exceeds the finite range. Underflow can produce subnormal values or zero when magnitude becomes too small, with device behavior affected by flush-to-zero policies. bfloat16 has a wide exponent range but coarse precision; float16 has a much narrower range.

Part 3 - Quantitative Prediction Before Execution

Use torch.finfo to calculate candidate thresholds before execution. Predict the first scale at which each operation becomes non-finite or zero for each dtype. Include accumulation length in reduction predictions and distinguish forward underflow from gradient underflow.

Part 4 - Experimental Design and Instrumentation

Sweep logarithmic input scales and operation depths for all three dtypes. Record values, finite masks, zero counts, relative error, and gradients against float64 or analytically known references. Synchronize and document hardware because subnormal handling can vary.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def range_probe(dtype, device="cuda"):
    information = torch.finfo(dtype)
    large = torch.tensor([information.max], dtype=dtype, device=device)
    small = torch.tensor([information.tiny], dtype=dtype, device=device)
    return {
        "maximum": large,
        "overflow": large * torch.tensor(2.0, dtype=dtype, device=device),
        "minimum_normal": small,
        "underflow": small * torch.tensor(0.25, dtype=dtype, device=device),
    }

def E09(device="cuda"):
    results = {}
    dtypes = [torch.float16, torch.bfloat16, torch.float32]
    for dtype in dtypes:
        results[str(dtype)] = range_probe(dtype, device)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not use only one hand-picked value. Verify thresholds with a sweep and inspect both finite and zero status. Avoid converting to Python floats before recording dtype behavior. Explain subnormal or flush-to-zero observations and validate gradients separately from forward results.

Part 7 - Engineering Interpretation and Philosophy

Numerical range failures are predictable resource limits, not mysterious training instability. A controlled reproduction provides the evidence needed to decide between a wider exponent, scaling, or a float32 computation island.

19.21.11 Exercise 10

Exercise Title: Identify Numerically Sensitive Operations and Force Selected Autocast Subregions to Execute in float32

Part 1 - Exercise Contract and Why It Matters

Identify unstable regions from measured error or non-finite values, then create minimal float32 islands inside a lower-precision autocast graph. Preserve the memory and throughput benefit of surrounding operations while repairing numerical behavior.

Part 2 - System and Memory Mental Model

Nested autocast contexts can disable automatic casting for a subregion, but incoming half-precision tensors may need explicit float conversion. Reductions, exponentials, normalization statistics, divisions by small values, and ill-conditioned linear algebra are common candidates, but evidence must select the actual boundary.

Part 3 - Quantitative Prediction Before Execution

Rank candidate operations by predicted range and cancellation risk. Estimate extra bytes, conversions, and latency for each proposed float32 island. Define the smallest acceptable island and the error or finite-value improvement it should produce.

Part 4 - Experimental Design and Instrumentation

Instrument a failing workload, then compare all-autocast, targeted float32 islands, and full float32 from identical state. Record operation error, gradients, peak VRAM, conversion traffic, kernel time, and end-to-end throughput. Expand the island only when the smaller boundary fails validation.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def sensitive_softmax_region(logits):
    with torch.autocast(device_type="cuda", enabled=False):
        float_logits = logits.float()
        probabilities = torch.softmax(float_logits, dim=-1)
    return probabilities

def mixed_region(x, weight):
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        logits = x @ weight
        probabilities = sensitive_softmax_region(logits)
    return probabilities

def E10(x, weight):
    return mixed_region(x, weight)
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that profiler events and tensor probes show the intended subregion in float32. Check output and gradient error, not only absence of NaN. Measure whether implicit conversions create unexpected temporaries or widen the island. Test boundary values and multiple seeds.

Part 7 - Engineering Interpretation and Philosophy

Selective precision is more powerful than an all-or-nothing dtype choice. The goal is to place accuracy where it protects semantics and reduced precision where it buys capacity and speed, using the smallest measured intervention.

19.21.12 Exercise 11

Exercise Title: Build a Mixed-Precision Policy That Assigns Different Dtypes to Parameters, Inputs, Activations, and Numerically Sensitive Computations

Part 1 - Exercise Contract and Why It Matters

Create an explicit, auditable policy for storage and compute dtypes across tensor roles. The policy must distinguish parameter storage, master parameters, inputs, activations, reductions, losses, gradients, optimizer state, and output reporting.

Part 2 - System and Memory Mental Model

Storage dtype and compute dtype are separate decisions. Autocast can feed lower-precision operands to eligible kernels while parameters remain float32. Gradients and optimizer state may use yet another policy. Conversions create memory traffic, temporary tensors, and possible loss of information at each boundary.

Part 3 - Quantitative Prediction Before Execution

For every tensor role, predict resident bytes, conversion count, arithmetic range, and expected error. Calculate a policy memory budget and identify hard float32 constraints. State how the policy changes under float16 versus bfloat16 hardware support.

Part 4 - Experimental Design and Instrumentation

Represent the policy as data rather than scattered casts. Apply it to a small model, log actual dtypes at boundaries, and compare against float32 and default autocast. Report peak memory, throughput, conversion operations, gradient error, optimizer-state bytes, and any policy violation.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class MixedPrecisionPolicy:
    parameter_storage: object = torch.float32
    input_compute: object = torch.float16
    activation_compute: object = torch.float16
    sensitive_compute: object = torch.float32
    optimizer_state: object = torch.float32

    def validate(self):
        allowed = {torch.float16, torch.bfloat16, torch.float32}
        values = [
            self.parameter_storage,
            self.input_compute,
            self.activation_compute,
            self.sensitive_compute,
            self.optimizer_state,
        ]
        return all(value in allowed for value in values)

def E11(activation_dtype=torch.float16):
    return MixedPrecisionPolicy(
        input_compute=activation_dtype,
        activation_compute=activation_dtype)
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify actual tensor and profiler dtypes against the declared policy. Detect redundant conversions, accidental permanent parameter casts, unsupported kernels, and optimizer state that silently uses a different dtype. A policy that saves memory but violates error constraints must be recorded as infeasible.

Part 7 - Engineering Interpretation and Philosophy

Mixed precision becomes manageable when represented as a resource policy rather than a sequence of ad hoc casts. Explicit roles make memory accounting, numerical review, and adaptation possible across models and hardware.

19.21.13 Exercise 12

Exercise Title: Compare Pure Half-Precision Training Against Autocast Mixed Precision and Explain Why Casting the Entire Model Is Not Equivalent

Part 1 - Exercise Contract and Why It Matters

Compare a model converted entirely to float16 or bfloat16 with a float32 model trained under autocast. Track stored parameters, operation dtypes, gradients, optimizer state, memory, speed, and numerical failures to explain the semantic difference.

Part 2 - System and Memory Mental Model

model.half changes persistent floating parameters and buffers, whereas autocast normally leaves storage in float32 and chooses compute dtype per eligible operation. Pure half can expose optimizer updates, reductions, normalization, and accumulations to limited range or precision. Autocast retains selected float32 paths.

Part 3 - Quantitative Prediction Before Execution

Predict which persistent components shrink only in pure half, which operations remain float32 only under autocast, and where pure half is expected to overflow or lose small updates. Estimate both parameter-state memory and activation memory before execution.

Part 4 - Experimental Design and Instrumentation

Clone identical initial weights into pure-half, autocast, and float32 branches. Use compatible inputs and optimizers, then run repeated training steps. Record peak VRAM, parameter and optimizer bytes, operation dtypes, throughput, loss, gradient and update error, and non-finite counts.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import torch

def pure_half_step(model, inputs, targets, loss_function):
    half_model = copy.deepcopy(model).half()
    outputs = half_model(inputs.half())
    loss = loss_function(outputs.float(), targets)
    loss.backward()
    return half_model, outputs, loss
```

```
def autocast_step(model, inputs, targets, loss_function):
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        outputs = model(inputs)
        loss = loss_function(outputs, targets)
    loss.backward()
    return model, outputs, loss

def E12(model, inputs, targets, loss_function):
    return {
        "pure_half": pure_half_step(model, inputs, targets, loss_function),
        "autocast": autocast_step(model, inputs, targets, loss_function),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Restore state before each branch and check parameter, buffer, gradient, and optimizer dtypes explicitly. Ensure loss computation is comparable. Report operations unsupported in pure half and distinguish a lower persistent-memory footprint from a valid training result.

Part 7 - Engineering Interpretation and Philosophy

Pure half precision and autocast solve different problems. One rewrites storage broadly; the other selects computation locally. Capacity gains cannot justify treating them as equivalent when their numerical contracts and optimizer behavior differ.

19.21.14 Exercise 13

Exercise Title: Profile Mixed-Precision Tensor Core Operations and Determine Whether Reduced Memory Traffic Produces Real Throughput Gains

Part 1 - Exercise Contract and Why It Matters

Use profiler evidence to determine whether mixed precision executes Tensor Core-eligible kernels and whether smaller operands reduce exposed memory traffic or step time. Separate theoretical FLOP capability from achieved end-to-end throughput.

Part 2 - System and Memory Mental Model

Tensor Core use depends on GPU architecture, dtype, shape alignment, library selection, and operation. Reduced operand width can lower memory traffic, but conversions, launch overhead, noneligible operations, communication, or input pipelines may remain on the critical path. Kernel speedup can be hidden at step level.

Part 3 - Quantitative Prediction Before Execution

For selected GEMM and convolution shapes, predict arithmetic intensity, transferred bytes, alignment eligibility, and expected kernel speedup. Identify a compute-bound case, a memory-bound case, and a small case dominated by overhead.

Part 4 - Experimental Design and Instrumentation

Profile float32, float16 autocast, and bfloat16 autocast after warm-up. Capture CUDA kernel time, shapes, memory activity, Tensor Core indicators available in the profiler, and end-to-end synchronized throughput. Sweep aligned and misaligned dimensions while holding useful work constant.

Part 5 - PyTorch/CUDA Implementation

```
from contextlib import nullcontext
import torch
from torch.profiler import ProfilerActivity, profile

def profile_region(workload, dtype):
    precision_context = (
        nullcontext()
        if dtype is torch.float32
        else torch.autocast(device_type="cuda", dtype=dtype))
    with profile(
            activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
            record_shapes=True,
            profile_memory=True) as current_profile:
        with precision_context:
            workload()
        torch.cuda.synchronize()
    return current_profile.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=20)

def E13(workload):
    results = {}
    dtypes = [torch.float32, torch.float16, torch.bfloat16]
    for dtype in dtypes:
        results[str(dtype)] = profile_region(workload, dtype)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not claim Tensor Core use from dtype alone. Correlate kernel names, shapes, hardware capability, and timing. Exclude warm-up and profiler overhead from final throughput measurements. Verify identical outputs within tolerance and report cases where a faster kernel does not improve the full step.

Part 7 - Engineering Interpretation and Philosophy

Specialized arithmetic is valuable only when it shortens the workload's critical path. Profiling links precision policy to executed kernels and prevents theoretical throughput or payload reduction from being reported as an achieved application gain.

19.21.15 Exercise 14

Exercise Title: Increase Batch Size Until float32 Reaches OOM and Measure How Much Additional Batch Capacity Mixed Precision Unlocks

Part 1 - Exercise Contract and Why It Matters

Find the maximum stable training batch size under a fixed VRAM budget for float32, float16 autocast, and bfloat16 autocast. Measure capacity, throughput, numerical behavior, and fragmentation rather than stopping at the first avoided OOM.

Part 2 - System and Memory Mental Model

Batch growth increases inputs, activations, saved tensors, and some workspaces, while parameters and optimizer state remain mostly fixed. OOM thresholds can be nonmonotonic because algorithm selection, allocator bins, fragmentation, and temporary peaks change with shape. Mixed precision reduces only dtype-sensitive components.

Part 3 - Quantitative Prediction Before Execution

Build a fixed-plus-variable memory model and predict the maximum batch for each mode. Estimate the theoretical capacity gain from the variable component rather than assuming a twofold increase. Define a safety margin below the observed maximum.

Part 4 - Experimental Design and Instrumentation

Search batch sizes in isolated trials, beginning with exponential growth and finishing with a bounded search. Run warm-up and several full training steps at every candidate. Record OOM stage, peak allocated and reserved VRAM, throughput, loss and gradient validity, and the largest size that survives repeated execution.

Part 5 - PyTorch/CUDA Implementation

```
from contextlib import nullcontext
import torch

def trial(run_step, batch_size, dtype):
    try:
        torch.cuda.reset_peak_memory_stats()
        precision_context = (
            nullcontext()
            if dtype is torch.float32
            else torch.autocast(device_type="cuda", dtype=dtype))
        with precision_context:
            run_step(batch_size)
        torch.cuda.synchronize()
        return {
            "success": True,
            "peak": torch.cuda.max_memory_allocated(),
            "error": None,
        }
    except torch.cuda.OutOfMemoryError as error:
        return {"success": False, "peak": None, "error": str(error)}

def E14(run_step, batch_sizes):
    results = {}
    for dtype in [torch.float32, torch.float16, torch.bfloat16]:
        dtype_results = []
        for batch_size in batch_sizes:
            trial_result = trial(run_step, batch_size, dtype)
            dtype_results.append((batch_size, trial_result))
        results[str(dtype)] = dtype_results
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

An OOM trial can leave allocator and Python state unsuitable for the next candidate, so isolate trials or perform verified cleanup outside the measured path. Confirm full forward, backward, and update success. Repeat the selected maximum and report a safe operating batch rather than a one-time edge result.

Part 7 - Engineering Interpretation and Philosophy

The practical value of memory reduction is often additional useful work per step. Capacity testing translates byte savings into batch size while exposing fixed memory, nonlinear workspaces, and the difference between a fragile maximum and an operational budget.

19.21.16 Exercise 15

Exercise Title: Increase Transformer Sequence Length Until float32 Reaches OOM and Measure the Context-Length Gain from Mixed Precision

Part 1 - Exercise Contract and Why It Matters

Measure the maximum stable Transformer sequence length under a fixed batch, model, attention implementation, and VRAM budget. Compare precision modes while accounting for linear and quadratic activation components and validating attention numerics.

Part 2 - System and Memory Mental Model

Sequence length grows token representations approximately linearly, while materialized attention scores can grow quadratically. Kernel-fused attention may avoid storing the full score matrix and change the scaling law. Precision reduces floating payload but does not alter indices, masks, allocator overhead, or every workspace.

Part 3 - Quantitative Prediction Before Execution

Derive a memory model with fixed, linear, and quadratic terms for the selected implementation. Predict maximum length for each dtype and explain why halving bytes does not necessarily double context length when a quadratic term dominates.

Part 4 - Experimental Design and Instrumentation

Use fixed batch, hidden size, layers, attention backend, checkpointing state, and padding policy. Search increasing lengths in isolated full-step trials. Record peak VRAM, reserved memory, tokens per second, attention output error, gradient validity, OOM stage, and the last repeatedly stable length.

Part 5 - PyTorch/CUDA Implementation

```
from contextlib import nullcontext
import torch

def sequence_trial(run_step, sequence_length, dtype):
    try:
        torch.cuda.reset_peak_memory_stats()
        precision_context = (
            nullcontext()
```

```
            if dtype is torch.float32
            else torch.autocast(device_type="cuda", dtype=dtype))
        with precision_context:
            metrics = run_step(sequence_length)
        torch.cuda.synchronize()
        return True, torch.cuda.max_memory_allocated(), metrics
    except torch.cuda.OutOfMemoryError as error:
        return False, None, str(error)

def E15(run_step, sequence_lengths):
    report = {}
    for dtype in [torch.float32, torch.float16, torch.bfloat16]:
        report[str(dtype)] = []
        for length in sequence_lengths:
            report[str(dtype)].append(
                (length, sequence_trial(run_step, length, dtype)))
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that attention backend and kernel choice remain documented across modes and lengths. Test complete backward and update, not forward alone. Detect non-finite attention probabilities or gradients before OOM. Repeat boundary lengths and retain a VRAM safety margin.

Part 7 - Engineering Interpretation and Philosophy

Context length is a workload capability produced by a memory policy and an attention algorithm together. Mixed precision buys bytes, but the graph's scaling law determines how those bytes translate into additional tokens.

19.21.17 Exercise 16

Exercise Title: Combine Mixed Precision with Activation Checkpointing and Determine Which Memory Components Each Technique Actually Reduces

Part 1 - Exercise Contract and Why It Matters

Combine autocast mixed precision with activation checkpointing and attribute every memory change to reduced tensor width, discarded activations, recomputation, or unchanged training state. Compare combined behavior against each technique alone under identical semantics.

Part 2 - System and Memory Mental Model

Mixed precision shrinks eligible tensor payload and may change kernels. Checkpointing removes selected saved activations and replays forward computation during backward. Their savings overlap on checkpointed tensors, so percentages are not simply additive. Recomputed operations must reproduce the intended autocast context and RNG behavior.

Part 3 - Quantitative Prediction Before Execution

Partition memory into parameters, gradients, optimizer state, retained activations inside and outside checkpoint regions, and workspaces. Predict float32 baseline, mixed-only, checkpoint-only, and combined peaks. Estimate replay FLOPs and whether lower precision accelerates recomputation.

Part 4 - Experimental Design and Instrumentation

Benchmark the four modes from cloned state with identical checkpoint boundaries and non-reentrant or reentrant choice documented. Record peak VRAM, saved-tensor bytes, replay count, step latency, throughput, output and gradient error, and RNG-sensitive behavior.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.utils.checkpoint import checkpoint

def checkpointed_forward(block, hidden_states, use_checkpoint):
    if use_checkpoint:
        return checkpoint(block, hidden_states, use_reentrant=False)
    return block(hidden_states)

def run_mode(block, hidden_states, dtype, use_checkpoint):
    with torch.autocast(device_type="cuda", dtype=dtype):
        return checkpointed_forward(
            block, hidden_states, use_checkpoint)

def E16(block, hidden_states):
    return {
        "mixed_only": run_mode(
            block, hidden_states, torch.float16, False),
        "mixed_checkpoint": run_mode(
            block, hidden_states, torch.float16, True),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify outputs and gradients against float32, preserve RNG where required, and ensure recomputation runs under the expected autocast policy. Measure actual saved tensors rather than inferring checkpoint success. Explain overlapping savings and report profiler overhead separately.

Part 7 - Engineering Interpretation and Philosophy

Memory techniques compose through the tensors they affect, not through headline percentages. Component attribution reveals whether a combination removes new bytes, shrinks the same bytes twice in theory, or moves cost onto recomputation.

19.21.18 Exercise 17

Exercise Title: Combine Mixed Precision with Activation Offloading and Measure the Reduction in Both VRAM Usage and CPU-GPU Transfer Volume

Part 1 - Exercise Contract and Why It Matters

Apply activation offloading under float32, float16 autocast, and bfloat16 autocast. Measure how reduced saved-tensor width changes GPU residency, host residency, D2H and H2D traffic, transfer time, overlap, and backward stalls.

Part 2 - System and Memory Mental Model

Offloading moves tensors saved by autograd, whose dtypes follow operation-specific precision policy. A 16-bit saved tensor can halve payload and transfer bytes relative to float32, but float32 islands remain wide. Latency contains fixed per-transfer overhead, allocation cost, synchronization, and bandwidth-dependent payload time.

Part 3 - Quantitative Prediction Before Execution

Use the saved-tensor trace to predict bytes moved by dtype and producer. Estimate D2H and H2D time from measured bandwidth plus fixed overhead, and identify small tensors for which width reduction will not halve latency. Predict host RAM and peak VRAM for each mode.

Part 4 - Experimental Design and Instrumentation

Run keep-only and offload modes for all precision policies from identical state. Record unique saved bytes by dtype, selected transfers, host and pinned peaks, D2H and H2D traffic, event wait time, peak VRAM, step latency, and gradient error. Preserve the same offload threshold and also compare an equal-VRAM policy.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class OffloadedTensor:
    cpu_tensor: object
    original_device: object
    logical_bytes: int

class TransferCounter:
    def __init__(self):
        self.d2h_bytes = 0
        self.h2d_bytes = 0

    def pack(self, tensor):
        size = tensor.numel() * tensor.element_size()
        self.d2h_bytes += size
        return OffloadedTensor(tensor.to("cpu"), tensor.device, size)

    def unpack(self, item):
        self.h2d_bytes += item.logical_bytes
        return item.cpu_tensor.to(item.original_device)
```

```
def E17(model_region, dtype):
    counter = TransferCounter()
    with torch.autograd.graph.saved_tensors_hooks(
            counter.pack, counter.unpack):
        with torch.autocast(device_type="cuda", dtype=dtype):
            output = model_region()
    return output, counter
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact hook is a blocking measurement baseline, not an optimized transport. Deduplicate aliases where physical traffic differs from logical saves, synchronize transfer timing, and verify outputs and gradients. Report wide tensors that remain after autocast and separate lower bytes from reduced exposed stall.

Part 7 - Engineering Interpretation and Philosophy

Precision and placement interact through the payload crossing the memory hierarchy. Smaller tensors can reduce both residency and traffic, but only measurement reveals whether bandwidth, fixed copy overhead, or backward dependency controls the final step time.

19.21.19 Exercise 18

Exercise Title: Build an Adaptive Precision Controller That Changes Selected Tensor Dtypes from VRAM Pressure and Numerical Error Measurements

Part 1 - Exercise Contract and Why It Matters

Build a feedback controller that selects float32, bfloat16, or float16 for eligible regions using VRAM pressure, measured error, non-finite events, and throughput. Decisions must be bounded, auditable, and stable rather than oscillating every step.

Part 2 - System and Memory Mental Model

Precision selection is a control problem with delayed and noisy observations. Lower precision can reduce memory and latency but increase error risk. High and low VRAM watermarks, error budgets, cooldown periods, and emergency promotion rules provide hysteresis and safety. Dtype changes can alter kernels and allocator state.

Part 3 - Quantitative Prediction Before Execution

For each region, estimate bytes saved and error sensitivity for every dtype. Define pressure and error thresholds, promotion and demotion order, observation windows, and a maximum change rate. Predict controller behavior for low memory, sudden numerical failure, and recovered pressure.

Part 4 - Experimental Design and Instrumentation

Replay workloads with variable batch or sequence length and injected numerical stress. Log every observation, decision, reason, predicted bytes, achieved peak, error, finite status, and latency. Compare against static float32, float16, and bfloat16 policies under the same accuracy and VRAM constraints.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class PrecisionObservation:
    peak_vram: int
    error: float
    finite: bool

class AdaptivePrecisionController:
    def __init__(self, high_watermark, low_watermark, error_limit):
        self.high_watermark = high_watermark
        self.low_watermark = low_watermark
        self.error_limit = error_limit
        self.dtype = torch.float32
        self.history = []

    def update(self, observation):
        if not observation.finite or observation.error > self.error_limit:
            self.dtype = torch.float32
            reason = "numerical protection"
        elif observation.peak_vram > self.high_watermark:
            self.dtype = torch.bfloat16
            reason = "memory pressure"
        elif observation.peak_vram < self.low_watermark:
            reason = "hold below low watermark"
        else:
            reason = "hold inside hysteresis band"
        self.history.append((observation, self.dtype, reason))
        return self.dtype

def E18(high_watermark, low_watermark, error_limit):
    return AdaptivePrecisionController(
        high_watermark, low_watermark, error_limit)
```

Part 6 - Measurement, Validation, and Failure Analysis

Test invalid watermark ordering, noisy measurements, repeated non-finite events, unsupported dtype regions, and workload changes. Require a float32 recovery path and verify that decisions actually change executed operation dtypes. Report oscillation, constraint violations, and adaptation overhead.

Part 7 - Engineering Interpretation and Philosophy

Adaptive precision treats numerical format as a schedulable resource. A trustworthy controller protects semantics first, uses hysteresis to remain stable, and leaves an evidence trail explaining why capacity was purchased with a particular precision choice.

19.21.20 Exercise 19

Exercise Title: Design and Benchmark a Memory-Budgeted Mixed-Precision PyTorch Training Strategy That Maximizes Model Size or Batch Size Without Violating Accuracy and VRAM Constraints

Part 1 - Exercise Contract and Why It Matters

Integrate dtype policy, autocast, selective float32 islands, capacity search, profiling, and validation into one memory-budgeted training strategy. Maximize a declared objective such as batch size, sequence length, or model width while satisfying hard VRAM and numerical constraints.

Part 2 - System and Memory Mental Model

The strategy has a planner and an executor. The planner predicts component bytes and ranks precision policies by capacity, error risk, and throughput. The executor applies autocast boundaries, measures the actual peak, validates outputs and gradients, and feeds evidence back to the planner. Feasibility precedes optimization.

Part 3 - Quantitative Prediction Before Execution

Enumerate candidate policies and workload sizes. For each, estimate parameter, optimizer, activation, saved-tensor, workspace, and allocator-safety bytes together with expected error and throughput. Reject candidates above budget or risk limits before ranking the feasible set.

Part 4 - Experimental Design and Instrumentation

Benchmark float32, default float16 and bfloat16 autocast, selective float32 islands, and the adaptive strategy from identical initial state. Search the workload objective, then report the largest repeatably feasible configuration, peak allocated and reserved VRAM, safety margin, throughput distribution, loss and gradient error, non-finite rate, and policy decisions.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class StrategyCandidate:
    name: str
    dtype: object
    workload_size: int
    predicted_vram: int
    predicted_error: float
    predicted_throughput: float

def feasible(candidate, vram_budget, error_budget, safety_margin):
    memory_limit = vram_budget - safety_margin
    return (
        candidate.predicted_vram <= memory_limit
        and candidate.predicted_error <= error_budget)
```

```
def choose_strategy(candidates, vram_budget, error_budget, safety_margin):
    accepted = []
    for candidate in candidates:
        if feasible(candidate, vram_budget, error_budget, safety_margin):
            accepted.append(candidate)
    accepted.sort(
        key=lambda item: (item.workload_size, item.predicted_throughput),
        reverse=True)
    return accepted[0] if accepted else None

def E19(candidates, vram_budget, error_budget, safety_margin):
    return choose_strategy(
        candidates, vram_budget, error_budget, safety_margin)
```

Part 6 - Measurement, Validation, and Failure Analysis

Predictions are admission filters, not proof. Execute the selected configuration repeatedly and reject it after any VRAM, finite-value, or error-budget violation. Include allocator fragmentation, warm-up, optimizer initialization, dynamic shapes, and tail latency. Compare against the strongest static feasible baseline.

Part 7 - Engineering Interpretation and Philosophy

A memory-budgeted precision strategy converts mixed precision from a local optimization into a constrained systems decision. Success is the largest useful workload that remains numerically valid, operationally stable, and explainable within a measured safety margin.

19.22 DMM20

Chapter Title: Gradient Scaling and Dynamic Loss Scaling
Specialization: Dynamic Memory Management and CUDA Systems

19.22.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Gradient Underflow, Overflow, Loss Scaling, and Their Relationship to Mixed-Precision Training

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model that follows a loss through scaling, backward, finite-value inspection, unscaling, clipping, optimizer update, and scale adjustment. Separate forward arithmetic precision from gradient representability and explain why loss scaling helps float16 gradients without increasing the information stored in the forward pass.

Part 2 - System and Memory Mental Model

Multiplying loss L by scale S multiplies every derivative by S through the chain rule. The larger gradient is more likely to remain representable in float16. Before the optimizer update, dividing by S restores the intended gradient. Overflow detection must happen before parameters are changed; a failed step is skipped and the scale is reduced.

Part 3 - Quantitative Prediction Before Execution

Predict the smallest gradient rescued by a chosen scale, the largest scaled gradient that remains finite, and the safe interval for S. Include accumulation dtype, reduction length, clipping threshold, optimizer state, and the distinction between loss overflow and gradient overflow.

Part 4 - Experimental Design and Instrumentation

Create controlled scalar and model experiments in float32, float16, and bfloat16. Record loss, scaled loss, raw gradients, unscaled gradients, finite masks, skipped updates, parameter deltas, and scale history. Fix seeds and compare every accepted update with a float32 reference.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class ScaleState:
    scale: float
    growth_factor: float
    backoff_factor: float
    growth_interval: int
    successful_steps: int = 0

def scaled_gradient(loss, parameter, scale):
    scaled_loss = loss * scale
    gradient = torch.autograd.grad(scaled_loss, parameter)[0]
    return gradient, gradient / scale

def E00(initial_scale=65536.0):
    return ScaleState(initial_scale, 2.0, 0.5, 2000)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not accept a finite loss as proof of finite gradients. Inspect every gradient before the update, verify that unscaled values match the reference within dtype-appropriate tolerances, and confirm that skipped steps leave parameters and optimizer state unchanged. Report underflow, infinity, NaN, and scale oscillation separately.

Part 7 - Engineering Interpretation and Philosophy

Loss scaling temporarily relocates gradients into a usable numerical range; it does not change the mathematical update when scaling and unscaling are correct. Dynamic scaling is therefore a numerical safety controller whose evidence is the sequence of accepted and rejected updates.

19.22.2 Exercise 01

Exercise Title: Construct Tiny float16 Gradients That Underflow to Zero and Compare Them Against float32 and bfloat16

Part 1 - Exercise Contract and Why It Matters

Construct analytically known gradients whose magnitudes cross the float16 normal and subnormal ranges. Compare stored gradient values in float16, bfloat16, and float32 and identify when nonzero mathematical derivatives become zero on the GPU.

Part 2 - System and Memory Mental Model

A gradient can vanish during an intermediate multiplication or when it is stored in a narrow dtype. float16 has a limited exponent range, while bfloat16 preserves a float32-like exponent range with fewer significand bits. Device flush-to-zero behavior can affect subnormal observations.

Part 3 - Quantitative Prediction Before Execution

Use torch.finfo to choose logarithmically spaced coefficients around each dtype threshold. Predict the exact derivative and classify it as normal, subnormal, rounded, or zero before execution.

Part 4 - Experimental Design and Instrumentation

Differentiate simple products and a short chain on CUDA for all three dtypes. Record analytical gradient, stored gradient, zero status, relative error, and the first coefficient that underflows. Repeat with and without a float32 parameter receiving a half-precision computation.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def tiny_gradient(dtype, coefficient, device="cuda"):
    parameter = torch.ones((), dtype=dtype, device=device, requires_grad=True)
    multiplier = torch.tensor(coefficient, dtype=dtype, device=device)
    loss = parameter * multiplier
    loss.backward()
    return parameter.grad.detach()

def E01(coefficients, device="cuda"):
    results = {}
    dtypes = [torch.float16, torch.bfloat16, torch.float32]
    for dtype in dtypes:
        gradients = []
        for coefficient in coefficients:
            gradients.append(tiny_gradient(dtype, coefficient, device))
        results[str(dtype)] = gradients
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Avoid converting coefficients to the target dtype before preserving the analytical reference. Record subnormal behavior on the tested GPU and distinguish a zero gradient from a zero loss. Synchronize failures and repeat boundary values.

Part 7 - Engineering Interpretation and Philosophy

Underflow is a representational failure that can be exposed with a tiny controlled graph. Once its location is measurable, scaling or a wider-exponent dtype can be evaluated as a targeted remedy.

19.22.3 Exercise 02

Exercise Title: Construct Excessively Large float16 Gradients That Overflow to Infinity and Trace Their Effect Through an Optimizer Step

Part 1 - Exercise Contract and Why It Matters

Create finite forward values whose derivatives exceed float16 range, then trace infinity through momentum, parameter updates, and subsequent losses. Compare an unsafe update with a protected path that rejects the step.

Part 2 - System and Memory Mental Model

Overflow can occur in backward even when the forward loss is finite. If infinity reaches an optimizer, momentum or variance state can become permanently non-finite and corrupt later steps. Detection must precede any mutation of parameter or optimizer state.

Part 3 - Quantitative Prediction Before Execution

Derive the gradient magnitude from the chosen function and predict the first input or multiplier that exceeds torch.finfo(float16).max. Predict which optimizer state tensors will be contaminated after one unsafe update.

Part 4 - Experimental Design and Instrumentation

Clone identical parameter and optimizer state into unsafe and guarded branches. Sweep gradient magnitudes, record finite status before and after step, parameter deltas, optimizer-state values, and recovery on the next normal batch.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import torch

def overflow_trial(parameter, optimizer, multiplier, allow_update):
    optimizer.zero_grad(set_to_none=True)
    loss = parameter * multiplier
    loss.backward()
    gradient_is_finite = bool(torch.isfinite(parameter.grad).all())
    before = parameter.detach().clone()
    if allow_update or gradient_is_finite:
        optimizer.step()
    after = parameter.detach().clone()
    return gradient_is_finite, before, after

def E02(parameter, optimizer, multiplier):
    return overflow_trial(parameter, optimizer, multiplier, True)
```

Part 6 - Measurement, Validation, and Failure Analysis

Inspect loss, gradients, parameters, and every tensor in optimizer state. A skipped update must cause no mutation. Restore state between trials and do not call zero_grad as a substitute for repairing contaminated optimizer state.

Part 7 - Engineering Interpretation and Philosophy

Overflow protection is transactional: either a numerically valid update and its state changes commit together, or the entire step is rejected.

19.22.4 Exercise 03

Exercise Title: Manually Multiply the Loss by a Fixed Scale Factor and Verify That Backpropagated Gradients Increase by the Same Factor

Part 1 - Exercise Contract and Why It Matters

Prove experimentally that multiplying a scalar loss by fixed S multiplies each parameter gradient by S. Use multiple layers, nonuniform gradient magnitudes, and several scales while keeping the forward graph identical.

Part 2 - System and Memory Mental Model

The chain rule gives the derivative of S times L with respect to a parameter as S times the derivative of L. The relationship holds before rounding or overflow; finite-precision arithmetic can break exact proportionality at extreme scales.

Part 3 - Quantitative Prediction Before Execution

Calculate reference gradients in float32 and predict scaled values for every parameter. Define absolute and relative tolerances and a scale range expected to remain finite.

Part 4 - Experimental Design and Instrumentation

Run reference and scaled backward passes from identical model state and inputs. Record per-parameter maximum error between scaled gradient and S times reference, zero counts, and non-finite counts.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def named_gradients(model):
    result = {}
    for name, parameter in model.named_parameters():
        if parameter.grad is not None:
            result[name] = parameter.grad.detach().clone()
    return result

def E03(model, loss, scale):
    model.zero_grad(set_to_none=True)
    scaled_loss = loss * scale
    scaled_loss.backward()
    return named_gradients(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

Rebuild the graph for each backward pass and compare cloned initial state. Check that S is represented in a suitable dtype and report rounding, underflow rescue, overflow, and parameters with no gradients separately.

Part 7 - Engineering Interpretation and Philosophy

Fixed scaling is the algebraic core of dynamic loss scaling. Proving proportionality before automation makes every later skip and scale adjustment interpretable.

19.22.5 Exercise 04

Exercise Title: Manually Unscale Gradients Before the Optimizer Step and Prove That the Final Parameter Update Matches an Unscaled Reference

Part 1 - Exercise Contract and Why It Matters

Implement fixed loss scaling followed by explicit in-place gradient division before optimizer.step. Demonstrate equivalence of gradients, parameter updates, and optimizer state against an unscaled reference.

Part 2 - System and Memory Mental Model

The optimizer must consume gradients divided by the same scale used on the loss. Unscaling after optimizer.step is too late because parameter and optimizer state have already incorporated the enlarged gradient.

Part 3 - Quantitative Prediction Before Execution

Predict every reference update for SGD and one stateful optimizer. State tolerances for unscaled gradients, parameters, momentum or variance, and loss on the following step.

Part 4 - Experimental Design and Instrumentation

Clone model and optimizer state into reference, correct-unscale, and missing-unscale branches. Compare gradients immediately before step and all mutated state immediately after step.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def unscale_gradients(model, scale):
    inverse_scale = 1.0 / scale
    for parameter in model.parameters():
        if parameter.grad is not None:
            parameter.grad.mul_(inverse_scale)

def E04(model, optimizer, loss, scale):
    optimizer.zero_grad(set_to_none=True)
    (loss * scale).backward()
    unscale_gradients(model, scale)
    optimizer.step()
    return model
```

Part 6 - Measurement, Validation, and Failure Analysis

Check gradient finiteness before and after unscale. Use identical optimizer hyperparameters and initialized state. Verify that the incorrect branch diverges by the predicted scale rather than merely reporting different loss.

Part 7 - Engineering Interpretation and Philosophy

Scaling remains mathematically invisible only when the optimizer boundary receives restored gradients. That boundary is the central invariant of the training loop.

19.22.6 Exercise 05

Exercise Title: Train a Small CUDA Model in float16 Without Gradient Scaling and Record When Gradients Become Zero, Infinite, or NaN

Part 1 - Exercise Contract and Why It Matters

Establish a pure float16 no-scaling failure baseline. Track per-layer gradients, parameter updates, loss, and optimizer state until underflow, overflow, or NaN appears.

Part 2 - System and Memory Mental Model

Small gradients can round to zero while large reductions can overflow. Once a non-finite value enters stateful optimizer buffers, later normal batches may not recover. Pure half storage also exposes parameter updates to limited precision.

Part 3 - Quantitative Prediction Before Execution

Predict vulnerable layers from activation scale, depth, loss magnitude, and gradient norms. Define zero-rate, non-finite-rate, and update-to-weight ratio thresholds before training.

Part 4 - Experimental Design and Instrumentation

Train from fixed state on a reproducible batch sequence. Record every step, layer, gradient minimum nonzero magnitude, zero fraction, infinity and NaN counts, parameter delta, and first failure step.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def gradient_health(model):
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        if gradient is None:
            report[name] = None
            continue
        report[name] = {
            "zero": int((gradient == 0).sum()),
            "infinite": int(torch.isinf(gradient).sum()),
            "nan": int(torch.isnan(gradient).sum()),
        }
```

```
    return report

def E05(model, optimizer, loss):
    optimizer.zero_grad(set_to_none=True)
    loss.backward()
    report = gradient_health(model)
    optimizer.step()
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not treat an improving loss as proof of healthy gradients. Inspect every layer and optimizer tensor. Preserve the first failing batch and state so the scaled experiment can replay it exactly.

Part 7 - Engineering Interpretation and Philosophy

A failure baseline identifies the numerical debt that scaling must repay and prevents stability claims from relying on an easy workload.

19.22.7 Exercise 06

Exercise Title: Add torch.amp.GradScaler to the Same Training Loop and Measure the Change in Numerical Stability

Part 1 - Exercise Contract and Why It Matters

Add GradScaler to the identical autocast training loop and quantify rescued gradients, skipped updates, scale changes, loss behavior, and throughput relative to the no-scaling baseline.

Part 2 - System and Memory Mental Model

GradScaler scales loss, unscales and checks gradients during step, skips unsafe optimizer updates, then adjusts its scale. It is useful for float16; bfloat16 often does not need the same underflow protection.

Part 3 - Quantitative Prediction Before Execution

Predict the initial transient, expected overflow frequency, stable scale range, and number of gradients rescued from zero. Estimate the runtime overhead of checks and scale bookkeeping.

Part 4 - Experimental Design and Instrumentation

Replay identical batches and state with scaling disabled and enabled. Record loss, scale before and after update, update-skipped inference, gradient health after unscale, peak VRAM, and synchronized step time.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E06(model, optimizer, inputs, targets, loss_function, scaler):
    optimizer.zero_grad(set_to_none=True)
```

```
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        outputs = model(inputs)
        loss = loss_function(outputs, targets)
    scale_before = scaler.get_scale()
    scaler.scale(loss).backward()
    scaler.step(optimizer)
    scaler.update()
    scale_after = scaler.get_scale()
    return loss.detach(), scale_before, scale_after
```

Part 6 - Measurement, Validation, and Failure Analysis

Use torch.amp.GradScaler with the API supported by the installed PyTorch version. Infer skipped steps carefully and verify parameters directly. Compare only after identical warm-up and state restoration.

Part 7 - Engineering Interpretation and Philosophy

Automation is valuable when its internal control signal remains observable. Scale history and accepted updates are part of the training evidence, not hidden implementation details.

19.22.8 Exercise 07

Exercise Title: Inspect the Gradient Scale Across Training Steps and Explain Why It Can Increase, Decrease, or Remain Constant

Part 1 - Exercise Contract and Why It Matters

Build a scale timeline and associate every transition with finite or non-finite gradients, growth interval progress, and optimizer-update status.

Part 2 - System and Memory Mental Model

The scale decreases after detected overflow according to the backoff factor. It grows after a configured number of consecutive successful updates and otherwise remains constant. A skipped update resets or interrupts growth progress.

Part 3 - Quantitative Prediction Before Execution

Simulate a known success-failure sequence and predict scale at every step from initial scale, growth factor, backoff factor, and growth interval.

Part 4 - Experimental Design and Instrumentation

Run a controlled training loop with injected overflow steps. Record scale before backward, after update, success counter, finite status, and parameter checksum. Compare observation with the predicted state machine.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E07(run_step, scaler, number_of_steps):
    history = []
```

```
    for step_index in range(number_of_steps):
        scale_before = scaler.get_scale()
        run_step(scaler, step_index)
        scale_after = scaler.get_scale()
        history.append({
            "step": step_index,
            "before": scale_before,
            "after": scale_after,
        })
    return history
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not assume a decreased scale is the only skip indicator across all configurations. Verify parameter changes and gradient finiteness. Record scaler configuration and software version with the timeline.

Part 7 - Engineering Interpretation and Philosophy

Dynamic scaling is understandable as a small state machine. Making transitions explicit turns numerical adaptation into reproducible system behavior.

19.22.9 Exercise 08

Exercise Title: Force an Overflow and Verify That Gradient Scaling Skips the Unsafe Optimizer Update Instead of Corrupting Model Parameters

Part 1 - Exercise Contract and Why It Matters

Inject a deterministic overflow into one gradient and prove that GradScaler prevents both parameter and optimizer-state mutation for that step.

Part 2 - System and Memory Mental Model

After unscale, GradScaler checks for non-finite gradients associated with the optimizer. If any are found, optimizer.step is not executed and the scale is backed off. The next valid batch can proceed from intact state.

Part 3 - Quantitative Prediction Before Execution

Predict scale change, parameter checksum, optimizer-state checksum, and step count for overflow and recovery steps.

Part 4 - Experimental Design and Instrumentation

Snapshot model and optimizer state, inject infinity after scaled backward, call scaler.step and scaler.update, then compare all tensors with the snapshot. Follow with a finite batch and verify recovery.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def clone_parameters(model):
    copies = []
    for parameter in model.parameters():
        copies.append(parameter.detach().clone())
    return copies

def E08(model, optimizer, scaler, loss):
    optimizer.zero_grad(set_to_none=True)
    before = clone_parameters(model)
    scaler.scale(loss).backward()
    first_parameter = next(model.parameters())
    first_parameter.grad.fill_(float("inf"))
    scaler.step(optimizer)
    scaler.update()
    after = clone_parameters(model)
    return before, after, scaler.get_scale()
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare optimizer state as well as parameters and ensure overflow is injected before scaler.step. Confirm a subsequent valid update succeeds. Test multiple optimizers because state mutation timing can differ.

Part 7 - Engineering Interpretation and Philosophy

Skipping is a correctness mechanism, not lost progress. One rejected update is cheaper than silently poisoning every future update.

19.22.10 Exercise 09

Exercise Title: Track Consecutive Successful Steps and Determine When Dynamic Loss Scaling Increases the Scale Factor

Part 1 - Exercise Contract and Why It Matters

Measure the exact success streak required for scale growth and verify that a single overflow changes the streak and scale as configured.

Part 2 - System and Memory Mental Model

Growth interval counts consecutive unskipped updates. When the interval is reached, scale is multiplied by the growth factor and the tracker restarts. Overflow applies backoff and resets stable progress.

Part 3 - Quantitative Prediction Before Execution

Write the expected scale sequence for several intervals, including an overflow immediately before and after a growth boundary.

Part 4 - Experimental Design and Instrumentation

Use deterministic finite batches and scheduled overflow injection. Record accepted updates, internal outcome inferred from state, scale transitions, and the first step at each new scale.

Part 5 - PyTorch/CUDA Implementation

```
def E09(run_step, scaler, schedule):
    records = []
    successful_steps = 0
    for step_index, force_overflow in enumerate(schedule):
        before = scaler.get_scale()
        update_happened = run_step(scaler, force_overflow)
        after = scaler.get_scale()
        if update_happened:
            successful_steps += 1
        else:
            successful_steps = 0
        records.append((step_index, successful_steps, before, after))
    return records
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify the run_step outcome from parameter or optimizer state rather than scale alone. Test off-by-one behavior at growth boundaries and record the exact scaler configuration.

Part 7 - Engineering Interpretation and Philosophy

Growth is earned confidence: repeated valid updates permit more aggressive scaling, while any failure returns the controller to caution.

19.22.11 Exercise 10

Exercise Title: Compare Several Initial Scale Values and Measure Their Effects on Early Training Stability, Overflow Frequency, and Convergence

Part 1 - Exercise Contract and Why It Matters

Sweep conservative, moderate, and aggressive initial scales while preserving identical training state and batch order. Measure warm-up failures, time to stable scale, rescued small gradients, and convergence.

Part 2 - System and Memory Mental Model

A scale that is too small may not prevent underflow; a scale that is too large causes early skipped updates and backoff. Dynamic adaptation can eventually converge, but the transient costs time and can interact with schedules.

Part 3 - Quantitative Prediction Before Execution

Predict a safe interval from measured gradient extrema and float16 range. For each initial scale, estimate required backoff steps and expected stable range.

Part 4 - Experimental Design and Instrumentation

Run isolated trials across multiple seeds. Record scale timeline, overflow count, skipped updates, gradient zero fraction, loss curve, final metric, peak VRAM, and total time to a fixed number of accepted updates.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E10(initial_scales, training_trial):
    results = {}
    for initial_scale in initial_scales:
        scaler = torch.amp.GradScaler(
            "cuda", init_scale=initial_scale)
        results[initial_scale] = training_trial(scaler)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare by accepted updates as well as attempted steps. Restore model, optimizer, RNG, scheduler, and batches for every trial. Preserve failed initial scales as evidence.

Part 7 - Engineering Interpretation and Philosophy

Initialization is a prior belief about gradient magnitude. A good prior shortens adaptation, while dynamic control protects correctness when that belief is wrong.

19.22.12 Exercise 11

Exercise Title: Sweep Growth and Backoff Factors and Discover How Aggressive Dynamic Scaling Changes Recovery from Numerical Failures

Part 1 - Exercise Contract and Why It Matters

Sweep growth and backoff factors with fixed growth interval to measure scale oscillation, skipped-update rate, recovery time, and useful gradient range.

Part 2 - System and Memory Mental Model

Large growth factors explore higher scales quickly but can overshoot repeatedly. Strong backoff recovers from overflow rapidly but may return to underflow-prone scales. The best balance depends on gradient nonstationarity.

Part 3 - Quantitative Prediction Before Execution

Simulate scale trajectories for each factor pair under a fixed success-failure schedule before training. Predict oscillation amplitude and attempts lost after a spike.

Part 4 - Experimental Design and Instrumentation

Run factor pairs on identical dynamic workloads with sudden loss spikes. Record scale, finite status, accepted update, gradient zero rate, time to recovery, loss, and throughput.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E11(factor_pairs, training_trial):
    results = {}
    for growth_factor, backoff_factor in factor_pairs:
        scaler = torch.amp.GradScaler(
            "cuda",
            growth_factor=growth_factor,
            backoff_factor=backoff_factor)
        key = (growth_factor, backoff_factor)
        results[key] = training_trial(scaler)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject invalid factor configurations and compare equal accepted updates. Report instability caused by the workload separately from oscillation created by the controller.

Part 7 - Engineering Interpretation and Philosophy

Growth and backoff determine how aggressively the controller searches numerical range. They are control parameters that must be evaluated against real gradient dynamics.

19.22.13 Exercise 12

Exercise Title: Unscale Gradients Before Gradient Clipping and Reproduce the Incorrect Result Produced by Clipping Scaled Gradients Directly

Part 1 - Exercise Contract and Why It Matters

Compare correct unscale-then-clip ordering with incorrect clipping of scaled gradients. Quantify the effective clipping threshold and resulting parameter update.

Part 2 - System and Memory Mental Model

Clipping scaled gradients at threshold C is equivalent to clipping true gradients near C divided by S. GradScaler.unscale_ must run before norm measurement and clipping, and only once per optimizer per step.

Part 3 - Quantitative Prediction Before Execution

Calculate true norm, scaled norm, correct clipping coefficient, and incorrect coefficient for chosen S and C. Predict parameter deltas in both branches.

Part 4 - Experimental Design and Instrumentation

Clone state into reference, correct, and incorrect branches. Record norms before and after unscale, returned clip norm, gradient tensors, parameter updates, and scaler outcome.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E12(model, optimizer, scaler, loss, maximum_norm):
    optimizer.zero_grad(set_to_none=True)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    total_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), maximum_norm)
    scaler.step(optimizer)
    scaler.update()
    return total_norm
```

Part 6 - Measurement, Validation, and Failure Analysis

Rebuild the graph and restore state for each ordering. Ensure the incorrect branch clips before unscale, then prove its effective threshold mathematically. Detect non-finite norms before step.

Part 7 - Engineering Interpretation and Philosophy

Gradient transformations must operate in a declared numerical coordinate system. Unscaling restores the units expected by clipping and the optimizer.

19.22.14 Exercise 13

Exercise Title: Combine Gradient Scaling with Gradient Accumulation and Determine the Correct Points for Scaling, Unscaling, and Optimizer Updates

Part 1 - Exercise Contract and Why It Matters

Implement microbatch accumulation with one consistent scale across the effective batch. Determine when to divide loss, backward, unscale, clip, step, update the scaler, and clear gradients.

Part 2 - System and Memory Mental Model

Each microbatch loss is scaled before backward. The scale should remain unchanged during one accumulation window. Unscale, clipping, finite checks, optimizer step, and scaler update occur once after the final microbatch.

Part 3 - Quantitative Prediction Before Execution

Derive the accumulated gradient for sum and mean loss conventions. Predict how dividing each microbatch loss by accumulation steps affects the final update and clipping norm.

Part 4 - Experimental Design and Instrumentation

Compare a large-batch reference with accumulated microbatches from identical samples. Record scale per microbatch, accumulated gradient, finite status, clipping norm, update, and memory peak.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E13(model, optimizer, scaler, microbatches,
        loss_function, accumulation_steps):
    optimizer.zero_grad(set_to_none=True)
    for inputs, targets in microbatches:
        with torch.autocast(device_type="cuda", dtype=torch.float16):
            outputs = model(inputs)
            loss = loss_function(outputs, targets)
            normalized_loss = loss / accumulation_steps
        scaler.scale(normalized_loss).backward()
    scaler.unscale_(optimizer)
    scaler.step(optimizer)
    scaler.update()
    return scaler.get_scale()
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exactly the intended number of microbatches or adjust normalization explicitly. Do not update scale or optimizer inside the window. Verify equivalence within tolerances and test overflow in an early microbatch.

Part 7 - Engineering Interpretation and Philosophy

Accumulation creates one logical optimizer transaction from several backward passes. Precision control must respect that transaction boundary.

19.22.15 Exercise 14

Exercise Title: Detect NaN and Infinite Gradients Before the Optimizer Step and Build a Per-Layer Numerical Failure Report

Part 1 - Exercise Contract and Why It Matters

Build a diagnostic report after unscale that locates NaN, positive and negative infinity, zeros, extreme magnitudes, and affected layers before the update.

Part 2 - System and Memory Mental Model

A global overflow flag protects the update but does not identify the source. Per-parameter aggregation connected to module names reveals whether failure originates in one layer and then propagates.

Part 3 - Quantitative Prediction Before Execution

Define warning thresholds from dtype range and reference gradient statistics. Predict which layer fails first in an injected experiment.

Part 4 - Experimental Design and Instrumentation

Unscale gradients, scan without modifying them, and record shape, dtype, finite counts, zero fraction, minimum nonzero magnitude, maximum magnitude, and norm per named parameter. Correlate with activations and loss.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def gradient_failure_report(model):
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        if gradient is None:
            report[name] = {"missing": True}
            continue
        finite = torch.isfinite(gradient)
        report[name] = {
            "missing": False,
            "nan": int(torch.isnan(gradient).sum()),
            "positive_infinity": int(torch.isposinf(gradient).sum()),
            "negative_infinity": int(torch.isneginf(gradient).sum()),
            "zero": int((gradient == 0).sum()),
            "finite": int(finite.sum()),
        }
    return report

def E14(model):
    return gradient_failure_report(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

Run the report after unscale and before any clipping that could hide magnitude. Avoid retaining graphs or full gradient copies unnecessarily. Verify counts on injected NaN and infinity patterns.

Part 7 - Engineering Interpretation and Philosophy

Protection answers whether a step is safe; diagnostics answer why it is unsafe. Both are required for engineering a robust training system.

19.22.16 Exercise 15

Exercise Title: Compare float16 with Dynamic Gradient Scaling Against bfloat16 Training Without Scaling Under the Same CUDA Workload

Part 1 - Exercise Contract and Why It Matters

Compare float16 autocast plus dynamic scaling with bfloat16 autocast without scaling under identical workload, memory budget, and acceptance criteria.

Part 2 - System and Memory Mental Model

float16 benefits from scaling because of narrow exponent range. bfloat16 often represents small gradients without scaling, but has coarser precision. Hardware kernel support and accumulation policy influence speed and error.

Part 3 - Quantitative Prediction Before Execution

Predict scale behavior, overflow rate, gradient zero rate, memory equality, throughput, and reference error for both modes. Identify workloads that favor range versus precision.

Part 4 - Experimental Design and Instrumentation

Replay cloned state and batch order for multiple seeds. Record accepted updates, scale history, non-finite and zero gradients, loss, gradient error, peak VRAM, runtime, and final metric.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E15(float16_trial, bfloat16_trial):
    float16_scaler = torch.amp.GradScaler("cuda")
    float16_result = float16_trial(float16_scaler)
    bfloat16_result = bfloat16_trial()
    return {
        "float16_with_scaling": float16_result,
        "bfloat16_without_scaling": bfloat16_result,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify native bfloat16 capability and identical operation coverage. Compare accepted rather than attempted updates and use float32 reference evidence. Report unsupported kernels and precision-sensitive divergence.

Part 7 - Engineering Interpretation and Philosophy

Scaling compensates for a format's range; choosing bfloat16 changes the format itself. The better system is determined by stability, accuracy, and achieved hardware performance together.

19.22.17 Exercise 16

Exercise Title: Measure the VRAM and Runtime Overhead of Gradient Scaling and Determine Whether Its Memory Cost Is Significant

Part 1 - Exercise Contract and Why It Matters

Isolate the memory and latency overhead of GradScaler from autocast and the model workload. Measure scaler state, finite checks, unscale, skipped-step handling, and synchronization effects.

Part 2 - System and Memory Mental Model

GradScaler stores little persistent state, but unscale and non-finite checks traverse gradients and launch kernels. The relative overhead depends on model size, number of gradient tensors, kernel launch cost, and whether the step is compute-bound.

Part 3 - Quantitative Prediction Before Execution

Estimate persistent bytes and bytes read or written during unscale. Predict overhead for many tiny parameters versus a few large tensors and for successful versus overflow steps.

Part 4 - Experimental Design and Instrumentation

Benchmark identical autocast steps with scaling disabled and enabled after warm-up. Record peak allocated and reserved VRAM, memory snapshots, kernel time, synchronized step latency distribution, throughput, and number of gradient tensors.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def timed_scaled_step(run_step, scaler):
    torch.cuda.reset_peak_memory_stats()
    torch.cuda.synchronize()
    start = time.perf_counter()
    run_step(scaler)
    torch.cuda.synchronize()
    return {
        "seconds": time.perf_counter() - start,
        "peak_allocated": torch.cuda.max_memory_allocated(),
        "peak_reserved": torch.cuda.max_memory_reserved(),
        "scale": scaler.get_scale(),
    }

def E16(run_step):
    scaler = torch.amp.GradScaler("cuda")
    return timed_scaled_step(run_step, scaler)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not include first-use initialization only in the scaled branch. Run repeated synchronized trials and report median and tail latency. Separate allocator noise from persistent scaler state and profiler overhead from production timing.

Part 7 - Engineering Interpretation and Philosophy

A safety mechanism should be measured, but its value is not judged by zero cost. The relevant question is whether overhead is small relative to prevented numerical failure and unlocked float16 throughput.

19.22.18 Exercise 17

Exercise Title: Implement a Minimal Dynamic Loss Scaler from Scratch That Detects Overflow and Adjusts the Scale Without Using GradScaler

Part 1 - Exercise Contract and Why It Matters

Implement scale, unscale, finite detection, conditional optimizer step, growth tracking, and backoff without calling GradScaler. Keep state transitions explicit and auditable.

Part 2 - System and Memory Mental Model

The scaler multiplies loss before backward, divides gradients once, checks all gradients, commits only finite updates, grows after a success interval, and backs off immediately after failure.

Part 3 - Quantitative Prediction Before Execution

Write the state transition table and predict scale history for a fixed finite-overflow schedule. Define lower and upper scale bounds and behavior for missing gradients.

Part 4 - Experimental Design and Instrumentation

Compare the custom scaler with GradScaler on deterministic injected failures. Verify parameter and optimizer state, scale timeline, skipped updates, clipping compatibility, and multiple optimizers.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class MinimalDynamicLossScaler:
    def __init__(self, initial_scale=65536.0,
                 growth_factor=2.0, backoff_factor=0.5,
                 growth_interval=2000):
        self.scale = initial_scale
        self.growth_factor = growth_factor
        self.backoff_factor = backoff_factor
        self.growth_interval = growth_interval
        self.successful_steps = 0

    def scale_loss(self, loss):
        return loss * self.scale

    def unscale_and_check(self, model):
        all_finite = True
        inverse_scale = 1.0 / self.scale
        for parameter in model.parameters():
            if parameter.grad is None:
                continue
            parameter.grad.mul_(inverse_scale)
            if not bool(torch.isfinite(parameter.grad).all()):
                all_finite = False
        return all_finite

    def update(self, successful):
        if not successful:
            self.scale *= self.backoff_factor
            self.successful_steps = 0
            return
        self.successful_steps += 1
```

```
        if self.successful_steps >= self.growth_interval:
            self.scale *= self.growth_factor
            self.successful_steps = 0

def E17():
    return MinimalDynamicLossScaler()
```

Part 6 - Measurement, Validation, and Failure Analysis

Prevent repeated unscale, clamp invalid scales, and ensure a failed step mutates nothing. Test sparse or missing gradients, multiple devices, gradient accumulation, exceptions, and optimizer closures as declared limitations.

Part 7 - Engineering Interpretation and Philosophy

Reimplementation exposes the controller's invariants. The goal is not replacing a mature library utility, but understanding the transactional and numerical responsibilities it fulfills.

19.22.19 Exercise 18

Exercise Title: Stress-Test the Custom Dynamic Loss Scaler with Sudden Loss Spikes, Long Stable Periods, Tiny Gradients, and Repeated Overflows

Part 1 - Exercise Contract and Why It Matters

Drive the custom scaler through adversarial regimes that exercise underflow rescue, rapid overflow recovery, long-term growth, repeated rejection, and transitions between regimes.

Part 2 - System and Memory Mental Model

A robust controller must avoid unbounded scale growth, prolonged underflow, oscillation around a failure threshold, and state corruption during consecutive skips. Nonstationary gradients expose weaknesses hidden by steady workloads.

Part 3 - Quantitative Prediction Before Execution

Predict the scale trajectory for each scripted regime and define maximum recovery steps, allowed skip rate, scale bounds, and gradient-health targets.

Part 4 - Experimental Design and Instrumentation

Create a deterministic schedule of tiny, normal, spike, and repeated-overflow losses. Record scale, success counter, gradient extrema, zero and non-finite counts, accepted update, parameter checksum, and recovery latency every step.

Part 5 - PyTorch/CUDA Implementation

```
def E18(training_step, scaler, regimes):
    history = []
    for step_index, regime in enumerate(regimes):
        result = training_step(scaler, regime)
        history.append({
            "step": step_index,
            "regime": regime,
```

```
            "scale": scaler.scale,
            "successful_steps": scaler.successful_steps,
            "result": result,
        })
    return history
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify scripted magnitudes at the actual gradient, not only the loss. Test boundary conditions for scale floor and ceiling, consecutive failures, and recovery after optimizer state remains unchanged. Preserve any oscillatory trace.

Part 7 - Engineering Interpretation and Philosophy

Stress testing asks whether the controller remains safe when its assumptions stop being stationary. Robustness is demonstrated by bounded state, valid updates, and explainable recovery.

19.22.20 Exercise 19

Exercise Title: Build and Benchmark a Numerically Robust Mixed-Precision PyTorch Training Loop with Automatic Scaling, Overflow Recovery, Gradient Clipping, and Detailed Scale Diagnostics

Part 1 - Exercise Contract and Why It Matters

Integrate autocast, GradScaler, accumulation support, unscale-before-clipping, non-finite diagnostics, conditional updates, scale telemetry, and reproducible benchmarking into one training loop.

Part 2 - System and Memory Mental Model

The loop is a numerical transaction: forward and scaled backward create a candidate update; unscale, diagnostics, and clipping validate and transform it; scaler.step commits only when safe; scaler.update adjusts future range. Measurement must not alter ordering.

Part 3 - Quantitative Prediction Before Execution

Define memory, throughput, gradient norm, error, skip-rate, scale-stability, and convergence budgets. Predict steady scale and recovery behavior for normal and injected-stress phases.

Part 4 - Experimental Design and Instrumentation

Benchmark float32, float16 without scaling, and the robust loop from identical states. Report peak allocated and reserved VRAM, latency distribution, throughput, loss, reference error, clipping norms, non-finite locations, scale history, skipped updates, and final metric.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class RobustMixedPrecisionTrainer:
    def __init__(self, model, optimizer, maximum_gradient_norm):
        self.model = model
```

```
        self.optimizer = optimizer
        self.maximum_gradient_norm = maximum_gradient_norm
        self.scaler = torch.amp.GradScaler("cuda")
        self.history = []

    def step(self, inputs, targets, loss_function):
        self.optimizer.zero_grad(set_to_none=True)
        with torch.autocast(device_type="cuda", dtype=torch.float16):
            outputs = self.model(inputs)
            loss = loss_function(outputs, targets)
        scale_before = self.scaler.get_scale()
        self.scaler.scale(loss).backward()
        self.scaler.unscale_(self.optimizer)
        gradient_norm = torch.nn.utils.clip_grad_norm_(
            self.model.parameters(), self.maximum_gradient_norm)
        self.scaler.step(self.optimizer)
        self.scaler.update()
        scale_after = self.scaler.get_scale()
        record = {
            "loss": float(loss.detach()),
            "gradient_norm": float(gradient_norm),
            "scale_before": scale_before,
            "scale_after": scale_after,
        }
        self.history.append(record)
        return record

def E19(model, optimizer, maximum_gradient_norm):
    return RobustMixedPrecisionTrainer(
        model, optimizer, maximum_gradient_norm)
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate parameter and optimizer state after every injected overflow, detect non-finite clipping norms, and confirm unscale occurs exactly once. Warm up before timing, compare accepted updates, and document API version, hardware, seeds, tolerances, and known limitations.

Part 7 - Engineering Interpretation and Philosophy

A robust training loop combines capacity and speed with evidence that every committed update is numerically admissible. Diagnostics, recovery, and reproducibility are part of the implementation, not optional monitoring.

19.23 DMM21

Chapter Title: Gradient Accumulation and Effective Batch Scaling
Specialization: Dynamic Memory Management and CUDA Systems

19.23.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Micro-Batches, Effective Batch Size, Gradient Accumulation, and Peak VRAM Reduction

Part 1 - Exercise Contract and Why It Matters

Construct a complete lifecycle for one logical optimizer update: divide the effective batch into micro-batches, execute forward and backward for each micro-batch, retain parameter gradients across the accumulation window, normalize the contribution correctly, perform one optimizer update, and then clear gradients. The final report must distinguish a micro-step from an optimizer step and a processed sample from an accepted update.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Gradient accumulation reduces the activation working set because only one micro-batch performs forward and backward at a time. Parameters, gradients, optimizer state, and many persistent workspaces do not shrink. Gradient tensors normally remain allocated across the window, while the autograd graph for a completed micro-batch should be released unless the program accidentally retains it. Consequently, accumulation changes the variable activation term but not the entire VRAM footprint.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

Let micro-batch size be b, accumulation steps be K, and distributed world size be W. The global effective batch size is

$$B_{\text{eff}} = bKW.$$

For a mean-reduced loss and equally sized micro-batches, the target gradient is

$$g = \frac{1}{K} \sum_{k=1}^{K} g_k.$$

A first-order memory model is

$$M_{\text{peak}}(b) \approx M_{\text{fixed}} + M_{\text{activation}}(b) + M_{\text{workspace}}(b),$$

where parameters, gradients, and optimizer state belong primarily to M_{fixed}.

Before execution, calculate the effective batch, expected optimizer-update count, activation payload, gradient payload, and a lower bound for peak VRAM. Predict which allocations survive between micro-steps and whether the final micro-step should have the same peak as the first. Include the expected throughput penalty caused by repeated launches and reduced kernel occupancy.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Use one CUDA model, one deterministic batch, and cloned initial model and optimizer state. Compare a full-batch update with several micro-batch decompositions that preserve the same effective batch. Record allocated and reserved VRAM at forward peak, after backward, before optimizer step, after optimizer step, and after zeroing gradients. Record step time, samples per second, gradient norms, parameter deltas, and graph-retention evidence.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def calculate_effective_batch_size(
        micro_batch_size,
        accumulation_steps,
        world_size):
    effective_batch_size = ...
    return effective_batch_size

def run_accumulation_window(
        model,
        optimizer,
        micro_batches,
        loss_function,
        accumulation_steps):
    optimizer.zero_grad(set_to_none=True)

    for micro_step_index in range(accumulation_steps):
        inputs, targets = micro_batches[micro_step_index]

        outputs = ...
        loss = ...
        normalized_loss = ...

        # Accumulate gradients without updating the parameters yet.
        ...
```

```
    # Perform exactly one optimizer update for the complete window.
    ...

    return ...

def E00(
        model,
        optimizer,
        micro_batches,
        loss_function,
        accumulation_steps,
        world_size):
    effective_batch_size = ...
    window_result = ...
    return effective_batch_size, window_result
```

Part 6 - Measurement, Validation, and Failure Analysis

Detect loss-normalization mistakes, premature zeroing, accidental optimizer steps inside the window, retained graphs, variable micro-batch sizes, and differences introduced by stochastic layers or batch-dependent normalization. A capacity result is invalid unless the final gradients and parameter update are compared with an appropriate reference.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Gradient accumulation exchanges time and launch efficiency for a smaller activation working set. It does not create free memory and it does not automatically reproduce large-batch semantics; those properties must be established by accounting, normalization, and measured equivalence.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.2 Exercise 01

Exercise Title: Train with a Full Batch and Measure Peak VRAM, Step Time, and Gradient Statistics as a Baseline

Part 1 - Exercise Contract and Why It Matters

Establish a full-batch reference that later accumulation experiments must match. The baseline must include a complete training transaction—gradient clearing, forward, loss, backward,

gradient inspection, optimizer update, and synchronized measurement—rather than a forward-only memory number.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

The full batch maximizes simultaneous activation residency and often gives efficient large kernels. Its peak may occur during forward, backward, or optimizer initialization depending on the model and optimizer. CUDA execution is asynchronous, allocator reservations persist, and the first optimizer update can allocate state that later steps reuse.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For batch size B, define throughput and update gradient norm as

$$T = \frac{B}{t_{\text{step}}}, \qquad \|g\|_2 = \sqrt{\sum_i \|g_i\|_2^2}.$$

Record both peak allocated memory $M_{\text{alloc}}^{\max}$ and peak reserved memory $M_{\text{reserved}}^{\max}$ because they describe live tensors and allocator capacity differently.

Compute parameter, gradient, optimizer-state, input, and approximate activation bytes before execution. Predict the peak stage and the difference between the first measured update and steady-state updates. Define expected gradient range, finite-value requirements, and timing variability.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run isolated warm-up steps, restore the documented measurement state, reset peak statistics, and execute repeated synchronized steps. Report median and tail latency, samples per second, loss, per-layer gradient norm and zero fraction, maximum gradient magnitude, parameter-update norm, and peak allocated and reserved VRAM.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import time
import torch

def collect_gradient_statistics(model):
    statistics = {}

    for parameter_name, parameter in model.named_parameters():
        if parameter.grad is None:
            continue

        gradient = parameter.grad
        statistics[parameter_name] = {
            "norm": ...,
            "maximum_absolute_value": ...,
            "zero_fraction": ...,
            "is_finite": ...,
        }

    return statistics

def E01(model, optimizer, inputs, targets, loss_function):
    optimizer.zero_grad(set_to_none=True)
    torch.cuda.reset_peak_memory_stats()

    torch.cuda.synchronize()
    start_time = time.perf_counter()

    outputs = ...
    loss = ...
    ...

    gradient_statistics = ...
    ...

    torch.cuda.synchronize()
    step_time = ...

    return {
        "loss": ...,
        "step_time": step_time,
        "peak_allocated": ...,
        "peak_reserved": ...,
        "gradient_statistics": gradient_statistics,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not compare a cold full-batch step with warmed accumulation. Verify that all samples and targets are identical and that the baseline fits without hidden retry or checkpointing. Preserve OOM as a result if the requested full batch cannot execute.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

A baseline is the semantic and systems control for the chapter. Every claimed memory saving or equivalence result is meaningful only relative to a fully specified reference update.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.3 Exercise 02

Exercise Title: Split the Same Batch into Micro-Batches and Accumulate Gradients Before One Optimizer Step

Part 1 - Exercise Contract and Why It Matters

Partition the exact full batch into an ordered sequence of micro-batches and accumulate their contributions into the same parameter gradient buffers. Execute one optimizer update only after every sample has contributed, and preserve a trace that maps sample ranges to micro-steps.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Calling backward repeatedly adds into existing parameter.grad tensors. Each micro-batch graph can be freed after its backward, while gradient buffers persist. The data partition, reduction convention, and loss normalization determine whether the accumulated gradient represents a sum or mean over the original full batch.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

If the full-batch objective is a sample mean and every micro-batch has size b, then

$$L_{\text{full}} = \frac{1}{K}\sum_{k=1}^{K} L_k, \qquad \nabla L_{\text{full}} = \sum_{k=1}^{K} \nabla\left(\frac{L_k}{K}\right).$$

For unequal micro-batch sizes b_k, weighting must follow b_k/B rather than blindly using $1/K$.

Predict the gradient norm after every micro-step and the final parameter delta. Estimate peak activation memory from the largest micro-batch, while keeping parameter, gradient, and optimizer memory fixed. State the number of forward and backward launches per optimizer update.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Slice a stored full batch without shuffling or augmentation changes. Log micro-batch indices, sizes, loss numerator, normalization weight, cumulative gradient norm, peak VRAM, and graph release after each backward. Compare the final state with the full-batch baseline.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def create_micro_batches(inputs, targets, micro_batch_size):
    micro_batches = []
    number_of_samples = ...

    start_index = 0
    while start_index < number_of_samples:
        end_index = ...
        micro_inputs = ...
        micro_targets = ...
        micro_batches.append((micro_inputs, micro_targets))
        start_index = end_index

    return micro_batches

def E02(
        model,
```

```
        optimizer,
        inputs,
        targets,
        loss_function,
        micro_batch_size):
    micro_batches = ...
    optimizer.zero_grad(set_to_none=True)

    for micro_inputs, micro_targets in micro_batches:
        outputs = ...
        micro_loss = ...
        normalized_loss = ...
        ...

    ...
    return ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that no optimizer step or zero_grad occurs inside the accumulation window. Detect dropped, repeated, or reordered samples and verify that model state such as running statistics does not invalidate equivalence.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Accumulation is repeated construction of one logical gradient. The correctness boundary is the optimizer update, not the individual micro-step.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.4 Exercise 03

Exercise Title: Prove That Correctly Scaled Gradient Accumulation Matches the Gradients of an Equivalent Full Batch

Part 1 - Exercise Contract and Why It Matters

Produce a numerical equivalence proof between one full-batch backward pass and an accumulation window that contains the same samples. The proof must cover loss, every named gradient, global norm, parameter update, and optimizer state—not only a single output tensor.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed

memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Linearity of differentiation gives equivalence when the objective decomposes over samples and normalization weights match. Floating-point reduction order can produce small differences. BatchNorm, dropout, random augmentation, token-count normalization, and other batch-coupled behavior can create legitimate semantic differences even with correct arithmetic scaling.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For sample losses ℓ_j and total batch size B,

$$L = \frac{1}{B}\sum_{j=1}^{B}\ell_j, \qquad \nabla_\theta L = \frac{1}{B}\sum_{j=1}^{B}\nabla_\theta \ell_j.$$

For micro-batch k with b_k samples and mean loss L_k,

$$\nabla_\theta L = \sum_{k=1}^{K}\frac{b_k}{B}\nabla_\theta L_k.$$

Calculate the expected weight for every micro-batch and define absolute and relative tolerances by dtype. Predict which parameters can differ most from reduction order and which model features must be disabled or controlled for an equivalence test.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Clone initial model and optimizer state. Execute full-batch and accumulation branches with identical inputs, RNG state, model mode, and numerical policy. Generate a named comparison table containing maximum absolute error, maximum relative error, norm difference, allclose status, and finite status for every gradient and updated parameter.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import copy
import torch

def clone_named_gradients(model):
    gradients = {}
    for parameter_name, parameter in model.named_parameters():
        if parameter.grad is None:
            gradients[parameter_name] = None
        else:
            gradients[parameter_name] = ...
    return gradients

def compare_named_gradients(
        reference_gradients,
        accumulated_gradients,
        absolute_tolerance,
        relative_tolerance):
    comparison = {}

    for parameter_name in reference_gradients:
        reference = reference_gradients[parameter_name]
        candidate = accumulated_gradients[parameter_name]

        # Compare missing gradients, shapes, values, and norms.
        comparison[parameter_name] = ...

    return comparison

def E03(model, optimizer, full_batch, micro_batches, loss_function):
    reference_model = ...
    accumulated_model = ...

    reference_gradients = ...
    accumulated_gradients = ...

    return compare_named_gradients(
        reference_gradients,
        accumulated_gradients,
        absolute_tolerance=...,
        relative_tolerance=...)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not hide missing gradients or compare references that have already been mutated. Explain every tolerance failure and repeat in float64 or a simpler deterministic model to distinguish algorithmic error from rounding order.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations

instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Equivalence is a claim with explicit assumptions. Proving it teaches where gradient accumulation is mathematically exact, numerically approximate, or semantically different.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.5 Exercise 04

Exercise Title: Reproduce Incorrect Gradient Magnitudes by Forgetting to Divide the Loss by the Accumulation Factor

Part 1 - Exercise Contract and Why It Matters

Deliberately omit loss normalization and demonstrate how the final gradient and parameter update are amplified. Preserve the incorrect branch as a regression test that catches this common accumulation error.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Backward adds each micro-batch gradient. If every micro-batch reports a mean loss and none is divided or weighted, the buffer contains the sum of K micro-batch means rather than the full-batch mean. Optimizer nonlinearities, clipping, momentum, and adaptive state can make the final damage more complex than a simple K-times parameter delta.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

With equal micro-batches, the incorrect gradient is

$$g_{\text{wrong}} = \sum_{k=1}^{K} g_k = K g_{\text{correct}}.$$

For plain SGD without clipping or momentum,

$$\Delta\theta_{\text{wrong}} = K \Delta\theta_{\text{correct}}.$$

This proportional update relationship need not hold for Adam, clipping, or weight decay interactions.

Predict gradient norm ratio, clipping behavior, and SGD parameter-delta ratio before running. For an adaptive optimizer, predict which state tensors change and avoid claiming a universal K-times update.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run full-batch, correctly normalized accumulation, and unnormalized accumulation from identical state. Compare per-micro-step cumulative norm, final gradient ratio, clip coefficient, parameter delta, optimizer state, and next-step loss.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def run_accumulation_branch(
        model,
        optimizer,
        micro_batches,
        loss_function,
        accumulation_steps,
        normalize_loss):
    optimizer.zero_grad(set_to_none=True)

    for inputs, targets in micro_batches:
        outputs = ...
        loss = ...

        if normalize_loss:
            backward_loss = ...
        else:
            backward_loss = ...

        ...

    gradients = ...
    parameter_state_before = ...
    ...
```

```
    parameter_state_after = ...

    return gradients, parameter_state_before, parameter_state_after

def E04(model, optimizer, micro_batches, loss_function, accumulation_steps):
    correct_result = ...
    incorrect_result = ...
    return correct_result, incorrect_result
```

Part 6 - Measurement, Validation, and Failure Analysis

Ensure the wrong result is caused only by missing normalization. Do not simultaneously change learning rate, scheduler, batch order, or zeroing policy. Check zero and near-zero reference gradients before computing ratios.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

A deliberately reproduced failure turns a silent scaling mistake into a measurable invariant that future training-loop changes can test automatically.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.6 Exercise 05

Exercise Title: Compare Peak VRAM Across Multiple Micro-Batch Sizes While Keeping Effective Batch Size Constant

Part 1 - Exercise Contract and Why It Matters

Sweep micro-batch size and accumulation steps while holding the effective batch constant. Build a memory curve that separates fixed training state from micro-batch-dependent activations and workspaces.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Using fewer samples per micro-step usually reduces activation peaks. Allocator bins, workspaces, padding, and shape-dependent algorithm selection can still make the curve non-smooth. Gradient buffers remain full-size, and repeated micro-steps do not multiply peak activation memory when graphs are released correctly.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For one device and fixed effective batch B, valid pairs satisfy

$$bK = B.$$

Measure the marginal memory slope

$$\alpha(b_1, b_2) = \frac{M_{\text{peak}}(b_2) - M_{\text{peak}}(b_1)}{b_2 - b_1}$$

rather than assuming perfect linearity.

List every valid factor pair, estimate activation bytes for each, and predict the fixed-memory intercept. State where throughput is expected to fall because micro-batches become too small.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run every pair in an isolated, warmed trial with identical model, optimizer, samples, precision, and update count. Record allocated and reserved peaks by phase, throughput, total update latency, gradient equivalence, and allocator snapshot summary.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def build_valid_configurations(effective_batch_size):
    configurations = []

    for micro_batch_size in range(1, effective_batch_size + 1):
        if effective_batch_size % micro_batch_size != 0:
            continue

        accumulation_steps = ...
```

```
        configurations.append(
            (micro_batch_size, accumulation_steps))

    return configurations

def measure_configuration(configuration, training_trial):
    micro_batch_size, accumulation_steps = configuration
    torch.cuda.reset_peak_memory_stats()
    result = ...
    return {
        "micro_batch_size": micro_batch_size,
        "accumulation_steps": accumulation_steps,
        "peak_allocated": ...,
        "peak_reserved": ...,
        "training_result": result,
    }

def E05(effective_batch_size, training_trial):
    configurations = ...
    measurements = []

    for configuration in configurations:
        measurement = ...
        measurements.append(measurement)

    return measurements
```

Part 6 - Measurement, Validation, and Failure Analysis

Detect graph retention, changing sample counts, unequal final windows, and OOM recovery side effects. Repeat each configuration and report a safety margin rather than a single lowest peak.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

The sweep exposes the real memory-time frontier. The best micro-batch is not automatically the smallest; it is the point that meets the budget with the least throughput cost.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.7 Exercise 06

Exercise Title: Measure Throughput Loss as Micro-Batches Become Smaller and Kernel Launch Overhead Becomes More Significant

Part 1 - Exercise Contract and Why It Matters

Measure how reducing micro-batch size changes kernel efficiency, launch count, host overhead, GPU idle gaps, and samples per second for a fixed effective batch.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Small micro-batches reduce parallel work per kernel while increasing the number of forward and backward passes per optimizer update. Launch latency, Python dispatch, data transfer, and synchronization can occupy a larger fraction of time. Some kernels also lose Tensor Core alignment or choose different algorithms.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For effective batch $B = bK$, define

$$T_{\text{update}}(b) = \sum_{k=1}^{K} (t_{f,k} + t_{b,k}) + t_{\text{opt}} + t_{\text{overhead}},$$

and

$$\text{throughput}(b) = \frac{B}{T_{\text{update}}(b)}.$$

Report GPU active time separately from synchronized wall time.

Predict launch-count growth and identify a micro-batch size below which occupancy or arithmetic intensity is likely to collapse. Estimate the memory saved per percentage point of throughput lost.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Profile selected configurations after warm-up. Record CPU and CUDA time, kernel count, median kernel duration, GPU idle gaps, data-loader time, optimizer time, synchronized update latency, and throughput. Use profiler runs for attribution and separate unprofiled runs for final performance.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA

before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import time
import torch

def time_accumulation_configuration(
        training_update,
        micro_batch_size,
        accumulation_steps,
        effective_batch_size):
    torch.cuda.synchronize()
    start_time = time.perf_counter()

    update_result = ...

    torch.cuda.synchronize()
    update_time = ...
    throughput = ...

    return {
        "micro_batch_size": micro_batch_size,
        "accumulation_steps": accumulation_steps,
        "update_time": update_time,
        "throughput": throughput,
        "update_result": update_result,
    }

def E06(configurations, training_update, effective_batch_size):
    results = []
    for micro_batch_size, accumulation_steps in configurations:
        result = ...
        results.append(result)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Avoid timing asynchronous CUDA work without synchronization. Exclude compilation and autotuning transients, and ensure data loading does not become a different bottleneck across configurations.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record

missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Accumulation spends execution efficiency to purchase memory capacity. Throughput attribution reveals exactly where that price is paid.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.8 Exercise 07

Exercise Title: Determine the Largest Micro-Batch That Fits a Fixed VRAM Budget and Maximizes GPU Utilization

Part 1 - Exercise Contract and Why It Matters

Search for the largest repeatably safe micro-batch under a strict VRAM limit, then verify that it delivers better utilization or throughput than smaller feasible candidates.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

The largest allocation that avoids one OOM is not necessarily operationally safe. Fragmentation, dynamic shapes, optimizer initialization, and asynchronous peaks require headroom. Feasibility and performance are separate filters.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

A candidate is admissible when

$$M_{\text{peak}}(b) + M_{\text{safety}} \leq M_{\text{budget}}.$$

For target effective batch B, its accumulation count is

$$K = \left\lceil \frac{B}{bW} \right\rceil,$$

with final-window weighting handled explicitly when equality is not exact.

Estimate the feasible upper bound from the memory model and choose a safety margin. Predict utilization and throughput ordering among nearby feasible sizes.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Use exponential growth to find a failure bracket, then a bounded search with isolated trials. Repeat the chosen size under representative dynamic inputs. Record peak VRAM, headroom, OOM stage, utilization proxy, throughput, and gradient validity.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def test_micro_batch_candidate(
        micro_batch_size,
        vram_budget,
        training_trial):
    try:
        torch.cuda.reset_peak_memory_stats()
        trial_result = ...
        peak_vram = ...
        fits_budget = ...
        return {
            "success": True,
            "fits_budget": fits_budget,
            "peak_vram": peak_vram,
            "result": trial_result,
        }
    except torch.cuda.OutOfMemoryError as error:
        return {
            "success": False,
            "fits_budget": False,
            "peak_vram": None,
            "error": str(error),
        }

def E07(candidate_sizes, vram_budget, training_trial):
    candidate_reports = []
    for micro_batch_size in candidate_sizes:
```

```
        report = ...
        candidate_reports.append(report)

    selected_candidate = ...
    return selected_candidate, candidate_reports
```

Part 6 - Measurement, Validation, and Failure Analysis

Recover from OOM in a clean trial rather than trusting a potentially damaged process state. Reject edge candidates that fail repeated execution or violate the safety margin.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

The optimum is the largest safe working set that keeps the GPU productive, not the largest tensor allocation that survives once.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.9 Exercise 08

Exercise Title: Build an Effective Batch Calculator from Micro-Batch Size, Accumulation Steps, and Distributed World Size

Part 1 - Exercise Contract and Why It Matters

Build an auditable calculator that distinguishes local micro-batch, local accumulated batch, global effective batch, samples per optimizer update, and optimizer updates per epoch.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

In data parallel training, each rank processes its own micro-batch and gradients are synchronized across ranks. Accumulation changes how many local backward passes contribute before an optimizer step. Distributed sampler padding, dropped samples, and partial windows can make nominal and observed effective batch differ.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

The nominal global effective batch is

$$B_{\text{eff}} = bKW.$$

With N observed samples and full windows, optimizer updates per epoch are approximately

$$U = \left\lceil \frac{N}{B_{\text{eff}}} \right\rceil,$$

but the final update may have a smaller observed batch and must be reported separately.

Calculate nominal local and global batch values for several configurations, including world size one. Predict the final update size with drop_last enabled and disabled.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Compare calculator output with counters inside a simulated or real distributed loop. Record samples processed by every rank, micro-steps, synchronization events, optimizer updates, padding, and dropped samples.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
from dataclasses import dataclass

@dataclass
class EffectiveBatchReport:
    micro_batch_size: int
    accumulation_steps: int
    world_size: int
    local_effective_batch: int
    global_effective_batch: int
    full_optimizer_updates: int
    final_update_samples: int

def validate_positive_integer(name, value):
    ...

def E08(
```

```
        dataset_size,
        micro_batch_size,
        accumulation_steps,
        world_size,
        drop_last):
    validate_positive_integer("dataset_size", dataset_size)
    validate_positive_integer("micro_batch_size", micro_batch_size)
    validate_positive_integer("accumulation_steps", accumulation_steps)
    validate_positive_integer("world_size", world_size)

    local_effective_batch = ...
    global_effective_batch = ...
    full_optimizer_updates = ...
    final_update_samples = ...

    return EffectiveBatchReport(...)
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate positive integer inputs, distinguish rank-local from global counts, and avoid assuming dataset length divides the distributed sampler or accumulation window.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Clear batch terminology prevents silent learning-rate, scheduler, and reproducibility errors when accumulation and distribution are combined.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.10 Exercise 09

Exercise Title: Handle a Final Partial Accumulation Window Correctly When Dataset Length Is Not Divisible by Accumulation Steps

Part 1 - Exercise Contract and Why It Matters

Handle the final window when fewer than K micro-batches remain. Preserve the intended sample-mean gradient, perform exactly one final optimizer update when appropriate, and report its actual effective batch.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed

memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Dividing every loss by the configured K underweights a partial window. Dividing by the number of remaining micro-batches works only for equal micro-batch sizes. The most general approach weights each mean loss by its sample count relative to total samples in the current window.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For final-window micro-batch sizes $b_1, \ldots, b_R$ and $B_f = \sum_{k=1}^{R} b_k$,

$$L_f = \sum_{k=1}^{R} \frac{b_k}{B_f} L_k, \qquad g_f = \sum_{k=1}^{R} \frac{b_k}{B_f} g_k.$$

Using $1/K$ when $R < K$ scales the update incorrectly.

Calculate final-window sample count, weights, optimizer-update count, and expected gradient norm. Compare drop, underweighted, and correctly weighted policies.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Choose dataset lengths that produce full windows, a one-micro-batch remainder, and unequal last micro-batch size. Compare each final update with a direct batch reference containing exactly the same remaining samples.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def collect_accumulation_windows(data_loader, accumulation_steps):
    current_window = []
```

```
    for batch in data_loader:
        current_window.append(batch)

        if len(current_window) == accumulation_steps:
            yield current_window
            current_window = []

    if len(current_window) > 0:
        yield current_window

def process_window(model, optimizer, window, loss_function):
    total_samples_in_window = ...
    optimizer.zero_grad(set_to_none=True)

    for inputs, targets in window:
        current_micro_batch_size = ...
        loss_weight = ...
        outputs = ...
        loss = ...
        ...

    ...
    return ...

def E09(model, optimizer, data_loader, loss_function, accumulation_steps):
    update_reports = []
    for window in collect_accumulation_windows(
            data_loader, accumulation_steps):
        update_report = ...
        update_reports.append(update_report)
    return update_reports
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not carry residual gradients into the next epoch unless explicitly designed. Verify scheduler and logging step counts and handle an empty remainder without creating a false optimizer update.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Partial windows expose whether accumulation logic represents samples or merely loop iterations. Correct weighting preserves the actual objective.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload

but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.11 Exercise 10

Exercise Title: Compare Zeroing Gradients Before and After an Accumulation Window and Diagnose Accidental Gradient Carry-Over

Part 1 - Exercise Contract and Why It Matters

Compare valid gradient-clearing placements and reproduce accidental carry-over between optimizer updates. Track gradient-buffer identity, existence, value, and memory behavior for zero tensors versus set_to_none.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Backward accumulates into parameter.grad. Gradients must be cleared once per logical update, either before a new window or immediately after the previous step. Clearing inside the window destroys contributions; never clearing mixes distinct effective batches. set_to_none can change allocation and first-write behavior.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

If update windows are $u = 1, 2, \ldots$, correct state satisfies

$$g^{(u)} = \sum_{k \in u} w_k g_k.$$

Without clearing, the next window receives

$$\widetilde{g}^{(u+1)} = g^{(u)} + g^{(u+1)},$$

which couples two optimizer updates incorrectly.

Predict gradient norms before first backward, after each micro-step, after optimizer step, and after clearing for each policy. Predict memory differences between zeroing values and setting references to None.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run clear-before, clear-after, clear-inside, and never-clear branches from identical state. Record gradient checksums and identities at every boundary, parameter updates, optimizer state, allocated VRAM, and next-window loss.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def snapshot_gradient_state(model):
    snapshot = {}
    for parameter_name, parameter in model.named_parameters():
        if parameter.grad is None:
            snapshot[parameter_name] = {
                "exists": False,
                "value": None,
            }
        else:
            snapshot[parameter_name] = {
                "exists": True,
                "value": ...,
            }
    return snapshot

def run_zeroing_policy(
        model,
        optimizer,
        windows,
        loss_function,
        zeroing_policy):
    timeline = []

    for window_index, window in enumerate(windows):
        # Apply only the selected clearing policy at this boundary.
        ...

        for inputs, targets in window:
            ...

        timeline.append(...)
        ...
```

```
    return timeline

def E10(model, optimizer, windows, loss_function):
    return ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Distinguish intentional accumulation from accidental carry-over. Optimizer.step does not clear gradients automatically. Ensure diagnostic logging does not itself retain gradient tensors.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Gradient lifetime is explicit program state. Correct clearing defines where one logical training update ends and the next begins.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.12 Exercise 11

Exercise Title: Combine Gradient Accumulation with torch.amp.GradScaler and Place Scale, Unscale, and Optimizer Operations Correctly

Part 1 - Exercise Contract and Why It Matters

Combine float16 autocast, GradScaler, and accumulation while preserving one scale across the complete window. Place unscale, finite checking, scaler.step, and scaler.update exactly once at the optimizer boundary.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Every normalized micro-batch loss is scaled before backward, so parameter buffers accumulate scaled gradients. Changing the scale inside the window would mix incompatible units. unscale_ converts the complete accumulated gradient once; scaler.step can then reject a non-finite window, and update adjusts the scale for the next window.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither

value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

With constant scale S during a window,

$$\widetilde{g} = \sum_{k=1}^{K} S w_k g_k = S \sum_{k=1}^{K} w_k g_k.$$

One unscale operation yields the intended gradient. If scales S_k differ within the window, no single division reconstructs the sum correctly.

Predict scale value at every micro-step, the final scaled norm, unscaled norm, overflow outcome, and whether the optimizer update commits. Include an overflow injected into an early micro-step.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Compare three branches: a full-batch float32 reference, accumulated autocast with GradScaler, and a deliberately incorrect branch that updates inside the window. Record scale timeline, finite status after unscale, skipped windows, parameter and optimizer checksums, peak VRAM, and throughput.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def run_scaled_accumulation_window(
        model,
        optimizer,
        scaler,
        micro_batches,
        loss_function,
        accumulation_steps):
    optimizer.zero_grad(set_to_none=True)
    scale_at_window_start = scaler.get_scale()

    for inputs, targets in micro_batches:
```

```
        with torch.autocast(
                device_type="cuda",
                dtype=torch.float16):
            outputs = ...
            loss = ...
            normalized_loss = ...

        scaled_loss = ...
        ...

        # The scale must not be updated inside this loop.
        ...

    # Unscale exactly once after the complete accumulation window.
    ...

    # Perform a protected optimizer step, then update the scale once.
    ...

    return {
        "scale_before": scale_at_window_start,
        "scale_after": ...,
        "window_result": ...,
    }

def E11(model, optimizer, scaler, micro_batches, loss_function):
    return ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not call scaler.update or unscale_ more than once per optimizer per window. If any micro-step overflows, the complete logical update must be rejected. Verify API behavior for the installed PyTorch version.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Accumulation and scaling share the same transaction boundary. Keeping numerical units stable across that boundary is the core correctness rule.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.13 Exercise 12

Exercise Title: Combine Gradient Accumulation with Gradient Clipping Without Clipping Intermediate Scaled or Partial Gradients Incorrectly

Part 1 - Exercise Contract and Why It Matters

Apply gradient clipping only after the complete logical gradient exists and, when GradScaler is active, only after it has been unscaled. Reproduce and quantify clipping of partial or scaled gradients as failure cases.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Clipping each micro-step changes the direction and magnitude of the final sum. Clipping a scaled gradient uses the threshold in the wrong units. The correct sequence is accumulate, unscale once if required, measure complete norm, clip, then step.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For clipping threshold C, the complete gradient transformation is

$$g_{\text{clip}} = g \min\left(1, \frac{C}{\|g\|_2}\right).$$

Generally,

$$\sum_k \text{clip}(g_k, C) \neq \text{clip}\left(\sum_k g_k, C\right).$$

Calculate individual, cumulative, scaled, unscaled, and final clipped norms for a controlled example with opposing micro-gradients. Predict parameter updates for correct and incorrect orderings.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run clip-after-window, clip-each-micro-step, and clip-scaled-gradient branches from cloned state. Record gradient direction similarity, norm, clip coefficient, parameter delta, and next loss.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics

immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def E12(
        model,
        optimizer,
        scaler,
        micro_batches,
        loss_function,
        maximum_gradient_norm):
    optimizer.zero_grad(set_to_none=True)

    for inputs, targets in micro_batches:
        with torch.autocast(
                device_type="cuda",
                dtype=torch.float16):
            outputs = ...
            loss = ...
            normalized_loss = ...

        ...

    # Restore the complete accumulated gradient to its true units.
    ...

    # Measure and clip only after accumulation and unscaling.
    gradient_norm_before_clipping = ...
    ...

    # Commit or skip the optimizer update through the scaler.
    ...

    return {
        "gradient_norm_before_clipping": gradient_norm_before_clipping,
        "gradient_norm_after_clipping": ...,
        "scale": ...,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Use the same norm type and parameter set in every branch. Detect non-finite norms before clipping and verify that logging occurs without mutating gradients.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Gradient clipping is a transformation of one complete optimizer update. Applying it to incomplete or differently scaled state changes the optimization algorithm.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.14 Exercise 13

Exercise Title: Measure Activation and Gradient Memory Across Accumulation Steps and Explain Which Memory Components Actually Shrink

Part 1 - Exercise Contract and Why It Matters

Create a phase-by-phase memory timeline across an accumulation window and attribute bytes to inputs, activations, saved tensors, gradients, parameters, optimizer state, workspaces, and allocator reservation.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Activation graphs should rise and fall during each micro-step. Parameter gradients appear during the first backward and then persist for accumulation. Parameters and initialized optimizer state remain fixed. If peak memory grows every micro-step, the program may be retaining graphs, losses, outputs, or references.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

A simplified peak after the first backward is

$$M_k \approx M_{\text{param}} + M_{\text{grad}} + M_{\text{opt}} + M_{\text{activation}}(b) + M_{\text{workspace}}.$$

Correct graph release implies M_k should not grow approximately linearly with k.

Predict the first allocation of gradient buffers, the recurring activation peak, and memory after each backward. Create an expected timeline before instrumentation.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Measure allocated and reserved VRAM at window start, before and after every forward and backward, before optimizer step, after step, and after zeroing. Combine allocator telemetry with saved-tensor bytes and memory snapshots for selected steps.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def capture_memory_point(label):
    return {
        "label": label,
        "allocated": ...,
        "reserved": ...,
        "maximum_allocated": ...,
        "maximum_reserved": ...,
    }

def E13(
        model,
        optimizer,
        micro_batches,
        loss_function):
    timeline = []
    optimizer.zero_grad(set_to_none=True)
    timeline.append(capture_memory_point("window_start"))

    for micro_step_index, (inputs, targets) in enumerate(micro_batches):
        timeline.append(capture_memory_point(
            f"micro_{micro_step_index}_before_forward"))

        outputs = ...
        loss = ...
```

```
        timeline.append(capture_memory_point(
            f"micro_{micro_step_index}_after_forward"))

        ...

        timeline.append(capture_memory_point(
            f"micro_{micro_step_index}_after_backward"))

    ...
    timeline.append(capture_memory_point("after_optimizer_step"))
    return timeline
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not infer component ownership from one scalar peak. Detect Python lists retaining losses or outputs, retain_graph usage, anomaly detection overhead, and profiler-induced retention.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Accumulation saves activation concurrency, not gradient storage. A memory timeline makes that distinction visible and exposes leaks that aggregate peaks hide.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.15 Exercise 14

Exercise Title: Compare Gradient Accumulation Against Activation Checkpointing Under the Same Peak VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Compare two different ways to meet the same measured VRAM budget: smaller micro-batches with more accumulation, and activation checkpointing with larger micro-batches and recomputation.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Accumulation reduces concurrent batch activations but repeats forward and backward launches. Checkpointing removes selected saved activations and replays forward regions during backward. They affect different axes and can produce different throughput, RNG, normalization, and communication behavior.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

Match achieved peak memory rather than nominal settings:

$$M_{\text{peak}}^{\text{accum}} \approx M_{\text{peak}}^{\text{checkpoint}} \leq M_{\text{budget}}.$$

Compare cost per accepted sample using

$$C = \frac{T_{\text{update}}}{B_{\text{eff}}}.$$

Estimate launch overhead for accumulation and replay FLOPs for checkpointing. Predict which model regions or batch sizes favor each technique.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Tune configurations until measured peaks are within a declared tolerance. Keep effective batch, precision, model, optimizer, and samples fixed. Record throughput, replay time, kernel count, gradient error, RNG behavior, and energy or GPU-time proxy.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch
from torch.utils.checkpoint import checkpoint

def run_accumulation_strategy(configuration, training_context):
    # Configure micro-batch size and accumulation steps.
    ...
    return ...
```

```
def run_checkpoint_strategy(configuration, training_context):
    # Configure checkpoint regions and the larger micro-batch.
    ...
    return ...

def compare_equal_budget_results(
        accumulation_result,
        checkpoint_result,
        vram_budget,
        peak_tolerance):
    # Reject comparisons that do not satisfy the same budget.
    ...
    return ...

def E14(
        accumulation_configuration,
        checkpoint_configuration,
        training_context,
        vram_budget):
    accumulation_result = ...
    checkpoint_result = ...
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not compare unmatched memory peaks or effective batches. Checkpointing must preserve required RNG state, and accumulation must control batch-dependent layers.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Equal-budget comparison reveals which resource is cheaper to spend: extra micro-step overhead or recomputation inside the graph.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.16 Exercise 15

Exercise Title: Combine Gradient Accumulation with Mixed Precision and Activation Checkpointing to Maximize Effective Batch Size

Part 1 - Exercise Contract and Why It Matters

Compose three techniques under one VRAM budget and attribute their overlapping savings and costs. Search for the largest validated effective batch rather than multiplying headline savings.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Mixed precision shrinks eligible tensor payload and changes kernels. Checkpointing discards selected saved activations. Accumulation reduces simultaneous examples. Their benefits overlap on activation bytes, while parameters, gradients, optimizer state, replay, launches, and scaling logic remain.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

The search objective is

$$\max_{b,K,P,C} \; B_{\text{eff}} = bKW$$

subject to

$$M_{\text{peak}}(b, P, C) + M_{\text{safety}} \leq M_{\text{budget}}, \quad E(P, C) \leq E_{\max},$$

where P is precision policy and C is checkpoint policy.

Build a component table identifying which technique affects each memory category. Predict feasible configurations, recomputation, scale behavior, and throughput before running the search.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Benchmark single techniques, pairwise combinations, and the full combination from identical state. Record effective batch, peak VRAM, safety margin, saved tensors, replay, micro-step count, scale history, throughput, gradient error, and convergence evidence.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch
from torch.utils.checkpoint import checkpoint

def configure_training_strategy(
        micro_batch_size,
        accumulation_steps,
        autocast_dtype,
        checkpoint_regions):
    strategy = {
        "micro_batch_size": micro_batch_size,
        "accumulation_steps": accumulation_steps,
        "autocast_dtype": autocast_dtype,
        "checkpoint_regions": checkpoint_regions,
    }
    return strategy

def run_combined_strategy(
        model,
        optimizer,
        scaler,
        strategy,
        effective_batch,
        loss_function):
    # Split the effective batch using the selected micro-batch size.
    micro_batches = ...

    # Execute checkpointed regions inside the intended autocast policy.
    ...

    # Accumulate scaled gradients and update once at the boundary.
    ...

    return ...

def E15(candidate_strategies, training_context, vram_budget):
    feasible_results = []
    for strategy in candidate_strategies:
        result = ...
        if ...:
            feasible_results.append(result)

    selected_result = ...
    return selected_result, feasible_results
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate every combined configuration independently. Ensure recomputation executes under the intended autocast context and that GradScaler updates only at accumulation boundaries.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Memory techniques compose through a shared graph and allocator. A combined strategy succeeds only when its interactions are measured, not when individual savings are added on paper.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.17 Exercise 16

Exercise Title: Build an Adaptive Accumulation Controller That Changes Micro-Batch Size and Accumulation Steps from Live VRAM Headroom

Part 1 - Exercise Contract and Why It Matters

Build a controller that observes live peak VRAM and adjusts micro-batch size while preserving a target effective batch through accumulation-step changes. Decisions must be bounded, stable, and applied only at safe update boundaries.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Memory headroom varies with sequence length, shape, allocator state, and temporary workspaces. Increasing micro-batch can improve utilization but risks OOM; decreasing it raises accumulation and overhead. High and low watermarks, cooldown, and conservative prediction prevent oscillation.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

Let measured headroom be

$$H = M_{\text{budget}} - M_{\text{peak}} - M_{\text{safety}}.$$

After choosing new b', preserve target batch B_t using

$$K' = \left\lceil \frac{B_t}{b'W} \right\rceil,$$

then report any final-window mismatch explicitly.

Define watermarks, candidate steps, cooldown, minimum and maximum micro-batch, and admission prediction. Simulate controller behavior for high headroom, low headroom, and noisy alternating inputs.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run scripted memory regimes and variable sequence lengths. Log observation, prediction, chosen configuration, reason, achieved peak, throughput, update frequency, and constraint violations. Compare with the best static safe configuration.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
from dataclasses import dataclass

@dataclass
class AccumulationConfiguration:
    micro_batch_size: int
    accumulation_steps: int
    effective_batch_size: int

@dataclass
class MemoryObservation:
    peak_vram: int
    vram_budget: int
    safety_margin: int
    throughput: float

class AdaptiveAccumulationController:
    def __init__(
            self,
            target_effective_batch,
```

```
            world_size,
            minimum_micro_batch,
            maximum_micro_batch,
            cooldown_updates):
        self.target_effective_batch = target_effective_batch
        self.world_size = world_size
        self.minimum_micro_batch = minimum_micro_batch
        self.maximum_micro_batch = maximum_micro_batch
        self.cooldown_updates = cooldown_updates
        self.history = []

    def propose(self, current_configuration, observation):
        headroom = ...
        proposed_micro_batch_size = ...
        proposed_accumulation_steps = ...
        reason = ...
        proposal = ...
        self.history.append((observation, proposal, reason))
        return proposal

def E16(controller, current_configuration, observation):
    return controller.propose(current_configuration, observation)
```

Part 6 - Measurement, Validation, and Failure Analysis

Never change accumulation count inside an active window. Reject candidates whose predicted headroom is negative, and include an emergency fallback after OOM. Test oscillation and stale peak observations.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Adaptive accumulation treats batch decomposition as a runtime scheduling decision. Stability and explainability matter as much as capacity.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.18 Exercise 17

Exercise Title: Recover Automatically from a Micro-Batch OOM by Reducing Micro-Batch Size and Increasing Accumulation Steps While Preserving Effective Batch Size

Part 1 - Exercise Contract and Why It Matters

Design a bounded OOM recovery transaction that abandons the failed window, restores clean gradient state, selects a smaller micro-batch, recalculates accumulation, and replays the same logical samples without duplication or loss.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

CUDA OOM can occur after partial forward or backward work. Partial gradients, graph references, RNG progress, and data-iterator position can make naive retry incorrect. Recovery requires a defined rollback boundary and a clean trial, not only empty_cache.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For target batch B_t and reduced micro-batch b', choose

$$K' = \frac{B_t}{b'W}$$

when divisible. Otherwise construct an explicitly weighted partial final micro-batch so the replayed sample count remains B_t.

For each fallback size, predict accumulation count, retry cost, memory peak, and maximum number of allowed retries. Define what state must be restored after failure.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Force OOM at known sizes, snapshot sample identifiers and checksums, and verify that the recovered update consumes every intended sample exactly once. Record failed stage, cleanup, retry configuration, peak VRAM, final gradients, parameter update, and recovery latency.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
import torch

def calculate_recovery_configuration(
        current_micro_batch_size,
        target_effective_batch_size,
        world_size):
    reduced_micro_batch_size = ...
    new_accumulation_steps = ...
    return reduced_micro_batch_size, new_accumulation_steps

def restore_clean_window_state(
        model,
        optimizer,
        window_checkpoint):
    # Restore gradients, RNG state, and any required mutable state.
    ...

def E17(
        training_window,
        model,
        optimizer,
        initial_configuration,
        target_effective_batch_size,
        world_size,
        maximum_retries):
    current_configuration = initial_configuration
    recovery_history = []

    for retry_index in range(maximum_retries + 1):
        window_checkpoint = ...

        try:
            result = ...
            return result, recovery_history
        except torch.cuda.OutOfMemoryError as error:
            ...
            current_configuration = ...
            recovery_history.append(...)

    raise RuntimeError("No safe micro-batch configuration was found")
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not continue from partial gradients or advance the data stream silently. Handle repeated OOM, minimum micro-batch failure, stochastic replay, distributed rank agreement, and optimizer state integrity.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations

instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

OOM recovery is a correctness-preserving rollback and reschedule operation. Merely surviving the exception is insufficient.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.19 Exercise 18

Exercise Title: Stress-Test Adaptive Gradient Accumulation with Variable Sequence Lengths and Track VRAM Peaks, Throughput, and Optimizer Update Frequency

Part 1 - Exercise Contract and Why It Matters

Stress the adaptive controller with changing sequence lengths, padding ratios, and memory demand. Measure whether it preserves the target effective batch and stable optimizer-update semantics while reacting to live pressure.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

Transformer activation memory can change sharply with sequence length and attention implementation. A configuration safe for one batch can fail on the next. Frequent adaptation changes micro-step count and optimizer-update wall-clock frequency, affecting schedules expressed in steps or tokens.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

For update u, record actual tokens

$$Q_u = \sum_{k=1}^{K_u} \sum_{j=1}^{b_u} \ell_{u,k,j},$$

where ℓ is non-padding sequence length. Samples per update may remain constant while tokens, memory, and compute vary substantially.

Construct short, medium, long, and adversarial length regimes. Predict micro-batch, accumulation count, peak VRAM, tokens per update, throughput, and adaptation delay for each.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Run deterministic and randomized length schedules. Log shape distribution, padding, configuration, peak VRAM, headroom, samples and tokens per update, optimizer updates per minute, throughput, OOM recovery, and gradient validity.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
def summarize_sequence_batch(inputs, attention_mask):
    sequence_statistics = {
        "batch_size": ...,
        "padded_length": ...,
        "non_padding_tokens": ...,
        "padding_fraction": ...,
    }
    return sequence_statistics

def E18(
        adaptive_controller,
        training_engine,
        variable_length_batches):
    stress_test_history = []

    for batch_index, batch in enumerate(variable_length_batches):
        inputs, targets, attention_mask = batch
        sequence_statistics = ...
        current_configuration = ...

        update_result = ...
        memory_observation = ...
        next_configuration = ...

        stress_test_history.append({
            "batch_index": batch_index,
            "sequence_statistics": sequence_statistics,
            "current_configuration": current_configuration,
```

```
            "update_result": update_result,
            "memory_observation": memory_observation,
            "next_configuration": next_configuration,
        })

    return stress_test_history
```

Part 6 - Measurement, Validation, and Failure Analysis

Detect oscillation, repeated retries, schedule drift, partial windows, and comparisons based only on samples when tokens drive work. Include the cost of adaptation and failed attempts.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

Dynamic workloads test whether accumulation policy is truly memory-aware or merely tuned to one static shape.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.23.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Memory-Aware Gradient Accumulation Engine That Maximizes Effective Batch Size Under a Strict VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Integrate batch calculation, micro-batch partitioning, weighted accumulation, mixed precision, clipping, memory telemetry, adaptive configuration, OOM rollback, and diagnostics into one engine. Its objective is the largest validated effective batch within a strict budget and numerical contract.

The learner must produce an executable experiment, a measurement table, and a short engineering conclusion. The experiment must preserve enough evidence to reconstruct which samples entered each optimizer update, which configuration was active, and whether the claimed memory or numerical behavior was actually observed. A result without controls, units, seeds, or a declared reference is incomplete.

Part 2 - System and Memory Mental Model

The engine needs a control plane and a training data plane. The control plane selects and revises configuration from measured headroom and throughput. The data plane executes one transactional window, preserves sample identity, accumulates gradients, validates the complete update, and commits or rolls back. Every decision requires a reason and measured outcome.

Reason separately about the CUDA allocator, live tensor storage, autograd graph lifetime, gradient-buffer lifetime, and optimizer-state lifetime. Current allocated memory describes live

allocations known to PyTorch; reserved memory also includes cached allocator blocks. Neither value alone identifies tensor ownership, so phase measurements and component accounting must accompany peak statistics.

Part 3 - Quantitative Prediction Before Execution

Choose configuration $c = (b, K, P, C)$ to maximize

$$J(c) = B_{\text{eff}}(c)$$

subject to

$$M_{\text{peak}}(c) + M_{\text{safety}} \leq M_{\text{budget}}, \quad E(c) \leq E_{\max}, \quad R_{\text{skip}}(c) \leq R_{\max}.$$

Among equal effective batches, rank by validated throughput and stability.

Build a candidate table containing predicted fixed and variable memory, effective batch, micro-steps, throughput, numerical risk, and safety margin. Define admission, fallback, and stopping rules before benchmarking.

Write the prediction before running CUDA. Every predicted quantity must have a unit, a scope, and an assumption. At minimum, predict effective samples per optimizer update, optimizer-update count, peak allocated VRAM, peak reserved VRAM, synchronized update latency, throughput, and the gradient statistic that will decide correctness.

Part 4 - Experimental Design and Instrumentation

Compare full batch, static accumulation, best static combined strategy, and adaptive engine from identical states. Test steady and variable sequences, forced OOM, partial windows, and overflow. Report capacity, peak VRAM, headroom, latency distribution, throughput, accepted update frequency, gradient error, retries, scale history, and final metric.

Use fixed seeds, identical initial model and optimizer states, the same ordered samples, the same precision policy, and the same model mode for controlled comparisons. Warm up CUDA before timing, synchronize only at deliberate measurement boundaries, reset peak statistics immediately before the measured region, and report median together with a tail statistic across repeated trials. Keep profiler runs separate from final latency measurements.

Part 5 - PyTorch/CUDA Implementation

Complete the following structure. The missing operations are intentionally represented by extttEllipsis; implement them from the contract, predictions, and measurement requirements above. Do not replace the experiment with a library trainer that hides accumulation boundaries or memory observations.

```
from dataclasses import dataclass
import torch

@dataclass
class EngineConfiguration:

    accumulation_steps: int
    effective_batch_size: int
    autocast_dtype: object
    maximum_gradient_norm: float

@dataclass
```

```
class EngineBudget:
    vram_budget: int
    safety_margin: int
    maximum_retries: int

class MemoryAwareAccumulationEngine:
    def __init__(
            self,
            model,
            optimizer,
            loss_function,
            configuration,
            budget):
        self.model = model
        self.optimizer = optimizer
        self.loss_function = loss_function
        self.configuration = configuration
        self.budget = budget
        self.scaler = ...
        self.history = []

    def split_effective_batch(self, inputs, targets):
        micro_batches = ...
        return micro_batches

    def execute_window(self, inputs, targets):
        window_checkpoint = ...
        micro_batches = ...

        self.optimizer.zero_grad(set_to_none=True)

        for micro_step_index, micro_batch in enumerate(micro_batches):
            # Run autocast forward and weighted backward.
            ...

        # Unscale, validate, clip, and commit exactly once.
        ...

        memory_report = ...
        numerical_report = ...
        return memory_report, numerical_report

    def recover_from_oom(self, failed_window):
        # Roll back and propose a smaller micro-batch configuration.
        ...

    def benchmark(self, batches):
        benchmark_report = ...
```

```
        return benchmark_report

def E19(
        model,
        optimizer,
        loss_function,
        initial_configuration,
        budget):
    engine = MemoryAwareAccumulationEngine(
        model,
        optimizer,
        loss_function,
        initial_configuration,
        budget)
    return engine
```

Part 6 - Measurement, Validation, and Failure Analysis

Require repeated feasibility, exact sample accounting, bounded retries, clean rollback, and gradient equivalence. The engine must fail explicitly when no configuration satisfies the budget instead of silently reducing the learning objective.

Validate loss, every named parameter gradient, updated parameters, and optimizer state against the declared reference using dtype-appropriate absolute and relative tolerances. Record missing gradients, zero fractions, non-finite values, OOM stage, and unsuccessful configurations instead of deleting them. Separate theoretical prediction, measured value, absolute error, relative error, and interpretation in the final report.

Part 7 - Engineering Interpretation and Philosophy

A memory-aware accumulation engine is a scheduler for training work. Its final product is not only a large effective batch, but a reproducible evidence trail showing that every committed update respected memory and numerical constraints.

The final recommendation must state which resource was saved, which cost increased, where the critical path moved, and under which workload and hardware the conclusion is valid. Preserve negative results and limitations: a memory technique that fits a larger workload but violates numerical equivalence, throughput requirements, or operational headroom has not solved the complete engineering problem.

19.24 DMM22

Chapter Title: Adaptive Batch Sizing Under Dynamic VRAM Budgets
Specialization: Dynamic Memory Management and CUDA Systems

19.24.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Batch Size, Sequence Length, Activation Memory, and Peak VRAM Scaling

Part 1 - Exercise Contract and Why It Matters

Build a memory ledger for one complete training update, from input transfer through gradient clearing. Identify who owns each allocation, when it becomes live, when it can be released, and whether its size depends on batch size b, padded sequence length L, hidden width d, or optimizer choice. Produce one lifecycle diagram, a numerical prediction sheet, and a phase measurement table. Explain why doubling the batch does not necessarily double peak VRAM.

Use a small MLP first and a Transformer-style block second. Prerequisites are autograd, tensor byte counts, mixed precision, and gradient accumulation from DMM19–DMM21. Use one CUDA device and eager execution initially. Training and inference need separate contracts: a successful forward pass cannot certify a training batch. Keep a logical optimizer batch distinct from the physical micro-batch that determines the immediate working set.

Part 2 - System and Memory Mental Model

Parameters persist across updates. Gradients appear during backward and may persist through accumulation. Optimizer state can be created lazily during the first update. Inputs, saved activations, attention intermediates, and operator workspaces have overlapping lifetimes. The peak is the maximum of their simultaneous totals; it is not the sum of separate maxima of each component. Views can share storage, so adding every tensor's logical byte count can double-count the same allocation.

Let A be live allocated bytes, R reserved allocator bytes, F device-global free bytes, and T device total bytes. Normally $A \le R$, while $T - F$ also includes other processes, CUDA context allocations, and memory outside the PyTorch allocator. Cached bytes $R - A$ are not all guaranteed to be reusable for an arbitrary next allocation. Fragment size, pending stream work, and allocator backend matter. Treat these as different observations, not interchangeable definitions of VRAM use.

For ordinary attention that materializes score matrices, a term proportional to bhL^2 can dominate. An efficient attention backend can avoid retaining that full matrix, so the same model dimensions do not imply the same memory curve. Record the actual backend and masks. A growing loss-history list that retains graphs is a lifetime bug, not an intrinsic batch-scaling law.

Part 3 - Quantitative Prediction Before Execution

Let P denote unique parameter elements and s bytes per stored element. Tensor payload is Ns bytes; $1\,\mathrm{MiB} = 2^{20}$ bytes and $1\,\mathrm{GiB} = 2^{30}$ bytes. A deliberately simplified FP32 Adam ledger is $4P$ parameter bytes, $4P$ gradient bytes, and $8P$ moment bytes, or $16P$ in total, excluding scalar state, workspaces, and temporary optimizer buffers. Do not apply this estimate blindly to every optimizer or precision policy.

$$M_{\mathrm{peak}}(b, L) = \max_{\tau} \{ M_{\mathrm{persistent}}(\tau) + M_{\mathrm{activation}}(b, L, \tau) + M_{\mathrm{workspace}}(b, L, \tau) \}.$$

At fixed shape and backend, a local approximation is

$$\widehat{M}(b, L) = M_0 + \alpha bLd + \beta bhL^2 + W(b, L).$$

Coefficients include layer count, dtype, and saved-tensor multiplicity. They are empirical, not universal constants.

For an illustrative fixed-length workload, let $M_0 = 2\,\mathrm{GiB}$ and the variable cost be $96\,\mathrm{MiB}$ per sample. Predict peaks for $b = 8, 16, 32$; then repeat with a $256\,\mathrm{MiB}$ workspace appearing at $b = 24$. Compute the ratios and show why a local linear model can miss a step change. Before CUDA execution, predict the peak phase and what changes when sequence length doubles.

Part 4 - Experimental Design and Instrumentation

1. Record GPU model, device identity, VRAM size, driver, CUDA runtime, PyTorch version, dtype, optimizer, model mode, attention backend, and allocator configuration. Fix CPU and CUDA seeds.

2. Save identical initial states on CPU. Measure the cold first update separately from warmed updates, including lazy optimizer initialization. Use a CPU master batch and transfer only the active physical batch.

3. Synchronize at measured-region boundaries and reset peak statistics there. Observe allocated and reserved bytes separately. Use the `mem_get_info` API in `torch.cuda` for a global snapshot. Global free memory is not a historical peak monitor.

4. Mark input transfer, forward, backward, optimizer update, and cleanup. End-of-phase counters can miss within-phase peaks; collect peak counters for the whole update and use separate diagnostic runs for finer attribution.

5. Sweep b at fixed L, then L at fixed b. Keep model width, layer count, loss, mode, and optimizer unchanged. Store scalar observations on CPU.

Use CUDA events for device timing and a synchronized wall clock for the end-to-end region. Report which includes transfer and allocation. Avoid per-operator synchronization in the throughput run.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
import torch.nn as nn

@dataclass
class MemoryObservation:
    phase: str
    allocated_bytes: int
    reserved_bytes: int
    peak_allocated_bytes: int
    peak_reserved_bytes: int
    global_free_bytes: int

def describe_unique_storage(model, optimizer):
```

```
    # Avoid counting aliased storage more than once.
    ledger = ...
    return ledger

def predict_peak(ledger, batch_size, sequence_length):
    # Separate persistent, activation, and workspace assumptions.
    prediction = ...
    return prediction

def observe_phase(device, phase):
    # Read counters and create a CPU-only observation.
    observation = ...
    return observation

def run_instrumented_update(model, optimizer, cpu_batch, policy):
    # Transfer only the active batch.
    ...
    # Measure forward, backward, update, and cleanup lifetimes.
    ...
    observations = ...
    return observations

def compare_cold_and_warm_runs(factory, cpu_batch, policy):
    # Recreate state and identify lazy allocations.
    report = ...
    return report

def E00(factory, cpu_batch, policy):
    # Produce the ledger, predictions, and measured phase table.
    result = ...
    return result
```

Part 6 - Measurement, Validation, and Failure Analysis

Your table must contain phase, b, L, predicted bytes, allocated bytes, reserved bytes, global free bytes, and a separate explanation of the residual. Check non-finite loss or gradients before accepting a run. For a small deterministic FP32 MLP, compare gradients and one parameter update to a reference with declared absolute and relative tolerances; initial tolerances such as 10^{-6} and 10^{-4} must be justified by the observed scale.

Fail the exercise if activation and workspace categories are silently merged, if first-update state is omitted, or if the report adds peaks from non-overlapping phases. Deliberately retain an output graph in a diagnostic run and distinguish that leak from a stable allocator cache. Restore the baseline before the final comparison.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A useful mental model predicts both a value and the conditions under which that value stops being reliable. State whether the bottleneck comes from persistent model state, shape-dependent intermediates, a workspace transition, or the available device budget. These causes require different interventions.

End with two falsifiable claims: one about changing b at fixed L, and one about changing L at fixed b. Identify the next measurement that could disprove each. The remainder of this chapter turns this ledger into an admission and scheduling policy; it does not replace measurement with a single bytes-per-sample constant.

19.24.2 Exercise 01

Exercise Title: Measure Peak CUDA Memory Across Increasing Batch Sizes and Build an Empirical Batch-to-VRAM Scaling Curve

Part 1 - Exercise Contract and Why It Matters

Create a reproducible batch-capacity dataset for a fixed CUDA training workload. Measure complete updates for increasing physical batch sizes, then fit and inspect a local scaling curve. Deliver raw trial records, an allocated-memory plot, a reserved-memory plot, and a latency or throughput plot with identical batch-size axes.

The primary artifact is evidence, not a fitted line alone. Every point must identify precision, input shape, warm-up policy, initial state, outcome, and repetition index. Begin with small batches and stop at a predeclared bound or a recoverable OOM. Training data should reside on CPU until the active batch is needed so the input pool does not dominate your measured capacity.

Part 2 - System and Memory Mental Model

Measured peaks combine a fixed baseline with shape-dependent work. An increasing sweep may reuse allocator blocks from earlier candidates, whereas a fresh worker begins with a different cache history. Both are valid experiments but answer different questions. Use isolated workers for an approximately independent capacity curve and a separate in-process sweep to study the intended runtime's cache history.

Warm-up removes some startup timing effects but can also initialize optimizer state and trigger kernel or workspace selection. A candidate must survive its cold lifecycle as well as repeated steady execution. Resetting peak statistics does not free tensors, initialize missing optimizer state, or subtract the baseline. A peak counter is an absolute process measurement since reset.

Feasible memory capacity and efficient execution capacity differ. The largest batch can lose throughput through kernel choices, transfer cost, or extra padding. Keep failed trials as censored outcomes with their phase; an OOM is not an exact measurement of the unknown requested peak.

Part 3 - Quantitative Prediction Before Execution

For two feasible measurements at fixed shape,

$$\widehat{\alpha} = \frac{M(b_2) - M(b_1)}{b_2 - b_1}, \qquad \widehat{M}_0 = M(b_1) - \widehat{\alpha} b_1.$$

For a fit over several points, inspect residuals $e_i = M_i - \widehat{M}(b_i)$ and the largest positive residual, since underprediction is the dangerous direction. Estimate uncertainty using repeated runs or held-out candidates rather than treating an in-sample fit as a guarantee.

Suppose illustrative peaks are 2.5 GiB at $b = 8$ and 3.0 GiB at $b = 16$. Derive the slope, intercept, and prediction at $b = 24$. Predict how your conclusion changes if that held-out batch measures 4.2 GiB. For measured wall time t_i seconds, report $Q_i = b_i/t_i$ samples/s. Later, for variable-length data, also report useful tokens/s; samples/s alone will not remain comparable.

Part 4 - Experimental Design and Instrumentation

1. Fix architecture, optimizer, dtype, and shape. Use candidate batches such as $1, 2, 4, 8, 12, 16$, extending only after successful checks. Declare the maximum candidate before probing.

2. In each worker, create identical state, record a cold update, then use at least five warm-up updates and ten measured updates if practical. Restore comparable logical state for correctness comparisons; do not mix those comparisons with uncontrolled warm-up drift.

3. Record absolute peak allocated and reserved bytes plus allocated baseline. Measure complete-update wall and device time separately. Save OOM stage and error class without retaining GPU tensors or traceback objects.

4. Repeat selected candidates and randomize order in a control. Fit on one subset and predict held-out intermediate and larger batches.

5. Plot individual points and a labelled fit. Mark failures as failures, never as zero-memory samples. Use MiB or GiB consistently.

Store creation settings with results so the curve can be regenerated after a backend or driver change. Keep profiler runs separate from timing runs.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class TrialRecord:
    batch_size: int
```

```
    repetition: int
    status: str
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    wall_seconds: object
    failure_phase: object

def run_candidate_worker(config, batch_size, repetition):
    # Create and warm the exact workload; measure complete updates.
    record = ...
    return record

def collect_scaling_trials(config, batch_sizes, repetitions):
    # Keep failures and successful observations separately.
    records = ...
    return records

def fit_memory_curve(training_records):
    # Do not use held-out trials to fit the model.
    fitted_model = ...
    return fitted_model

def evaluate_prediction(fitted_model, held_out_records):
    # Report signed residuals and unsafe underprediction.
    errors = ...
    return errors

def export_curves(records, fitted_model, output_path):
    # Export CPU-only tables and labelled plots.
    ...

def E01(config, batch_sizes, repetitions, output_path):
    records = ...
    fitted_model = ...
    validation = ...
    return records, fitted_model, validation
```

Part 6 - Measurement, Validation, and Failure Analysis

Require consistent units, a reproducible worker seed, and evidence that each successful point includes backward and optimizer update. Compare warm-up and measured peaks so a lower steady-state number cannot hide a cold-start failure. Report median and p95 latency; state the repetition count and the limited precision of tail statistics from a small sample.

Reject a curve if live memory grows across identical repetitions without an explained lifetime change, if timing ends before queued GPU work completes, or if persistent GPU copies of the dataset contaminate the baseline. Audit baseline recovery after each candidate. A failed fit is useful: preserve its residual pattern for E07 rather than deleting inconvenient points.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved

bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

An empirical curve is conditional on architecture, shape, precision, allocator, and execution history. State the interpolation range supported by data and the extrapolation range that remains speculative.

Recommend a candidate for subsequent search using both uncertainty and runtime cost. Explain why a curve that accurately predicts allocated bytes may still miss device-global pressure or fragmentation. Its engineering value lies in making uncertainty visible before a controller begins acting on the estimate.

19.24.3 Exercise 02

Exercise Title: Estimate the Largest Safe Batch Size from Free VRAM Before Launching the First Training Step

Part 1 - Exercise Contract and Why It Matters

Build a conservative preflight estimator that proposes an initial physical batch before the target job performs its first update. Inputs must include a device snapshot, a workload fingerprint, future persistent allocations, a memory model, and a safety policy. Output a proposed batch, its assumptions, and a reasoned refusal when even one sample is not admissible.

Distinguish zero-trial prediction from a calibrated estimate using earlier measurements. Reuse an E01 profile only when shape, optimizer, dtype, and backend match. An estimator with no profile must state its weaker evidence and use analytic bounds or a small conservative proposal. Predictions remain provisional until a complete update validates them.

Part 2 - System and Memory Mental Model

Free VRAM is an instantaneous device-global observation. It can fall between measurement and allocation. A snapshot before model creation differs from one after loading parameters: define the boundary explicitly. Count only future incremental demand against remaining free memory; otherwise the estimator may charge an already resident model twice.

Conversely, parameters exclude future gradient buffers, lazy optimizer moments, inputs, activations, and temporary update buffers. Omitting these creates an optimistic first-step estimate. Cached memory already owned by this process may help, but $R - A$ does not guarantee that an arbitrary allocation can use all those bytes. Use zero cache credit for a conservative base policy and study alternative credits separately.

The job budget and device availability are different constraints. A process can exceed its application budget while the GPU still has free memory. Admission must satisfy both. Isolation or resource reservation is needed for guarantees against arbitrary external demand; a preflight Python check cannot create that isolation.

Part 3 - Quantitative Prediction Before Execution

Let A_0 be allocated bytes already present, F_0 global free bytes, J the allocated-byte job cap, S_J job headroom, and S_D device headroom. Let ΔM_0 be future fixed demand and α incremental per-sample cost. A conservative model is

$$C_0 = \min(J - S_J - A_0,\ F_0 - S_D), \qquad \Delta M_0 + \alpha b \le C_0.$$

For positive α,

$$b_{\text{estimate}} = \left\lfloor \frac{C_0 - \Delta M_0}{\alpha} \right\rfloor .$$

If the numerator is negative, do not force a minimum batch of one. Report no feasible prediction. Round down to required batch granularity.

Assume $F_0 = 3\,\text{GiB}$, $S_D = 512\,\text{MiB}$, $\Delta M_0 = 768\,\text{MiB}$, and $\alpha = 80\,\text{MiB/sample}$, with a nonbinding job cap. Calculate the proposal and remaining headroom. Repeat when another process consumes 600 MiB. These are hypothetical inputs, not claims about your device.

Part 4 - Experimental Design and Instrumentation

1. Test the CPU-side arithmetic before CUDA. Include negative headroom, zero slope, missing profile, and a budget below resident state.

2. Snapshot after model loading but before the first target update. Identify gradient and optimizer allocations still absent. Record time, device identity, and profile provenance.

3. Generate proposals under several margins and later compare them to full-step capacity. Freeze predictions so measured results cannot retroactively change the original proposal.

4. Measure overshoot, undershoot, and refusal rates. Count unsafe overestimates separately from conservative proposals.

5. Change length, optimizer, or precision to create stale profiles. Require fingerprint mismatch detection before reusing calibration.

Hint: `torch.cuda.mem_get_info(device)` returns bytes. Convert display units at export time, not repeatedly inside admission logic.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PreflightSnapshot:
    allocated_bytes: int
    reserved_bytes: int
    free_bytes: int
```

```
    total_bytes: int
    timestamp_seconds: float

@dataclass
class CapacityProposal:
    batch_size: object
    predicted_increment_bytes: object
    admissible: bool
    reason: str

def capture_preflight_snapshot(device):
    snapshot = ...
    return snapshot

def validate_profile(profile, workload_fingerprint):
    # Refuse incompatible or insufficient calibration.
    verdict = ...
    return verdict

def estimate_future_fixed_bytes(model_spec, optimizer_spec):
    # Count only allocations absent at the snapshot boundary.
    future_fixed_bytes = ...
    return future_fixed_bytes

def propose_initial_batch(snapshot, profile, budgets, limits):
    # Respect both job and device headroom constraints.
    proposal = ...
    return proposal

def compare_prediction_with_capacity(proposal, measurements):
    comparison = ...
    return comparison

def E02(device, profile, workload_fingerprint, budgets, limits):
    snapshot = ...
    proposal = ...
    return proposal
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate hand-computed byte-level cases. Predicted increment plus device margin must not exceed snapshot availability under the chosen cache policy. Check that increasing the margin cannot increase the proposed batch when other inputs remain fixed.

Classify errors as stale measurement, wrong fixed-state accounting, incorrect slope, workspace transition, or external interference. Do not label every OOM an arithmetic failure. Report the largest measured candidate separately from the largest repeatedly safe candidate. Show an explicit no-fit case, since silently proposing one sample can create an endless retry loop.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved

bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Preflight estimation reduces expensive trial work; it is not proof of future availability. Explain the cost of conservatism and what evidence would justify reducing it. Preserve the distinction between a good first proposal and a validated operating point.

Conclude with a policy for missing or stale calibration: conservative launch, controlled probing, or explicit deferral. Tie that decision to failure cost and available headroom rather than inventing a universal safety factor.

19.24.4 Exercise 03

Exercise Title: Implement a Linear Search That Increases Batch Size Until the First CUDA Out-of-Memory Failure

Part 1 - Exercise Contract and Why It Matters

Implement an ascending search over integer batch sizes. Increase from a small candidate by a declared increment until the first genuine CUDA allocation OOM or configured ceiling. Return the last validated success, first failing candidate, complete history, and a status distinguishing a found boundary from a bounded search without failure.

Every trial must represent complete updates and repeated feasibility, not model construction alone. Search is disposable: trial updates must not advance the real job or consume its sample cursor. Use fresh isolated CUDA workers as the primary design, making cleanup and state equivalence explicit at the cost of process startup time.

Part 2 - System and Memory Mental Model

OOM may occur during transfer, forward, backward, lazy optimizer initialization, or an update workspace allocation. A backward failure can leave partial gradients; an optimizer failure may follow partial parameter or state mutation. Retrying that object without restoration changes the experiment.

Use the spawn process model and create CUDA state inside the child. Retain CPU-only configuration and results in the parent. Worker exit releases its allocations, but external pressure may still change between trials. In-process alternatives need reference cleanup and full-state restoration. Emptying cache cannot free live tensors or repair mutated optimizer state.

Catch the specific CUDA OOM condition. Shape errors, unsupported kernels, device assertions, and unrelated runtime exceptions are not capacity evidence. Fatal device errors may require discarding the CUDA context. A timeout or crashed worker must have a distinct status rather than being guessed to mean OOM.

Part 3 - Quantitative Prediction Before Execution

For $b_k = b_{\text{start}} + k\Delta b$, let $\phi(b_k)$ mean that every required trial update completed and passed numerical checks. A first failure brackets a boundary only at the tested resolution:

$$b_{\text{last success}} \leq b_{\max} < b_{\text{first failure}},$$

assuming a stable budget and monotone feasibility. If $\Delta b > 1$, untested integer batches remain inside the interval.

For a true threshold of 19, a start of 1, and increments of 1 versus 4, predict trial counts, last success, first failure, and bracket width. For a failure on the candidate grid, the trial count is $1+(b_{\text{fail}}-b_{\text{start}})/\Delta b$. Add startup, warm-up, and repeated-update cost to predict total search time; counting function calls alone can hide most of the cost.

Part 4 - Experimental Design and Instrumentation

1. Build a CPU fake trial function with configurable threshold, unrelated exception, timeout, and no-fit outcome. Validate bookkeeping without GPU allocation.

2. Recreate each candidate from identical CPU state and ordered data. Perform a cold update plus repeated warmed updates. Return only scalar statistics, error class, and failure phase.

3. Set maximum candidate, attempts, and timeout. Record pre-trial headroom; stop on changed environment rather than claiming a stationary capacity boundary.

4. Rerun the last success in a fresh worker after observing the first OOM. Explain inconsistency and lower confidence if necessary.

5. Keep real training untouched. Subsequently launch a new production instance at a separately chosen safe operating batch.

The deliberate OOM belongs in a bounded isolated experiment. Do not terminate unrelated CUDA processes as a cleanup strategy.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import multiprocessing as mp
import torch

@dataclass
class SearchLimits:
    first_batch: int
    increment: int
    maximum_batch: int
    maximum_attempts: int
    timeout_seconds: float
```

```
def trial_worker(configuration, batch_size, result_channel):
    # Initialize CUDA in this child and run complete trials.
    # Distinguish allocation OOM from every other failure.
    ...

def launch_isolated_trial(configuration, batch_size, timeout):
    # Use spawn, collect scalar results, and join safely.
    trial_result = ...
    return trial_result

def linear_capacity_search(trial_function, limits):
    # Maintain last success, first OOM, and all attempts.
    # Distinguish no-fit, ceiling, timeout, and other error.
    search_report = ...
    return search_report

def revalidate_last_success(configuration, search_report):
    validation = ...
    return validation

def E03(configuration, limits):
    # Do not pass real training state into trial workers.
    report = ...
    return report

def main():
    # Build CPU-only configuration and invoke the exercise.
    ...

if __name__ == "__main__":
    main()
```

Part 6 - Measurement, Validation, and Failure Analysis

Check first-candidate OOM, success at ceiling, non-unit increments, and no feasible candidate. Verify that the returned success was actually tested. Log bytes, shape, precision, duration, repetition count, and failure stage. A first-OOM boundary is not a strictly safe production configuration.

Verify cleanup through the global snapshot after worker exit, allowing for unrelated activity and driver state. Compare identically initialized successful runs for finite losses and expected parameter changes. Reject searches that advance real data iterators, ignore worker failures, or retain GPU tensors through stored exception tracebacks.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Linear search offers a transparent baseline for faster searches. Its cost grows with the number of candidates, but dense evidence can reveal irregular behavior that sparse search misses.

Explain what it proved: feasibility at specific conditions, increment, and confidence. Separately explain what remains unknown about future input shapes, external processes, and sustained operation. That distinction matters when binary search and adaptive control reuse this trial interface.

19.24.5 Exercise 04

Exercise Title: Replace Linear Search with Binary Search to Find the Maximum Feasible Batch Size Using Fewer Trial Runs

Part 1 - Exercise Contract and Why It Matters

Replace E03's ascending search with bracket construction and binary refinement. Reuse exactly the same complete-update trial contract so the comparison measures search strategy rather than different definitions of feasibility. Return tested bounds, candidate history, probe count, wall time, and a termination reason. A ceiling reached without failure is a lower-bound result, not proof of an unconstrained maximum.

Support a known bracket and an unknown bracket. For the latter, use bounded expansion before refinement. Include no-fit at batch one, exact endpoint success, and a ceiling below the actual capacity. Preserve the real training state through the disposable-worker design.

Part 2 - System and Memory Mental Model

Binary search needs a stable predicate: success at b should imply success at smaller candidates under the same shape, precision, state, and budget. Kernel selection, workspace transitions, allocation history, and external pressure can violate practical monotonicity. Fewer probes therefore buy less direct evidence about irregular regions.

Maintain a feasible lower bound that was actually tested and an infeasible upper bound that was actually tested. A synthetic sentinel is not an OOM measurement. With stride constraints, search indices in the admissible candidate list rather than mixing integer batch values and index arithmetic. Repeated contradictory outcomes mean the predicate is uncertain; they are not permission to keep an arbitrary earlier answer.

Use fresh workers to stabilize allocator state and repeat near-boundary candidates. This reduces avoidable variation but cannot freeze another process's demand. If monotonicity is contradicted, report the contradiction and fall back to a bounded local sweep or a conservative tested configuration.

Part 3 - Quantitative Prediction Before Execution

Given a tested feasible l and infeasible u, an integer midpoint satisfies

$$m = \left\lfloor \frac{l+u}{2} \right\rfloor, \qquad l < m < u$$

while $u - l > 1$. The bracket width decreases roughly by half per probe. Refinement requires at most $\lceil \log_2(u-l) \rceil$ probes for a monotone integer predicate, excluding endpoint tests and repetition.

Starting from $l = 8$ and $u = 64$ with a hypothetical threshold of 37, write the complete predicted probe sequence and bound changes by hand. Compare with a unit-stride linear search.

For expansion, include its separate $O(\log b_{\max})$ probes and the ceiling checks. Compute total runtime as

$$t_{\text{search}} = \sum_i (t_{\text{startup},i} + t_{\text{warm},i} + t_{\text{trial},i}),$$

because faster probe counts do not guarantee lower time when workers differ in launch overhead or candidate size.

Part 4 - Experimental Design and Instrumentation

1. Implement a deterministic fake predicate for capacities 0, 1, 37, and a capacity beyond the ceiling. Verify termination and exact tested bounds.
2. Add a deliberately nonmonotone fake predicate and a time-varying one. Define how contradictory measurements invalidate the bracket.
3. Run linear and binary search against the same CUDA worker, seed, shape, optimizer state, and repetition requirements.
4. Use bounded expansion only if no upper failure is known. Log each expansion and never allocate beyond the declared candidate ceiling.
5. Recheck the proposed maximum and its immediate admissible neighbor. Measure total search time and the time of this validation separately.

Record an environmental fingerprint per trial, including global free memory. The binary-search controller should remain CPU-only and independently testable.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class CapacityBracket:
    last_feasible: object
    first_infeasible: object
    maximum_allowed: int
    environment_fingerprint: str
```

```
def establish_bracket(trial_function, initial_batch, limits):
    # Perform bounded expansion and distinguish ceiling from OOM.
    bracket = ...
    history = ...
    return bracket, history

def refine_bracket(trial_function, bracket, history):
    # Implement termination and preserve tested-bound invariants.
    result = ...
    return result

def detect_contradictions(history):
    # Compare outcomes only within compatible environments.
    contradictions = ...
    return contradictions

def validate_boundary(trial_function, candidate, limits):
    # Repeat the success and test the neighboring candidate.
    evidence = ...
    return evidence

def E04(trial_function, initial_batch, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require strict bracket shrinkage, no duplicate midpoint loop, and no invented successful endpoint. Test non-unit candidate strides and a bracket of width one. Every returned batch must have completed its full feasibility trial. Failures other than allocation OOM must leave the search with a distinct error status.

Compare final capacities with E03 only under comparable stable conditions. Report both calls saved and seconds saved. If results disagree, rerun a small neighborhood and inspect shape, budget, optimizer-state, and workspace differences. Do not hide disagreement by presenting only the faster method.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Binary search is an efficiency improvement built on an assumption about feasibility. State where that assumption was tested and where it remains uncertain. A short search log can be less persuasive than a longer stable one when the device is shared.

Choose whether your production runtime should use binary search, a local sweep, or profile-guided admission. Base the choice on measured probe cost, repeatability, and the risk of an incorrect boundary.

19.24.6 Exercise 05

Exercise Title: Add a Configurable VRAM Safety Margin and Explain Why Running at the Exact OOM Boundary Is Unsafe

Part 1 - Exercise Contract and Why It Matters

Extend the capacity policy with absolute and relative headroom, explicit accounting scope, and uncertainty allowance. Compare three operating choices: largest observed feasible batch, batch with fixed-byte margin, and batch with a combined fixed/relative margin. Deliver a capacity-versus-risk table and a justified operating recommendation.

The contract must define whether the cap concerns allocated bytes, reserved bytes, or device-global usage. Use allocated-byte admission plus a separate global-headroom observation as the base experiment. Label cached reservations separately. A successful allocation is not sufficient if the application margin was violated.

Part 2 - System and Memory Mental Model

Exact-boundary operation leaves no room for uncommon shapes, delayed frees, workspace variation, prediction error, or another process. Repeated success on one batch establishes only observed feasibility. A safety reserve reduces exposure to bounded disturbances; it cannot defeat unbounded demand or a race after the final check.

Absolute margins protect a minimum number of bytes, while relative margins scale with the selected budget. Define their composition explicitly: maximum or sum gives different policies. Do not silently change the rule between estimation and runtime. Distinguish model-error allowance from operational reserve so the same uncertainty is not charged twice accidentally.

Allocated and reserved peaks may occur at different instants. A high reserved value can reflect a harmless cache or a costly footprint on a shared GPU. Your job policy may limit both, but subtracting reserved bytes from global free memory again would double-count already unavailable memory.

Part 3 - Quantitative Prediction Before Execution

For a declared total job budget J, define

$$S_J = \max(S_{\text{absolute}}, \rho J), \qquad \widehat{M}_{\text{upper}}(b) = \widehat{M}(b) + U(b).$$

Admit a candidate only if

$$\widehat{M}_{\text{upper}}(b) + S_J \leq J.$$

Use an additional incremental device-availability check from E02. $U(b)$ represents prediction uncertainty, not the safety margin itself. A percentile of positive residuals is one empirical choice; it is not a hard upper bound.

For $J = 8\,\text{GiB}$, a $512\,\text{MiB}$ absolute margin, and $\rho = 0.10$, calculate the usable cap in bytes. Suppose a candidate predicts $7.1\,\text{GiB}$ and uncertainty is $0.2\,\text{GiB}$. Decide admission before measuring. Repeat for $J = 6\,\text{GiB}$ and explain which margin component binds. Compare these results with the sum rule.

Part 4 - Experimental Design and Instrumentation

1. Choose a baseline workload and its measured curve. Keep dtype, optimizer, shape, and initial state identical across policies.

2. Sweep several margins within an application cap smaller than physical VRAM. Count policy violations even if CUDA does not raise OOM.

3. Inject a bounded temporary workspace in diagnostic trials and include a longer input already declared in the disturbance envelope.

4. Run repeated updates, collecting peak allocated bytes, reserved peak, snapshot headroom, successful throughput, and time spent refusing work.

5. Recompute decisions from the stored log. The offline and online admission results must match for identical observations.

Use a common wall-clock evaluation horizon. Repeatedly rejecting all batches is safe only in a trivial sense; report lost useful work and no-fit duration.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class SafetyPolicy:
    job_budget_bytes: int
    absolute_margin_bytes: int
    relative_margin: float
    device_margin_bytes: int
    uncertainty_mode: str

def calculate_job_margin(policy):
    margin_bytes = ...
    return margin_bytes

def estimate_upper_peak(profile, candidate, uncertainty):
    upper_peak_bytes = ...
    return upper_peak_bytes

def admit_candidate(snapshot, prediction, policy):
    # Check job scope and incremental device availability.
    decision = ...
```

```
    return decision

def audit_realized_margin(trial_record, policy):
    # A completed update can still violate the policy.
    audit = ...
    return audit

def E05(trial_function, profile, policies, disturbances):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Test zero and negative budgets, relative margins outside the allowed range, and a margin larger than the budget. A no-fit result must be explicit. Check monotonicity of admission as the margin grows and verify all arithmetic uses bytes before formatting.

Report violation count, OOM count, minimum observed headroom, useful throughput, and refusals separately. A headroom snapshot does not prove the minimum global free memory between samples. State sampling resolution and observation limits. Describe any bounded stress that defeated the selected margin and which assumption failed.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Safety is a resource tradeoff with an operating envelope. A larger reserve may waste capacity or may improve useful throughput by avoiding costly retries. Judge it using accepted work over total elapsed time.

Recommend a margin together with its measurement scope, uncertainty estimate, tested disturbances, and fallback behavior. Avoid presenting a fixed percentage as universally correct across devices, shapes, or workloads.

19.24.7 Exercise 06

Exercise Title: Compare Estimated Batch Capacity Against Measured Capacity for CNN, MLP, and Transformer-Style PyTorch Workloads

Part 1 - Exercise Contract and Why It Matters

Compare prediction quality across MLP, CNN, and Transformer workloads. Build and measure a separate memory profile for each, predict a safe batch under a common application cap, and validate it using E03 or E04. Deliver an architecture specification, predicted and measured capacities, and an explanation of the error for each family.

The purpose is not to declare one architecture more efficient in general. Their tasks, input units, and computations differ. Compare prediction error and capacity within each fixed workload; treat cross-family throughput as separate sample definitions unless you establish a common task.

Part 2 - System and Memory Mental Model

An MLP often exposes dense hidden activations with approximately linear batch dependence. A CNN adds spatial feature maps, convolution workspace choices, layout effects, and possibly batch-dependent normalization. A Transformer adds padded length, attention backend, mask shape, and potentially quadratic intermediates. Similar parameter counts therefore do not imply similar peaks.

Keep complete-update accounting common: parameters, gradients, optimizer state, inputs, saved activations, and temporary buffers. Use FP32 and a fixed optimizer initially to avoid confounding architecture with precision. BatchNorm changes statistics with the physical batch, so use a batch-independent baseline or label that semantic difference explicitly.

Each profile needs a fingerprint containing layer sizes, input shape, precision, optimizer, model mode, and backend. Reusing an MLP slope for a CNN is intentionally a negative control, not a plausible generic estimator. If a workload fails at batch one, lower its dimensions and publish the change.

Part 3 - Quantitative Prediction Before Execution

Use local models such as

$$\begin{aligned}\widehat{M}_{\mathrm{MLP}}(b) &= M_0 + \alpha b d,\\ \widehat{M}_{\mathrm{CNN}}(b) &= M_0 + \alpha b \sum_{\ell} C_\ell H_\ell W_\ell + W_{\mathrm{conv}}(b),\\ \widehat{M}_{\mathrm{attn}}(b, L) &= M_0 + \alpha b L d + \beta b h L^2 + W(b, L).\end{aligned}$$

These equations are modelling hypotheses, not exact architecture formulas. For measured safe capacity b^* and predicted $\widehat{b}$, report

$$e_b = \widehat{b} - b^*, \qquad e_{\mathrm{relative}} = \frac{\widehat{b} - b^*}{b^*},$$

with no relative-error value when $b^* = 0$. Positive error is an unsafe overestimate; negative error represents conservatism.

Before running, rank expected sensitivity to doubling spatial resolution, hidden width, and sequence length. Predict which rank might change with an efficient attention backend. Include byte predictions at two small batches per architecture and reserve a third for validation.

Part 4 - Experimental Design and Instrumentation

1. Define small reproducible architectures with documented dimensions. Use synthetic CPU inputs and compatible regression or classification targets. Disable dropout for exact numerical controls.

2. Hold optimizer, precision, application budget, and safety policy fixed. Measure separate cold and warm baselines for each architecture.

3. Calibrate on small feasible batches, then freeze the prediction. Use a separate capacity search to obtain measured safe capacity.

4. Repeat after changing only one shape parameter: image resolution, feature width, or sequence length. Require profile invalidation or explicit shape-conditioned prediction.

5. Produce one plot per workload and a shared prediction-error table. Keep confidence intervals or repetition ranges next to measured capacities.

Use the same complete-update timing definition. Record backend selection and layout instead of inferring them from model class names.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
import torch.nn as nn

@dataclass
class WorkloadSpecification:
    family: str
    input_shape: tuple
    model_dimensions: dict
    precision_name: str
    optimizer_name: str

def build_mlp(specification):
    model = ...
    return model

def build_cnn(specification):
    model = ...
    return model

def build_transformer(specification):
    model = ...
    return model

def calibrate_workload(specification, candidate_batches):
    profile = ...
    return profile

def measure_safe_capacity(specification, budget, search_limits):
    capacity_report = ...
```

```
    return capacity_report

def compare_prediction_errors(predictions, measurements):
    comparison = ...
    return comparison

def E06(specifications, budget, search_limits):
    # Preserve separate units, shapes, and profiles per workload.
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a finite loss and finite gradients for every accepted architecture. Check a small deterministic update against that architecture's own reference, using dtype-appropriate tolerances. There is no meaningful equality test between unrelated model outputs.

Detect stale cross-family calibration, omitted convolution workspaces, inconsistent optimizer state, and incompatible target shapes. Keep the batch-one no-fit outcome in the table if it occurs. Explain prediction errors using measured phases or profiler evidence rather than stereotypes about model families.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A reusable estimator needs a reusable interface, not one universal slope. Identify which metadata must select a profile and which measurements can be shared across families.

Conclude with a profile-selection policy and the conditions that trigger recalibration. Explain whether the limiting uncertainty came from persistent state, shape, workspace selection, or changing device availability.

19.24.8 Exercise 07

Exercise Title: Detect Nonlinear Batch Memory Growth Caused by Temporary Buffers and Operator Workspace Allocations

Part 1 - Exercise Contract and Why It Matters

Investigate a memory curve that departs from a linear batch model. Locate the transition, associate it with an execution phase, and separate a workspace change from graph retention, allocator history, or input-shape changes. Deliver a residual plot, a phase trace, and evidence supporting or rejecting the proposed cause.

Do not assume your GPU will naturally exhibit a convenient discontinuity. If no natural transition is observed, publish that negative result and use an explicitly labelled synthetic temporary buffer to validate your detector. The controlled demonstration must never be presented as a measured kernel implementation detail.

Part 2 - System and Memory Mental Model

Operator implementations may switch algorithms as shapes change. Workspace size can then jump even when tensor payload grows smoothly. The temporary buffer may be released before an end-of-phase observation, leaving only a peak counter or trace as evidence. Optimizer implementations can also allocate temporary tensor lists or buffers.

Reserved-memory steps can arise from allocator block acquisition without equivalent jumps in live tensor demand. Conversely, an allocation outside the PyTorch allocator may affect global usage without appearing in its tensor snapshots. Keep measurement scope attached to each causal claim.

Changing batch order may change allocator fragmentation and cache reuse. A steadily growing current allocation after cleanup points toward retained references; a reproducible isolated peak jump at one shape suggests a different mechanism. Neither observation alone identifies a specific kernel. Use a separate profiler run to connect the transition with an operator.

Part 3 - Quantitative Prediction Before Execution

For adjacent candidates, define a finite-difference slope

$$s_i = \frac{M(b_{i+1}) - M(b_i)}{b_{i+1} - b_i}.$$

Compare s_i with the baseline slope and variation across repetitions. A simple change model is

$$\widehat{M}(b) = M_0 + \alpha b + W_{\text{jump}}\, \mathbf{1}_{b \geq b_c}.$$

It describes one transition; it does not establish its physical cause. Predict the residual pattern if you fit one straight line across the jump.

For illustrative $M_0 = 1\,\text{GiB}$, $\alpha = 40\,\text{MiB/sample}$, $W_{\text{jump}} = 384\,\text{MiB}$, and $b_c = 20$, compute peaks at $b = 16, 19, 20, 21, 24$. Determine the slope immediately across the boundary and the conservative prediction error below and above it. Specify a detection threshold using repeated-run noise before examining real results.

Part 4 - Experimental Design and Instrumentation

1. Start from an E01 workload with frozen shapes, precision, backend settings, and optimizer. Collect a coarse sweep, then a dense local sweep around suspected transitions.

2. Compare isolated workers, ascending order, and descending order. Record allocated baseline, peak, reserved peak, and global snapshots.

3. Use `torch.profiler` with memory and shape recording in a diagnostic run. Treat its overhead separately from benchmark latency.

4. Trace forward, backward, and optimizer phases. If using allocator snapshots, record PyTorch version and allocator backend, and recognize memory outside the allocator as an observation limit.

5. Inject a temporary tensor of declared byte size in one chosen phase. Retain it only for that phase, then compare the detector's result with the known intervention.

If testing algorithm-related settings, change one setting per experiment and retain the default-setting result as a reference.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
from torch.profiler import profile, ProfilerActivity

@dataclass
class TransitionCandidate:
    left_batch: int
    right_batch: int
    observed_slope: float
    baseline_slope: float
    evidence_label: str

def calculate_local_slopes(records):
    slopes = ...
    return slopes

def detect_transitions(records, noise_model):
    candidates = ...
    return candidates

def run_diagnostic_profile(workload, batch_size, output_path):
    # Capture shapes, phases, and memory in a separate run.
    trace_summary = ...
    return trace_summary

def inject_temporary_workspace(phase, requested_bytes, device):
    # Leave the controlled allocation and lifetime to the learner.
    workspace = ...
    return workspace

def distinguish_peak_jump_from_retention(records, traces):
    diagnosis = ...
    return diagnosis
```

```
def E07(workload, candidate_batches, noise_model):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that the detector rejects ordinary repeated-run noise and recognizes the labelled injected jump at the expected interval. Compare current post-cleanup allocation with peak allocation to distinguish retained storage from temporary demand. Check that diagnostic tensors are not kept in the measurement log.

Reject unsupported causal claims: a residual alone does not prove a convolution workspace, and a reserved-memory jump alone does not prove a larger activation tensor. If the transition disappears with isolated workers, report allocator history as a plausible explanation and test it directly.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A capacity model should encode regimes when the data show regimes. Explain whether to use piecewise calibration, an uncertainty envelope, or more conservative admission around a transition.

State the evidence supporting each interpretation and what remains unobserved. Good engineering can conclude that a transition exists while remaining uncertain about its exact low-level allocation source.

19.24.9 Exercise 08

Exercise Title: Build a Batch Controller That Shrinks the Next Batch When Peak VRAM Crosses a High-Watermark Threshold

Part 1 - Exercise Contract and Why It Matters

Build a one-way controller that can hold or reduce the next physical batch. It observes a completed update's peak and a fresh budget snapshot, then selects an admissible batch for the next update. Deliver the decision trace, reasons for each shrink, a comparison against a static batch, and an explicit no-fit outcome when batch one cannot satisfy the policy.

This exercise does not yet attempt growth. Keep that separation so a shrink decision can be evaluated without a competing expansion rule. Preserve sample identity when smaller batches change the data iterator. For numerical equivalence tests, replay the same logical update through weighted accumulation; otherwise acknowledge that changing update batch changes training semantics.

Part 2 - System and Memory Mental Model

The controller has delayed information: a peak from update t describes past work, while the next input and budget can differ. Shrinking the next batch cannot undo a violation that

already occurred. Combine retrospective high-watermark feedback with prospective admission for the next known shape. Record both reasons when they disagree.

A naive proportional reduction based on total peak assumes all memory scales with batch. Persistent parameters and optimizer state invalidate that assumption. Predict the variable portion separately, and use a conservative tested fallback if calibration is unreliable. A smaller batch is not automatically enough when the budget falls below persistent state.

Operate at a clear boundary after an update is committed and transient graph references are released. Do not resize live inputs in the middle of backward. Keep the control function pure and CPU-only; GPU telemetry is an input, not a hidden side effect. Clear separation allows synthetic traces to exercise rare transitions without generating real OOMs.

Part 3 - Quantitative Prediction Before Execution

Let J_t be the current allocated-byte job cap and M_t the completed update peak. Define $u_t = M_t/J_t$ only for $J_t > 0$. A high watermark $0 < h < 1$ triggers review when $u_t \geq h$. If the desired next cap is hJ_{t+1} and a local model is $M_0 + \alpha b$, then

$$b_{\text{target}} \leq \left\lfloor \frac{hJ_{t+1} - M_0 - U}{\alpha} \right\rfloor,$$

where U is uncertainty. Apply integer, minimum, maximum, and device-headroom constraints explicitly. The threshold is not a substitute for E05's margin.

Assume $M_0 = 2\,\text{GiB}$, $\alpha = 128\,\text{MiB/sample}$, $b_t = 24$, and $J_{t+1} = 5\,\text{GiB}$ with $h = 0.85$. Predict a candidate with $U = 128\,\text{MiB}$. Compare it with blindly halving b_t and with proportional scaling of the total peak. Explain each policy's expected remaining headroom.

Part 4 - Experimental Design and Instrumentation

1. Create a deterministic budget trace with a steady segment followed by two reductions. Replay it through a pure controller before CUDA.

2. Choose a static baseline that is feasible initially. Feed the controller peak observations plus next-shape metadata and budget timestamps.

3. Apply the selected batch only at the next update boundary. Keep a CPU queue of unconsumed sample identifiers; smaller batches must not skip or duplicate samples.

4. Compare feedback-only shrink with feedback plus preflight admission. Count violations during the first update after each budget reduction.

5. Record previous batch, selected batch, utilization, cap, predicted peak, observed peak, reason, and accepted samples per wall-clock second.

Treat application-cap violations separately from CUDA OOM, since the device can have more physical memory than the test budget.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ShrinkObservation:
    completed_batch: int
    peak_bytes: int
    next_budget_bytes: int
    next_shape: tuple
    timestamp_seconds: float

@dataclass
class BatchDecision:
    selected_batch: object
    action: str
    reason: str
    predicted_peak_bytes: object

def evaluate_high_watermark(observation, policy):
    trigger = ...
    return trigger

def propose_smaller_batch(observation, profile, policy):
    # Separate fixed state from batch-dependent memory.
    decision = ...
    return decision

def admit_next_batch(decision, snapshot, next_shape, policy):
    validated_decision = ...
    return validated_decision

def consume_sample_prefix(cpu_queue, selected_batch):
    # Commit the cursor only when the training contract allows it.
    batch_record = ...
    return batch_record

def E08(workload, budget_trace, profile, policy):
    trace = ...
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Test equality at the threshold, budget zero, minimum batch, negative predicted headroom, and stale observations. The one-way controller must never increase batch size. A no-fit decision must lead to deferral or an explicit stop, not an infinite sequence of identical failing attempts.

Audit sample IDs and accepted update counts. For deterministic replay, compare the resulting logical gradient and parameters with the static reference. Record how many updates elapsed before headroom recovered after each disturbance. If only future updates recover, do not claim that the triggering violation was prevented.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Shrink control is a reaction to evidence and a proposal about future demand. Discuss its response delay, conservatism, and dependence on accurate shape metadata. Identify a disturbance it can handle and one it cannot.

Explain whether lowering the batch restored useful operation or merely postponed an unavoidable no-fit state. A controller needs an honest stopping condition as much as it needs a recovery action.

19.24.10 Exercise 09

Exercise Title: Build a Batch Controller That Gradually Increases Batch Size When Sustained VRAM Headroom Is Available

Part 1 - Exercise Contract and Why It Matters

Add cautious growth after sustained successful operation below a low watermark. Require a configurable observation window, a bounded growth step, and preflight validation of the proposed larger batch. Compare this policy with immediate growth and with a permanently conservative static batch. Report recovered capacity and the cost of failed or rejected probes.

Growth must use only observations available at decision time. A benchmark oracle may know future budgets, but the implemented controller must not. Do not increase the real learning batch accidentally: use a fixed logical batch when assessing equivalent training, and label variable-update-batch experiments separately.

Part 2 - System and Memory Mental Model

One low-memory update can be an unusually short input or a temporary budget increase. Sustained evidence reduces that noise but delays exploitation. Headroom alone does not establish that a larger batch improves throughput. The controller should require validated useful-work benefit or at least measure it after a bounded trial.

Define consecutive success using actual accepted optimizer updates, not attempted updates or micro-steps. An OOM, margin violation, overflow-skipped update, changed shape class, or stale budget may invalidate the observation window. Specify exactly which events reset it.

The counter and growth limit belong to the controller state. Warm-up and rejected trials must not masquerade as steady successful operation. When a proposed shape enters an unprofiled region, either run an isolated calibration trial or refuse speculative growth. Keep probing cost in the end-to-end throughput denominator.

Part 3 - Quantitative Prediction Before Execution

Let l be a low watermark and k the required consecutive accepted observations satisfying $u_t \leq l$. Define a counter c_t whose update you must specify for success, violation, skip, and profile change. A bounded proposal may be expressed as

$$b_{\text{proposal}} \leq \min(b_{\max},\, b_t + \Delta b,\, \lfloor (1+\gamma) b_t \rfloor).$$

Explain how integer rounding can prevent progress at small b_t and define an explicit admissible-grid rule rather than forcing unsafe growth.

For $b_t = 8$, $k = 4$, and an additive increment of two, manually replay the following utilizations with $l = 0.60$:

$$(0.55,\ 0.56,\ 0.82,\ 0.54,\ 0.53,\ 0.52,\ 0.51).$$

Predict the first growth opportunity. Then repeat with an overflow skip on the sixth observation. For a successful growth, compare additional useful samples with probe time:

$$Q_{\text{net}} = \frac{N_{\text{accepted}}}{t_{\text{training}} + t_{\text{probing}} + t_{\text{recovery}}}.$$

Part 4 - Experimental Design and Instrumentation

1. Use a synthetic trace containing sustained headroom, a single low outlier, a budget increase, and an abrupt budget decrease after growth.

2. Validate the counter and action sequence on CPU. Fix the rule for which events count as accepted updates.

3. Run the CUDA workload from a conservative batch. Admit each growth proposal against the current budget and next known shape.

4. Compare at least two patience values and two growth increments. Keep safety margin and shrink rule identical across conditions.

5. Measure time to recover a useful batch, rejected growth attempts, post-growth violations, and net throughput over the entire trace.

Use repeated trials with the same workload ordering. Report a no-benefit growth result if larger batches fit but do not improve useful throughput.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class GrowthState:
    current_batch: int
    consecutive_accepted_low: int
    last_growth_update: object
    profile_fingerprint: str

def classify_growth_observation(observation, policy):
    classification = ...
    return classification

def update_patience_state(state, classification, policy):
    next_state = ...
    return next_state

def propose_growth(state, profile, next_shape, policy):
    # Apply integer limits and uncertainty-aware admission.
    proposal = ...
    return proposal

def validate_growth_benefit(before_records, after_records):
    benefit = ...
    return benefit

def E09(workload, trace, initial_state, policy):
    # Count probe and recovery time in the final comparison.
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check off-by-one patience errors, repeated growth without fresh evidence, and a stale counter surviving an OOM. Test minimum and maximum batches, small multiplicative increments, and a low watermark never reached.

Your trace must explain every hold and growth action. Accepted work must exclude failed retries and overflow-skipped optimizer updates. State how small timing differences are treated as noise. Reject a policy that claims a gain solely by excluding its calibration or probe costs.
Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Growth is an investment in future throughput. Discuss when the observation window is too short to trust and when it is so long that available capacity goes unused.

Recommend a growth policy for one measured workload, with a stopping rule when larger batches provide no benefit. The goal is useful progress within constraints, not reaching the largest integer on the batch-size axis.

19.24.11 Exercise 10

Exercise Title: Add Hysteresis to Adaptive Batch Sizing and Prevent Batch Size from Oscillating Between Two Values

Part 1 - Exercise Contract and Why It Matters

Combine shrink and growth into a controller with distinct low and high watermarks, growth patience, and a cooldown. Demonstrate how a single threshold can alternate between two batch sizes under noisy observations, then measure whether the revised controller reduces unnecessary changes without delaying emergency shrink.

Deliver a state-transition table, a manually predicted decision trace, and a CUDA replay comparing the policies. Preserve each decision's raw observation, smoothed statistic if used, state, and reason. Smoothing must not conceal a hard admission failure.

Part 2 - System and Memory Mental Model

Changing batch size changes the measured utilization. A controller using the same threshold for both directions can create its own oscillation: the small batch looks underutilized, the larger batch looks overutilized, and each observation reverses the previous action.

A deadband $l < h$ separates growth and shrink triggers. Patience rejects short low-memory transients; cooldown limits repeated growth after a recent change. None guarantees stability for arbitrary noise, discrete batch jumps, or rapidly changing budgets. Quantization matters when moving one sample changes memory more than the deadband width.

Emergency admission failure must override growth cooldown. If smoothing is used for ordinary adaptation, retain raw peak and fresh budget checks for safety. State resets are part of the design: old patience should not survive a profile change, failed attempt, or a large drop in the available budget.

Part 3 - Quantitative Prediction Before Execution

Let u_t denote observed utilization and optionally use

$$\bar{u}_t = \lambda u_t + (1 - \lambda)\bar{u}_{t-1}, \qquad 0 < \lambda \leq 1.$$

Define growth below l, ordinary shrink above h, and hold in between. Calculate the memory change caused by one batch increment: $\Delta M \approx \alpha \Delta b$. Compare $\Delta M / J$ with the width $h - l$ to predict whether one discrete action can jump across the band.

For batches 12 and 16 producing utilizations near 0.72 and 0.86, predict a single-threshold controller at 0.80. Then try $l = 0.70$, $h = 0.90$, patience three, and cooldown two accepted updates. Construct a separate emergency trace where the budget suddenly drops. Measure switching count

$$N_{\text{switch}} = \sum_{t=2}^{n} \mathbf{1}_{b_t \neq b_{t-1}}$$

along with time to regain safe operation and accepted throughput.

Part 4 - Experimental Design and Instrumentation

1. Implement controller transitions as a pure function of state and observation. Hand-check boundary equalities at both watermarks.

2. Replay constant load with small measurement noise, alternating short and long inputs, a step budget decrease, and a temporary budget increase.

3. Compare single threshold, deadband only, and deadband with patience and cooldown. Keep growth increment and memory model fixed.

4. Execute one reproducible CUDA trace. Separate raw observations from any filtered utilization and log emergency overrides explicitly.

5. Measure switch count, rejected proposals, response delay, no-fit duration, margin violations, and useful throughput.

Do not tune thresholds on the same trace used for the final comparison. Hold out a second trace to expose overfitting to a particular pattern.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ControllerState:
    batch_size: int
    low_count: int
    cooldown_remaining: int
    filtered_utilization: object
    profile_fingerprint: str

@dataclass
class HysteresisPolicy:
    low_watermark: float
    high_watermark: float
    patience: int
    cooldown_updates: int

def transition_controller(state, observation, policy, profile):
```

```
    # Emergency safety has priority over ordinary cooldown.
    next_state = ...
    decision = ...
    return next_state, decision

def replay_controller(initial_state, observations, policy, profile):
    trace = ...
    return trace

def measure_switching_and_response(trace):
    metrics = ...
    return metrics

def E10(workload, training_trace, held_out_trace, policy):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject invalid policies with $l \geq h$, negative patience, or negative cooldown. Verify that no ordinary growth occurs during cooldown while emergency shrink remains possible. Test counter resets and exact threshold equalities.

Demonstrate at least one trace where oscillation decreases and one where discrete shapes or fast budget changes still force legitimate switching. Do not label all switching as failure. Distinguish unnecessary reversals from required safety actions, and report any stability gained by sacrificing throughput or response speed.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Hysteresis makes a controller less sensitive to ambiguous observations. It does not remove the need for a reliable admission model or fresh budget. Explain the feedback mechanism behind the observed oscillation and how the chosen band changes it.

State where your policy balances response and stability well, and where finer batch increments, shape buckets, or stronger isolation would be a better intervention than wider thresholds.

19.24.12 Exercise 11

Exercise Title: Adapt Batch Size to Variable Input Shapes and Demonstrate Why Sample Count Alone Is an Insufficient Memory Predictor

Part 1 - Exercise Contract and Why It Matters

Extend the controller so admission depends on the next input shape as well as sample count. Compare equal-size batches with different sequence lengths or image resolutions. Build

a shape-conditioned predictor, demonstrate a failure of a batch-only model, and document the response to unseen shapes.

Deliver a shape manifest, a memory-versus-shape dataset, prediction errors, and a decision trace that includes the next batch's actual padded shape. Shape metadata must be available before transferring the full batch to CUDA; discovering the shape only after an OOM defeats preflight admission.

Part 2 - System and Memory Mental Model

For padded sequences, one long item increases the padded length of the entire batch. For images, resizing or collating to a larger spatial grid increases every feature map downstream. Hidden workspace changes can compound these payload effects. Sample count is therefore only one feature.

Distinguish maximum padded length from the sum of useful lengths. Masks may exclude padding from the loss while dense kernels still process or allocate for padded positions. A model using packed or variable-length attention follows a different contract and needs a separate profile.

A shape fingerprint should include dimensions, dtype, layout, attention backend, and checkpoint policy. Interpolation inside a measured shape range has stronger evidence than extrapolation to an unseen context length. Set explicit maximum dimensions and a conservative fallback for unprofiled shapes. Keep persistent-state accounting shared where it truly remains fixed.

Part 3 - Quantitative Prediction Before Execution

For padded sequences with lengths L_i, define

$$L_{\max} = \max_i L_i, \quad N_{\text{padded}} = bL_{\max}, \quad N_{\text{useful}} = \sum_i L_i.$$

A simple shape model is

$$\widehat{M}(b, L_{\max}) = M_0 + \alpha bL_{\max} + \beta bL_{\max}^2 + W(b, L_{\max}).$$

If length doubles at fixed b, predict the change in the linear term and the quadratic term separately. Do not assume both terms dominate.

Compare length sets $(128, 128, 128, 128)$ and $(128, 128, 128, 1024)$. Calculate useful and padded token counts, padding fractions, and relative quadratic score-matrix sizes under ordinary dense attention. Repeat the reasoning for square images whose side length doubles. State which parts of each prediction require empirical confirmation.

Part 4 - Experimental Design and Instrumentation

1. Create a CPU dataset with stable sample IDs and several known length or resolution classes, including rare larger inputs.

2. Calibrate at a grid of batch sizes and shapes, holding architecture, optimizer, precision, and backend fixed. Reserve shapes for validation.

3. Compare a batch-only predictor with a shape-conditioned one on the same held-out inputs and budgets.

4. Introduce a single long outlier into an otherwise short batch. Record the collated shape before CUDA transfer and the controller decision.

5. Test a shape outside the calibration domain. Require explicit deferral, conservative probing, or another declared fallback.

For loss comparisons, normalize over the intended samples or valid tokens and keep the mask definition identical across batching arrangements.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ShapeDescriptor:
    sample_ids: tuple
    sample_count: int
    padded_shape: tuple
    valid_elements: int
    backend_name: str

def inspect_cpu_batch_shape(samples, collator_policy):
    descriptor = ...
    return descriptor

def fit_shape_conditioned_profile(calibration_records):
    profile = ...
    return profile

def check_shape_domain(descriptor, profile):
    domain_verdict = ...
    return domain_verdict

def select_batch_for_shape(cpu_queue, budget, profile, policy):
    # Inspect the actual collated shape before GPU allocation.
    proposal = ...
    return proposal

def evaluate_shape_prediction(profile, held_out_records):
    errors = ...
```

```
    return errors

def E11(dataset, shape_grid, budgets, policy):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check a one-item batch, equal lengths, one extreme outlier, and an input outside the supported domain. Zero-length or empty inputs need an explicit data policy, not an accidental division by zero. Verify masks, target alignment, sample IDs, and loss denominators.

Report unsafe underprediction by shape class, not just an average that hides rare long inputs. Confirm that a smaller sample count can still consume more memory when its padded shape is larger. A controller passes only if its decisions use the actual prospective batch shape. **Evidence format.** Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Admission is about the shape of work, not a single count. Explain the smallest set of metadata that predicts your workload well enough to make safe choices. More features are useful only when they improve held-out decisions.

Identify the remaining uncertainty from operator workspaces, padding, backend selection, and unobserved shapes. This motivates token-aware scheduling and length bucketing in the next exercises.

19.24.13 Exercise 12

Exercise Title: Build a Token-Budget Batch Scheduler for Variable-Length Transformer Sequences Instead of Using a Fixed Number of Samples

Part 1 - Exercise Contract and Why It Matters

Build a scheduler that forms Transformer batches under a declared token budget and a separate memory admission check. Begin with dense padded execution. Compare fixed sample count, useful-token-only budgeting, and padded-token budgeting augmented by a shape-aware memory estimate. Deliver batch manifests, utilization metrics, and a correctness audit.

Keep every sample exactly once in the intended epoch unless an explicit data policy says otherwise. Do not silently truncate long sequences or discard a sample that exceeds the budget. Such a sample must be isolated, deferred with a reason, or rejected through a documented contract.

Part 2 - System and Memory Mental Model

A useful-token budget counts real content. A padded-token budget approximates dense linear work. Neither alone bounds a quadratic attention term when the maximum length changes. Equal token totals can correspond to very different sequence geometries and workspace choices.

The collator's actual execution representation matters. Padded tensors, packed sequences, and variable-length attention kernels need different predictors. This exercise uses padded tensors unless the learner builds and validates an explicitly separate packed backend.

Queue policy also affects learning and fairness. Greedily filling batches with short sequences may starve long ones or reorder the data substantially. Use bounded lookahead and preserve sample IDs. Declare maximum waiting time or a fair fallback for deferred long samples. Loss masking and normalization must remain aligned with the chosen per-token or per-sequence objective.

Part 3 - Quantitative Prediction Before Execution

For a proposed batch $\mathcal{B}$, define

$$U(\mathcal{B}) = \sum_{i \in \mathcal{B}} L_i, \qquad P(\mathcal{B}) = |\mathcal{B}| \max_{i \in \mathcal{B}} L_i.$$

With padded-token budget K, require $P(\mathcal{B}) \leq K$ and also

$$\widehat{M}_{\text{upper}}(\mathcal{B}) + S_J \leq J.$$

For materialized attention, test whether a separate $|\mathcal{B}|L_{\max}^2$ term is necessary.

Two hypothetical batches have eight sequences of length 128 and one sequence of length 1024. Both have 1024 useful tokens and no padding. Calculate their respective bL^2 values and explain why token count alone does not equate attention memory. For lengths $(120, 130, 140, 900)$, compare useful and padded tokens when batched together versus splitting off the long sequence. Compute padding efficiency $\eta = U/P$ for each arrangement.

Part 4 - Experimental Design and Instrumentation

1. Create a reproducible length distribution with short, medium, and rare long sequences. Keep an immutable CPU sample-ID ledger.

2. Define useful-token and padded-token units explicitly. Inspect the collated shape before admitting a proposal.

3. Compare the three schedulers under the same memory budget, precision, backend, and total useful-token workload.

4. Add a single sample exceeding the padded-token budget. Exercise the declared fallback without silently changing its content.

5. Measure useful tokens/s, padded tokens/s, padding efficiency, queue delay, batch-size distribution, peak memory, and refusal reasons.

For the numerical control, aggregate gradients over identical logical token sets with the same valid-token denominator. Disable stochastic and batch-dependent effects for the exact comparison.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed

seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class SequenceRecord:
    sample_id: int
    length: int
    payload_reference: object
    arrival_index: int

@dataclass
class TokenBatch:
    sample_ids: tuple
    useful_tokens: int
    padded_tokens: int
    maximum_length: int
    predicted_peak_bytes: int

def summarize_proposed_batch(sequence_records):
    summary = ...
    return summary

def check_token_and_memory_limits(summary, budgets, profile):
    decision = ...
    return decision

def schedule_token_batch(queue, budgets, profile, fairness_policy):
    # Leave packing, lookahead, and fairness decisions incomplete.
    batch = ...
    next_queue_state = ...
    return batch, next_queue_state

def handle_oversized_sample(sample, budgets, policy):
    outcome = ...
    return outcome

def audit_epoch_coverage(input_ids, emitted_batches):
    audit = ...
    return audit
```

```
def E12(dataset, budgets, profile, fairness_policy):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify both admission constraints for every emitted batch, exact ID coverage, valid masks, and target alignment. Test empty input, one sample, equal lengths, budget equality, and an oversized sequence. Check that deferred samples eventually receive an explicit outcome.

Demonstrate the equal-token, unequal-memory counterexample. A scheduler that enforces only useful tokens has not proved a VRAM bound. Compare loss and logical gradients with the fixed reference; different per-sequence weighting must be reported as an objective change, not numerical noise.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Token budgeting is meaningful only when its token unit matches execution. Explain which memory terms your budget constrains and which still require shape-aware admission.

Discuss the tradeoff between packing efficiency, queue latency, and sample order. Recommend a policy whose useful throughput gain survives the cost of collation, lookahead, and fairness handling.

19.24.14 Exercise 13

Exercise Title: Sort and Bucket Variable-Length Sequences and Measure How Reduced Padding Changes Maximum Safe Batch Capacity

Part 1 - Exercise Contract and Why It Matters

Build a length-bucketing policy and compare it with unbucketed random batches and a global length-sort baseline. Measure how padding reduction changes physical batch capacity, useful-token throughput, and ordering. Deliver per-bucket profiles and a coverage audit for the complete dataset.

Global sorting is an efficiency reference, not automatically a training recommendation. It can correlate sample order with difficulty or labels. Use shuffled bucket order and shuffled contents, or bounded-window sorting, and state precisely which order changes the final method permits.

Part 2 - System and Memory Mental Model

Bucketing limits the longest sequence that determines dense batch padding. This can reduce saved activations and attention intermediates without changing model parameters. The gain depends on the length distribution, backend, loss masking, and how tightly each bucket is formed.

A single safe batch size across all buckets may waste capacity on short inputs. Separate per-bucket capacities can exploit that headroom, but switching shapes affects cache history,

kernel selection, and possibly compilation overhead. Keep eager execution initially and treat compiled execution as a separate extension with recompilation costs included.

Reducing padding does not reduce the mathematical number of real tokens. Useful-token throughput is therefore a better comparison than padded-token throughput. A faster run that skips long samples, changes the loss denominator, or over-represents short samples violates the experiment.

Part 3 - Quantitative Prediction Before Execution

For batch j, define padding waste

$$W_j = b_j L_{\max,j} - \sum_{i \in j} L_i, \qquad \eta_{\text{epoch}} = \frac{\sum_j \sum_{i \in j} L_i}{\sum_j b_j L_{\max,j}}.$$

If the variable memory term is proportional to $bL_{\max}$, reducing the bucket's maximum length can increase feasible b approximately inversely with length after subtracting fixed state. A quadratic term produces a different capacity ratio; derive both predictions.

For lengths $(64, 80, 96, 112, 512, 576, 640, 704)$, compare two mixed batches of four with two batches grouped by length. Specify the mixed grouping before calculating; do not select it after seeing the result. Calculate total padded tokens, waste, and efficiency. Predict capacity under a fixed byte cap for short and long buckets using an E11 profile.

Part 4 - Experimental Design and Instrumentation

1. Freeze a dataset with sample IDs, lengths, and labels or targets. Save one random-order baseline permutation.

2. Define bucket boundaries before tuning capacity. Compare fixed-width, quantile, or bounded-window buckets using a held-out length distribution.

3. Measure safe capacity per bucket with the same full-update contract, optimizer state, dtype, and margin.

4. Execute complete epochs with no dropped final partial batches. Shuffle bucket order and internal order under recorded seeds.

5. Report useful tokens/s, padding efficiency, per-bucket batch capacity, peak VRAM, time in collation, and waiting time for rare long samples.

For gradient equivalence, compare a common fixed logical sample set and objective. For longer training, separately evaluate whether reordered batches change learning behavior; memory equivalence alone cannot answer that question.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class BucketSpecification:
    lower_length: int
    upper_length: int
    maximum_batch: object
    profile_fingerprint: str

def assign_length_buckets(sequence_records, boundaries):
    buckets = ...
    return buckets

def shuffle_bucket_schedule(buckets, seed, order_policy):
    schedule = ...
    return schedule

def calibrate_bucket_capacity(bucket, workload, budget):
    capacity = ...
    return capacity

def build_bucketed_batches(schedule, capacities, tail_policy):
    batches = ...
    return batches

def compare_padding_and_coverage(reference_ids, batches):
    audit = ...
    return audit

def E13(dataset, boundaries, workload, budget, order_policy):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Check boundary inclusivity so every length belongs to exactly one bucket. Test empty buckets, one oversized item, equal lengths, and final partial batches. Confirm exact ID coverage and unchanged valid-token count.

Measured capacity must include the optimizer step and switching between buckets, not isolated forward passes only. Report when isolated per-bucket profiles underestimate the runtime peak after shape transitions. Separate padding savings from changes caused by reordered samples or different loss normalization.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Bucketing changes the representation and order of work rather than the underlying model. Explain whether its gain came from lower peak demand, less useless arithmetic, better kernel shapes, or a combination.

Recommend boundaries and a shuffle policy with explicit limits on ordering bias and queue delay. If the length distribution is narrow, a negative result may justify avoiding the added scheduling complexity.

19.24.15 Exercise 14

Exercise Title: Dynamically Trade Micro-Batch Size Against Gradient Accumulation Steps While Preserving a Target Effective Batch Size

Part 1 - Exercise Contract and Why It Matters

Build a planner that changes physical micro-batch size under memory pressure while preserving a fixed logical optimizer batch. This exercise uses one GPU and a target of B samples per accepted update. The planner must handle nondivisible micro-batch sizes, replay after failure, and the final partial dataset window without silently changing weights.

Deliver a partition manifest for every logical update, gradient comparisons against a full-batch reference, sample-ID accounting, and memory/throughput measurements. Keep token-weighted objectives as a separate declared variant. Distributed synchronization is outside the base implementation; do not pretend that multiplying by world size solves unequal-rank weighting.

Part 2 - System and Memory Mental Model

The physical batch controls activation lifetime, while the logical batch controls the samples contributing to one optimizer update. When the micro-batch size changes, a fixed integer accumulation count may no longer produce the desired logical total. The final micro-batch may need fewer samples.

Mean-reduced losses over unequal micro-batches need weighting by sample count. For a token objective, use the number of valid loss-bearing tokens, not padded positions or sequence count. Backpropagating unweighted micro-batch means overweights smaller groups.

Hold parameters fixed until the logical window is complete, accumulate gradients, and update once. Keep data on CPU until each micro-batch is needed. Storing the entire effective batch on GPU can erase the memory benefit. For exact controls, use batch-independent layers and disable dropout; BatchNorm and random masks can break equivalence even with correct loss weights.

Part 3 - Quantitative Prediction Before Execution

For physical sizes $b_1, \ldots, b_K$,

$$\sum_{k=1}^{K} b_k = B, \qquad \mathcal{L} = \sum_{k=1}^{K} \frac{b_k}{B} \overline{\mathcal{L}}_k, \qquad \nabla\mathcal{L} = \sum_{k=1}^{K} \frac{b_k}{B} \nabla\overline{\mathcal{L}}_k.$$

For a constant upper micro-batch size b, $K = \lceil B/b \rceil$ but the last b_k may be smaller. For valid-token counts n_k, replace b_k/B with $n_k / \sum_j n_j$ for the token-average objective.

With $B = 100$ and upper micro-batches 32, 24, and 16, write the exact partitions and weights. Predict the total gradient error caused by dividing every micro-batch mean by K instead. For a tail window containing only 37 samples, state whether to process a smaller logical update, carry it forward, or drop it explicitly; implement the chosen policy without claiming that 37 samples equal the target of 100.

Part 4 - Experimental Design and Instrumentation

1. Create a small deterministic model whose full batch fits for reference. Save model, optimizer, and input state on CPU.

2. Compare several partitions of the same logical sample set, including nondivisible sizes and a mid-plan reduction before the next micro-batch.

3. Accumulate weighted contributions and perform exactly one optimizer update. Record gradient values before the update and parameter changes after.

4. Apply a dynamic budget trace while preserving the logical sample IDs. If an attempt fails, discard its partial window and replay from restored state rather than adding duplicate gradients.

5. Measure physical peak, micro-step count, accepted update frequency, and samples/s over total time. Include planning and retry costs.

Define the complete rollback boundary for parameters, buffers, optimizer, RNG, scaler if present, and the sample cursor. A gradient reset alone is insufficient after partial optimizer mutation.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class LogicalWindow:
    sample_ids: tuple
    target_samples: int
```

```
    actual_samples: int
    normalization_count: int

def plan_micro_batches(window, maximum_micro_batch):
    # Preserve the exact total, including the final remainder.
    plan = ...
    return plan

def calculate_loss_weight(micro_batch, logical_window, objective):
    weight = ...
    return weight

def execute_weighted_micro_step(model, micro_batch, weight, policy):
    # Leave forward, loss construction, and backward incomplete.
    observation = ...
    return observation

def commit_logical_update(model, optimizer, window, policy):
    # Validate and update once, after all contributions.
    commit_record = ...
    return commit_record

def restore_failed_window(snapshot, runtime):
    # Restore all state covered by the transaction contract.
    ...

def E14(runtime, cpu_dataset, target_batch, budget_trace):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify $\sum b_k = B$ for full windows and exact coverage for tails. Compare all named gradients and updated parameters, not only loss or gradient norm. Use scale-aware absolute/relative tolerances and report maximum discrepancies.

Inject failure after an early micro-step and verify that replay includes each sample exactly once in the accepted update. Test batch one, $b > B$, nondivisible targets, and token masks with unequal valid counts. Document expected inequivalence from batch-dependent layers instead of disguising it as floating-point error.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Adaptive physical batching can preserve the learning objective only when the runtime explicitly preserves logical sample membership and weights. Explain which state belongs to that

logical transaction.

Discuss the price of smaller micro-batches in launch overhead and update latency, alongside the memory saved. The target effective batch is a training choice, not a quantity that should drift whenever VRAM changes.

19.24.16 Exercise 15

Exercise Title: Combine Adaptive Batch Sizing with Mixed Precision and Quantify How Precision Changes the Controller's Feasible Search Space

Part 1 - Exercise Contract and Why It Matters

Compare adaptive batching under FP32, FP16 autocast with gradient scaling, and BF16 autocast where supported. Build separate capacity profiles and measure how precision changes feasible physical batch size, numerical error, and accepted useful throughput.

Keep model architecture, optimizer, logical batch, data order, and safety policy fixed. Precision is selected at a declared logical update boundary. Do not reuse an FP32 profile unchanged for autocast or infer that reduced element size necessarily doubles batch capacity.

Part 2 - System and Memory Mental Model

Autocast selects operation dtypes; it is not equivalent to converting all parameters and optimizer state to half precision. A common autocast setup keeps parameters and optimizer state in FP32 while reducing selected activation and intermediate storage. Sensitive operations can remain FP32. The actual memory change depends on which terms dominate.

FP16 needs a numerical stability policy, commonly gradient scaling. Keep the scale fixed while accumulating one logical update; unscale once after all contributions, then validate or clip as required, and perform the scaler-managed step/update at the effective-update boundary. An overflow skip is not accepted training progress.

BF16 availability and performance must be checked on the actual device. Unsupported configurations receive an explicit status. Changing precision can also change kernel and workspace selection, so every precision profile needs measured shape coverage and a separate uncertainty estimate.

Part 3 - Quantitative Prediction Before Execution

For precision policy p,

$$\widehat{M}_p(b, L) = M_{\text{fixed},p} + M_{\text{variable},p}(b, L) + W_p(b, L).$$

If $M_{\text{fixed}} = 3\,\text{GiB}$ and FP32 variable cost is $100\,\text{MiB/sample}$, predict capacity under a usable $6\,\text{GiB}$ cap. Repeat assuming only the variable term halves. Compare the resulting capacity ratio with the simplistic factor of two.

Define numerical error against an FP32 reference, for example

$$E_g = \frac{\|g_p - g_{\text{ref}}\|_2}{\max(\|g_{\text{ref}}\|_2, \epsilon)}.$$

The selected configuration must satisfy memory and numerical constraints, not memory alone. Before execution, predict which policy improves accepted tokens/s and which has the highest overflow risk; state the assumptions behind both predictions.

Part 4 - Experimental Design and Instrumentation

1. Check CUDA and dtype support, then create identical FP32 master parameters and optimizer settings for each policy.

2. Calibrate each policy independently using full updates, including cold state creation, autocast behavior, and gradient-scaler overhead.

3. Use E14 to preserve the same logical batch while adapting physical sizes. Keep correct sample or valid-token weighting.

4. Compare gradient and parameter errors on a small deterministic case, then benchmark repeated realistic updates with declared tolerances.

5. Log dtype policy, scale, overflow skips, physical batch, accumulation count, memory, wall time, and accepted useful throughput.

Use `torch.autocast` and `torch.amp.GradScaler` according to the installed PyTorch API. Record precision-policy changes and invalidate incompatible calibration before the next admission decision.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PrecisionPolicy:
    name: str
    autocast_dtype: object
    scaling_enabled: bool
    absolute_tolerance: float
    relative_tolerance: float

def check_precision_support(device, policy):
    support = ...
    return support

def create_policy_scaler(policy):
    scaler = ...
    return scaler
```

```
def run_precision_window(runtime, window, micro_plan, policy):
    # Keep scale constant across the complete accumulation window.
    # Unscale, validate, and commit only at its boundary.
    result = ...
    return result

def calibrate_precision_profile(workload, policy, shapes):
    profile = ...
    return profile

def compare_numerical_and_memory_results(reference, candidates):
    comparison = ...
    return comparison

def E15(workload, policies, logical_batch, budget_trace):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject unsupported BF16 as unsupported, not OOM. Verify no parameter casting occurred accidentally when the intended policy was autocast. Check finite losses, gradient error, parameter changes, and optimizer-step acceptance. Do not infer skipped updates solely from an optimizer return value.

Test one injected overflow and verify it does not inflate accepted throughput or advance a scheduler that is defined per accepted update. Compare capacity using identical logical work and report memory, speed, and accuracy tradeoffs separately. A lower-memory unstable policy is not a winning configuration.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Precision changes the feasible set, the numerical behavior, and sometimes the kernel implementation. Explain which memory component actually shrank and whether additional capacity translated to useful progress.

Recommend a precision-aware controller policy with separate calibration, numerical acceptance thresholds, and profile invalidation rules. Avoid switching precision opportunistically without recording its effect on training semantics and error.

19.24.17 Exercise 16

Exercise Title: Combine Adaptive Batch Sizing with Activation Checkpointing and Decide When Increasing Recomputation Is Better Than Reducing Batch Size

Part 1 - Exercise Contract and Why It Matters

Compare two responses to a tighter budget: reduce physical batch size or checkpoint more activation regions. Search a small declared set of micro-batch/checkpoint configurations while preserving the logical batch. Select by accepted useful throughput subject to memory and numerical constraints, and explain when recomputation pays for itself.

Deliver a configuration table, phase timings, memory curves, gradient comparisons, and a decision rule. Include the possibility that neither intervention can help because persistent parameters and optimizer state already exceed the budget.

Part 2 - System and Memory Mental Model

Activation checkpointing retains fewer forward intermediates and reconstructs them during backward. It can lower activation storage while adding compute, but recomputation itself has a peak and temporary workspaces. Input tensors required to rerun a region and outputs needed elsewhere still have lifetimes. It does not generally remove optimizer state or parameter storage.

Use an explicit checkpoint API policy, such as `use_reentrant=False`, and record it. Stochastic operations and mutable module buffers need careful equivalence checks. RNG preservation helps reproduce random operations, but arbitrary stateful side effects are not made safe automatically. Start with stateless blocks and dropout disabled, then investigate stochastic cases separately.

Reducing batch can increase micro-step count and launch overhead. Checkpointing at a larger physical batch might maintain more efficient kernels but pay additional backward recomputation. Which is faster depends on the actual workload and hardware; memory savings alone cannot decide. Change checkpoint policy only at a logical-window boundary.

Part 3 - Quantitative Prediction Before Execution

For logical batch B, candidate physical size b, and checkpoint plan c, use

$$K = \lceil B/b \rceil , \qquad t_{\text{update}}(b,c) = \sum_{k=1}^{K} \Big(t_{\text{fwd},k} + t_{\text{bwd},k} + t_{\text{recompute},k} \Big) + t_{\text{optimizer}} + t_{\text{overhead}}.$$

The exact final micro-batch size still follows E14. Choose among candidates with predicted upper peak plus margin within the cap and acceptable gradient error.

For an illustrative $B = 64$, suppose $b = 8$ without checkpointing needs 10 ms per micro-step, while $b = 16$ with checkpointing needs 17 ms. Ignoring common optimizer cost initially, predict update time and throughput. Then add a 20 ms policy-switch/calibration cost amortized over one versus 100 updates. Explain why the preferred action can depend on how long the budget regime lasts.

Part 4 - Experimental Design and Instrumentation

1. Partition a deterministic model into checkpointable blocks. Document which tensors cross each boundary and which buffers can change.

2. Compare no checkpointing, selected blocks, and a more extensive plan. Calibrate each plan separately at several physical batch sizes.

3. Preserve identical logical sample sets, loss weights, optimizer, and precision. Compare gradients and parameters with an uncheckpointed reference.

4. Benchmark full updates under two budgets: one that permits all plans and one that forces a tradeoff. Include cold switching and warm steady cost.

5. Add a budget trace whose tight period is short, then long. Measure whether switching cost is repaid in accepted useful work.

Use separate diagnostic timing to attribute recomputation. A total backward time increase alone is not an exact measurement of the recomputed region.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
from torch.utils.checkpoint import checkpoint

@dataclass
class CheckpointPlan:
    plan_name: str
    selected_blocks: tuple
    preserve_rng_state: bool
    use_reentrant: bool

def execute_block_with_policy(block, inputs, checkpoint_plan):
    # Implement the explicit checkpoint API policy.
    outputs = ...
    return outputs

def profile_batch_checkpoint_pair(workload, batch_size, plan):
    result = ...
    return result

def estimate_logical_update_cost(profile, logical_batch):
    cost = ...
    return cost

def select_recompute_or_shrink(candidates, budget, quality_limits):
    decision = ...
    return decision
```

```
def validate_checkpoint_equivalence(reference, candidate):
    errors = ...
    return errors

def E16(workload, plans, logical_batch, budget_trace):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check finite loss, all parameter gradients, parameter updates, and mutable buffers. A matching loss with mismatched buffers is insufficient. Test checkpointed blocks with and without random operations and report the assumptions required for the comparison.

Confirm full-update peaks include recomputation and optimizer state. Report candidates that use more memory or run slower than expected. Reject a recommendation based only on larger feasible batch if accepted throughput falls after recomputation and switching costs.
Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The correct intervention depends on the bottleneck. Recomputation can be valuable when memory-bound activations prevent efficient batch sizes; it can be wasteful when compute is already limiting.

Explain the measured break-even regime and what invalidates it after a shape, precision, or hardware change. Recommend a bounded candidate search with profile reuse, rather than assuming maximal checkpointing is always the most memory-efficient end-to-end plan.

19.24.18 Exercise 17

Exercise Title: React to External VRAM Pressure from Another CUDA Process and Reduce Batch Size Without Restarting the Training Job

Part 1 - Exercise Contract and Why It Matters

Build a controlled two-process experiment: a training runtime and a separate pressure worker that allocates a bounded amount of VRAM on the same physical GPU. The trainer must observe reduced availability, shrink future physical batches, preserve logical updates, and remain alive through recoverable allocation OOM.

Deliver coordinated and uncoordinated pressure traces, accepted-update accounting, rollback evidence, and a no-fit/defer outcome. Do not terminate unrelated processes. The worker is created and controlled by this experiment, has a declared allocation ceiling, and releases its memory through an explicit command or cleanup path.

Part 2 - System and Memory Mental Model

PyTorch process counters do not include the worker's live tensors. A device-global free-memory snapshot can reveal pressure but cannot prevent new allocations immediately after the check. Use a coordinated mode first, where the pressure worker changes demand at known logical boundaries; then test an asynchronous mode to expose the race.

OOM recovery is a transaction problem as well as a memory problem. Backward may leave partial gradients, and optimizer operations may mutate some state before failure. A retry must restore model parameters, buffers, optimizer state, CPU/CUDA RNG, scaler state if used, and sample cursor according to the declared window boundary. Clear failed graph references before retry. Cache release is only optional cleanup of unused blocks.

Store independent CPU snapshots, not aliased views of live state. Snapshot creation, restoration, and host-memory use have costs and must be measured. Keep the checkpoint alive until the update commit is confirmed. A fatal CUDA error is outside recoverable allocation OOM; exit with a recoverable checkpoint rather than claiming all device errors can be repaired in place.

Part 3 - Quantitative Prediction Before Execution

Let worker demand change from E_t to E_{t+1}. A measured free-memory change is only an observation, since other allocations and reservations can change simultaneously. With trainer allocated baseline A_t and free bytes F_t, conservatively require

$$\widehat{\Delta M}_{\text{upper}}(b) \le \min(J - S_J - A_t,\ F_t - S_D)$$

when giving no credit for reusable cache.

Assume the trainer needs a 1.4 GiB incremental peak and requires 0.4 GiB device headroom. Predict admission with $F_t = 2.5\,\text{GiB}$, then after a worker adds 1 GiB. Predict the outcome if that addition occurs after admission instead. For recovery, report

$$Q_{\text{accepted}} = \frac{N_{\text{committed}}}{t_{\text{normal}} + t_{\text{failed}} + t_{\text{restore}} + t_{\text{deferred}}}.$$

Define maximum retries and a no-fit waiting policy before running.

Part 4 - Experimental Design and Instrumentation

1. Use spawn to create a dedicated pressure worker, initialize CUDA inside it, and verify both processes refer to the same physical GPU.

2. Exchange ready/allocated/released acknowledgements. Bound requested bytes relative to a measured safe envelope and handle worker OOM explicitly.

3. Run a coordinated pressure step between logical updates. Compare a static trainer with the adaptive trainer under identical work.

4. Run a bounded asynchronous pressure change during forward or backward. Catch allocation OOM, end the failed attempt, release references, restore the entire transaction, and replay with a smaller plan.

5. Test failure after a deliberately partial optimizer mutation using a controlled fault hook. Require full restoration before accepting another update; resetting gradients alone must fail this test.

6. Release worker allocations in cleanup even if training fails. Verify the trainer process remained alive for recoverable cases.

Track application-cap violations separately from OOM. Do not claim a strict global reserve between samples in the uncoordinated mode.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import multiprocessing as mp
import torch

@dataclass
class PressureCommand:
    command_id: int
    action: str
    requested_bytes: int

@dataclass
class WindowSnapshot:
    model_state_cpu: object
    optimizer_state_cpu: object
    scaler_state: object
    rng_state: object
    data_cursor: object

def pressure_worker(command_channel, event_channel, device_spec):
    # Allocate only this worker's bounded test buffers.
    # Acknowledge completion and release them in cleanup.
    ...

def capture_window_snapshot(runtime):
    # Create independent CPU copies, including mutable buffers.
    snapshot = ...
    return snapshot

def execute_recoverable_attempt(runtime, window, micro_plan):
    # Keep failure scope separate so graph references can die.
```

```
    outcome = ...
    return outcome

def restore_transaction(runtime, snapshot):
    # Restore all state, even after partial optimizer mutation.
    ...

def react_to_pressure(runtime, window, snapshot, limits):
    # Bound retries; defer explicitly if one sample cannot fit.
    result = ...
    return result

def E17(runtime, pressure_schedule, limits):
    report = ...
    return report

def main():
    # Create CPU-only configuration and spawn the test worker.
    ...

if __name__ == "__main__":
    main()
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify accepted sample IDs, optimizer counters, scaler state, mutable buffers, and parameters against a clean replay from the same transaction snapshot. Test OOM before backward, after partial accumulation, and after partial optimizer mutation. The last case specifically invalidates gradient-reset-only recovery.

Bound attempts, snapshot age, and deferred time. Distinguish no-fit, worker failure, allocation OOM, and fatal device error. Record trainer PID continuity without claiming that context-fatal errors were survived. Snapshots and pressure buffers must not leak across windows. Report the minimum observed headroom with sampling limitations.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A live controller can adapt to measured external demand but cannot reserve future VRAM merely by observing it. Explain the stronger guarantee in coordinated mode and the best-effort behavior in asynchronous mode.

Discuss the price of transactional recovery: CPU snapshot memory, copying, lost work, and latency. Recommend how the runtime should defer or stop when no plan fits, while preserving a usable checkpoint and honest progress log.

19.24.19 Exercise 18

Exercise Title: Stress-Test the Adaptive Batch Controller with Sudden Sequence-Length Spikes, Fragmentation, Temporary Memory Peaks, and Changing VRAM Availability

Part 1 - Exercise Contract and Why It Matters

Build a reproducible adversarial test suite for the controller developed so far. Cover shape spikes, changing device availability, temporary workspaces, allocator-history pressure, numerical skips, and failures at different transaction phases. Deliver a scenario manifest, expected invariants, event traces, and a failure report for every unsuccessful case.

Stress testing must separate two goals: deterministic controller logic testing with synthetic observations, and real CUDA integration testing. A simulated OOM validates state handling but does not prove allocator recovery. A GPU trace validates one runtime environment but does not exhaust all controller transitions.

Part 2 - System and Memory Mental Model

Sequence spikes change the demanded shape. External workers change availability. Temporary buffers change within-step peak. Retained live tensors and allocator fragmentation can reduce the ability to satisfy a large request despite seemingly sufficient totals. These are different mechanisms and need separate labels.

Allocator fragmentation is backend- and history-dependent. Create varied allocation sizes, retain selected live blocks, release others, and replay a large request; then compare with a fresh-worker baseline. If evidence supports only live-memory pressure, report it that way. Do not call every OOM with reserved memory present fragmentation.

The controller should preserve sample identity, logical weights, bounded retries, and complete rollback regardless of disturbance. Safety, progress, and observability are distinct invariants. A controller that never starts work can avoid OOM but fails useful progress; a fast controller that loses samples fails correctness.

Part 3 - Quantitative Prediction Before Execution

Define a scenario with phase-indexed events $\mathcal{S} = \{(t_i, \text{phase}_i, \text{event}_i, \text{size}_i)\}$. Use logical update or phase indices for reproducible replay rather than relying only on wall-clock sleep timing.

$$R_{\text{violation}} = \frac{N_{\text{margin violations}}}{N_{\text{attempts}}}, \qquad A_{\text{retry}} = \frac{N_{\text{attempts}}}{N_{\text{commits}}}.$$

When the denominator is zero, report undefined and the no-progress reason. Also report recovery latency, accepted useful throughput, and minimum observed headroom.

Before running, predict outcomes for: a length doubling, a temporary 256 MiB buffer at backward, a budget below persistent state, and an OOM after partial optimizer mutation. Declare which should shrink, retry, defer, or stop. For repeated tests with zero observed failures, avoid claiming zero true risk; under independent identical trials, the approximate rule-of-three bound is $3/n$, and correlated stress trials may not satisfy that assumption.

Part 4 - Experimental Design and Instrumentation

1. Write at least eight scenarios, each with event schedule, seed, maximum demand, timeout, expected invariant, and cleanup behavior.

2. Test pure logic with budget equality, stale snapshots, contradictory profiles, repeated failures at batch one, and growth during cooldown.

3. Run CUDA cases for a rare long input, temporary forward/backward workspace, external pressure, and changing allocation history.

4. Separate fault injection from real allocation failures in the log. Use fresh-worker controls to investigate suspected fragmentation.

5. Audit transaction state after each injected failure and compare a successful replay to a clean deterministic reference.

6. Repeat representative scenarios with different seeds and an unseen disturbance schedule. Include test harness overhead in reports where it affects measured response time.

Terminate only workers created by this experiment. Cleanup must execute after expected and unexpected errors, and original sample manifests remain immutable evidence.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class StressEvent:
    update_index: int
    phase: str
    event_type: str
    magnitude: object

@dataclass
class StressScenario:
    name: str
    seed: int
    events: tuple
    maximum_attempts: int
    expected_outcome: str

def replay_synthetic_observations(controller, scenario):
    trace = ...
    return trace
```

```
def create_allocator_history(device, allocation_plan):
    # Keep retained live blocks distinct from released cache.
    history_handle = ...
    return history_handle

def execute_cuda_scenario(runtime, scenario, fault_hooks):
    result = ...
    return result

def audit_transaction_invariants(before, after, sample_ledger):
    audit = ...
    return audit

def classify_failure_evidence(result, fresh_worker_control):
    diagnosis = ...
    return diagnosis

def E18(runtime_factory, scenarios):
    # Export every outcome, including no-progress scenarios.
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require explicit evidence for every invariant: no duplicated accepted sample, no missing sample, correct loss denominator, no update before a complete window, no partial state surviving rollback, and bounded retries. Check that cleanup returns the live-memory baseline within a declared tolerance, while allowing documented cache reservations.

Report all failures, their seeds, phase, classification, and minimal reproducer. Distinguish a valid no-fit refusal from a controller deadlock. Measure recovery time only for recoverable scenarios; do not hide permanent failures by omitting them from the denominator.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Stress tests describe an operating envelope, not universal immunity. Explain which failure classes the suite covers and which remain outside the runtime's assumptions, including fatal device errors and unbounded external allocation.

Prioritize improvements by lost accepted work, correctness impact, and frequency in the declared workload. Preserve negative results as design evidence instead of tuning the stress suite until every chart looks stable.

19.24.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Adaptive Batch Runtime That Maximizes Throughput While Maintaining a Strict Dynamic VRAM Safety Margin

Part 1 - Exercise Contract and Why It Matters

Integrate profiling, shape-aware admission, bounded capacity search, hysteresis, token scheduling, exact logical accumulation, precision, checkpointing, telemetry, and transactional recovery into one runtime. Select the highest-throughput validated configuration from a finite declared candidate set while enforcing explicit job-budget admission constraints. Deliver the runtime skeleton completed by the learner, benchmark manifests, raw traces, and an engineering decision report.

Define the meaning of strict before claiming it. In the base experiment, budget changes occur at coordinated logical-update boundaries and workloads remain inside a declared shape/disturbance envelope. Require no observed margin violation there. Under arbitrary asynchronous external allocation, the runtime can provide conservative admission and recovery, not a hard physical guarantee. Report that mode separately.

Part 2 - System and Memory Mental Model

Separate four responsibilities: telemetry observes state; the planner proposes a configuration; admission accepts or refuses it; the executor commits a complete logical update or restores its snapshot. Logging must record the inputs and reason behind each decision. A profile learned from one shape, dtype, backend, or checkpoint plan is not automatically valid for another.

The configuration contains physical batch size, shape/token limits, precision, checkpoint plan, and an exact logical-window partition. The executor owns model and optimizer state, RNG, scaler, sample cursor, and any learning-rate schedule whose progress follows accepted updates. Failed attempts cannot advance accepted-work counters.

Memory fit is a constraint, not the optimization objective. The largest batch may be slower than a smaller one. Include calibration, shape collation, snapshot copying, retries, deferrals, and policy switching in net throughput. Reserve a held-out workload trace for evaluation; the controller must not inspect future budgets or lengths beyond its declared lookahead.

Strict enforcement has layers. A predicted upper envelope supports admission, post-step observations audit realized peaks, and resource isolation supports stronger device-level guarantees. A percentile model plus a reserve is an empirical policy, not proof against all possible workspaces and external processes.

Part 3 - Quantitative Prediction Before Execution

Let $\mathcal{C}_t$ be the finite validated candidate set and let c specify batch, precision, checkpoint plan, and shape policy. Optimize

$$c_t^* = \arg\max_{c \in \mathcal{C}_t} \widehat{Q}_{\text{accepted}}(c)$$

subject to

$$\begin{aligned} \widehat{M}_{\text{upper}}(c, x_t) + S_{J,t} &\le J_t, \\ \widehat{\Delta M}_{\text{upper}}(c, x_t) + S_{D,t} &\le F_t, \\ E_{\text{numerical}}(c) &\le \varepsilon_{\max}, \\ \sum_k b_{t,k} &= B_t. \end{aligned}$$

The device inequality gives no cache credit in the conservative base policy. Document any refinement and avoid double-counting resident state.

Compute the realized objective as accepted useful samples or tokens divided by total benchmark wall time. Report the unit and objective normalization. Build a pre-run table of at least

six candidate configurations with predicted peak, uncertainty, physical batch, accumulation plan, throughput, and error. Identify dominated candidates and explain any exclusion before seeing the held-out results.

Distinguish an empirical best candidate from a global optimum. An offline oracle with future trace knowledge may be an upper comparison bound but is not a deployable causal controller.

Part 4 - Experimental Design and Instrumentation

1. Implement independent telemetry, profile registry, planner, admission, executor, and event-log interfaces. Validate pure CPU decision logic first.

2. Create a deterministic numerical reference and verify exact sample membership, weights, gradients, optimizer updates, and rollback behavior.

3. Compare four baselines: conservative static batch, largest repeatedly safe static batch, simple reactive shrink/grow, and the integrated runtime. Keep logical work, precision eligibility, and candidate opportunities fair.

4. Run a steady trace, a coordinated dynamic-budget trace, a variable length trace, and the E18 stress suite. Evaluate asynchronous pressure separately from the strict coordinated contract.

5. Tune only on a training trace, freeze policy, then evaluate held-out traces with repeated seeds. Measure warm-up, calibration, cold first update, and steady execution as separate categories.

6. Export raw scalar event logs and aggregate results. Include accepted useful throughput, median/p95 update latency, margin violations, OOMs, retries, no-fit duration, prediction error, switches, and numerical error.

Define acceptance thresholds before benchmarking. At minimum require exact sample accounting, complete rollback, bounded recovery, finite accepted updates, and no observed margin violations in the coordinated envelope. Failure to beat a strong static baseline is a valid measured conclusion.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region, and measure complete updates. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass

    comparison = ...
    return comparison

def E19(workload, profiles, policy, limits, held_out_traces):
    runtime = ...
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit every commit against the sample manifest, normalization denominator, optimizer-step count, and numerical reference. Inject failure at transfer, backward, and partial optimizer update; compare the accepted replay against a clean transaction. Validate scheduler and scaler progression if present. Check that state restoration includes buffers and that snapshots are independent copies.

Check each realized peak against the cap and margin active during that attempt. A completed update with insufficient headroom is still a policy violation. Do not replace peak allocated bytes with a lower end-of-step counter. Report reserved memory and global observations separately and state what cannot be observed between samples.

Use common evaluation work or a declared common time horizon across baselines. Do not count failed attempts, duplicate replayed tokens, or overflow-skipped updates as accepted work. Report uncertainty across repetitions and preserve all no-fit cases. The runtime passes

the correctness contract even if its performance result is negative; a throughput claim requires evidence beyond merely fitting a larger batch.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The product is a trustworthy scheduler for constrained training work. Its evidence should explain why each configuration was admitted, what work was actually committed, and how failures affected progress.

Conclude with the strongest claim your experiments support: the best validated configuration or controller under specified budgets, shapes, hardware, and numerical constraints. State the limits of the strict coordinated guarantee and the best-effort asynchronous mode. Recommend deployment only within that measured envelope, with profile invalidation, bounded fallback, and reproducible diagnostics.

19.25 DMM23

Chapter Title: CUDA Out-of-Memory Detection and Recovery
Specialization: Dynamic Memory Management and CUDA Systems

19.25.1 Exercise 00

Exercise Title: Build a Precise Mental Model of CUDA OOM Causes, Failure Boundaries, Allocator State, and Recoverable Versus Non-Recoverable Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model for an allocation failure during CUDA training. Distinguish failure to obtain storage from a corrupted execution context, and distinguish a recoverable CUDA context from a recoverable training transaction. Deliver a memory ledger, a failure-boundary table, and a decision diagram connecting detection, diagnosis, cleanup, rollback, reconfiguration, and either retry or explicit termination.

Use one GPU, eager PyTorch, and a small model. DMM19–DMM22 provide the precision, accumulation, and admission prerequisites. Distributed collectives, CUDA graph capture, custom kernels, and external side effects require additional contracts and are outside the base experiment. A successful retry must preserve accepted training work, not merely avoid another exception.

Part 2 - System and Memory Mental Model

OOM means a requested allocation could not be satisfied under the current conditions. Demand includes resident parameters, gradients, optimizer state, inputs, saved activations, temporary workspaces, and library allocations. Pressure may come from other processes, retained Python references, non-reusable allocator fragments, or a brief overlap of otherwise manageable buffers. Several causes can coexist.

Allocated bytes describe live allocator-managed tensor storage; reserved bytes also include allocator-held blocks. Global free bytes describe the device at one instant. Their difference is not a complete map of reusable blocks. A failed request does not become a successful live allocation, so the recorded peak can be lower than the memory the operation attempted to require. Driver and library allocations may be outside PyTorch snapshots.

An allocation OOM often leaves the CUDA context usable after failed work is unwound. It does not undo mutations already performed. Forward can change buffers and RNG; backward can leave partial gradients; an optimizer can modify some parameters before a later allocation fails. Illegal-address and device-assert failures are different error classes and can make further CUDA execution unusable. Repeated cache clearing is not a remedy for them. For device-fatal conditions, preserve an existing CPU checkpoint and exit.

Part 3 - Quantitative Prediction Before Execution

Let A_t be current allocated bytes, R_t reserved bytes, F_t global free bytes, and q the requested allocation. In a simplified allocator, failure depends on suitable reusable blocks and possible segment acquisition, not merely on whether $q > F_t$. Avoid treating $R_t - A_t$ as one freely coalescible block.

$$M_{\text{live}}(\tau) = M_{\text{persistent}}(\tau) + M_{\text{transient}}(\tau), \qquad M_{\text{peak}} = \max_{\tau} M_{\text{live}}(\tau).$$

Construct a hypothetical trace with $A = 5\,\text{GiB}$, $R = 6\,\text{GiB}$, $F = 1\,\text{GiB}$, and a request for $1.5\,\text{GiB}$. Explain why the three scalar counters cannot alone prove whether reuse and retry can satisfy that request.

Represent logical training state as

$$S = (\theta, \mathcal{B}, \mathcal{G}, \mathcal{O}, \mathcal{R}, \mathcal{A}, \mathcal{D}, \mathcal{H}),$$

where the components are parameters, mutable buffers, gradients, optimizer, RNG, AMP scaler, data cursor, and scheduler state. For each failure phase, predict which components may have changed. Separate exact rollback from equivalence after changing micro-batch partition: dropout and BatchNorm can make the latter a different computation.

Part 4 - Experimental Design and Instrumentation

1. Describe allocation, forward, backward, optimizer, and commit boundaries. Specify the last known-good state before each attempt.

2. Use a bounded disposable allocation experiment to observe one genuine OOM. Do not intentionally corrupt the CUDA context.

3. Use labelled fault injection for forward, backward, and partial optimizer mutation. Injection tests state handling; it is not evidence of real allocator behavior.

4. Record the phase where the exception surfaces and the last completed phase. CUDA work is asynchronous, so these may not establish the exact origin without diagnostic synchronization.

5. Classify outcomes as success, retryable allocation OOM, no feasible configuration, unrelated error, or context-fatal error. State which require no further CUDA calls.

Produce a small state audit before and after each attempt. Keep CPU-only evidence and avoid retaining the exception object or its tensor-owning frames.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class FailureBoundary:
    phase: str
    last_completed_phase: str
    exception_type: str
    context_status: str
    state_may_be_mutated: bool

def describe_training_state(runtime):
    state_ledger = ...
    return state_ledger

def capture_memory_ledger(device, phase):
    memory_ledger = ...
    return memory_ledger

def classify_failure(exception_record, phase_evidence):
    # Do not infer recoverability from the message alone.
    classification = ...
    return classification

def decide_recovery_boundary(classification, state_ledger):
    decision = ...
    return decision

def audit_post_failure_state(before, after):
    state_difference = ...
    return state_difference
```

```
def E00(runtime, controlled_scenarios):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require separate evidence for context usability, restored training state, and successful admitted work. A small allocation after OOM checks only a limited aspect of context usability. It does not prove gradients or optimizer state are correct.

Reject classifications that equate every RuntimeError with OOM, assume forward is side-effect free, or count a failed attempt as an accepted update. Check that all requested quantities include units and measurement time. If origin or allocator details are unobserved, retain an unknown classification rather than inventing a diagnosis.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Recovery has two obligations: regain a viable memory configuration and preserve the training transaction. Explain why satisfying only one is insufficient.

Conclude with a precise recoverability contract for this chapter. It should allow bounded in-process recovery from allocation pressure while refusing unsupported guarantees about context-fatal errors, arbitrary external allocations, and untracked side effects.

19.25.2 Exercise 01

Exercise Title: Trigger a Controlled CUDA OOM with a Single Oversized Tensor Allocation and Capture the Full PyTorch Exception Context

Part 1 - Exercise Contract and Why It Matters

Create a bounded isolated experiment that issues one oversized CUDA tensor allocation and records the resulting exception. Capture its complete message, formatted traceback, type, requested shape and dtype, device identity, timestamp, phase, and surrounding memory observations. Deliver a structured incident record and a successful small-allocation control.

Use a dedicated spawned worker, with CUDA initialized inside it. Choose a request just above physical device capacity under ordinary PyTorch device allocation, not an absurd dimension that first triggers integer overflow or a shape-validation error. The parent receives only CPU strings and scalar metadata. The experiment must not allocate a huge CPU source tensor.

Part 2 - System and Memory Mental Model

A request made through a CUDA allocation API can fail before any tensor storage is successfully created. There may therefore be no tensor object to delete. The allocator may already have attempted internal cache release or retries before presenting the error; the exception-time snapshot need not match the immediately preceding snapshot.

The exception message is evidence, not a stable structured schema. Some versions include requested allocation size and process memory detail; do not assume every message contains identical fields or units. The requested shape/dtype supplied by this experiment gives an independent payload estimate. Allocator rounding can make the actual request differ.

A traceback object holds stack frames and their local references. Serialize the traceback to text without capturing locals, then let the exception scope end. Storing the exception itself in a report can retain GPU objects from more complex attempts. Full context means complete relevant execution metadata, not arbitrary tensor contents or every local variable.

Part 3 - Quantitative Prediction Before Execution

For a tensor with dimensions $n_1, \ldots, n_k$ and element size s bytes,

$$q_{\text{payload}} = s \prod_{i=1}^{k} n_i.$$

Using a byte tensor makes the intended payload directly auditable. Let T be total physical bytes and choose a small declared increment δ, giving $q_{\text{payload}} = T + \delta$ in a fresh ordinary device-allocation worker. Bound δ and verify the dimension is representable before requesting storage.

For a hypothetical $T = 8\,\text{GiB}$ and $\delta = 64\,\text{MiB}$, calculate the element count for `uint8` and the corresponding count for `float32`. Predict current and peak allocated counters after the failed request: they should not be interpreted as if the oversized storage were created. Also predict the outcome of a separate 1 MiB control request, subject to the actual available environment.

Part 4 - Experimental Design and Instrumentation

1. Validate the request on CPU, establish upper bounds, and record device total capacity. Fail explicitly if no CUDA device is available.

2. In a fresh worker, initialize a small control allocation and release it. Synchronize at the declared boundary and capture the pre-request record.

3. Issue the single oversized request. Capture the specific CUDA OOM type when raised; other exceptions must remain separately classified.

4. Format the full traceback as text without local-variable capture. Attempt best-effort scalar telemetry only for a usable allocation-OOM context, preserving any secondary diagnostic failure separately.

5. Leave the exception scope. Perform a small recovery control in the same worker, report its result, then exit and join cleanly.

Record whether the environment imposed an allocator limit or another constraint. A limited-process OOM and a physical-capacity OOM need distinct labels even when they raise the same exception class.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer

update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import multiprocessing as mp
import traceback
import torch

@dataclass
class AllocationSpecification:
    shape: tuple
    dtype_name: str
    requested_payload_bytes: int
    device_identity: str

def choose_bounded_oversized_request(device_total, increment):
    specification = ...
    return specification

def serialize_exception_context(error, metadata):
    # Return text and scalars, never exception or frame objects.
    record = ...
    return record

def allocation_attempt(specification):
    # Leave the actual allocation and OOM detection incomplete.
    outcome = ...
    return outcome

def allocation_worker(configuration, result_channel):
    # Run controls and the failed request inside this worker.
    ...

def E01(configuration):
    # Spawn, receive CPU-only evidence, and join with a timeout.
    report = ...
    return report

def main():
    ...

if __name__ == "__main__":
```

```
main()
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that the raised failure is CUDA allocation OOM, not a host allocation error, integer overflow, or invalid shape. Compare computed payload bytes with any requested-size field present in the raw message; preserve both and explain rounding or unit ambiguity.

Require a complete traceback string and enough metadata to reproduce the attempt. Verify that serialized output contains no tensor, exception, frame, or traceback objects. Distinguish a successful same-worker control from success in a newly created process. Worker timeout and diagnostic failure must not be silently converted into successful recovery.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

This exercise establishes the smallest reproducible OOM incident. Explain what its failure proves about the request and what it does not prove about training-state recovery.

Use the incident schema as the foundation for later handlers. Reliable diagnostics preserve raw evidence while keeping the failed allocation scope free to release its references.

19.25.3 Exercise 02

Exercise Title: Distinguish Capacity OOM, Fragmentation-Related OOM, Temporary-Peak OOM, and Memory-Leak OOM Through Reproducible Experiments

Part 1 - Exercise Contract and Why It Matters

Construct four controlled scenarios with different intended pressure mechanisms: excessive live demand, fragmented allocation history, a brief temporary peak, and unintended reference retention over iterations. Deliver the intervention for each, its measured signature, and a diagnosis with evidence strength rather than an unjustified categorical label.

The four names are causal hypotheses, not necessarily mutually exclusive runtime exception types. A leak eventually creates a capacity problem, and a temporary workspace can fail in a fragmented allocator. Keep ground-truth interventions separate from what a diagnostic tool could infer from counters.

Part 2 - System and Memory Mental Model

Capacity pressure arises when necessary simultaneous live demand cannot fit. Temporary-peak pressure appears when overlapping buffers exceed capacity briefly even though end-of-step usage looks small. A retention leak leaves objects live beyond their intended lifetime, creating baseline growth. Fragmentation concerns whether available allocator blocks can serve the particular request under backend-specific reuse and segment rules.

High reserved bytes alone do not prove fragmentation. Compare allocation history, inactive split statistics where meaningful, actual block layout, and a fresh-process control with similar live payload. Native allocator statistics do not transfer unchanged to `cudaMallocAsync`. If

fragmentation cannot be demonstrated reliably on the device, report that result instead of relabelling ordinary live-memory pressure.

For a leak intervention, deliberately retain graph-connected outputs in a bounded Python container. A control retaining detached GPU tensors still retains their storage, while a CPU scalar log does not retain those GPU outputs. This helps separate graph retention from intentional storage retention and from an allocator cache.

Part 3 - Quantitative Prediction Before Execution

Define end-of-iteration live baseline A_i and within-iteration peak P_i. For a bounded retention intervention of roughly r bytes per iteration,

$$A_i \approx A_0 + ir$$

until storage reuse or more complex graph lifetimes change the approximation. For a temporary workspace of w bytes, expect a peak increase near w only when its lifetime overlaps the existing maximum.

Create a hypothetical stable baseline of 2 GiB, ordinary peak of 3 GiB, retained growth of 64 MiB/iteration, and a transient buffer of 512 MiB. Predict baseline and peak traces for ten iterations under each intervention. Do not add maxima from non-overlapping phases.

For fragmentation, list the extra evidence needed beyond A, R, and F. Predict why two runs with similar totals can yield different outcomes for one large request, and why a fresh-worker success is suggestive but not sufficient unless other conditions match.

Part 4 - Experimental Design and Instrumentation

1. Establish a repeatable no-pressure reference, recording cold and warmed allocator behavior and the backend.

2. Increase simultaneous live payload for the capacity case, with a bounded maximum and an explicit cleanup list.

3. Insert one temporary buffer during a chosen forward, backward, or optimizer phase; release it before the next iteration.

4. Retain outputs in a bounded list, then compare graph-connected, detached-GPU, and CPU-scalar variants under identical work.

5. Create alternating allocation sizes and retained live blocks for the fragmentation candidate. Compare with reordered allocations and a fresh-worker control.

6. Repeat each case and classify mixed signatures as mixed or undetermined. Never infer a unique cause from message wording alone.

Keep diagnostic profiling separate from final timing measurements.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use

a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PressureScenario:
    mechanism: str
    maximum_live_bytes: int
    maximum_iterations: int
    allocation_order: tuple
    seed: int

def run_capacity_intervention(workload, scenario):
    evidence = ...
    return evidence

def run_temporary_peak_intervention(workload, scenario):
    evidence = ...
    return evidence

def run_reference_retention_intervention(workload, scenario):
    evidence = ...
    return evidence

def run_fragmentation_candidate(workload, scenario):
    evidence = ...
    return evidence

def classify_pressure_evidence(evidence, control):
    # Preserve uncertainty and permit multiple contributing causes.
    diagnosis = ...
    return diagnosis

def E02(workload, scenarios):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Require known intervention sizes and lifetimes, a matched control, and repeated observations. Verify live memory returns after deliberate retention is removed. A stable reserved cache with stable allocated baseline must not be diagnosed as a growing leak.

For fragmentation, state which backend statistics are meaningful and which are absent or not applicable. A zero in an unsupported metric is not evidence of no fragmentation. Preserve inconclusive scenarios and identify a measurement that could resolve them.
Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Diagnosis is an argument built from interventions and observations. Explain why the proposed recovery action addresses the measured cause: smaller work, shorter overlap, reference cleanup, or a different allocation pattern.

Avoid a universal cache-clearing remedy. The same exception class can represent several memory mechanisms, and the cheapest effective response depends on distinguishing them.

19.25.4 Exercise 03

Exercise Title: Record memory_allocated, memory_reserved, Free VRAM, and Peak Memory Immediately Before a Deliberate OOM

Part 1 - Exercise Contract and Why It Matters

Build a low-overhead telemetry recorder around one deliberately failing allocation or training phase. Capture current allocated and reserved bytes, their peaks, global free and total bytes, timestamps, device identity, and the next requested operation. Deliver pre-attempt, exception-time, and post-cleanup records with explicit observation ordering.

The phrase immediately before means the last available observation before the declared request, not an atomic view of the whole GPU. Identify the gap between that observation and allocation. Do not reconstruct a missing pre-failure record from counters sampled after cleanup.

Part 2 - System and Memory Mental Model

Counter reads occur at different times and have different scopes. Allocated and reserved counters belong to the selected process/device allocator; global free bytes include effects of other processes. Peak counters measure successful allocations since their reset, not the size of the request that failed.

CUDA execution and cross-stream frees can be asynchronous. A synchronized diagnostic boundary makes the experiment easier to interpret but changes overlap and can move the peak. Keep a minimally instrumented run for performance and a synchronized run for attribution. State which produced each observation.

An OOM handler can itself fail while collecting information. Preserve the last-known pre-attempt record on CPU, and treat exception-time telemetry as best effort. Do not allocate large diagnostic tensors on the already constrained GPU. Peak resets must not erase the evidence of an earlier phase in the same attempt.

Part 3 - Quantitative Prediction Before Execution

Let A_0 be live bytes at region start and P_A the peak since reset. The incremental observed rise is $P_A - A_0$, not P_A itself. Let P_R be peak reserved bytes. In general,

$$\max_{\tau} R(\tau) - \max_{\tau} A(\tau) \neq \max_{\tau} \Big(R(\tau) - A(\tau) \Big).$$

Thus subtracting the two independently timed peaks does not yield maximum cached bytes.

For observations $A_0 = 2\,\text{GiB}$, $P_A = 3.5\,\text{GiB}$, $P_R = 4\,\text{GiB}$, and a failed $1\,\text{GiB}$ request, calculate the observed rise. Explain why $4.5\,\text{GiB}$ is not automatically the required true peak. The request may occur at a different live baseline or after internal allocator retries.

Predict how resetting peaks after the OOM would change the report. Define the timing uncertainty $\Delta t = t_{\text{request}} - t_{\text{last snapshot}}$ and record it whenever the request boundary can be instrumented.

Part 4 - Experimental Design and Instrumentation

1. Define a CPU-only record schema with values, units, timestamp, scope, and availability status for each metric.
2. Initialize the context and fixed state, synchronize the declared start, then reset peak counters before the measured attempt.
3. Capture the final pre-request snapshot and a phase marker. Run the failing request and retain the pre-request record unchanged.
4. Capture best-effort exception-time metrics before cleanup, then a separate post-cleanup snapshot. Record secondary errors.
5. Compare synchronized diagnostic and ordinary asynchronous runs. Report their different overhead and observability.

Use the CUDA memory counter APIs and `mem_get_info` from `torch.cuda`; verify installed-version names before implementing.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class MemoryRecord:
    attempt_id: str
    phase: str
```

```
    monotonic_time: float
    allocated_bytes: object
    reserved_bytes: object
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    free_bytes: object
    total_bytes: object
    diagnostic_errors: tuple

def begin_measured_region(device, synchronization_policy):
    baseline = ...
    return baseline

def read_memory_record(device, attempt_id, phase):
    # Preserve unavailable metrics and their failure reasons.
    record = ...
    return record

def capture_attempt_timeline(workload, request, policy):
    # Keep pre-request evidence immutable across cleanup.
    timeline = ...
    return timeline

def compare_observation_scopes(timeline):
    interpretation = ...
    return interpretation

def E03(workload, request, synchronization_policies):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check nonnegative byte values, correct device selection, and monotonic record ordering. Treat $A \leq R$ as an allocator-accounting expectation to investigate, not a licence to discard conflicting measurements. Global and process counters are not simultaneous enough to establish arbitrary exact equalities.

Demonstrate that the failed request does not appear as successfully allocated storage. Verify the original pre-failure record survives both cleanup and a failing diagnostic read. Report data gaps explicitly instead of filling them with zero or a later value.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Telemetry is valuable when its time and scope are clear. Explain which conclusions can be supported by your trace and which require an allocation history or operator-level profile.

Choose a production logging frequency that balances evidence and overhead. A low-overhead last-known record plus bounded incident escalation may be more useful than continuously perturbing every allocation.

19.25.5 Exercise 04

Exercise Title: Build a Safe try/except CUDA OOM Handler That Separates Memory Failures from Unrelated Runtime Errors

Part 1 - Exercise Contract and Why It Matters

Design a handler that recognises CUDA allocation OOM, records the failure, ends the failed attempt's scope, and permits a bounded recovery decision. Unrelated exceptions must propagate with their original context. Deliver an exception-routing table, synthetic routing tests, and one genuine allocation-OOM integration test.

Keep the handler's responsibilities narrow. It classifies and captures evidence; later exercises decide how to change work and restore training. It must not silently clear arbitrary state, skip data, or treat every exception as permission to halve the batch.

Part 2 - System and Memory Mental Model

Use the specific CUDA OOM exception exposed by the supported PyTorch version. Broad RuntimeError handling plus substring matching is fragile: message wording changes and unrelated errors can contain similar phrases. If a legacy compatibility path is required, declare the supported version and test it explicitly instead of weakening the primary path.

Failed function frames can retain model outputs, losses, and autograd graphs through the traceback. Converting the error to a CPU-only record and leaving that scope lets references be released before another large attempt. Retrying deeply inside the same exception block can preserve the very memory that caused the problem.

Diagnostic errors must not replace the original training failure. Preserve a primary failure record and a secondary diagnostic-error list. For device-fatal or unclassified errors, stop the recovery path; do not assume that telemetry calls or new allocations are safe. A retry budget should also bound time, not only attempt count.

Part 3 - Quantitative Prediction Before Execution

Define mutually exclusive routing outcomes for one observed exception: allocation OOM, unrelated error, and explicitly identified fatal context error. The routing class is separate from the eventual action: an OOM can still lead to no-fit termination.

Let $r_{\max}$ be allowed retries after the initial attempt. Maximum attempts are $1 + r_{\max}$; make that convention explicit. For per-attempt time t_i, diagnostic time d_i, and cleanup time c_i,

$$t_{\text{incident}} = \sum_i (t_i + d_i + c_i).$$

Set a wall-time limit as well as $r_{\max}$.

Build a hand-classified matrix containing a true allocation OOM, a shape-mismatch RuntimeError, a ValueError from configuration, a timeout, and a failure in the report writer. Predict the primary outcome, allowed diagnostics, propagation behaviour, and whether another CUDA attempt is authorised by the runtime contract. Do not induce a device assert just to fill a test row.

Part 4 - Experimental Design and Instrumentation

1. Test exception routing with labelled synthetic exceptions and no GPU work. Preserve tracebacks when unrelated exceptions propagate.

2. Implement a small attempt function whose locals include temporary objects. Return only an outcome record after its scope has unwound.

3. Add CPU-only diagnostic serialization without tensor locals. Inject failure into the serializer and verify primary evidence survives.

4. Run E01's genuine CUDA OOM and compare routing with the synthetic case. Mark their evidence sources distinctly.

5. Demonstrate bounded retries and a time-limit outcome. Recovery must occur outside the failed exception scope with an explicit new proposal.

Record context health as known usable, known fatal, or unknown. A generic message alone should not be used to assert device health.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import traceback
import torch

@dataclass
class AttemptOutcome:
    status: str
    primary_error_type: object
    primary_error_text: object
    traceback_text: object
    diagnostic_errors: tuple
    retry_eligible: bool

def format_cpu_failure_record(error, phase, metadata):
    record = ...
    return record
```

```
def run_attempt_in_own_scope(workload, configuration):
    # Implement narrow exception routing and preserve other errors.
    # Return no tensor-owning exception or traceback objects.
    outcome = ...
    return outcome

def collect_best_effort_diagnostics(primary_record, telemetry):
    enriched_record = ...
    return enriched_record

def enforce_retry_limits(history, time_budget, retry_budget):
    decision = ...
    return decision

def E04(workload, injected_cases, limits):
    routing_report = ...
    return routing_report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact routing for every test case. An unrelated failure must not be converted into a retry or a false successful result. Check that the original exception remains primary when diagnostics fail.

Use weak references or a controlled lifetime probe to show the failed scope can release temporary objects. Inspect serializable records for tensor, frame, traceback, and exception objects. Verify that retry count and time budgets terminate even when every attempt produces OOM.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A safe handler preserves meaning. It distinguishes insufficient memory from a broken program and preserves enough evidence for the next decision without prolonging failed object lifetimes.

Explain why exception routing belongs below recovery policy. Keeping them separate makes it possible to change the recovery strategy without accidentally swallowing new classes of bugs.

19.25.6 Exercise 05

Exercise Title: Release Dead Tensor References After OOM and Prove Which Allocations Remain Alive Because Python Still Holds References

Part 1 - Exercise Contract and Why It Matters

Build a reference-lifetime experiment that explains why memory can remain allocated after a variable is deleted or a failed function returns. Compare direct aliases, views, detached tensors, graph-connected outputs, container references, closures, and exception tracebacks. Deliver an ownership diagram and a before/after allocation table.

Restrict cleanup to objects created by the experiment. Model parameters and optimizer state may remain live intentionally; deleting them to improve a memory counter does not demonstrate a valid recovery path.

Part 2 - System and Memory Mental Model

Python names refer to objects; tensor objects can share underlying storage. Deleting one name does not free storage still referenced by another tensor or graph. A detached tensor may share storage with its source, and a view can keep a large base allocation alive even when its own logical shape is small. An independent clone owns separate storage rather than freeing the original allocation.

Autograd may retain tensors needed by a future backward pass. Saving a loss or output tensor in a history list can therefore retain more than its visible payload. Converting a scalar observation to a CPU number avoids keeping that graph in the log, although extracting a CUDA scalar can introduce synchronization and should be timed separately.

Garbage collection addresses unreachable Python objects, including cycles; it cannot free objects still intentionally reachable. A weak reference becoming dead proves a particular Python object died, not that all aliases to its storage disappeared. Storage-lifetime evidence must combine reference controls and allocator observations.

Part 3 - Quantitative Prediction Before Execution

Let an experiment allocate one storage of N elements of size s, with k aliases. Its payload is Ns, not kNs. If a small view covers $m \ll N$ elements, the view's logical bytes ms need not equal the retained base allocation.

For a hypothetical 256 MiB base tensor, a 1 MiB view, one detached alias, and one independent clone, predict live storage after deleting each owner in a declared order. Explain which deletions change Python reachability without releasing any allocator bytes.

$$\Delta A = A_{\text{before}} - A_{\text{after}}$$

measures released live allocator storage at the observation boundaries, subject to asynchronous work and other allocations.

For a bounded history of graph-connected outputs, predict whether memory growth follows visible output payload alone. State which internal graph storage makes the analytic estimate only a lower bound.

Part 4 - Experimental Design and Instrumentation

1. Warm the allocator with a small control, then record a clean live baseline. Use allocation sizes large enough to distinguish signal from minor bookkeeping variation.

2. Construct each ownership case independently and record storage identity without using it as a long-term reference.

3. Remove one owning reference at a time. Synchronize at the declared boundary and observe live and reserved bytes separately.

4. Compare reachable containers with a deliberately unreachable cycle. Use garbage collection only where the object-lifetime experiment calls for it, and measure its cost.

5. Reproduce a failed attempt whose traceback is retained, then replace the retained exception with formatted text and let the failure scope end.

6. Verify the same model and optimizer remain usable after cleanup.

Keep lifetime probes weak where possible; a diagnostic tool must not become the last strong reference to the object it is studying.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import gc
import weakref
import torch

@dataclass
class OwnershipObservation:
    case_name: str
    removed_owner: str
    tensor_object_alive: bool
    allocated_bytes: int
    reserved_bytes: int

def create_alias_and_view_case(device, payload_bytes):
    ownership_handles = ...
    return ownership_handles

def create_graph_retention_case(model, inputs):
    ownership_handles = ...
    return ownership_handles

def observe_after_owner_release(handles, owner_name, device):
    # Remove only the designated experiment-owned reference.
    observation = ...
```

```
    return observation

def compare_exception_object_with_text_record(workload):
    evidence = ...
    return evidence

def prove_model_state_survived_cleanup(runtime, reference):
    audit = ...
    return audit

def E05(runtime, ownership_cases):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require an explicit list of owners, their removal order, and predicted versus observed storage changes. Check that a view or detached alias can outlive the original Python tensor object. Do not treat a dead weak reference as sufficient proof of storage release.

Verify post-cleanup live allocation returns near the controlled baseline, while reserved cache may remain. Check model parameters, optimizer references, and a subsequent update for correctness. If logging changes the observed lifetime, identify and remove that instrumentation artifact.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Reference cleanup is an ownership operation, not a command that magically frees everything unused by the current line of code. Explain which layer owns each remaining allocation and whether that ownership is justified.

Recommend logging and attempt-scope patterns that prevent accidental retention without deleting training state. These design choices are often more effective than repeated allocator-cache operations.

19.25.7 Exercise 06

Exercise Title: Test torch.cuda.empty_cache() During Recovery and Prove Why It Cannot Free Memory Still Owned by Live PyTorch Tensors

Part 1 - Exercise Contract and Why It Matters

Measure cache release under three conditions: live tensors remain, tensor owners are released, and released blocks coexist with retained fragments or pending work. Compare live allocated bytes, reserved bytes, global free memory, and the cost of the next allocation. Deliver a controlled before/after table and a recovery recommendation supported by evidence.

The goal is to establish what cache release can and cannot do. It must not be described as deletion of model state, a universal fragmentation repair, or a substitute for reducing a genuinely oversized working set.

Part 2 - System and Memory Mental Model

PyTorch's allocator can retain unused blocks for reuse. Releasing unused cache can return releasable memory to the device allocator and make it available to other applications. Storage owned by live tensors remains allocated. Blocks tied to live parts of an allocation or pending stream work may not be releasable at the chosen instant.

Because cached blocks were already reusable by the process under allocator rules, clearing them need not increase that process's ability to run the same working set. It may change fragmentation behaviour in particular cases, and it can increase later allocation cost by removing reusable cache. Allocator backends differ; record the selected backend and do not assume an exact reservation drop.

An OOM may occur only after internal allocator retries and cache-release attempts. Therefore another manual cache clear is not guaranteed to change the outcome. First determine whether unnecessary references or future demand changed. Separate logical state restoration from allocator cleanup.

Part 3 - Quantitative Prediction Before Execution

Let A be live allocated bytes and R reserved bytes before cache release. The gap $R - A$ is an upper accounting quantity for unused reservations, not a guaranteed release amount. In a controlled single-process experiment, expect no removal of live tensor payload:

$$A_{\text{after}} \approx A_{\text{before}}$$

when owners remain and no other workload changes.

For illustrative $A = 2\,\text{GiB}$ and $R = 3\,\text{GiB}$, predict the range of plausible reservation changes if all, some, or none of the unused blocks are releasable. Then remove a 512 MiB tensor's last owner and predict the difference between immediate live-storage release and later reservation release.

Measure the tradeoff

$$t_{\text{recovery}} = t_{\text{reference cleanup}} + t_{\text{cache release}} + t_{\text{next allocation}}.$$

Predict why a per-step cache-clear policy can lose throughput even if global free memory looks larger between updates.

Part 4 - Experimental Design and Instrumentation

1. Use a dedicated worker and a fixed allocation pattern. Record baseline and backend, then retain a known live tensor.

2. Call cache release while that tensor remains reachable. Verify its content and observe allocated and reserved values.

3. Release its last owner, observe again, then release unused cache. Keep these as separate experimental stages.

4. Repeat with another live alias and with a controlled allocation history that may leave non-releasable fragments. Report inconclusive cases.

5. Compare no manual cache release, release only after OOM cleanup, and release before every update under the same work.

Time synchronization and cache operations explicitly. A noisy global free reading on a shared GPU is not an exact measure of this process's release.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class CacheExperimentRecord:
    stage: str
    allocated_bytes: int
    reserved_bytes: int
    global_free_bytes: int
    elapsed_seconds: float
    live_tensor_valid: object

def create_controlled_cache_state(device, allocation_plan):
    handles = ...
    return handles

def observe_cache_release_with_live_owners(handles, device):
    record = ...
    return record

def observe_release_after_owner_cleanup(handles, device):
    record = ...
    return record

def benchmark_cache_policy(workload, policy, repetitions):
    measurements = ...
    return measurements

def E06(workload, allocation_plan, policies):
```

```
comparison = ...
return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the live tensor to remain readable and unchanged after cache release. Verify that deleting only one of several aliases does not release their shared storage. Separate reservation change from live allocation change in all charts.

Keep failed recovery attempts in the comparison. A successful retry after both deleting references and clearing cache does not prove cache release was the necessary cause; include the reference-cleanup-only control. Report next-allocation latency and accepted throughput, not only the temporary rise in global free memory.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Cache release changes allocator ownership of unused blocks. It does not reduce the live workload by itself. Explain when returning unused blocks is helpful for cooperation with other processes and when it adds cost without solving the incident.

Recommend the narrowest effective cleanup policy for the measured workload, with a clear distinction between reference lifetime, allocator reuse, and physical device availability.

19.25.8 Exercise 07

Exercise Title: Reset a Failed Training Iteration Without Corrupting Model Parameters, Gradients, Optimizer State, or Random Number State

Part 1 - Exercise Contract and Why It Matters

Implement transactional rollback for one logical optimizer update. Capture independent CPU state before the window, inject failures at different phases, restore the last committed state, and compare a replay with a clean reference. Deliver a state inventory, snapshot cost, restore cost, and a component-by-component correctness report.

Begin at a clean gradient boundary, recording whether each gradient is absent or a tensor. Use a deterministic model for exact tests. The base runtime owns all state it mutates; external database writes, arbitrary callbacks, and uncontrolled data-loader workers need additional handling and are not silently covered by a model state dictionary.

Part 2 - System and Memory Mental Model

Model parameters are only part of a training transaction. Buffers such as running statistics can change during forward. Optimizer moments and per-parameter step counters can change during an update. RNG includes Python, NumPy when used, CPU PyTorch, and each CUDA generator used by the attempt. Data order, prepared augmentation, scaler, and scheduler progress also belong to the contract.

A state dictionary can contain references to live storage. Make independent CPU copies before mutation; copying a dictionary alone is insufficient. Restore parameter values without

breaking the optimizer's association with parameter objects, or recreate and rebind both explicitly. Absent gradients and zero-valued gradients can have different optimizer semantics, including whether a parameter is updated.

AMP recovery must restore a coherent scaler lifecycle. A saved scaler state may not capture transient per-optimizer state from a failed unscale/step phase. Recreate the scaler from a clean committed checkpoint or otherwise establish a documented fresh lifecycle before replay. Likewise, restore RNG before recreating stochastic work. Restoring the seed does not guarantee identical results after changing kernel shapes or micro-batch partitions.

Part 3 - Quantitative Prediction Before Execution

Let S_0 be the committed snapshot and S_f the state after a failed partial update. Rollback should establish

$$\text{restore}(S_f, S_0) = S_0$$

for all state covered by the contract, before retry. For deterministic replay of the same plan, compare S_{retry} with S_{clean}. Use exact equality for counters, IDs, and RNG states, and declared absolute/relative tolerances for numerical tensors.

For a model with P FP32 parameters and Adam moments, estimate CPU snapshot payload of parameters and two moments as $12P$ bytes, then add buffers, gradients if included, counters, and serialization overhead. For $P = 10^7$, calculate MiB and predict copy/restore time from a measured transfer bandwidth rather than a marketing specification.

Construct a partial-optimizer fault after some parameters have changed. Predict why clearing gradients and restoring only model parameters cannot reproduce the next Adam update.

Part 4 - Experimental Design and Instrumentation

1. Materialize the exact CPU input window and sample IDs before the snapshot, so replay does not depend on uncontrolled prefetch or augmentation.

2. Capture independent model, optimizer, buffer, gradient-presence, RNG, scaler, scheduler, and cursor state at the committed boundary.

3. Inject faults after forward mutation, after partial backward, and after deliberately partial optimizer mutation. Label synthetic faults.

4. End the failed scope, clean temporary references, restore all components, then perform a clean replay of the same plan.

5. Compare with a no-failure reference from the same snapshot. Measure CPU memory, snapshot time, restore time, and accepted-update latency.

6. Mutate one live tensor after snapshot to prove snapshot independence.

For initial exact testing, use batch-independent layers and no dropout. Add stochastic cases only with explicit equality or distributional criteria.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use

a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import torch

@dataclass
class TrainingCheckpoint:
    model_cpu: object
    optimizer_cpu: object
    gradient_state: object
    rng_states: object
    scaler_state: object
    scheduler_state: object
    data_state: object

def capture_independent_checkpoint(runtime, prepared_window):
    checkpoint = ...
    return checkpoint

def inject_phase_failure(runtime, failure_phase, mutation_plan):
    # Leave controlled partial mutation and fault injection incomplete.
    ...

def restore_committed_state(runtime, checkpoint):
    # Preserve parameter bindings and reset transient scaler lifecycle.
    ...

def compare_state_components(reference, candidate, tolerances):
    audit = ...
    return audit

def replay_from_checkpoint(runtime, checkpoint, prepared_window):
    outcome = ...
    return outcome

def E07(runtime, prepared_window, failure_cases, tolerances):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equality for sample cursor, counters, RNG, scheduler progress, and gradient-presence pattern. Compare parameters, buffers, and nested optimizer tensors individually. Matching loss alone does not certify rollback.

Test snapshots before and after lazy optimizer-state initialization. Check independence of nested tensor copies and correct optimizer bindings after restoration. Verify the retry applies exactly one accepted update. Include a deliberately incomplete rollback control and show the state component that reveals its error.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Rollback converts recovery from guesswork into a transaction with a testable boundary. Explain which costs the full snapshot incurs and which failures could permit a cheaper specialised rollback only after proving that no additional state mutated.

Define the supported replay semantics clearly: exact same-plan replay under deterministic conditions, numerical equivalence for compatible repartitioning, or a separately justified stochastic criterion.

19.25.9 Exercise 08

Exercise Title: Detect an OOM During Forward and Retry the Same Input with a Smaller Micro-Batch Without Restarting the Process

Part 1 - Exercise Contract and Why It Matters

Recover from a forward allocation OOM by replaying the same logical input window through smaller physical micro-batches. Preserve the process, sample membership, target alignment, and one-update learning objective. Deliver a phase trace, retry plan, same-process evidence, and a numerical comparison against a clean execution of the final successful plan.

Keep the master input window on CPU and transfer only the active micro-batch. Slicing a full GPU batch after failure may retain its oversized storage and defeat recovery. Use a bounded retry policy and return no-fit when the smallest admissible input still cannot run.

Part 2 - System and Memory Mental Model

Forward is not necessarily free of state changes. Dropout consumes random numbers, BatchNorm updates buffers, and hooks may mutate application state. A forward failure late in the model can therefore require rollback even when no backward call began. Use E07's transaction boundary unless the model has a proven narrower side-effect contract.

When a forward attempt fails, its frame can retain inputs and partial outputs through the exception traceback. End the failed scope and release temporary owners before retrying. A smaller new allocation cannot help if failed graphs and large inputs remain live elsewhere.

Splitting inputs does not universally preserve the same mathematical computation. Batch-dependent normalisation, contrastive objectives, and cross-sample operations can change. Use a sample-separable loss and batch-independent model for the base equivalence test. Compare stochastic runs with a declared criterion rather than demanding unexplained bitwise equality across changed shapes.

Part 3 - Quantitative Prediction Before Execution

For a logical window of B samples and micro-batch sizes b_k,

$$\sum_k b_k = B, \qquad \mathcal{L} = \sum_k \frac{b_k}{B} \overline{\mathcal{L}}_k.$$

Retain the intended denominator even when the last micro-batch is short. An approximate peak model is $M_{\text{fixed}} + \alpha b + W(b)$. Shrinking b affects variable demand, not all persistent memory.

For $B = 30$, predict partitions for upper micro-batches 16, 8, and 4. Suppose forward at 16 fails but 8 fits. Calculate the final partial micro-batch and its weight. Predict memory savings if $M_{\text{fixed}} = 2\,\text{GiB}$ and $\alpha = 64\,\text{MiB/sample}$, ignoring workspace changes initially.

Include wasted first-attempt time and restoration in throughput:

$$Q = \frac{B}{t_{\text{failed}} + t_{\text{restore}} + t_{\text{successful window}}}.$$

Do not compare only the final successful attempt with the static baseline.

Part 4 - Experimental Design and Instrumentation

1. Create a deterministic sample-separable model and CPU window with immutable IDs. Save a committed snapshot.

2. Establish a controlled forward pressure threshold in an isolated calibration, then trigger a genuine forward OOM or use a clearly labelled fault hook when hardware conditions do not permit a reliable trigger.

3. Record the surfacing phase and last completed marker. End the failed scope and verify temporary live allocations are released.

4. Restore the snapshot, reduce the physical plan, and replay the entire logical window with correct weights and one final update.

5. Compare with a clean reference that starts from the same snapshot and uses the eventual successful micro-batch plan.

6. Record process identity, attempt count, state audits, peaks, accepted IDs, and full incident time.

Probe at most a bounded set of smaller plans. If batch one fails, stop or defer explicitly rather than retrying an identical request forever.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import os
import torch

@dataclass
class ForwardRetryPlan:
    logical_sample_ids: tuple
    maximum_micro_batch: int
    retry_index: int
    normalization_count: int

def execute_forward_attempt(runtime, cpu_micro_batch, plan):
    # Report only CPU metadata after the failed scope unwinds.
    outcome = ...
    return outcome

def release_failed_forward_owners(runtime, outcome):
    # Keep committed model and optimizer state intact.
    ...

def propose_smaller_forward_plan(previous_plan, limits):
    next_plan = ...
    return next_plan

def replay_logical_window(runtime, checkpoint, cpu_window, plan):
    result = ...
    return result

def audit_forward_recovery(reference, recovered, sample_ids):
    audit = ...
    return audit

def E08(runtime, cpu_window, initial_plan, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify each logical sample appears once in the accepted update, even when several failed attempts processed it speculatively. Check loss weights, final remainder, parameters, buffers, optimizer state, and gradient values against the compatible reference.

Test early and late forward failures, a short final micro-batch, and batch-one no-fit. Verify process continuity and ensure the CPU input master is not accidentally replaced by a full-window GPU tensor. Report any semantic limitation from stochastic or batch-dependent layers.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Forward recovery reduces the active working set while preserving a logical transaction. Explain how ownership cleanup, rollback, and repartitioning each contribute a different part of the solution.

Recommend the largest tested safe retry plan only within the observed shape and budget. A forward success still does not certify that the subsequent backward and optimizer phases fit.

19.25.10 Exercise 09

Exercise Title: Detect an OOM During Backward and Recover Without Accidentally Applying Partial or Stale Gradients

Part 1 - Exercise Contract and Why It Matters

Recover from a backward OOM without applying partially accumulated or stale gradients. Demonstrate failure after some parameter gradients exist, reset the complete failed logical window, and replay from the committed snapshot. Deliver per-parameter gradient evidence and a comparison against a clean successful update.

The base policy discards all gradient work from the failed logical window. Selective salvage is an advanced extension requiring a proof of which contributions are complete and nonduplicated; it must not be the implicit behaviour of the first implementation.

Part 2 - System and Memory Mental Model

Backward executes many gradient computations, not one atomic operation. Some parameters may have new gradients while others still have none or retain earlier accumulation contributions. An OOM does not mark those tensors with a reliable complete-window flag.

The partially consumed autograd graph is also not a reusable transaction. Some intermediates may already be freed, while others remain reachable through failure frames. Reusing it with graph-retention settings does not establish correct gradient coverage. Rebuild forward computation from restored state and replay the full logical window.

Clearing gradients is necessary for the base strategy but may not be sufficient: earlier forwards can mutate buffers and RNG, and hooks can change custom state. If failure occurs before the optimizer, parameter values may still match the snapshot, yet the complete state audit remains necessary. Gradient presence and values both matter.

Part 3 - Quantitative Prediction Before Execution

Let g_j be the intended total gradient of parameter j, and let $\widetilde{g}_j$ be an unknown partial value after failure. Naively replaying into existing buffers produces

$$g_j^{\text{wrong}} = \widetilde{g}_j + g_j$$

when replay contributes a full window. In general, the unknown partial term differs by parameter and cannot be corrected by one global factor.

For two equally weighted micro-batches, suppose the first contribution completed and the second backward failed midway. Write the possible gradient states for three parameters: complete, partial, and untouched by the failing pass. Predict why matching the overall gradient norm cannot prove correctness.

Measure per-parameter error

$$E_j = \frac{\|g_j^{\text{retry}} - g_j^{\text{ref}}\|_2}{\max(\|g_j^{\text{ref}}\|_2, \epsilon)}.$$

Before running, predict error under full rollback, gradient-reset-only with mutable buffers, and naive continuation.

Part 4 - Experimental Design and Instrumentation

1. Use a deterministic multi-layer model and a logical window that contains at least two micro-batches. Save the committed state.

2. Trigger or inject a backward failure after selected gradients have been written. Capture presence and summary values on CPU.

3. Run a labelled incorrect control that demonstrates stale gradient contamination without committing it to the main runtime.

4. End the failed scope, discard all window gradients, restore the transaction, and rebuild forward/backward using a smaller safe plan.

5. Compare every parameter gradient before the update, then compare parameters and optimizer state after the single accepted update.

6. Repeat with forward-mutated buffers and with AMP, treating numerical overflow separately from allocation OOM.

Do not step the optimizer from a failed backward result. Diagnostic gradient copying must be bounded so it does not become a new failure source.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class GradientObservation:
    parameter_name: str
    gradient_present: bool
    finite_status: object
    norm_value: object
    contribution_status: str

def capture_partial_gradient_evidence(model, size_limit):
    evidence = ...
    return evidence

def run_backward_attempt(runtime, window, micro_plan, fault_hook):
    outcome = ...
    return outcome

def invalidate_failed_gradient_window(runtime, checkpoint):
    # Discard the complete logical window and restore its state.
    ...

def rebuild_and_replay_backward(runtime, checkpoint, window, plan):
    recovered = ...
    return recovered

def compare_named_gradients(reference, recovered, tolerances):
    errors = ...
    return errors

def E09(runtime, window, failure_cases, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no optimizer step before a complete validated backward window. Check gradient presence, finite status, per-parameter values, and accepted sample counts. A norm-only or loss-only comparison is insufficient.

Test failure in the first micro-batch, after earlier successful micro-batches, and at different layers. Verify no tensors from a partially used graph are reused on replay. If hooks or buffers mutate, confirm their state is restored or explicitly excluded from supported models.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Backward recovery must treat unknown partial gradients as uncommitted work. Explain why complete-window replay is a simple correctness baseline even when it wastes computation.

Discuss what evidence would be required for finer-grained salvage. Any optimisation must preserve exactly the same accepted gradient contributions, not just reduce the number of repeated kernels.

19.25.11 Exercise 10

Exercise Title: Implement Recursive Batch Splitting That Automatically Divides an OOMing Batch Until Every Sub-Batch Fits in VRAM

Part 1 - Exercise Contract and Why It Matters

Build a recursive partition planner that splits an OOMing batch into smaller ordered sub-batches. Include odd batch sizes, a minimum leaf size, bounded depth, and a singleton no-fit outcome. Deliver the split tree, attempt history, accepted leaf manifest, and exact sample-coverage proof.

For training, use a conservative transaction model: a failure refines the partition, then the complete logical window is rolled back and replayed. Do not preserve earlier successful leaf gradients accidentally while replaying those leaves again. Distinguish this training contract from independent inference calls where leaf outputs can be safely concatenated.

Part 2 - System and Memory Mental Model

A split tree represents a partition of the logical sample set. Every internal node must produce disjoint children whose union is the parent, preserving the declared order. A leaf becomes feasible only after the required forward, backward, and relevant complete-window phases have been validated.

Success at a small isolated leaf does not guarantee the final optimizer step fits, especially when lazy state is created there. Likewise, aggregating all leaf outputs on GPU can recreate the original memory problem. Stream CPU-only evidence and retain only state required by the training transaction.

Recursion cannot shrink a singleton's sequence length or persistent model state. If the smallest leaf fails, return no-fit for this action and allow a different recovery strategy later. Bounds on depth alone do not bound repeated whole-window replay; track total attempts and time as separate limits.

Part 3 - Quantitative Prediction Before Execution

For a node containing $n > 1$ samples, use a balanced integer partition:

$$n_{\text{left}} = \lfloor n/2 \rfloor, \qquad n_{\text{right}} = n - n_{\text{left}}.$$

If splitting all the way to singletons, the resulting binary tree contains at most $2B - 1$ nodes and has balanced depth $\lceil \log_2 B \rceil$. These are tree bounds, not bounds on GPU calls when failed windows are replayed repeatedly.

For $B = 13$ and a hypothetical feasible leaf limit of four, draw the tree, list leaf sizes, and verify their weights sum to one for a sample-average objective. Predict how much earlier leaf work must be replayed if a later leaf fails.

Define a progress measure based on unresolved splittable nodes or maximum failing leaf size. Prove that each refinement makes progress, while a singleton failure exits explicitly.

Part 4 - Experimental Design and Instrumentation

1. Validate the planner on CPU with a fake feasibility function. Test $B = 1$, odd sizes, exact thresholds, and no feasible leaf.

2. Maintain immutable sample ranges in tree nodes. Check disjointness, coverage, and order after every refinement.

3. Integrate with a CUDA attempt function and E07 rollback. On failure, refine the implicated leaf and restart the logical window from its committed snapshot.

4. Validate the complete optimizer update, not only individual leaves. Retain a bound on retries and elapsed time across the whole tree.

5. Compare with repeated global halving under the same input and budget. Measure total work replayed and accepted throughput.

If an inference-only variant is implemented, compare it separately and explain why its output-handling and transaction rules differ.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class BatchNode:
    node_id: str
    start_index: int
    stop_index: int
    depth: int
    status: str

def split_failed_node(node, minimum_leaf_size):
    # Produce disjoint ordered children or a no-fit outcome.
    children = ...
    return children
```

```
def audit_partition_tree(root_ids, leaf_nodes):
    coverage_audit = ...
    return coverage_audit

def refine_partition_after_failure(tree, failed_node, limits):
    refined_tree = ...
    return refined_tree

def execute_partition_transaction(runtime, window, tree):
    # Discard all window gradients if any required phase fails.
    outcome = ...
    return outcome

def replay_refined_tree(runtime, checkpoint, window, tree, limits):
    result = ...
    return result

def E10(runtime, window, initial_tree, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require leaf sizes to be positive, ordered, disjoint, and exhaustive. No recursive call may receive the same unsplittable input indefinitely. Check depth, total-attempt, and wall-time limits independently.

Verify every accepted sample contributes once with the correct weight despite repeated speculative processing. Compare gradients and the final optimizer state with a clean execution of the final leaf plan. Test optimizer-step OOM after all leaves individually succeed and return it as a separate recovery failure.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Recursive splitting localises shape pressure and provides an auditable partition tree. It is not a universal OOM solution because some demand does not scale with sample count.

Explain whether finer partitioning saved time compared with global halving once whole-window replay was counted. Prefer the simpler strategy when the extra tree machinery provides no measured benefit.

19.25.12 Exercise 11

Exercise Title: Preserve the Intended Effective Batch Size After OOM Recovery by Combining Micro-Batch Reduction with Gradient Accumulation

Part 1 - Exercise Contract and Why It Matters

Integrate OOM recovery with exact logical-batch accumulation. A retry may change physical partitioning but must preserve the same logical samples, loss denominator, accepted optimizer-step count, and scheduler progress. Deliver partition manifests, gradient comparisons, and a recovery-aware training trace.

Use a sample-separable objective first. Add a valid-token-average variant with masking and unequal sequence lengths. Batch-coupled losses need specialised algorithms and must not be claimed equivalent through ordinary accumulation alone.

Part 2 - System and Memory Mental Model

For equal-sized micro-batches, dividing each mean loss by a constant accumulation count can be correct. Recovery often produces unequal sizes, making that shortcut wrong. Weight each contribution according to the logical objective: sample counts for a sample mean, or valid loss-bearing token counts for a token mean.

The optimizer, gradient clipping, scaler progression, and accepted-update scheduler belong at the logical boundary. With AMP, keep the scale consistent through the accumulation window. OOM rollback must restore a coherent scaler lifecycle before replay; numerical overflow is a separate outcome that must not be treated as insufficient VRAM.

Changing physical batch size should not cause the data cursor to commit early. Keep immutable prepared inputs and advance accepted state once. Regularisation, auxiliary losses, and metrics need their own normalisation rules so a term is not multiplied by the number of retry micro-batches.

Part 3 - Quantitative Prediction Before Execution

For logical count N and micro-batch counts n_k,

$$\sum_k n_k = N, \qquad \mathcal{L} = \sum_k \frac{n_k}{N} \overline{\mathcal{L}}_k, \qquad g = \sum_k \frac{n_k}{N} \nabla \overline{\mathcal{L}}_k.$$

Use the intended logical denominator, not the size of a failed physical attempt. Define behaviour for zero valid tokens explicitly.

For a 100-sample window, compare partitions capped at 32, 24, and 16. Write all sizes and weights. For valid-token counts $(200, 500, 300)$, compute the weights and compare them with equal micro-batch weighting.

For a final dataset tail of 37 samples, state whether to accept a smaller logical update, carry it to the next epoch, or drop it explicitly. Do not label that window as 100 effective samples without adding real, accounted-for data. Predict the accepted update count under the chosen policy.

Part 4 - Experimental Design and Instrumentation

1. Create a reference logical window whose full-batch computation fits on a small deterministic model. Save committed state.

2. Trigger failure under a larger physical plan, then recover with an unequal partition and replay the same sample IDs.

3. Compare exact weighting with a labelled incorrect equal-weight control. Capture gradients before the single final optimizer update.

4. Add clipping after the complete gradient is available. For AMP, use the appropriate unscale/validate/clip/step boundary once per window.

5. Test overflow skip, zero-valid-token data, and a final partial dataset window under declared policies.

6. Record accepted samples or valid tokens, retries, physical plan, optimizer steps, scheduler steps, scaler state, and full wall time.

The base experiment is single-device. Multiple ranks with unequal work require collective agreement and correctly derived global weights.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class LogicalObjective:
    sample_ids: tuple
    denominator_kind: str
    normalization_count: int
    tail_policy: str

def build_recovery_partition(window, maximum_micro_batch):
    partition = ...
    return partition

def determine_contribution_weight(micro_batch, objective):
    weight = ...
    return weight

def accumulate_recovery_window(runtime, partition, objective):
    # Leave weighted loss, backward, and scaler placement incomplete.
    outcome = ...
    return outcome
```

```
def validate_and_commit_once(runtime, objective, outcome):
    commit_record = ...
    return commit_record

def audit_accepted_update_semantics(reference, recovered):
    audit = ...
    return audit

def E11(runtime, windows, initial_plan, recovery_limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check count conservation, nonoverlapping sample IDs, correct token masking, and exact accepted step counts. Compare every named gradient, updated parameter, and optimizer state with the compatible reference. Report non-finite values separately from allocation failures.

Test an OOM late in accumulation and ensure no earlier contribution is duplicated after replay. A scaler skip must not be counted as an accepted update if the benchmark defines acceptance by optimizer commit. Document the treatment of auxiliary objectives and tail windows.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The effective batch is a learning contract. Memory recovery is allowed to change execution only within the semantics that contract permits. Explain how normalisation and commit accounting preserve it.

Report the cost of smaller micro-batches and full-window retries alongside memory savings. A runtime that survives OOM by quietly changing sample weights has not recovered the intended training job.

19.25.13 Exercise 12

Exercise Title: Recover from a Sequence-Length OOM by Dynamically Reducing Token Budget Instead of Only Reducing Sample Count

Part 1 - Exercise Contract and Why It Matters

Recover from variable-length sequence pressure using a token-aware partitioner and shape-aware admission. Compare sample-count reduction, useful-token budgeting, and padded-token budgeting with an explicit attention-memory model. Deliver the original and recovered batch manifests, memory measurements, and exact valid-token accounting.

Preserve sequence content, targets, masks, and the intended logical objective. Lowering a token budget is a scheduling change; it is not permission to truncate text or change context

length silently. A singleton that exceeds memory requires another strategy or an explicit no-fit outcome.

Part 2 - System and Memory Mental Model

One long sequence can force an entire dense batch to use a large padded length. Useful-token count measures content, while padded-token count better reflects some dense activations. Neither alone bounds all attention implementations: materialised score matrices can scale with bL^2, and workspace choices can add discontinuities.

Recovery should inspect CPU length metadata before rebuilding CUDA inputs. Preserve a logical window of prepared samples and change its physical packing, while weighting the loss by the original valid-token denominator if that is the objective.

Bucketing can reduce padding without shortening a sequence, but it changes execution order and may change stochastic behaviour. Compare deterministic clean replay of the final schedule. Packed attention or sequence chunking requires a separate validated contract; arbitrary chunks do not preserve full-context attention dependencies.

Part 3 - Quantitative Prediction Before Execution

For a proposed dense batch $\mathcal{B}$,

$$U = \sum_{i \in \mathcal{B}} L_i, \qquad P = |\mathcal{B}| L_{\max}, \qquad C_{\text{attn}} = |\mathcal{B}| L_{\max}^2.$$

A token cap constrains a declared unit, for example $P \leq K$. Admission must also constrain predicted upper bytes under the selected backend and precision.

Compare eight sequences of length 128 with one of length 1024. Both contain 1024 useful tokens, but calculate their respective C_{attn} values. For lengths $(128, 160, 192, 1024)$, compute padding when batched together and when the long item is isolated.

Before execution, predict the outcome of reducing the sample count to one for a sequence whose singleton peak already exceeds the cap. State which recovery actions can preserve its full context and which would change the learning task.

Part 4 - Experimental Design and Instrumentation

1. Freeze a CPU dataset with IDs, actual lengths, masks, and target counts. Include rare long sequences and one declared oversized singleton.

2. Trigger or inject a sequence-related OOM and record the exact collated shape, not just sample count.

3. Restore the logical transaction and propose a smaller padded-token budget with shape-aware validation.

4. Repack without dropping or truncating tokens. Execute the complete logical update with the original normalisation denominator.

5. Compare with a clean final-plan reference and with sample-only halving. Measure useful tokens/s, padding, retries, memory, and no-fit time.

6. Route singleton no-fit to a later recovery action or explicit deferral; do not loop on an impossible token cap.

For every sample, preserve a content identity or checksum computed on CPU so accidental truncation is detectable.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class SequenceWindow:
    sample_ids: tuple
    sequence_lengths: tuple
    valid_token_counts: tuple
    content_identities: tuple

def inspect_failed_sequence_shape(failure_record, cpu_window):
    shape_evidence = ...
    return shape_evidence

def propose_reduced_token_budget(previous_budget, limits):
    proposal = ...
    return proposal

def repack_without_truncation(window, token_budget, memory_profile):
    plan = ...
    return plan

def classify_oversized_singletons(plan, memory_profile, limits):
    no_fit_items = ...
    return no_fit_items

def replay_token_weighted_window(runtime, checkpoint, window, plan):
    outcome = ...
    return outcome

def E12(runtime, sequence_windows, token_policy, limits):
    report = ...
```

```
return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify identical sequence content, valid tokens, targets, and masks before and after recovery. Check exact sample coverage and the original loss denominator. Compare gradients and accepted parameters with the compatible clean reference.

Test a zero-valid-token item, one extreme outlier, equal-token batches with different shapes, and a singleton no-fit. Report whether the token budget measures useful or padded tokens. A lower token total is not itself proof of lower peak VRAM.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Token-aware recovery changes how unchanged sequence work is grouped. Explain which memory terms it reduces and why some full-context sequences still need a different intervention.

Recommend a policy that preserves content and makes no-fit visible. Silent truncation may keep the process alive while changing the task, which is outside this recovery contract.

19.25.14 Exercise 13

Exercise Title: Build a Recovery Ladder That Tries Smaller Batch Size, Activation Checkpointing, CPU Offload, and Lower Precision in a Defined Order

Part 1 - Exercise Contract and Why It Matters

Implement an ordered recovery ladder: reduce the physical batch, add activation checkpointing, offload saved activations to CPU, and use a permitted lower-precision policy. Define whether stages accumulate changes or replace the previous configuration; use cumulative stages as the base experiment. Deliver the ladder trace, eligibility decisions, quality checks, and a terminal no-fit result.

Each stage begins from a restored logical transaction and a fresh graph. Keep sequence content and logical batch fixed. Precision changes require an explicit numerical acceptance contract; they must not silently replace an exactness requirement. The ladder is a predefined policy, not yet a claim of optimal cost.

Part 2 - System and Memory Mental Model

The actions target different memory components. Smaller micro-batches reduce the active input/activation working set. Checkpointing trades saved activations for recomputation. Saved-activation CPU offload trades GPU storage for host storage and transfers. Autocast can reduce selected intermediate dtypes without halving all model and optimizer state. Combined savings are not generally additive because actions may target the same tensors.

Define CPU offload narrowly: offload tensors saved for backward, using a supported saved-tensor mechanism such as `save_on_cpu`. Do not move the entire model to CPU and assume optimizer bindings, device placement, and throughput remain unchanged. Pinned host memory, transfer ordering, source lifetime, and CPU RAM limits belong to the offload contract.

Changing a checkpoint or offload policy affects graph construction, so activate it before the replay forward. Changing precision requires compatible autocast/scaler handling and new calibration. Some transitions temporarily require both old and new allocations; admission must cover transition peak, not only steady-state memory.

Part 3 - Quantitative Prediction Before Execution

For cumulative stage k, define configuration c_k and measure

$$\Delta M_k = M_{\text{peak}}(c_{k-1}) - M_{\text{peak}}(c_k).$$

Do not estimate the total by adding isolated savings from incompatible baselines. A valid stage must satisfy GPU cap, host-memory cap, numerical tolerance, and replay invariants.

For a hypothetical $B = 64$, compare smaller micro-batches with a checkpointed/offloaded version at the same logical batch. Suppose offloaded payload is H bytes and effective transfer bandwidth is v bytes/s. The transfer-only estimate for one outward and one inward copy is $2H/v$, before overlap, allocation, and contention effects. Calculate this for $H = 512\,\text{MiB}$ and a measured $v = 10\,\text{GiB/s}$.

Predict why a lower precision stage can be rejected despite fitting memory, and why adding offload after checkpointing may save less than offload alone.

Part 4 - Experimental Design and Instrumentation

1. Define each ladder stage, its prerequisites, maximum attempts, expected targeted storage, and permitted numerical error.

2. Calibrate stages on small inputs. Check checkpoint API settings, offload host capacity, dtype support, and scaler lifecycle.

3. Begin with a controlled OOM. Restore the committed transaction, apply the next eligible stage, and replay the entire logical window.

4. Measure transition peak, steady peak, host-memory demand, transfer cost, recomputation, accepted throughput, and numerical error.

5. Test unavailable BF16, insufficient host RAM, singleton pressure, and stages that save no measurable GPU memory.

6. Verify final no-fit after all eligible stages fail. Preserve a usable CPU checkpoint and a complete action history.

Use simple stateless blocks for initial checkpoint/offload equivalence. Keep asynchronous-transfer optimisation as a separately validated extension.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
from torch.utils.checkpoint import checkpoint
from torch.autograd.graph import save_on_cpu

@dataclass
class RecoveryStage:
    name: str
    maximum_micro_batch: object
    checkpoint_plan: object
    saved_tensor_offload: bool
    precision_policy: object
    numerical_tolerance: object

def validate_stage_prerequisites(stage, runtime, resource_snapshot):
    eligibility = ...
    return eligibility

def configure_replay_graph(runtime, stage):
    # Apply graph-construction policies before forward replay.
    configuration = ...
    return configuration

def estimate_transition_peak(current_stage, next_stage, profile):
    estimate = ...
    return estimate

def execute_ladder_stage(runtime, checkpoint_state, window, stage):
    result = ...
    return result

def run_ordered_recovery_ladder(runtime, window, stages, limits):
    # Restore the committed transaction between failed stages.
    outcome = ...
    return outcome

def E13(runtime, window, stages, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check stage order, cumulative configuration identity, bounded attempts, and a recorded reason for every skipped stage. Verify that failure at one stage cannot leave modified parameters or scaler state in the next.

Compare accepted gradients, parameters, and buffers under the declared numerical criteria. Check CPU memory and transfer lifetime when offload is active. Reject claims of additive savings unless the experiment actually demonstrates them. A precision stage that violates quality limits is ineligible even if memory fits.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A fixed ladder makes recovery predictable and auditable. Its order encodes preferences about recomputation, transfer, and numerical change, but those preferences may not minimise time on every GPU.

Explain which stage solved each incident and why. Use these measurements to motivate cost-aware selection rather than making the ladder more complex without evidence.

19.25.15 Exercise 14

Exercise Title: Rank Recovery Actions by Estimated Memory Saving and Runtime Penalty and Choose the Cheapest Strategy That Can Satisfy the Missing VRAM

Part 1 - Exercise Contract and Why It Matters

Build a cost-aware selector over a finite set of validated recovery configurations. Rank actions or compatible combinations by expected time to accepted work while satisfying GPU, host-memory, and numerical constraints. Compare the selector with E13's fixed ladder.

Deliver per-action profiles, uncertainty estimates, predicted and observed choices, and the regret relative to the best measured candidate under the same incident. Treat the missing-VRAM estimate as uncertain; the failed request size is not automatically the amount an action must save.

Part 2 - System and Memory Mental Model

The exception may reveal one requested allocation, but that request occurred at a particular live baseline after possible internal retries. Global free memory and cached blocks have different roles. Additional future workspaces may still be needed. Therefore subtracting free bytes from the message's request size does not provide a universal deficit.

Use a calibrated upper-demand model or bounded candidate probes to estimate feasibility. An action's saving must be measured against the current configuration and shape. Checkpointing plus offload or lower precision may have overlapping effects, so profile combinations rather than blindly summing individual reductions.

Cost includes activation of a policy, state restoration, graph rebuilding, recomputation, transfer, and future update time. A costly transition can pay off over a long budget regime but lose for one short incident. Use only information available at decision time; future regime duration is an assumption or estimate, not privileged knowledge.

Part 3 - Quantitative Prediction Before Execution

For predicted upper peak $\widehat{M}_{\text{upper}}$ and usable cap $J - S$, define an estimated deficit

$$\widehat{D} = \max(0, \widehat{M}_{\text{upper}} + S - J).$$

This is a model-derived quantity, not a direct reading from OOM text. For candidate a over a horizon of H accepted updates, compare

$$C(a) = t_{\text{restore}}(a) + t_{\text{transition}}(a) + H\, t_{\text{update}}(a) + \widehat{C}_{\text{failure}}(a).$$

Require upper predicted peak and transition peak to fit, plus quality and host-resource constraints.

Create a hypothetical table where micro-batch reduction saves 400 MiB at 20 ms/update, checkpointing saves 900 MiB at 35 ms/update, and offload saves 700 MiB at 28 ms/update, with distinct transition costs. For a 600 MiB estimated deficit, rank eligible actions at horizons one and 100. Supply transition costs before ranking and explain how uncertainty can change eligibility.

Part 4 - Experimental Design and Instrumentation

1. Build separate profiles for each action and selected combination, including transition demand and full-update cost.
2. Split incident traces into calibration and held-out evaluation. Freeze the selector before seeing held-out outcomes.
3. For each incident, record the demand estimate, uncertainty, eligible candidates, chosen action, and predicted cost.
4. Replay from identical snapshots under the fixed ladder and the cost-aware selector. Include failed probes and restoration time.
5. Measure the best candidate offline on the same incident as a comparison reference; do not give its future result to the online selector.
6. Test an action with high mean saving but variable peak and an incident outside the profile's shape domain.

If no candidate is credibly feasible, defer or run a bounded conservative probe. Do not always select the cheapest action regardless of uncertainty.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class RecoveryActionProfile:
    action_id: str
    predicted_peak_bytes: int
    uncertainty_bytes: int
    transition_peak_bytes: int
    transition_seconds: float
    update_seconds: float
    host_bytes: int
    numerical_error: float

def estimate_incident_demand(incident, workload_profile):
    estimate = ...
    return estimate

def filter_feasible_actions(profiles, resources, quality_limits):
    candidates = ...
    return candidates

def estimate_action_cost(profile, horizon, failure_model):
    cost = ...
    return cost

def select_lowest_cost_recovery(candidates, horizon, policy):
    decision = ...
    return decision

def compare_with_measured_best(decisions, measured_candidates):
    regret_report = ...
    return regret_report

def E14(runtime, incidents, action_profiles, policy):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate unit consistency and compare predicted memory saving with measured complete-update peaks. Check that transition peak, host RAM, and numerical limits are included in eligibility.

Report unsafe underprediction, unnecessary conservatism, action ranking errors, and end-to-end time regret. Do not count a fast failed action as a low-cost success. Test no feasible candidate, stale profile, and nonadditive action combinations. State how small cost differences are treated when measurement noise exceeds the apparent benefit.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved

bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The cheapest recovery is the one that restores accepted progress at lowest total cost within constraints. It may differ from both the action with greatest memory saving and the one with fastest isolated kernel time.

Explain when profile-based selection outperforms a simple ladder and when uncertainty makes the simpler policy preferable. Preserve the finite candidate-set limit of any optimality claim.

19.25.16 Exercise 15

Exercise Title: Detect Repeated OOM-Recovery Oscillation and Add Hysteresis So the Runtime Does Not Immediately Return to an Unsafe Configuration

Part 1 - Exercise Contract and Why It Matters

Prevent a runtime from repeatedly returning to a configuration that just failed. Add failure memory, separate grow/shrink thresholds, growth patience, cooldown, and explicit conditions for revalidating a previously failed configuration. Deliver a policy state table and traces comparing an eager-growth baseline with the revised controller.

Key failure memory by relevant workload and resource conditions: batch, padded shape, precision, checkpoint/offload policy, backend, and budget regime. A failure for one long shape should not prohibit all short inputs forever, but it must not be forgotten after a single successful small update.

Part 2 - System and Memory Mental Model

An OOM can cause batch reduction, which then creates headroom. A naive controller interprets that headroom as permission to restore the same unsafe batch, generating a repeating failure cycle. Switching policies can also incur repeated graph rebuilding, transfers, and checkpoint costs.

Use a deadband between ordinary growth and shrink triggers, require several accepted stable updates before growth, and retain the evidence of recent failure. Cooldown should delay speculative growth, not block emergency safety actions. Raw admission failures must override a smoothed utilisation estimate.

Failure memory needs an expiry or revalidation rule. A larger stable budget, a revised shape profile, or a validated new configuration can justify another probe. Time passage alone may be weak evidence. Count accepted logical updates, not failed attempts or successful micro-steps, toward growth patience.

Part 3 - Quantitative Prediction Before Execution

Let b_t be physical batch and u_t observed utilisation under a declared cap. Choose $l < h$ for growth and shrink triggers. Define switching count and repeated-incident rate:

$$N_{\text{switch}} = \sum_{t=2}^{n} \mathbf{1}_{c_t \neq c_{t-1}}, \qquad R_{\text{repeat}} = \frac{N_{\text{repeated equivalent OOM}}}{N_{\text{attempts}}}.$$

Configuration c_t includes more than batch size. Define equivalence of incidents by a documented fingerprint.

Manually replay a workload where batch eight fits at utilisation 0.55 and batch twelve OOMs at the same budget. Compare immediate regrowth with patience four and cooldown six accepted updates. Then introduce a real budget increase and predict when a bounded revalidation should be permitted. Explain why wider hysteresis alone cannot make an infeasible configuration fit.

Part 4 - Experimental Design and Instrumentation

1. Implement pure CPU transitions for failure memory, cooldown, patience, and configuration selection.
2. Replay a constant-budget failure cycle, alternating long/short shapes, a brief budget increase, and a sustained budget increase.
3. Add emergency pressure during cooldown and verify immediate shrink or deferral remains possible.
4. Compare controller variants with the same admission model, action set, and retry budget.
5. Run a reproducible CUDA trace and measure repeated OOMs, switches, lost work, time to regain useful capacity, and net throughput.

Tune on one trace and retain a separate evaluation trace. Log every decision that reopens a previously failed configuration, including its new evidence.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class FailureMemoryEntry:
    configuration_key: str
    shape_key: str
    budget_regime: str
    last_failure_update: int
    revalidation_required: bool

Part 6 - Measurement, Validation, and Failure Analysis

Test threshold equality, cooldown off-by-one errors, stale patience surviving OOM, and growth counters advanced by failed attempts. Verify a failed configuration cannot be selected without its declared revalidation condition.

Demonstrate fewer avoidable reversals while reporting any delayed capacity recovery. Legitimate switches caused by changing shapes or budgets are not automatically oscillation bugs. Check that failure memory remains bounded and does not permanently exclude newly feasible configurations.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Recovery policies need memory of failure as well as measurements of current headroom. Explain the causal loop that produced repeated OOM and how the new state breaks it.

Recommend a stability policy with explicit revalidation rules. Avoid claiming universal stability: discrete configuration changes, unseen shapes, and rapidly changing external pressure can still require frequent legitimate adaptation.

19.25.17 Exercise 16

Exercise Title: Capture memory_stats() and a CUDA Memory Snapshot Automatically When Recovery Attempts Repeatedly Fail

Part 1 - Exercise Contract and Why It Matters

Build a bounded diagnostic escalation policy for repeated allocation OOM. Capture allocator statistics, configuration, and a memory snapshot when the failure threshold is reached. Deliver the trigger trace, snapshot metadata, capture overhead, and a fallback record for diagnostic failure.

Use lightweight scalar records continuously and an explicitly bounded history policy when pre-failure allocation history is needed. Enabling history only after an incident cannot reconstruct earlier allocation events. State whether a snapshot represents current allocator state, recorded history, or both.

Part 2 - System and Memory Mental Model

Allocator statistics include current and peak quantities and accumulated event counters. Examples can include allocation retries, OOM count, and inactive split bytes, but availability and interpretation depend on the installed version and allocator backend. Native allocator metrics are not all meaningful under `cudaMallocAsync`.

Snapshots describe memory visible to the PyTorch allocator. Other CUDA libraries, communication buffers, and external processes may consume memory absent from that snapshot. Compare scope with global observations without claiming an exact attribution from their difference.

History and snapshot interfaces can include private APIs such as `_record_memory_history` or a snapshot-dump helper. Check the installed interface and version, isolate it behind an adapter, and record unsupported status rather than crashing the recovery engine. History storage consumes host memory; bound event count and escalation frequency. A ring buffer may overwrite old evidence.

Capture failures must remain secondary. An allocation-constrained or context-fatal runtime may not support further diagnostics. Preserve existing CPU evidence, cap output volume, and avoid recursive escalation when the diagnostic path itself fails.

Part 3 - Quantitative Prediction Before Execution

Let o_t be an accumulated allocator OOM counter. Compute the delta $o_t - o_{\text{baseline}}$ only when counter scope and reset history match. Peak-stat resets and accumulated-stat resets have different meanings; never assume resetting one resets the other.

If each stored history event costs an observed average of e host bytes and the limit is N, predict

$$H_{\text{history}} \approx Ne$$

plus indexing, stack, and serialization overhead. For a hypothetical $N = 20{,}000$ and $e = 1\,\text{KiB}$, calculate the baseline estimate and propose a host-memory cap with measured uncertainty.

Design a trigger such as three OOMs within one logical window, with at most one expensive snapshot per incident. Predict trigger behaviour for failure sequences separated by success, configuration changes, or a new incident ID. Define whether these reset the threshold.

Part 4 - Experimental Design and Instrumentation

1. Inspect supported statistics and snapshot interfaces before the experiment. Record PyTorch version, allocator backend, and adapter status.

2. Enable bounded history before a controlled workload when earlier events are required; otherwise label the snapshot as current-state only.

3. Generate repeated failures with a configured threshold and capture statistics before cleanup when feasible, then a separate post-cleanup record. Preserve their ordering.

4. Serialize the snapshot to a local diagnostic artifact with metadata, size, checksum, and incident ID. Keep recovery reports CPU-only.

5. Inject missing API, file-write failure, and history-limit cases. Verify no diagnostic error replaces the original OOM or triggers recursion.

6. Compare runtime and host-memory overhead with diagnostics disabled, lightweight-only, and escalated modes.

Match any recorded OOM event to the incident using device, phase, and time evidence; do not assume the last event necessarily belongs to it.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class DiagnosticPolicy:
    repeated_oom_threshold: int
    maximum_history_entries: int
    maximum_snapshot_bytes: int
    maximum_captures_per_incident: int

def inspect_diagnostic_capabilities(torch_module, device):
    capabilities = ...
    return capabilities
```

```
def configure_bounded_memory_history(capabilities, policy):
    # Adapt to the installed version; no assumed private signature.
    history_handle = ...
    return history_handle

def should_escalate_diagnostics(incident_history, policy):
    decision = ...
    return decision

def capture_allocator_evidence(device, capabilities, phase):
    evidence = ...
    return evidence

def persist_snapshot_best_effort(evidence, incident_id, limits):
    artifact_record = ...
    return artifact_record

def E16(runtime, failure_schedule, diagnostic_policy):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify trigger count, one-capture limits, counter scope, and reset behaviour. Distinguish genuine allocator OOM counts from synthetic exceptions that may not increment allocator counters.

Check snapshot artifact integrity, version metadata, event truncation, and the timestamp relative to cleanup. Mark absent or inapplicable metrics explicitly. Demonstrate that a failure before history was enabled lacks retrospective trace evidence.

Require the original incident to remain reportable if snapshot capture or writing fails. Report measured diagnostic time and host-memory cost; do not hide them in the recovery benchmark.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Diagnostic escalation spends resources to reduce uncertainty. Explain which questions a snapshot answered that scalar counters could not, and which remained outside allocator visibility.

Recommend a bounded history and capture policy based on incident frequency, memory cost, and usefulness. More recorded data is not automatically more reliable evidence if its scope and timing are unclear.

19.25.18 Exercise 17

Exercise Title: Build an OOM Incident Report That Identifies the Failed Allocation Size, Peak VRAM, Active Memory, Reserved Memory, and Current Runtime Policy

Part 1 - Exercise Contract and Why It Matters

Create a machine-readable incident schema and a human-readable report for each OOM episode. Include the failed request size when known, observed memory peaks, active/live memory fields, reserved memory, runtime configuration, attempts, recovery actions, and final outcome. Deliver a sample report generated from an actual controlled incident and tests for incomplete evidence.

Use explicit provenance for each value: application-known request, message-derived value, snapshot event, allocator counter, or unavailable. The report must not invent a failed allocation size when the source does not expose one.

Part 2 - System and Memory Mental Model

One incident can contain several failed attempts followed by success or no-fit termination. Keep incident IDs, attempt IDs, logical update IDs, and action IDs distinct. The first failure describes the initiating problem; later failures describe how proposed fixes performed.

Active/live memory is ambiguous unless defined. Report allocated tensor bytes and, when supported, the allocator's active-byte statistic as separate fields with their API scope. Do not label both as an interchangeable single number. Peak allocated bytes describe successful allocations during the declared interval, not the attempted missing storage.

Message parsing is optional enrichment. Preserve the raw message and version, and tolerate wording, units, and missing fields. A snapshot OOM event may provide a more direct request size, but must be correlated to the correct attempt. Use null with a reason rather than zero for unknown quantities.

Include physical device identity, process-local index, allocator, precision, physical and logical batch, padded shape, checkpoint/offload policy, budget, margin, and profile version. These determine whether two incidents represent the same configuration.

Part 3 - Quantitative Prediction Before Execution

Store all byte values canonically while preserving original displayed units. Use $1\,\mathrm{MiB} = 2^{20}$ and $1\,\mathrm{GiB} = 2^{30}$; do not silently interpret an ambiguous unit string as exact bytes.

For a request reported as 768 MiB, a known application payload of 750 MiB, and an allocator snapshot showing a rounded request, retain each observation with its provenance. Explain why allocator overhead or rounding may differ from payload.

$$t_{\text{incident}} = t_{\text{final outcome}} - t_{\text{first failure}}, \qquad N_{\text{wasted}} = N_{\text{speculatively processed}} - N_{\text{accepted}}.$$

Define speculative work carefully when the same sample is replayed. Report accepted unique samples or valid tokens separately.

Before implementation, fill an example schema by hand with one unknown request size and one missing exception-time memory reading.

Part 4 - Experimental Design and Instrumentation

1. Define typed fields, units, required metadata, optional evidence, and schema version. Separate observations from causal interpretation.

2. Build the report from immutable CPU event records. Preserve the original message and formatted traceback without frame objects.

3. Add bounded message parsing with tests for known supported formats, missing fields, ambiguous units, and changed wording.

4. Correlate a snapshot event when available and retain disagreements rather than overwriting earlier evidence silently.

5. Render a compact summary with initial failure, attempted actions, accepted outcome, lost time, and unresolved uncertainty.

6. Test report generation after both successful recovery and terminal no-fit, including unavailable diagnostic artifacts.

Do not embed training tensor contents in an incident report. Configuration, shape, state identifiers, and scalar evidence should be enough to link to a controlled reproducer.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import json
import torch

@dataclass
class EvidenceValue:
    value: object
    unit: str
    source: str
    timestamp: object
    unavailable_reason: object

@dataclass
class IncidentIdentity:
    incident_id: str
    logical_update_id: str
    device_identity: str
    schema_version: str
```

```
def extract_optional_request_size(raw_message, version):
    # Preserve unknown or ambiguous values with a reason.
    request_evidence = ...
    return request_evidence

def correlate_snapshot_event(incident, snapshot_metadata):
    correlation = ...
    return correlation

def assemble_incident_report(identity, events, artifacts):
    report = ...
    return report

def validate_report_schema(report):
    validation = ...
    return validation

def render_human_incident_summary(report):
    summary_text = ...
    return summary_text

def E17(incident_events, diagnostic_artifacts):
    report = ...
    summary = ...
    return report, summary
```

Part 6 - Measurement, Validation, and Failure Analysis

Require schema validation, correct units, immutable attempt ordering, and explicit unavailable values. Check that the report never substitutes a post-cleanup reading for a missing pre-failure reading.

Compare derived counts and durations with the raw event log. Test multiple attempts, conflicting request-size evidence, missing snapshots, and a final no-fit outcome. A diagnosis must cite its observations and permit uncertainty; message parsing alone cannot establish a unique cause such as fragmentation.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

An incident report is an evidence trail for a future engineer. Explain whether that engineer can reproduce the configuration, understand why each action was chosen, and identify what remains unknown without replaying the original conversation.

Prefer a small trustworthy schema over a large report full of inferred numbers presented as measurements. The report should support comparison across versions without hiding differences in measurement scope.

19.25.19 Exercise 18

Exercise Title: Stress-Test the Recovery Engine with Random Batch Sizes, Variable Sequence Lengths, Artificial VRAM Pressure, and Deliberate Memory Leaks

Part 1 - Exercise Contract and Why It Matters

Build a seeded stress suite for the integrated recovery engine. Vary batch sizes and sequence lengths, apply a controlled external pressure worker, create bounded intentional reference leaks, and inject failures at distinct transaction phases. Deliver scenario manifests, expected invariants, traces, and a minimal reproducer for each failure.

Use deterministic CPU control tests alongside real CUDA integration tests. Synthetic exceptions validate control flow but do not prove allocator behaviour. Real OOM tests validate one hardware/runtime environment but cannot exhaust every state transition.

Part 2 - System and Memory Mental Model

Randomness is useful only when failures remain reproducible. Record the generator seed and realised event schedule. Use logical update and phase indices for coordinated tests; wall-clock timing can introduce uncontrolled variation. Keep asynchronous pressure as a separately labelled stress mode.

An intentional leak is experiment-owned retention with a strict size and iteration limit. The engine should diagnose growing live baseline and identify unresolved ownership, not delete arbitrary tensors from unknown owners. If the owner cannot release memory, correct behaviour may be deferral or termination with preserved state.

Artificial pressure comes from a worker created by the test on the same physical GPU. Use acknowledgements, byte limits, and cleanup. Never terminate unrelated processes. Deliberate context corruption is unnecessary for this suite; test fatal-error routing synthetically. Verify accepted-work invariants independently of whether recovery eventually succeeds.

Part 3 - Quantitative Prediction Before Execution

Let a realised scenario be

$$\mathcal{S} = \{(u_i, p_i, e_i, m_i)\}_{i=1}^{n},$$

where u_i is logical update, p_i phase, e_i event type, and m_i magnitude or shape. Persist this schedule for replay. Define

$$R_{\text{recovery}} = \frac{N_{\text{recovered recoverable incidents}}}{N_{\text{declared recoverable incidents}}}, \qquad A_{\text{attempt}} = \frac{N_{\text{attempts}}}{N_{\text{accepted updates}}}.$$

Report undefined ratios when their denominator is zero and explain the outcome. Do not remove terminal failures from the dataset.

Before running, predict response to an oversized singleton, a 256 MiB temporary pressure pulse, a leak accumulating 32 MiB/update, and partial optimizer mutation. Specify which should retry, change strategy, diagnose, defer, or terminate. Derive the maximum retained leak under the chosen bound.

Part 4 - Experimental Design and Instrumentation

1. Write at least ten scenarios including no-pressure control, forward OOM, backward OOM, partial optimizer failure, long singleton, temporary pressure, persistent pressure, bounded leak, repeated oscillation, and diagnostic-write failure.

2. Generate bounded random shape schedules with saved seeds and retain a held-out distribution for evaluation.

3. Run synthetic controller tests first, then representative genuine CUDA scenarios. Keep evidence labels distinct.

4. Audit sample IDs, loss weights, optimizer/scaler/scheduler progress, rollback state, retry bounds, and process continuity.

5. Release test-owned pressure and leak containers in cleanup. Record live and reserved memory after recovery, separately.

6. Reduce any failing schedule to the smallest retained event set that reproduces it, without deleting the original trace.

Measure host-memory and diagnostic overhead as well as GPU memory. A recovery engine can fail through unbounded CPU snapshots even when its CUDA allocations are controlled.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import multiprocessing as mp
import torch

@dataclass
class StressEvent:
    logical_update: int
    phase: str
    event_kind: str
    magnitude: object
    evidence_mode: str

@dataclass
```

```
class StressLimits:
    maximum_live_pressure_bytes: int
    maximum_leak_bytes: int
    maximum_attempts: int
    maximum_wall_seconds: float

def generate_seeded_schedule(seed, shape_limits, event_limits):
    schedule = ...
    return schedule

def execute_controlled_pressure_worker(channels, device, limits):
    ...

def apply_bounded_reference_leak(owner, event, limits):
    observation = ...
    return observation

def run_stress_scenario(runtime_factory, schedule, limits):
    result = ...
    return result

def audit_stress_invariants(reference_manifest, result):
    audit = ...
    return audit

def minimise_failure_schedule(schedule, replay_function):
    minimal_schedule = ...
    return minimal_schedule

def E18(runtime_factory, seeds, scenario_limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact accepted sample accounting, finite accepted gradients, correct logical weights, complete rollback, bounded attempts, and cleanup of experiment-owned resources. Verify that a recovered parameter update matches the compatible clean reference.

Separate recoverable allocation incidents, valid no-fit refusals, unrelated exceptions, and diagnostic failures. Test that a growing leak is not mistaken for harmless reserved cache. Report PID continuity for successful in-process recovery and preserve every terminal outcome. Repeated success in a bounded suite is evidence of that tested envelope, not universal immunity to OOM.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Stress testing asks whether recovery remains correct under combinations of disturbances, not merely whether an exception can be caught. Explain which invariant failed first in each unsuccessful scenario.

Prioritise improvements by lost accepted work and correctness impact. Preserve difficult cases and negative results instead of narrowing the test distribution until the engine appears reliable.

19.25.20 Exercise 19

Exercise Title: Build and Benchmark a Self-Recovering PyTorch Training Runtime That Survives CUDA OOM Events and Dynamically Reconfigures Memory Strategy Without Restarting

Part 1 - Exercise Contract and Why It Matters

Integrate narrow OOM detection, bounded diagnostics, ownership cleanup, transactional rollback, shape-aware splitting, exact accumulation, recovery-action selection, hysteresis, and incident reporting into one single-GPU training runtime. It must survive declared recoverable allocation OOMs in the same process and preserve accepted training semantics while changing execution policy.

Deliver the learner-completed runtime, configuration schema, incident reports, raw traces, and a benchmark against simpler baselines. Define terminal outcomes for singleton no-fit, exhausted resources, unrelated errors, and context-fatal conditions. The chapter title's without-restarting claim applies to the recoverable allocation envelope, not every possible CUDA error.

Part 2 - System and Memory Mental Model

Use explicit boundaries between observation, policy selection, admission, attempt execution, rollback, and commit. The executor owns all mutable state covered by E07. The policy sees CPU-only observations and proposes a configuration. The incident recorder captures evidence without retaining failed graphs.

The runtime begins a logical window from a committed checkpoint, materialises its CPU data, validates an execution plan, and attempts the update. On allocation OOM, it records bounded evidence, unwinds the failed scope, restores state, and chooses a permitted alternative. On success, it validates and commits exactly once. On no-fit or exhaustion, it preserves a usable checkpoint and reports the reason.

Restoration must include transient execution lifecycles where persistent state dictionaries are insufficient, such as a scaler already unscaled within a failed attempt. Model buffers, parameter bindings, prepared inputs, RNG, scheduler counters, and custom supported hooks also matter. Do not retain both failed GPU graphs and a newly constructed replay.

Arbitrary asynchronous external allocation cannot be prevented by a preflight free-memory check. Admit conservatively and measure recovery under such pressure separately from coordinated tests. Distributed runtimes require cross-rank agreement and collective-failure handling; they are outside this single-device implementation.

Part 3 - Quantitative Prediction Before Execution

For accepted useful work N_{acc}, measure

$$Q_{\text{net}} = \frac{N_{\text{acc}}}{t_{\text{normal}} + t_{\text{failed}} + t_{\text{snapshot}} + t_{\text{restore}} + t_{\text{diagnostic}} + t_{\text{deferred}}}.$$

Define nonoverlapping time categories so elapsed time is not double-counted. Also report the direct full wall-clock denominator. Choose a finite candidate configuration c subject to

$$\begin{aligned} \widehat{M}_{\text{upper}}(c,x) + S_J &\le J, \\ \widehat{\Delta M}_{\text{upper}}(c,x) + S_D &\le F, \\ H_{\text{CPU}}(c) &\le H_{\max}, \\ E_{\text{numerical}}(c) &\le \varepsilon_{\max}. \end{aligned}$$

Use an explicitly conservative cache-credit policy for incremental device admission. Enforce exact logical membership and weighting as correctness conditions, not optional performance metrics.

Before benchmarking, predict incident count, recovery latency, snapshot memory, accepted throughput, and the winning strategy for three workloads: stable shape, variable length, and external pressure. Estimate how often recovery must occur before a conservative static batch becomes faster than a more aggressive adaptive policy.

Part 4 - Experimental Design and Instrumentation

1. Implement independent interfaces for telemetry, snapshots, attempt execution, admission, recovery policy, and incident reporting. Validate pure CPU state transitions before CUDA integration.

2. Establish a small deterministic numerical reference. Check full-state restoration after forward, backward, and partial optimizer failure, then verify a clean accepted replay.

3. Compare conservative static batching, fail-fast execution, simple batch-halving recovery, and the integrated runtime. Keep logical work, eligible precision policies, and data order comparable.

4. Run steady, variable-length, coordinated pressure, and asynchronous pressure traces. Apply E18's held-out stress cases.

5. Include cold initialization, lazy optimizer state, calibration, snapshotting, failed attempts, action transitions, diagnostics, and deferral in the end-to-end benchmark.

6. Export memory peaks, accepted samples or valid tokens, accepted updates, median/p95 incident latency, retry amplification, action switches, numerical errors, host-memory use, and terminal outcomes.

7. Require same-process continuity for successful recoverable incidents. Report unsupported fatal-context outcomes separately.

Do not hide fail-fast baseline termination by comparing only its short pre-failure runtime with a completed recovery run. Use a common work target or time horizon and report completion status alongside speed.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer

update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

    return benchmark_report
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires exact logical sample accounting, correct loss normalisation, finite accepted updates, coherent scaler and scheduler progress, bounded retries, and complete state restoration. Compare accepted gradients and parameter updates with a compatible clean reference using declared tolerances. Audit mutable buffers and nested optimizer state, not only model outputs.

Inject failures at transfer, forward, backward, and after partial optimizer mutation. Verify no partial update survives rollback and that cleanup does not delete required model state. Validate terminal no-fit, exhausted host memory, unsupported precision, diagnostic failure, and unrelated-error propagation.

Report all incidents and all overhead. Failed or replayed samples are speculative work, not additional accepted progress. Separate application-margin violations from physical CUDA OOM, and distinguish snapshot scope from total device use. If the integrated runtime loses to a strong static baseline, retain that result and explain why.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A self-recovering runtime is a transaction engine under resource constraints. Its success is accepted training progress with preserved semantics and a clear evidence trail, not the absence of uncaught exceptions alone.

Conclude with the operating envelope actually demonstrated: device, allocator, shapes, objectives, precision policies, pressure bounds, and recovery limits. Explain which errors are handled in process, which result in a checkpointed stop, and which require a fresh CUDA process. Recommend the simplest measured policy that satisfies those requirements.

19.26.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Memory-Aware Scheduling Across Compute, Transfer, Placement, Prefetch, Eviction, and Recovery Decisions

Part 1 - Exercise Contract and Why It Matters

Construct a scheduler model that coordinates the lifetime and movement of data as well as the order of computation. Identify tasks for forward, backward, input transfer, parameter prefetch, activation offload, eviction, and recovery. Deliver a dependency graph, a storage-ownership ledger, and a timeline showing when each resource is required and released.

Use one GPU with eager PyTorch and explicit coarse tasks. The scheduler chooses when supported calls are submitted; it does not preempt arbitrary CUDA kernels or replace autograd's internal scheduling. Begin with immutable inference weights, then add a training case with resident parameters and a clearly defined logical optimizer-update boundary.

Part 2 - System and Memory Mental Model

A task can be dependency-ready but memory-inadmissible, or fit memory while its inputs are still in transfer. Submission, device execution, completion, and storage release are distinct events. A completed forward may leave outputs and saved activations alive for backward. Eviction can require a host allocation and copy before any GPU storage is releasable.

Placement records must identify storage, location, validity, version, owners, pending readers, and transfer completion. A CPU copy is a useful backing store only if it contains the version required by future work. Deleting a Python name does not release storage still owned by a view, autograd graph, optimizer, or another stream.

Separate allocator reservations from application reservations. Allocator-reserved bytes are real memory held by PyTorch; a scheduler reservation is a promise for admitted future work. They cannot be subtracted or added indiscriminately. Likewise, stream ordering protects data dependencies while allocator lifetime tracking protects reuse; neither alone supplies the other.

Recovery is a control transition that stops dependent admission, settles or safely abandons managed work, and restores the supported transaction. It cannot make a fatal CUDA context healthy or guarantee availability against an arbitrary external allocator.

Part 3 - Quantitative Prediction Before Execution

For a set of live storage objects $\mathcal{L}(t)$, count unique storage:

$$M_{\text{live}}(t) = \sum_{s \in \mathcal{L}(t)} \text{bytes}(s).$$

Shared aliases must not appear as independent payloads. Let A_t be materialised live bytes and U_t outstanding commitments for additional bytes not yet materialised. A conservative job policy is

$$A_t + U_t + S_J \leq J_t.$$

As promised storage materialises, reconcile its commitment into actual ownership without counting it twice. A pending eviction contributes no immediate negative demand.

For a toy $J = 8\,\text{GiB}$ and $S_J = 0.5\,\text{GiB}$, suppose $A = 4\,\text{GiB}$ and $U = 1\,\text{GiB}$. Predict admission of a task needing an additional $1.75\,\text{GiB}$. Then suppose a planned eviction promises $1\,\text{GiB}$ but its copy is incomplete: explain why that promise does not change the current answer. Draw the ownership transfer after the copy, last reader, and actual release complete.

Part 4 - Experimental Design and Instrumentation

1. Describe a small workload as a directed acyclic task graph. Include compute that depends on prefetched data and backward that retains forward-produced activations.

2. Annotate each task with required versions, incremental peak, persistent outputs, temporary storage, host demand, and stream.

3. Hand-simulate ready, reserved, submitted, completed, and retired states. Show why completion need not mean all bytes are freed.

4. Implement a serial CUDA reference and compare a proposed schedule against its outputs and, where relevant, gradients.

5. Add one delayed transfer and one bounded memory-budget reduction. Record whether the scheduler waits, changes placement, or defers work.

Use a CPU simulation to explore event order before introducing concurrent CUDA streams. Do not intentionally create a use-after-free on the GPU.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class TaskDescriptor:
    task_id: str
    task_kind: str
    dependency_ids: tuple
    required_storage_versions: tuple
    incremental_peak_bytes: int
    retained_output_bytes: int

@dataclass
class StorageOwnership:
    storage_id: str
    version: int
    location: str
    owner_ids: tuple
    last_use_events: tuple

def build_workload_graph(workload_specification):
    graph = ...
    return graph

def describe_storage_lifetimes(graph):
    ledger = ...
    return ledger

def simulate_admission_and_completion(graph, budgets, event_order):
    timeline = ...
    return timeline
```

```
def compare_with_serial_reference(reference, scheduled_result):
    audit = ...
    return audit

def E00(workload_specification, budgets, event_order):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify graph dependencies, unique-storage accounting, version validity, and release after the last required use. Show a task that fits bytes but must wait for data, and a ready task that must wait for capacity.

Compare serial and scheduled results under declared numerical tolerances. For training, preserve logical sample membership and optimizer update count. Reject timelines that free saved activations after forward completion or credit unfinished eviction as available memory. Label unknown external demand and unsupported execution modes.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Memory-aware scheduling coordinates promises, data readiness, and lifetimes. Explain how this differs from selecting the next operation solely by duration or free-byte snapshots.

Conclude with the scheduler's ownership boundary: which calls, allocations, transfers, and state transitions it controls. Guarantees must be limited to that boundary and the validity of its resource estimates.

19.26.2 Exercise 01

Exercise Title: Define a Runtime Memory State Vector from Free VRAM, Reserved Memory, Active Memory, RAM Usage, Transfer Load, and Pending Work

Part 1 - Exercise Contract and Why It Matters

Design a typed runtime state vector for scheduler decisions. Include GPU live allocation, allocator reservations, global free memory, host-memory availability and usage, scheduler-owned pinned storage, transfer backlog, pending work, logical commitments, and observation age. Deliver a schema, collection adapter, and replayable state trace.

For every field, declare its unit, source, scope, update frequency, and unavailable-state representation. A compact vector is useful only if its entries retain their meaning. Do not combine unrelated measurements into a single unqualified memory-pressure percentage.

Part 2 - System and Memory Mental Model

Allocated tensor bytes and an allocator's active-byte statistic are not interchangeable names. Record them separately when available. Some allocator metrics are backend-specific, so absence

or inapplicability is different from zero. Global free memory reflects the whole device at one instant, while process counters describe a narrower ownership scope.

Process resident RAM and system available RAM answer different questions. Scheduler-owned pinned bytes are usually a subset of host allocations, not an independent amount to add to process RSS. Track managed buffers by ownership and report system observations separately. Avoid claiming exact machine-wide pinned usage from a process-local registry.

Transfer load includes queued and in-flight bytes, direction, measured bandwidth, and completion events. A queue length is not bandwidth, and a copy submission is not completed transfer. Pending work includes dependencies and resource commitments, not just the number of tasks.

The vector is a time-labelled observation, not an atomic GPU snapshot. Use an observation epoch and a ledger version; stale data must be recognised before admission.

Part 3 - Quantitative Prediction Before Execution

One possible state is

$$s_t = (A_t, R_t, F_t, X_t, H_t, P_t, Q_t^{\text{in}}, Q_t^{\text{out}}, U_t, N_t^{\text{ready}}, a_t),$$

where X is a supported active-byte metric, H is host available memory, P managed pinned bytes, Q transfer backlog, U unmaterialised commitments, and a observation age. Keep device identity and validity metadata alongside the vector.

Define job headroom $h_J = J - S_J - A - U$. A conservative device check gives no cache credit and considers $F - S_D - U_{\text{device}}$ for future allocations. Do not subtract allocator-reserved bytes from F again.

For $A = 3\,\text{GiB}$, $R = 4\,\text{GiB}$, $F = 2\,\text{GiB}$, and $U = 0.75\,\text{GiB}$, calculate job and device headroom under explicitly chosen caps and margins. Then mark the transfer-bandwidth estimate unavailable and propose a decision rule that does not interpret it as zero-cost transfer.

Part 4 - Experimental Design and Instrumentation

1. Define the schema and units before implementing probes. Use integer bytes for accounting and seconds for timestamps.

2. Collect CPU-only telemetry from a fixed workload. Record counter sources and supported allocator backend.

3. Maintain pinned-buffer and commitment ledgers explicitly. Compare them with broad host/GPU observations without forcing equalities that their scopes do not justify.

4. Inject missing metrics, stale timestamps, a changed budget epoch, and transfer completion arriving between reads.

5. Replay stored vectors through a simple admission policy and verify deterministic decisions for identical inputs.

Measure collection overhead at several sampling frequencies. Choose a lightweight boundary sampler before adding expensive continuous profiling.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate

measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class RuntimeState:
    device_identity: str
    observation_epoch: int
    timestamp_seconds: float
    allocated_bytes: object
    reserved_bytes: object
    active_bytes: object
    global_free_bytes: object
    host_available_bytes: object
    managed_pinned_bytes: int
    pending_transfer_bytes: dict
    unmaterialised_commitment_bytes: int
    ready_task_ids: tuple
    unavailable_fields: tuple

def collect_gpu_observations(device, capabilities):
    observations = ...
    return observations

def collect_host_observations(host_probe, ownership_registry):
    observations = ...
    return observations

def reconcile_pending_work(task_registry, transfer_registry):
    pending_state = ...
    return pending_state

def validate_state_freshness(state, budget_epoch, policy):
    verdict = ...
    return verdict

def E01(runtime, sampling_policy):
```

```
state_trace = ...
return state_trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Check units, device identity, timestamps, ledger version, and explicit missing fields. Test stale state and backend-specific unsupported statistics. A negative derived headroom must remain visible rather than being silently clipped and treated as valid capacity.

Compare repeated collection on an idle controlled workload and explain variation. Ensure collection creates no persistent GPU tensors and does not count pinned RAM twice. Verify pending transfers leave the backlog only under the declared completion condition.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The state vector is an interface between uncertain measurements and decisions. Explain which fields are authoritative scheduler records and which are external observations.

Recommend a sampling and freshness policy that matches task duration and disturbance speed. More frequent collection is useful only if it improves decisions enough to justify its overhead.

19.26.3 Exercise 02

Exercise Title: Build a PyTorch Scheduler That Selects the Next Executable Operation Only When Its Estimated Memory Requirement Fits the Current Budget

Part 1 - Exercise Contract and Why It Matters

Implement a serial admission scheduler that selects dependency-ready tasks only when their estimated additional peak fits the current GPU and host budgets. Use one compute stream initially. Deliver admission decisions, refusal reasons, completion records, and a comparison with an unrestricted serial reference.

Distinguish a task that must wait for an existing completion from one that can never fit under the current policy. Provide bounded waiting, no-fit detection, and an explicit outcome for an empty ready queue caused by a dependency error.

Part 2 - System and Memory Mental Model

Task memory must describe additional demand above the currently materialised state. A profiled absolute peak often includes parameters already resident; adding it to the live baseline double-counts them. Conversely, profiling forward alone misses later backward or optimizer requirements if the task contract includes those phases.

Admission is a compound predicate: prerequisites are valid and ready, the resource estimate is compatible with the shape and policy, budgets permit the reservation, and execution is supported. Memory fit cannot justify reading incomplete data or a stale parameter version.

The serial baseline has at most one active task but may retain outputs from earlier tasks. Release temporary storage only after completion; keep persistent outputs in the ownership ledger. A task's completion does not reset live memory to the starting baseline automatically.

Part 3 - Quantitative Prediction Before Execution

For candidate i, let d_i be an upper estimate of additional peak above the current state and u_i an uncertainty allowance if not already included. Require

$$A_t + U_t + d_i + u_i + S_J \le J_t, \qquad d_i + u_i + S_D \le F_t - U_{\text{device},t}.$$

The second inequality is a conservative no-cache-credit policy. Apply a corresponding host-memory check when tasks allocate RAM. Choose one uncertainty convention and avoid charging it twice.

Let the usable additional job budget be 1.5 GiB. Three ready tasks require 0.6, 1.2, and 1.8 GiB including uncertainty. Predict admissible tasks. Then suppose the first task retains a 0.4 GiB output: recompute the next admission rather than restoring the full initial headroom.

Write a manual schedule with one memory wait, one dependency wait, and one irreducible no-fit.

Part 4 - Experimental Design and Instrumentation

1. Define simple tensor tasks with known inputs, outputs, and temporary storage. Assign a fixed application cap below physical VRAM.
2. Build a CPU admission simulator and hand-check the proposed schedule before CUDA execution.
3. Execute one task at a time, recording baseline, region peak, completion, and retained outputs. Reconcile the ledger at each boundary.
4. Compare predicted and observed increments. Refuse incompatible profiles rather than silently using an old shape estimate.
5. Introduce a budget reduction before admission, then a controlled change during execution to expose the limit of preflight checks.

Use DMM23's narrow OOM routing if estimates fail. Recovery is a separate path, not evidence that admission was correct.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class AdmissionDecision:
    task_id: str
    admitted: bool
    reason: str
    incremental_upper_bytes: int
    observation_epoch: int

def identify_ready_tasks(graph, completed_tasks, storage_registry):
    ready_tasks = ...
    return ready_tasks

def estimate_additional_demand(task, runtime_state, profiles):
    estimate = ...
    return estimate

def evaluate_task_admission(task, state, estimate, budgets):
    decision = ...
    return decision

def execute_serial_task(task, runtime):
    completion_record = ...
    return completion_record

def reconcile_retained_outputs(completion_record, ledger):
    updated_ledger = ...
    return updated_ledger

def E02(runtime, task_graph, budgets):
    schedule_report = ...
    return schedule_report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify each admitted task was ready, used the intended data version, and respected the predicted budget. Audit observed peaks separately: a completed task can violate the application cap without CUDA OOM.

Test a task exactly at the margin, a task below physical capacity but above the application cap, retained outputs, no-fit, and a dependency cycle. Require numerical agreement with the serial reference and explicit failure reasons rather than an indefinite idle loop.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Admission converts an estimate into a controlled commitment. Explain the distinction between a prediction-respecting schedule and a proven physical-memory bound.

State where inaccurate demand, stale availability, or allocations outside the scheduler can invalidate the decision. This serial baseline provides the correctness reference for later concurrent policies.

19.26.4 Exercise 03

Exercise Title: Assign Memory Costs to Forward, Backward, Transfer, Prefetch, and Eviction Tasks and Compare Estimated Costs Against Real Measurements

Part 1 - Exercise Contract and Why It Matters

Build task-level resource profiles for forward, backward, H2D/D2H transfer, prefetch, and eviction. Describe resource lifetimes rather than assigning only one unsigned memory number to each task. Deliver calibrated profiles, held-out prediction errors, and an explanation of how profiles compose in a schedule.

Use fixed shapes and policies first, then validate at unseen compatible sizes. Keep GPU persistent state, host staging, retained outputs, temporary workspace, transfer bytes, and release conditions separate.

Part 2 - System and Memory Mental Model

Forward can produce activations retained until backward. Backward consumes those activations, creates or accumulates gradients, and uses temporary workspaces. Transfer often requires source and destination to coexist. Prefetch creates future residency before consumption. Eviction is a protocol that may allocate host storage and copy data before a GPU release becomes possible.

A transfer's logical direction does not imply the immediate sign of its GPU memory effect. H2D creates a destination; D2H leaves the source live until copy completion and all readers finish. Shared storage and aliases can prevent an anticipated release. Represent release as a completion-conditioned event, not negative admission cost.

Isolated task peaks do not automatically compose. Absolute profiles can repeat the same resident baseline, while concurrent tasks can overlap temporaries or share buffers. Calibrate incremental profiles and preserve storage identity. Profile diagnostic runs separately from timing runs because instrumentation may change execution.

Part 3 - Quantitative Prediction Before Execution

Represent task cost by a structured tuple

$$c_i = (d_i^{\mathrm{GPU}}, d_i^{\mathrm{host}}, p_i^{\mathrm{retained}}, r_i^{\mathrm{conditional}}, v_i^{\mathrm{H2D}}, v_i^{\mathrm{D2H}}, t_i).$$

Here d denotes peak additional demand, p retained output bytes, r a release eligible only after its guards, v transfer payload, and t measured duration. Do not add retained bytes again if they are already inside peak demand during the task.

For a 256 MiB activation offload, predict peak host demand, source GPU lifetime, transfer volume, and earliest GPU release. If a live alias remains, predict the realised release. For a forward that peaks at 3.5 GiB from a 2 GiB baseline and ends at 2.6 GiB, compute incremental peak and retained growth.

Use signed residual $e_i = M_i^{\text{observed}} - M_i^{\text{predicted}}$ and analyse positive residuals explicitly because they threaten admission safety.

Part 4 - Experimental Design and Instrumentation

1. Specify each task's region, storage inputs, created outputs, owners, and guards for completion and release.
2. Measure fixed-shape tasks in controlled runs with identical initial model and optimizer state where applicable.
3. Collect GPU peak, post-task live bytes, host demand, transferred bytes, and duration. Record cold and warmed behaviour separately.
4. Fit profiles on a calibration subset and test held-out sizes or lengths. Retain uncertainty and unsupported-domain information.
5. Compose two tasks serially, then a permitted overlapping pair. Compare union-of-lifetimes prediction against observed peak.
6. Add a retained-alias control for eviction and a workspace-spike control for compute.

Use supported stream events and host readiness checks for transfer timing; a nonblocking submission time is not transfer duration.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class TaskCostProfile:
    task_kind: str
    shape_key: str
    additional_gpu_peak_bytes: int
    additional_host_peak_bytes: int
    retained_output_bytes: int
    conditional_release_bytes: int
```

```
    h2d_bytes: int
    d2h_bytes: int
    duration_seconds: float
    release_guards: tuple

def measure_task_region(task, controlled_state, instrumentation):
    measurements = ...
    return measurements

def build_incremental_profile(task, measurements):
    profile = ...
    return profile

def predict_composed_lifetimes(tasks, profiles, storage_registry):
    prediction = ...
    return prediction

def evaluate_held_out_costs(profiles, held_out_measurements):
    errors = ...
    return errors

def E03(runtime, task_specifications, shape_grid):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify no baseline is counted twice and no release is credited before all its guards. Check that transferred bytes agree with the intended unique payload, while allocator rounding and metadata are reported separately.

Require finite outputs and gradient agreement for compute tasks. For transfers, verify content after proper completion; for eviction, verify the backing version and actual GPU release. Preserve failed predictions and explain whether shape, aliasing, workspace, or overlap caused the residual.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A resource profile is a description of demand over time. Explain which fields the scheduler needs for admission, which for placement, and which for evaluating future cost.

Choose the smallest profile family that predicts held-out schedules well enough. A compact but honest model is preferable to a single precise-looking peak number that hides lifetimes and retained outputs.

19.26.5 Exercise 04

Exercise Title: Implement a First-Fit Memory Scheduler That Admits Operations According to Available VRAM and Observe Its Utilization Inefficiencies

Part 1 - Exercise Contract and Why It Matters

Implement a queue-first feasible policy: scan dependency-ready tasks in a fixed order and select the first one whose resource contract fits. Name this application scheduling rule explicitly so it is not confused with the CUDA allocator's block-placement algorithm. Deliver a deterministic trace and counterexamples showing unused capacity, critical-path delay, or starvation.

Use a CPU discrete-event model to examine overlapping admitted work, then validate a serial CUDA implementation with the same task costs and dependencies. Real concurrent GPU execution is added in E12; simulation results must not be labelled measured CUDA utilisation.

Part 2 - System and Memory Mental Model

Queue order is a policy choice. Scanning beyond an oversized head avoids one form of head-of-line blocking, but small later tasks can delay a large task repeatedly. Selecting the earliest fitting item also ignores duration, downstream dependencies, retained outputs, and future releases.

Empty capacity is not necessarily inefficiency. A task may be dependency-blocked, resources may be reserved for admitted work, or the remaining capacity may be too small for any safe candidate. Compare against a feasible alternative schedule, not an impossible ideal that fills every byte.

Tasks need not relinquish all memory at completion. Retained outputs can reduce the next task's admissible space. Reserve demand before submission in the simulation and reconcile actual ownership at completion in CUDA. Unused reservations and live output storage are different reasons for apparent headroom loss.

Part 3 - Quantitative Prediction Before Execution

With ready queue $\mathcal{Q}_t$ and incremental upper demand d_i, select the earliest i satisfying the complete admission predicate. Memory fit alone can be expressed as $d_i \leq h_t$ only after headroom h_t has included margins and outstanding commitments.

Consider 10 abstract memory units and ready tasks with (d_i, t_i) equal to $(6, 8)$, $(5, 1)$, and $(4, 1)$, with units and seconds respectively. Compare fixed queue orders in a nonpreemptive discrete-event simulation. Declare which tasks may overlap and release all storage at completion for this toy case. Then add a downstream task dependent on the second item and predict how queue order changes makespan.

Measure memory slack area

$$I_M = \int_0^T \Big(J - S - M_{\text{committed}}(t) \Big)\, dt$$

in byte-seconds, together with makespan and useful completed work. Low slack is not itself evidence of high compute efficiency.

Part 4 - Experimental Design and Instrumentation

1. Implement a pure ready-queue selector with stable ordering and an explicit tie rule. Hand-check admission on a small task set.

2. Simulate arrivals, dependencies, completion events, and retained outputs. Compare at least three queue orders.

3. Construct one large-task starvation case and one case where first-fit performs as well as a more expensive policy.

4. Run serial CUDA tasks from controlled initial states and compare measured costs with the simulation inputs.

5. Record queue wait, admission refusals, memory slack, critical-path delay, and accepted throughput.

Bound queue waiting and report impossible-to-fit tasks. Do not classify every wait as a scheduler bug when no legal alternative exists.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class QueueEntry:
    task_id: str
    arrival_order: int
    ready_since: object
    additional_peak_bytes: int
    retained_bytes: int

def select_first_feasible(ready_queue, state, admission_policy):
    selection = ...
    return selection

def advance_simulated_completions(simulation_state, event_queue):
    next_state = ...
    return next_state

def simulate_first_fit(task_graph, queue_order, resource_limits):
    trace = ...
```

```
    return trace

def execute_serial_first_fit(runtime, graph, queue_order, limits):
    measurements = ...
    return measurements

def compare_queue_orders(traces, reference_work):
    comparison = ...
    return comparison

def E04(runtime, task_graph, queue_orders, limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that only ready, fitting tasks are selected and that the earliest feasible task is chosen under the declared ordering. Test an empty queue, all tasks blocked, a too-large task, and retained outputs that change later feasibility.

Require identical completed task sets and numerical outputs across policy comparisons. Report starvation separately from valid no-fit. Distinguish measured CUDA times from simulated overlap, and compare memory slack alongside makespan rather than treating fuller memory as an automatic performance improvement.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

First-fit is a transparent baseline with low decision overhead. Explain which workload properties make its simplicity valuable and which expose its lack of duration or dependency awareness.

Use the counterexample to motivate the next policy while preserving the cases where first-fit remains competitive. More scheduling logic must earn its cost through measured improvement.

19.26.6 Exercise 05

Exercise Title: Implement a Best-Fit Scheduler That Chooses Workloads Based on Remaining VRAM After Admission and Compare Fragmentation Behavior

Part 1 - Exercise Contract and Why It Matters

Implement an application best-fit policy that chooses the ready admissible task leaving the least predicted headroom after admission. Compare it with E04 using the same dependencies, arrivals, costs, and budgets. Deliver schedules, queue delays, memory slack, and an allocator-behaviour study with appropriate controls.

Define best-fit as task selection, not physical allocation placement. The scheduler does not control exact CUDA block addresses. A smaller residual application budget is not proof of reduced allocator fragmentation.

Part 2 - System and Memory Mental Model

Best-fit can pack current capacity tightly but ignore future releases or critical dependencies. A large low-priority task may occupy memory for a long time and delay several short useful tasks. Retained outputs can make a locally efficient choice globally expensive.

Task ordering changes allocation history and may influence allocator reuse, but backend behaviour, size classes, stream activity, and live aliases also matter. High reserved memory alone does not establish fragmentation. Compare current/peak live bytes, supported inactive split metrics, and block-history evidence where available.

Use fresh-process controls to separate policy effects from history carried over between experiments. Keep allocator configuration unchanged. If both task policies produce indistinguishable allocator behaviour, report that instead of attributing a hypothetical benefit to the word best-fit.

Part 3 - Quantitative Prediction Before Execution

For feasible ready set $\mathcal{F}_t$, define

$$i^* = \arg\min_{i \in \mathcal{F}_t} (h_t - d_i).$$

Declare tie-breaking by arrival order or another fixed rule. Host capacity and dependencies remain constraints even if GPU residual is the ranking criterion.

With $h_t = 10$ units, candidate demands $3, 7, 9$ and durations $1, 2, 20$ seconds, predict the selected item. Construct a dependency where choosing the nine-unit task delays the critical path. Compare makespan with first-fit under a specified order.

Define allocator reservation overhead $R - A$ as a descriptive quantity, not a fragmentation score. For native-backend inactive split bytes I, explain the limited meaning of I/R and why it cannot be compared blindly across backends. Predict which measurements would support an actual reuse advantage.

Part 4 - Experimental Design and Instrumentation

1. Test the selector on CPU for ties, no feasible task, and host-inadmissible candidates that otherwise fit GPU memory.

2. Replay identical synthetic task graphs under first-fit and best-fit. Include short and long tasks with retained outputs.

3. Execute fixed-shape CUDA allocation/compute workloads in fresh workers under each ordering, with repeated seeds.

4. Record live and reserved baselines, peaks, supported allocator statistics, and reuse behaviour after completion.

5. Add a controlled mixed-size allocation history and compare fresh-worker versus continued-process outcomes.

Treat allocator diagnostics as separate runs when their overhead would distort timing. Preserve explicit backend metadata.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class CandidateResidual:
    task_id: str
    remaining_gpu_bytes: int
    arrival_order: int
    admissible: bool

def calculate_candidate_residuals(ready_tasks, state, policy):
    residuals = ...
    return residuals

def select_best_fit(residuals, tie_policy):
    task_id = ...
    return task_id

def measure_allocator_history(runtime, ordered_tasks, diagnostics):
    evidence = ...
    return evidence

def compare_slack_and_fragmentation(first_fit, best_fit, backend):
    # Keep application slack distinct from allocator evidence.
    comparison = ...
    return comparison

def E05(runtime_factory, task_graphs, budgets):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify minimum residual among all actually feasible candidates, stable tie-breaking, and preserved dependency order. Check complete work and numerical equivalence before comparing performance.

Do not claim reduced fragmentation from lower slack or lower reserved memory alone. Require matched histories and backend-valid evidence. Report queue starvation, critical-path delays, and decision overhead even if best-fit fills memory more densely.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Best-fit optimises a local packing criterion. Explain whether that criterion aligned with useful progress in the measured workload.

Recommend it only where its capacity use outweighs duration and dependency costs. State any allocator conclusions separately and limit them to the observed backend and allocation history.

19.26.7 Exercise 06

Exercise Title: Build a Priority Scheduler That Favors Compute Tasks over Prefetch and Eviction When GPU Execution Would Otherwise Stall

Part 1 - Exercise Contract and Why It Matters

Build a priority policy that keeps useful compute supplied without starving the transfers and evictions needed to make that compute ready. Compare it with first-fit and strict compute-first ordering. Deliver priority reasons, stall attribution, fairness metrics, and accepted useful throughput.

Define eligible compute as dependency-ready and memory-admissible. A task with missing parameters is not ready compute merely because its task type says forward. A prerequisite transfer or capacity- releasing eviction may need temporary priority promotion.

Part 2 - System and Memory Mental Model

Task type alone is insufficient for priority. A speculative prefetch for distant work can wait, while a transfer that unblocks the next critical compute is urgent. Similarly, unnecessary eviction can waste bandwidth, but an eligible eviction may be required before any compute can fit.

Use critical-path information or estimated time-to-use to distinguish urgent prerequisites from optional lookahead. Propagate urgency to their dependency chain. Add aging or bounded waiting so lower-ranked tasks cannot be postponed indefinitely by a steady stream of compute.

CUDA kernels already running are not made preemptible by a Python priority queue. The scheduler controls future submissions and stream dependencies. Stream priority is a separate device feature, not a guarantee that a submitted high-priority task immediately interrupts all other activity.

Part 3 - Quantitative Prediction Before Execution

Define an illustrative ranking tuple with hard eligibility first, then critical-path class, deadline slack, and waiting age. For a task with expected time-to-use D_i and prerequisite service time T_i, slack is

$$s_i = D_i - T_i.$$

Negative slack predicts exposure to a stall unless another task can cover it. Units must be seconds, not a mixture of bytes and arbitrary priorities.

Construct a trace with ready compute lasting 4 ms, a required parameter transfer lasting 3 ms, and a speculative transfer lasting 8 ms. Predict schedules under strict compute-first and urgency-aware priority. Then add an eviction required for the compute destination. Explain why its priority must change despite its task type.

Measure dependency-induced idle time and memory-induced idle time separately. A lower idle interval is valuable only if accepted work and correctness remain unchanged.

Part 4 - Experimental Design and Instrumentation

1. Annotate a small task graph with critical successors and estimated durations. Hand-label urgent versus speculative movement.

2. Replay first-fit, compute-first, and dependency-aware priority in a discrete-event simulator with the same resource constraints.

3. Add continuous compute arrivals to test transfer starvation, then add aging or a maximum waiting rule.

4. Validate one CUDA schedule against a serial reference. Measure complete wall time and task intervals rather than enqueue times alone.

5. Attribute stalls to missing data, capacity, dependency, or host scheduling overhead using recorded evidence.

Do not use a sampled GPU-busy percentage as the sole objective. Report completed useful tasks, samples, or tokens per second.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class TaskPriorityEvidence:
    task_id: str
    critical_successor: object
    predicted_slack_seconds: object
    waiting_seconds: float
    urgency_class: str

def identify_compute_blockers(graph, ready_state, memory_state):
    blockers = ...
    return blockers

def propagate_dependency_urgency(graph, blockers, duration_profiles):
    urgency = ...
    return urgency

def rank_eligible_tasks(tasks, urgency, fairness_policy):
    ranking = ...
    return ranking

def attribute_compute_stalls(event_trace):
    stall_report = ...
    return stall_report

def E06(runtime, task_graph, priority_policies):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that a prerequisite can outrank speculative work and that priority never bypasses dependency or memory checks. Test a graph where only eviction can create progress.

Require bounded waiting or an explicit no-fit/dependency error. Compare outputs and accepted task counts across policies. Report whether reduced compute stalls increased transfer traffic, decision overhead, or long-task waiting time.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Favouring compute means protecting its supply chain, not always selecting compute-labelled tasks first. Explain how dependency urgency changed the effective priorities.

Recommend the least complex priority scheme that reduces measured critical stalls while preserving fairness and bounded resource use.

19.26.8 Exercise 07

Exercise Title: Add Dependency Tracking So Memory-Safe Operations Cannot Execute Before Their Required Parameters, Inputs, or Activations Are Ready

Part 1 - Exercise Contract and Why It Matters

Implement dependency and data-version tracking alongside memory admission. A task must not execute until required inputs, parameters, activations, and transfers are valid for its version. Deliver a task DAG, storage-readiness registry, event trace, and tests for missing, cyclic, stale, and failed dependencies.

Distinguish host submission readiness from actual device start readiness. A consumer can sometimes be enqueued with an explicit stream wait before its producer completes, but it must not execute its read before the producer's completion event.

Part 2 - System and Memory Mental Model

Logical dependencies state what data or prior update is required. CUDA events and stream waits implement execution ordering. Tensor ownership and allocator lifetime tracking ensure the storage remains valid through the consumer's use. These are three separate responsibilities.

Parameter and activation identities require versions. A cached parameter copy from an earlier optimizer update may have the right shape and enough allocated bytes but still be semantically wrong. A failed producer must not mark its outputs valid or release dependent tasks for execution.

Completion of a transfer makes its destination ready only after the relevant event. For asynchronous D2H, CPU consumers also need completion before reading the destination. Enqueuing a wait on a GPU stream does not by itself make data ready for immediate host access.

Part 3 - Quantitative Prediction Before Execution

For task i with predecessor set $\mathrm{pred}(i)$, logical readiness requires valid outputs of all predecessors. In a duration model,

$$t_i^{\mathrm{start}} \geq \max_{j \in \mathrm{pred}(i)} t_j^{\mathrm{complete}}.$$

Resource limits may delay it further. Submission can precede this start when a correct stream dependency is installed.

For parameter prefetch taking 3 ms, input transfer taking 2 ms, and forward taking 5 ms, predict the earliest forward start if both transfers can begin at time zero on permitted engines. Then impose a shared serial copy resource and recompute the bound. Do not assume two named streams imply two independent copy engines.

Represent storage readiness as $(\mathrm{id}, \mathrm{version}, \mathrm{location}, \mathrm{event})$. Give a counterexample where all byte checks pass but the version or event does not satisfy the consumer.

Part 4 - Experimental Design and Instrumentation

1. Validate a DAG on CPU, including cycle detection, unknown predecessors, and stable task identities.

2. Track produced versions and consumer requirements separately from physical buffer addresses.

3. Simulate delayed and failed producers. Verify their consumers remain blocked or receive a propagated failure outcome.

4. Implement CUDA events for supported producer-consumer edges. Compare a fully synchronised reference with explicit stream waits.

5. Add an asynchronous D2H result and require host readiness before content validation.

Test unsafe-ordering logic in simulation; do not rely on repeated racy GPU executions to establish a safe dependency implementation.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class DataRequirement:
    storage_id: str
    required_version: int
    required_location: str

@dataclass
class ProducerRecord:
    task_id: str
    output_versions: tuple
    completion_event: object
    outcome: str

def validate_dependency_graph(task_graph):
    validation = ...
    return validation

def check_required_versions(task, storage_registry):
    verdict = ...
    return verdict

def install_consumer_waits(task, producer_records, target_stream):
    # Establish execution ordering before consumer reads.
    wait_record = ...
```

```
    return wait_record

def publish_successful_outputs(task, completion, storage_registry):
    updated_registry = ...
    return updated_registry

def propagate_producer_failure(task_graph, failed_task):
    affected_tasks = ...
    return affected_tasks

def E07(runtime, task_graph, delayed_producers):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check every consumer's required version and actual start ordering. Verify no output is published from a failed producer. Test missing dependencies, cycles, duplicate completion notifications, and a parameter update invalidating a prefetched old version.

Compare serial and scheduled numerical outputs. Distinguish event completion evidence from host enqueue timestamps. Verify storage remains alive through all consumers, including side-stream users. Memory fit without these properties is not correct scheduling.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Dependency tracking turns a collection of individually safe tasks into a correct execution graph. Explain where host readiness, device ordering, and storage lifetime differ.

State how the registry handles version changes and failures so future placement and prefetch decisions cannot accidentally resurrect stale data.

19.26.9 Exercise 08

Exercise Title: Build a Scheduler That Chooses Between Waiting for Free VRAM and Evicting Existing Tensors Based on Estimated Stall Cost

Part 1 - Exercise Contract and Why It Matters

Implement a decision between waiting for a known release and evicting eligible resident data to admit blocked work. Compare estimated time to useful compute under both choices. Deliver a release forecast, victim eligibility evidence, selected action, and measured counterfactual cost in controlled replay.

Waiting must be bounded and tied to an event that can actually progress. Eviction must preserve a valid backing version or a supported recomputation path. Do not treat deleting arbitrary autograd tensors as a valid eviction operation.

Part 2 - System and Memory Mental Model

A pending task may release storage soon, making waiting cheaper than a copy out followed by a copy back. Conversely, waiting for an uncertain external process can stall indefinitely while an eligible local victim could enable progress.

Estimate release time from known completion events and lifetimes, not just task duration. A task may complete but leave an output needed later. An eviction may need pinned host staging, copy bandwidth, a valid destination, and completion of all GPU readers before releasing storage. Account for its transient peak.

Resource deadlock is possible even with an acyclic data graph: blocked tasks hold memory needed by the operations that would release it. Identify circular resource waits and no-fit states. Reserve enough control resources for a permitted recovery or offload action when the design requires them.

Part 3 - Quantitative Prediction Before Execution

Let T_w be time until sufficient confirmed release for the blocked task. Let T_e include victim readiness, required copying, and actual release. Add expected future reload cost T_r and contention cost T_c when comparing eviction:

$$C_{\text{wait}} = \widehat{T}_w, \qquad C_{\text{evict}} = \widehat{T}_e + p_{\text{reuse}}\widehat{T}_r + \widehat{T}_c.$$

These are modelled incremental costs; overlapping components must not be summed twice. State the horizon and uncertainty.

For a known release in 4 ms versus eviction requiring 2 ms outbound and 3 ms expected reload with reuse probability 0.8, compare the simple costs before adding contention. Recompute when the waiting event cannot progress until the blocked task executes. Explain why this is a deadlock issue rather than a larger finite wait estimate.

Predict the decision when host staging cannot be allocated.

Part 4 - Experimental Design and Instrumentation

1. Build a controlled graph with a blocked compute task, one independently progressing release, and one reloadable immutable victim.

2. Measure release and transfer costs separately, then freeze the prediction before choosing an action.

3. Replay the incident with waiting and eviction from identical states to estimate the counterfactual cost.

4. Vary time-to-release, victim size, reuse distance, and transfer contention one factor at a time.

5. Add a resource-wait cycle and an unknown external release. Require cycle detection or bounded deferral with an explicit reason.

Verify content and version after reload. For training, only use eviction mechanisms already proven compatible with the logical update contract.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate

measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ReleaseForecast:
    storage_id: str
    eligible_release_bytes: int
    completion_event: object
    estimated_seconds: object
    independent_progress: bool

def forecast_confirmable_releases(runtime, blocked_task):
    forecasts = ...
    return forecasts

def estimate_eviction_path(victim, resources, transfer_profile):
    estimate = ...
    return estimate

def detect_resource_wait_cycle(task_graph, ownership_registry):
    cycle_report = ...
    return cycle_report

def choose_wait_or_evict(wait_forecasts, eviction_options, policy):
    decision = ...
    return decision

def compare_counterfactual_replays(runtime_factory, incident):
    comparison = ...
    return comparison

def E08(runtime, blocked_tasks, decision_policy):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that predicted releases are not credited before completion and last use. Verify a waited-for event can progress independently of the blocked task. Test unknown completion time, insufficient host staging, no eligible victim, and resource deadlock.

Require numerical correctness after any reload and exact victim version identity. Compare predicted and observed stalls including future reload. A fast immediate eviction can still lose over the declared horizon.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Waiting and eviction are alternative investments in future progress. Explain which uncertainty dominated the decision and how a shorter horizon can change the preferred action.

Recommend a bounded policy with a clear fallback when neither choice can make progress. An honest no-fit result is preferable to an unbounded wait disguised as scheduling.

19.26.10 Exercise 09

Exercise Title: Schedule Parameter Prefetch Early Enough to Hide Transfer Latency Without Consuming VRAM Too Far Ahead of Use

Part 1 - Exercise Contract and Why It Matters

Build just-in-time parameter prefetch for a sequential inference workload whose immutable layer weights have CPU backing. Choose launch lead time from measured transfer duration and expected compute time-to-use. Deliver a timeline, exposed transfer stalls, prefetched residency, and output agreement with a fully resident reference.

Use fixed-version inference parameters first so placement can change without altering autograd or optimizer bindings. A training extension must separately preserve parameter identity, version, gradient flow, and backward requirements. Replacing an nn.Parameter with a detached CPU/GPU copy is not a valid training offload scheme.

Part 2 - System and Memory Mental Model

Prefetch hides latency only when transfer can overlap independent compute and complete before the consumer. Pinned source buffers, appropriate streams, available copy resources, and real workload independence matter. A nonblocking API return does not demonstrate overlap.

The destination consumes GPU storage before first use and may remain necessary through later consumers. CPU pinned sources must stay valid and unmodified until transfer completion. Consumer execution needs a dependency wait, while destination storage must remain protected until all its stream uses finish.

Forecast time-to-use can change with shape, batch, compute contention, and scheduler decisions. Prefetching too far ahead increases residency and can crowd out active computation. Use bounded lookahead and preserve the required parameter version. Do not refill a buffer while a previous consumer still reads it.

Part 3 - Quantitative Prediction Before Execution

For payload q_i, measured effective bandwidth v_i, and setup/queue delay a_i,

$$\widehat{T}_i^{\text{copy}} = a_i + q_i/v_i.$$

If predicted use is at t_i^{use}, target launch near $t_i^{\text{use}} - \widehat{T}_i^{\text{copy}} - \delta_i$, subject to resource admission and nonnegative available lead time. δ_i is an uncertainty allowance, not free capacity.

For a 64 MiB layer and measured 12 GiB/s transfer rate, estimate copy duration before setup overhead. Compare lead opportunities from one 3 ms compute block versus two such blocks.

Measure early residency cost as

$$C_{\text{residency}} = \sum_i q_i \max(0, t_i^{\text{first use}} - t_i^{\text{destination allocation}}).$$

Use actual allocation time, since memory may be consumed before the copy finishes. Predict how deeper lookahead changes this cost.

Part 4 - Experimental Design and Instrumentation

1. Create CPU-backed immutable layer weights and a fully resident reference model. Assign explicit version IDs.
2. Measure copy and compute durations across representative sizes. Separate pinned-buffer preparation from transfer time.
3. Compare demand loading, one-layer lookahead, and time-to-use-based prefetch under the same GPU budget.
4. Track destination allocation, copy start/completion, consumer start, and final storage release.
5. Vary compute duration and bandwidth contention, then measure late arrivals and unnecessarily early residency.
6. Check a bounded GPU buffer pool whose reuse waits for all required consumers.

Use event traces to establish overlap and retain the serial reference for numerical validation.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ParameterPrefetch:
    layer_id: str
    parameter_version: int
    payload_bytes: int
    predicted_use_seconds: float
    copy_duration_seconds: float
    destination_buffer_id: object

def estimate_parameter_use_times(layer_graph, compute_profiles):
    use_times = ...
    return use_times

def select_prefetch_launches(candidates, state, lookahead_policy):
    launches = ...
    return launches

def submit_versioned_parameter_copy(candidate, transfer_stream):
    transfer_record = ...
    return transfer_record

def bind_ready_inference_weights(layer, transfer_record, stream):
    # Preserve immutable-version and consumer-ordering contracts.
    binding = ...
    return binding

def audit_prefetch_lifetimes(event_trace, buffer_registry):
    audit = ...
    return audit

def E09(inference_workload, transfer_profiles, budgets):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require reference-equivalent outputs, correct layer/version selection, and complete transfers before consumer reads. Verify source pin-buffer lifetime and destination protection. Do not infer correctness from the absence of CUDA errors.

Measure exposed stalls, copy overlap, peak GPU and pinned host bytes, residency byte-seconds, and end-to-end latency. Check delayed copies, variable compute duration, and a full destination pool. A deeper prefetch queue is not automatically a performance improvement.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an

explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Good prefetch arrives early enough to be useful and late enough to avoid unnecessary residency. Explain the measured lead-time window and its sensitivity to changing workload speed.

State the inference-only parameter-placement boundary and what additional machinery a training implementation would require. This prevents a scheduling optimisation from silently breaking gradient or optimizer semantics.

19.26.11 Exercise 10

Exercise Title: Detect Over-Prefetching and Dynamically Delay Future Transfers When Prefetched Data Begins Crowding Out Active Compute Memory

Part 1 - Exercise Contract and Why It Matters

Detect when prefetched residency and pending destination commitments consume capacity needed by near-term compute. Add a bounded prefetch controller that delays future submissions while preserving already required transfers. Compare fixed lookahead with dynamic throttling under variable compute speed and budgets.

Deliver a prefetch-residency trace, reasons for delayed transfers, compute-admission stalls, and net throughput. Keep submitted copies distinct from unsent proposals: ordinary queued CUDA work cannot be assumed safely cancellable.

Part 2 - System and Memory Mental Model

Over-prefetching is a relationship between future residency and current demand, not merely a large queue length. A few large unused destinations can be more harmful than many small transfers already near consumption. Combine bytes, time-to-use, and compute's projected peak.

Track materialised unused destinations separately from unmaterialised copy commitments so their costs are not counted twice. A transfer submitted but not completed still needs source and destination lifetime protection. Marking it obsolete does not make its memory instantly releasable.

Throttle work that has not yet been submitted. If already submitted data becomes unnecessary, wait for safe completion and last-use conditions before retiring it. Keep urgency for the next compute prerequisite so throttling does not create the very stall it is intended to avoid.

Part 3 - Quantitative Prediction Before Execution

Let P_t be live prefetched bytes not yet consumed, U_t^P their unmaterialised commitments, and C_t the conservative additional requirement of near-term compute. A policy may require

$$A_t + U_t + C_t + S_J \leq J_t$$

before accepting discretionary prefetch, with each term reconciled to avoid overlap. Also impose a configurable prefetch-residency limit.

For a usable cap of 6 GiB, live baseline 3 GiB including 1 GiB of unused prefetch, outstanding commitments of 0.5 GiB, and imminent compute demand of 2 GiB, decide whether an extra 0.75 GiB prefetch can be admitted. Do not add P_t again when it is already inside A_t.

Measure wasted transfer fraction as bytes evicted or invalidated before any valid use divided by completed prefetched bytes, with an explicit zero-denominator rule.

Part 4 - Experimental Design and Instrumentation

1. Use E09's versioned workload and a fixed lookahead baseline. Create a trace where compute slows and prefetched residency grows.
2. Record live unused bytes, future commitments, time-to-use, compute demand, and transfer urgency at each decision.
3. Add throttle/release thresholds and bounded pending work. Delay only unsent discretionary transfers.
4. Introduce a budget drop after some copies are submitted. Track them to safe completion instead of assuming cancellation.
5. Compare stalls, memory peaks, unused residency, wasted transfer volume, and accepted useful throughput.

Include one workload where generous prefetch remains beneficial so the controller is not tuned to suppress every transfer.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PrefetchPressure:
    live_unused_bytes: int
    unmaterialised_bytes: int
    imminent_compute_bytes: int
    earliest_use_seconds: object
    submitted_transfer_ids: tuple

def classify_prefetch_pressure(registry, compute_forecast, state):
    pressure = ...
```

```
    return pressure

def select_unsent_transfers_to_delay(queue, pressure, policy):
    delayed_ids = ...
    return delayed_ids

def retire_obsolete_completed_prefetch(registry, completion_events):
    # Release only after all lifetime and version guards.
    retired_records = ...
    return retired_records

def update_prefetch_throttle(controller_state, observation, policy):
    next_state = ...
    return next_state

def E10(runtime, workload_trace, prefetch_policies):
    comparison = ...
    return comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify no double-counting of materialised destinations and commitments. Check that urgent prerequisites still progress while discretionary prefetch is delayed.

Test a budget drop during a copy, invalidated versions, empty queues, and destination reuse after completion. Compare numerical outputs and verify no host source mutation occurs before copy completion. A claimed cancellation must not release storage still used by submitted CUDA work.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Prefetch is useful only when it reduces exposed latency more than the residency it imposes. Explain which signals detected crowding before a compute OOM.

Recommend a policy balancing near-term compute headroom and transfer readiness. State how quickly it responds and when already submitted work limits immediate recovery.

19.26.12 Exercise 11

Exercise Title: Integrate Eviction Decisions into the Scheduler and Select Victims from Reuse Distance, Size, Reload Cost, and Current Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Build an eviction selector over explicitly managed, reloadable storage. Rank eligible victims using reclaimable size, predicted reuse, reload/transfer cost, and memory pressure. Deliver

eligibility evidence, victim choices, realised releases, and future reload cost compared with simple size- or recency-based policies.

Start with immutable prefetched inference data and clean CPU backing. Training activations may be evicted only through a supported offload/recomputation mechanism that preserves autograd's contract. Arbitrary deletion of saved tensors is not a valid policy implementation.

Part 2 - System and Memory Mental Model

Eligibility precedes ranking. A tensor with an in-flight reader, an invalid backing version, an unresolved writer, or necessary untracked aliases cannot be assumed immediately reclaimable. Logical size and reclaimable storage can differ because several objects share a base allocation.

Reuse distance may be measured in future task count or estimated time; keep that unit explicit. A small soon-needed tensor may be expensive to evict despite a low byte size, while a large distant immutable copy may be a good victim. Predictions can be wrong, so record actual next use and policy error.

Offloading dirty data needs host capacity and transfer work before release. Dropping a clean cache copy with valid backing can be cheaper. Retiring storage still requires correct stream and ownership guards. Pressure changes how much must be reclaimed, not whether those guards can be bypassed.

Part 3 - Quantitative Prediction Before Execution

Let D be required additional headroom and r_j the conservatively reclaimable bytes of eligible victim j. Choose a set $\mathcal{V}$ satisfying

$$\sum_{j \in \mathcal{V}} r_j \geq D$$

while minimising a declared predicted eviction-plus-reload cost. Shared storage invalidates a naive sum unless victim groups are deduplicated and jointly releasable.

For three clean victims of 128, 256, and 512 MiB, with expected next-use times 2, 20, and 100 ms, assign measured reload costs and select a set to reclaim 300 MiB. Compare largest-first, farthest-reuse, and cost-aware choices.

If using a score, normalise byte, time, and reuse features before combining them. Explain why adding raw bytes to milliseconds produces an arbitrary ranking.

Part 4 - Experimental Design and Instrumentation

1. Build a storage registry with version, backing state, owner count, last-use events, logical size, and reclaimable storage group.

2. Construct a controlled task graph with known future uses for an offline comparison and limited lookahead for the online policy.

3. Evaluate victim eligibility before ranking. Include aliases, in-flight readers, and dirty data as negative cases.

4. Execute valid evictions, measure actual release, and track later reload latency and transferred bytes.

5. Compare simple and cost-aware policies on held-out reuse patterns and changing pressure.

Do not give the online policy future information beyond its declared lookahead; an omniscient victim order is only a comparison bound.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class EvictionCandidate:
    storage_group_id: str
    version: int
    reclaimable_bytes: int
    backing_valid: bool
    pending_reader_events: tuple
    predicted_reuse_seconds: object
    estimated_reload_seconds: float

def identify_eligible_victims(storage_registry, event_state):
    candidates = ...
    return candidates

def rank_victim_groups(candidates, pressure, cost_policy):
    ranking = ...
    return ranking

def select_reclaim_set(ranking, required_headroom):
    selection = ...
    return selection

def retire_storage_after_guards(runtime, selected_groups):
    realised_releases = ...
    return realised_releases

def compare_predicted_and_actual_reuse(eviction_log, use_trace):
    errors = ...
    return errors
```

```
def E11(runtime, task_trace, eviction_policies):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify valid backing versions, no in-flight readers at release, and no double-counted storage groups. Compare predicted reclaimable bytes with observed live-allocation reduction. An alias-held allocation must not be reported as freed.

Reload and compare content with the reference before later use. For supported training offload, compare gradients and accepted updates. Test no eligible victim and insufficient host capacity; both require explicit wait/defer outcomes.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Eviction is a prediction about future value under present pressure. Explain where your reuse model was accurate and where wrong predictions created unnecessary traffic or stalls.

Recommend a victim policy together with its eligibility rules, not a ranking formula alone. Correct lifetime management is a prerequisite for every performance comparison.

19.26.13 Exercise 12

Exercise Title: Coordinate Multiple CUDA Streams Through a Central Scheduler and Prevent Unsafe Concurrent Memory Use

Part 1 - Exercise Contract and Why It Matters

Coordinate compute and transfer streams through a central task scheduler. Enforce data dependencies, storage lifetime, and aggregate resource admission before submission. Deliver a multi-stream event trace, comparison with a serial reference, and a memory audit covering overlapping operations.

Begin with one compute stream and one transfer stream; add a second compute or transfer stream only after the first design passes. Extra streams are execution queues, not a guarantee of simultaneous kernels, independent bandwidth, or faster work.

Part 2 - System and Memory Mental Model

Operations on one stream are ordered, but cross-stream consumers need explicit dependencies. An event recorded after a producer can make a consumer stream wait without blocking the host. For CPU consumption of D2H data, the host must observe actual copy completion before reading it.

Data ordering and allocation lifetime are separate. A tensor used on a side stream must remain protected through that use. Use an explicit ownership protocol, appropriate allocator stream tracking such as `record_stream`, or documented manual lifetime management. Allocator tracking does not insert the producer-consumer data dependency by itself.

Concurrent tasks overlap temporaries, destinations, and retained outputs. Each individually fitting task can still cause aggregate OOM. A central admission decision must account for all active commitments. Host function return means work was submitted, not that resources are ready to retire.

If a task fails, later submitted work may still exist. Stop new dependent admissions, preserve in-flight ownership, and settle managed events safely before rollback. Do not overwrite buffers that a still-running stream may use.

Part 3 - Quantitative Prediction Before Execution

For disjoint incremental task lifetimes $m_i(t)$ above resident baseline M_0,

$$M_{\text{concurrent}}(t) = M_0 + \sum_i m_i(t).$$

Shared allocations must be deduplicated. A conservative upper envelope sums active task bounds, but adding absolute isolated peaks would count M_0 repeatedly.

With a 2 GiB baseline, compute demand 1.5 GiB, and transfer-destination demand 1 GiB, compare serial and overlapping peaks under explicit lifetimes. Decide whether overlap fits a usable 4 GiB cap.

For compute time 8 ms and copy time 5 ms, the ideal fully overlapped lower comparison is $\max(8, 5)$ ms, while serial time is 13 ms. Add dependency, launch, and bandwidth effects before treating either as a measured result.

Part 4 - Experimental Design and Instrumentation

1. Build a fully serial correct baseline with fixed data. Record outputs and gradients where the workload trains.

2. Declare stream ownership, producer events, consumer waits, and final-use events for every shared buffer.

3. Add central admission and a provisional commitment ledger before enabling overlap. Test bookkeeping with a CPU simulator.

4. Execute the supported multi-stream graph and capture actual compute/copy intervals. Use a joined end event or declared synchronised boundary for full-schedule timing.

5. Compare serial, dependency-correct overlap, and a conservative nonoverlap fallback under the same cap.

6. Inject delayed completion and allocation failure through controlled hooks. Verify no resource is retired early.

Avoid global synchronisation after every task in the performance run, since it would destroy the overlap being evaluated.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use

a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class StreamTaskHandle:
    task_id: str
    stream_id: str
    completion_event: object
    protected_storage_ids: tuple
    reservation_id: str

def construct_scheduler_streams(device, stream_policy):
    streams = ...
    return streams

def install_task_dependencies(task, producers, target_stream):
    dependency_record = ...
    return dependency_record

def protect_cross_stream_storage(task, ownership_registry):
    protection_record = ...
    return protection_record

def submit_admitted_task(task, stream, reservation):
    handle = ...
    return handle

def retire_completed_handles(handles, ownership_registry):
    retirements = ...
    return retirements

def E12(runtime, task_graph, stream_policy, budgets):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require numerical equivalence with the serial reference and event evidence for all cross-stream reads. Check that source pinned buffers remain valid during H2D and host reads wait for D2H completion.

Audit aggregate peak, commitment lifetime, duplicate completion, and allocation failure with other tasks still in flight. Verify stream tracking is not mistaken for data synchronisation. Report actual overlap and useful throughput; two stream names alone do not prove concurrency or speedup.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Concurrency is safe only when execution order, ownership, and aggregate resources agree. Explain which constraint limited overlap in the measured workload.

Recommend the smallest stream set that provides a benefit under the budget. More concurrency can raise memory and contention enough to reduce accepted throughput.

19.26.14 Exercise 13

Exercise Title: Build a Memory Reservation System That Prevents Concurrent Tasks from Independently Assuming the Same Free VRAM Is Available

Part 1 - Exercise Contract and Why It Matters

Implement atomic application reservations for future task memory. Selection, feasibility checking, and reservation creation must share a consistent ledger epoch so two submissions cannot both claim the same headroom. Deliver reservation state transitions, concurrency tests, and a CUDA audit of materialisation and release.

Application reservations are logical promises, not physical CUDA allocations. They prevent oversubscription only among cooperating scheduler-managed work and only within the validity of demand estimates. External processes and hidden unprofiled allocations remain outside that guarantee.

Part 2 - System and Memory Mental Model

Two host submitters can read identical free-memory snapshots and independently admit tasks whose combined demand exceeds the cap. The GIL is not a substitute for an explicit compound check-and-reserve operation. Use one event-loop owner or a lock-protected transaction, with generation IDs for stale events.

As promised storage materialises, it moves from unmaterialised commitment into actual ownership. Do not keep the full promise and add all materialised bytes again, or refund the entire reservation at first allocation while later workspaces remain. Completion converts persistent outputs into resident ownership; only genuinely retired temporary demand is released.

Exact materialisation accounting can be difficult for opaque PyTorch calls. A conservative alternative uses a reconciled resident baseline plus full additional task envelopes until completion, without adding observed in-flight allocations again. Refresh the baseline only at a safe reconciliation point or through trusted ownership events.

Reservation expiry cannot free bytes used by already submitted CUDA work. Cancellation before submission and retirement after submission have different rules. Duplicate and late callbacks must be idempotent and version-checked.

Part 3 - Quantitative Prediction Before Execution

With materialised live bytes A and additional unmaterialised commitments U,

$$A + U + S_J \leq J.$$

A trusted materialisation of x bytes changes $A \leftarrow A + x$ and $U \leftarrow U - x$, preserving the accounted total. Further task demand remains reserved. In the envelope alternative, account

$$M_{\text{accounted}} = M_{\text{resident}} + \sum_{i \in \text{active}} d_i,$$

and do not separately add the same active allocations.

For available headroom 1.5 GiB and two submitters requesting 1 GiB each, manually interleave a broken check-then-reserve sequence and the atomic sequence. Show the required rejection or wait.

For a task reserving 1 GiB that completes with a 256 MiB retained output, calculate the maximum releasable commitment under the declared reconciliation model. Explain why submit-time return releases nothing by itself.

Part 4 - Experimental Design and Instrumentation

1. Define states for planned, reserved, submitted, completed-with-outputs, cancelled-before-submit, and retired. Specify legal transitions and their accounting effects.

2. Use deterministic CPU interleaving tests for two submitters, then multithreaded tests if the implementation permits threads.

3. Test partial materialisation, retained outputs, early cancellation, duplicate completion, and stale generation IDs.

4. Integrate with E12 and compare the ledger with measured allocator observations at safe reconciliation boundaries.

5. Introduce a budget reduction while reservations exist. Stop new admission and resolve outstanding work; do not retroactively claim the old promises never existed.

Keep GPU, host, and pinned-buffer commitments separately scoped, while documenting which host quantities are subsets.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import threading
import torch

@dataclass
class Reservation:
    reservation_id: str
    task_id: str
    generation: int
    gpu_upper_bytes: int
    host_upper_bytes: int
    state: str

class ReservationLedger:
    def __init__(self, budgets, accounting_mode):
        self.budgets = budgets
        self.accounting_mode = accounting_mode
        self.entries = ...
        self.epoch = ...
        self.lock = ...

    def try_reserve(self, task, demand, observation):
        # Perform one atomic check-and-reserve transaction.
        decision = ...
        return decision

    def mark_submitted(self, reservation_id, generation, handle):
        ...

    def reconcile_materialisation(self, ownership_event):
        ...

    def complete_task(self, handle, retained_outputs):
        ...

    def cancel_unsubmitted(self, reservation_id, generation):
        ...

    def audit_invariants(self):
        audit = ...
        return audit

def E13(runtime, concurrent_submission_cases, budgets):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify no two cooperating submissions overspend one ledger epoch. Check invariants after

every transition, including exceptions during submission. Test that a submitted task cannot be released by timeout alone.

Require exact handling of retained outputs and no double counting of active allocations. Compare at reconciled boundaries rather than asserting all telemetry reads are atomic. Record external-pressure OOM separately from a reservation-bookkeeping failure.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Reservations coordinate intent before the allocator acts. Explain the protection they provide among cooperating tasks and the assumptions that limit it.

Choose between detailed materialisation tracking and conservative envelopes based on observability and cost. A slightly conservative correct ledger is preferable to an optimistic one that refunds memory before work is finished.

19.26.15 Exercise 14

Exercise Title: Add High- and Low-Watermark Memory Pressure States and Change Scheduling Behavior Before the Runtime Reaches OOM

Part 1 - Exercise Contract and Why It Matters

Add normal, pressured, critical, and no-fit scheduling states with distinct high and low watermarks. Change discretionary prefetch, admission concurrency, and permitted recovery behaviour before physical OOM. Deliver a transition table, manually predicted traces, and observed response delay.

Define the monitored quantity precisely: use application- accounted demand relative to a job budget for the primary state and retain device/host checks as separate constraints. High allocator reservations caused by idle cache must not automatically be interpreted as high live compute demand.

Part 2 - System and Memory Mental Model

Hysteresis prevents noise near one threshold from repeatedly switching policy. A high watermark enters pressure; a lower watermark plus sustained evidence exits it. Critical admission failure must override ordinary patience or smoothing.

Pressure changes policy for future work. It cannot instantly cancel already running kernels or free submitted copy buffers. A sudden cap below existing commitments requires stopped admission, orderly completion or supported recovery, and an honest report of the temporary violation.

Avoid a feedback loop where pressure pauses the very eviction or prerequisite transfer needed for progress. Emergency eligibility and dependency urgency remain active. No-fit is a distinct state when the required resident working set cannot satisfy current limits.

Part 3 - Quantitative Prediction Before Execution

Let $M_t^{\text{accounted}}$ be the ledger's consistent demand measure and define $u_t = M_t^{\text{accounted}}/J_t$ for $J_t > 0$. Choose thresholds $0 < l < h < c < 1$ with declared entry/exit rules; absolute admission constraints still apply.

For $l = 0.65$, $h = 0.80$, and $c = 0.92$, manually replay

$$(0.60,\ 0.82,\ 0.78,\ 0.81,\ 0.64,\ 0.63,\ 0.95).$$

Use two accepted stable observations for pressure exit. Predict prefetch and concurrency decisions at each point. Then halve the budget without changing live demand and explain the immediate state change.

Measure response latency from pressure observation to changed admission, and separately to realised memory reduction. Those times differ when existing work is still in flight.

Part 4 - Experimental Design and Instrumentation

1. Implement state transitions as a pure CPU function and check exact threshold equalities and invalid budgets.
2. Replay steady noise, slow pressure growth, a cap step down, and a prolonged no-fit state.
3. Map each state to explicit changes in optional prefetch, concurrency, victim search, and admission conservatism.
4. Run a CUDA workload under a cap below physical VRAM. Count cap/margin violations even when no OOM occurs.
5. Compare single-threshold and hysteretic policies on a held-out trace, including their throughput cost.

Log raw observations, any filtered values, state transitions, and the reason for emergency overrides.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PressureState:
```

```
    state_name: str
    stable_low_count: int
    last_transition_time: float
    budget_epoch: int

@dataclass
class PressureThresholds:
    low: float
    high: float
    critical: float
    exit_patience: int

def classify_resource_pressure(runtime_state, ledger, budgets):
    observation = ...
    return observation

def transition_pressure_state(previous, observation, thresholds):
    next_state = ...
    return next_state

def select_state_dependent_actions(state, ready_graph, policy):
    actions = ...
    return actions

def audit_pressure_response(event_trace):
    metrics = ...
    return metrics

def E14(runtime, budget_trace, thresholds):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify valid threshold ordering, explicit zero-budget handling, and pressure-exit patience. Test that raw admission failure overrides a smoothed low utilisation reading.

Check no new discretionary work is admitted after critical pressure unless its contract allows it, while necessary release work can still progress. Distinguish cap reduction below existing commitments from a new-admission bookkeeping error. Report both violations and delayed progress.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Pressure states provide early behavioural changes, not retroactive control of past allocations. Explain which signals gave useful warning and which changed too quickly for preventive action.

Recommend thresholds and patience for the measured workload with an explicit no-fit policy. Avoid treating one utilisation percentage as universally safe across shapes and allocators.

19.26.16 Exercise 15

Exercise Title: Dynamically Choose Between Larger Batches, Activation Checkpointing, CPU Offloading, and Reduced Precision from Current Memory Pressure

Part 1 - Exercise Contract and Why It Matters

Choose a configuration at logical update boundaries from physical batch sizes, checkpoint plans, saved-activation CPU offload, and permitted precision policies. Increase batch only when headroom and useful-throughput evidence justify it; use memory-saving alternatives when pressure rises. Deliver a candidate table, selection trace, and numerical validation.

Preserve the target logical batch through weighted accumulation. Apply precision and graph-construction changes only between committed logical windows. Placement changes also need a safe boundary. Only enable training offload mechanisms already proven compatible with autograd and optimizer state.

Part 2 - System and Memory Mental Model

The candidate actions affect different resources. Larger physical batches can improve kernel efficiency but raise activation demand. Checkpointing trades saved tensors for recomputation. Offload adds host residency and transfer pressure. Autocast can change selected intermediate storage and numerical error without halving all persistent state.

Combined gains are not additive because actions may target the same tensors. Each candidate requires compatible shape, backend, precision, and checkpoint/offload calibration. Transition costs and temporary duplicate buffers may exceed the steady-state peak of either configuration.

Apply changes after a committed update and safe retirement of transfers involving affected storage versions. Keep scaler state coherent and the scale fixed across an accumulation window. Numerical overflow and allocation pressure remain distinct outcomes.

Part 3 - Quantitative Prediction Before Execution

For candidate $c = (b, p, k, o)$, where b is physical batch, p precision, k checkpoint plan, and o offload policy, select useful throughput subject to

$$\begin{aligned} \widehat{M}_{\text{upper}}(c) + S_J &\le J, \\ \widehat{H}_{\text{upper}}(c) &\le H_{\max}, \\ E_{\text{numerical}}(c) &\le \varepsilon_{\max}. \end{aligned}$$

Check transition peak separately. For logical sample count B, partitions must satisfy $\sum_j b_j = B$, with weights b_j/B for sample-average losses. Valid-token objectives use their original valid-token denominator.

For $B = 100$, compare upper micro-batches 32 and 16 with the exact final remainder. Create at least four candidate profiles with measured or explicitly hypothetical GPU, host, transfer, and latency costs. Predict selections in normal and pressured states before running.

Part 4 - Experimental Design and Instrumentation

1. Establish a deterministic FP32 reference with a small model, batch-independent layers, and fixed sample IDs.

2. Calibrate a finite candidate set, including combinations, with complete training updates and lazy optimizer state.

3. Validate gradients, parameters, and buffers under each candidate's declared numerical tolerance.

4. Apply a changing budget trace. Select policies only at permitted update boundaries with safe transfer retirement.

5. Compare fixed configurations with the adaptive policy, counting calibration, transitions, retries, and host pressure.

6. Test unsupported dtype, insufficient host RAM, and no feasible candidate.

Use explicit checkpoint and AMP APIs appropriate to the installed version; do not infer capability from a policy name.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
from torch.utils.checkpoint import checkpoint

@dataclass
class TrainingCandidate:
    micro_batch_size: int
    precision_name: str
    checkpoint_plan: str
    offload_policy: str
    profile_key: str
    quality_limit: float

def enumerate_supported_candidates(capabilities, policy_limits):
    candidates = ...
    return candidates
```

```
def validate_candidate_semantics(candidate, logical_objective):
    validation = ...
    return validation

def estimate_candidate_and_transition_costs(current, candidates):
    estimates = ...
    return estimates

def choose_boundary_configuration(estimates, resources, pressure):
    decision = ...
    return decision

def apply_configuration_at_safe_boundary(runtime, decision):
    transition_record = ...
    return transition_record

def E15(runtime, logical_windows, budget_trace, candidate_set):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact logical sample coverage and accepted update counts, plus numerical agreement under declared criteria. Check that unsupported precision is rejected explicitly and that offload respects host capacity.

Verify no policy changes within a live graph or partial accumulation window. Test a transition whose temporary peak exceeds both steady profiles. Report cases where a larger batch fits but lowers accepted throughput.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Memory pressure narrows the feasible configuration set; it does not identify the fastest correct policy by itself. Explain the measured compute, transfer, and numerical tradeoffs behind each selected configuration.

Recommend bounded, profile-aware adaptation with a conservative fallback. Retain the distinction between changing execution and changing the learning objective.

19.26.17 Exercise 16

Exercise Title: Build a Cost Function That Balances GPU Utilization, Peak VRAM, PCIe Traffic, Recomputation, and Total Step Latency

Part 1 - Exercise Contract and Why It Matters

Design and evaluate a dimensionally consistent scheduling cost function that compares accepted work, step latency, GPU memory, transfer traffic, and recomputation. Keep memory, host-resource, dependency, and numerical constraints as hard eligibility conditions. Deliver a candidate metric table, normalisation choices, sensitivity analysis, and selection on held-out workloads.

Do not allow a favourable weighted score to excuse an OOM, wrong output, or invalid dependency. Compare schedules that perform the same logical work under the same observation scope before ranking their resource tradeoffs.

Part 2 - System and Memory Mental Model

Raw bytes, seconds, and utilisation percentages cannot be added meaningfully without normalisation or explicit conversion coefficients. Reference scales should be fixed from calibration or a declared baseline, not recomputed per candidate so the objective changes while ranking.

GPU busy time is not necessarily useful compute. Copies, recomputation, and failed work can increase activity while accepted throughput falls. A union of useful-compute event intervals gives a duty fraction, not hardware occupancy or SM efficiency. State the exact metric and measurement tool.

Step wall time already includes effects of overlap, contention, and recomputation. Additional cost terms may encode resource preferences, but are not extra independent seconds to add to an already measured critical path. Discuss correlation and avoid claiming that summing all task durations equals concurrent makespan.

Weights reflect operating priorities. Use a Pareto view alongside a weighted score to show when conclusions depend strongly on arbitrary coefficients.

Part 3 - Quantitative Prediction Before Execution

For feasible candidate c, an illustrative score is

$$C(c) = w_T\, T(c)/T_{\text{ref}} + w_M\, M_{\text{peak}}(c)/J \\ + w_P\, V_{\text{PCIe}}(c)/V_{\text{ref}} + w_R\, T_{\text{recompute}}(c)/T_{\text{ref}} - w_U\, U_{\text{useful}}(c).$$

All terms are dimensionless after the declared normalisation. Choose nonnegative weights and explain the subtraction of a bounded useful-duty metric. Do not double-count transfer directions when V_{PCIe} already includes both.

Construct three hypothetical candidates: one with low latency/high VRAM, one with lower VRAM/more PCIe traffic, and one with lower traffic/more recomputation. Supply their values and reference scales before choosing weights. Compute rankings under latency-focused and transfer-limited preferences, then identify dominated candidates.

For useful-compute intervals I_i, define $U_{\text{useful}} = |\bigcup_i I_i|/T$; summing overlapping interval lengths can incorrectly produce a value above one.

Part 4 - Experimental Design and Instrumentation

1. Define metrics, units, scope, and hard constraints. Freeze reference scales using a calibration workload.

2. Measure complete schedules including submission overhead, policy transitions, failed work, and recovery.

3. Attribute recomputation and transfer volume in separate diagnostic runs when needed. State attribution uncertainty.

4. Rank a finite feasible candidate set under several declared weight choices and plot the tradeoffs.

5. Select weights on calibration traces and evaluate the chosen policy on held-out shapes and pressure regimes.

6. Compare with minimising full-step wall time alone. Explain whether extra terms improve the intended operating goal.

Keep accepted samples or useful tokens as an independent throughput measure so a high activity score cannot hide less useful work.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ScheduleMetrics:
    wall_seconds: float
    peak_gpu_bytes: int
    pcie_bytes: int
    recomputation_seconds: float
    useful_compute_duty: float
    accepted_work: int
    constraints_satisfied: bool

def validate_metric_scopes(metrics, measurement_contract):
    validation = ...
    return validation

def normalise_metrics(metrics, fixed_reference_scales):
    normalised = ...
    return normalised

def evaluate_schedule_cost(normalised_metrics, weights):
    cost = ...
```

```
    return cost

def identify_pareto_candidates(candidate_metrics):
    frontier = ...
    return frontier

def test_weight_sensitivity(candidates, weight_sets, held_out):
    analysis = ...
    return analysis

def E16(runtime, candidate_policies, calibration_and_test_traces):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject invalid reference scales, mixed units, and scores assigned to infeasible candidates as if they were eligible. Check useful-duty values remain within their defined range.

Verify rankings against hand-computed cases and report sensitivity to weights and measurement noise. Compare full-wall-time throughput across equal logical work. Do not claim a global optimum outside the tested candidate set or a hardware-occupancy improvement from a duty metric.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A cost function makes preferences explicit; it does not remove judgement. Explain which resource tradeoff the chosen weights express and which constraints remain non-negotiable.

Recommend a policy only when its advantage survives reasonable uncertainty or explain the tradeoff when no candidate is uniformly best.

19.26.18 Exercise 17

Exercise Title: Reproduce Scheduler Thrashing Caused by Rapidly Alternating Prefetch, Eviction, and Batch-Size Decisions and Stabilize It with Hysteresis

Part 1 - Exercise Contract and Why It Matters

Create a reproducible feedback loop in which speculative prefetch consumes headroom, eviction removes soon-needed data, reload consumes bandwidth, and batch adaptation reverses earlier decisions. Stabilise it with coordinated hysteresis, minimum residency where safe, action cooldown, and failure memory. Deliver causal traces and net throughput comparisons.

Differentiate avoidable policy churn from legitimate responses to changing budgets or versions. The controller must still react promptly to critical pressure and cannot protect a minimum residency interval at the expense of correctness or required memory constraints.

Part 2 - System and Memory Mental Model

Independent local controllers can work against each other. A prefetcher may regard free bytes after eviction as spare capacity and immediately refill them; a batch controller may then increase compute demand and trigger another eviction. Each decision seems locally plausible while the combined schedule repeatedly transfers the same data.

Use one shared state and coherent action priorities. Record why data was evicted, which future consumer still needs it, and what evidence justifies refetching it. Cooldown can suppress speculative reversals, while a dependency-critical reload must remain eligible.

Minimum residency and reuse penalties are soft policy rules constrained by safety. Emergency pressure may override them for eligible victims, but lifetime guards cannot be overridden. A cancelled unsent prefetch and retirement of an in-flight copy are still different actions.

Part 3 - Quantitative Prediction Before Execution

For storage version v, count prefetch/eviction cycles before accepted reuse. Define excess traffic relative to a declared necessary-transfer baseline:

$$V_{\text{excess}} = V_{\text{observed}} - V_{\text{necessary}}, \qquad R_{\text{churn}} = \frac{N_{\text{avoidable reversals}}}{N_{\text{accepted updates}}}.$$

Explain how the baseline and avoidability label are derived; do not mark every repeat transfer as unnecessary.

Construct a trace with two 512 MiB prefetched objects and a compute working-set increase that repeatedly displaces one. Calculate H2D/D2H volume for three cycles under a stated clean-copy or dirty-offload policy.

Predict the effect of separate low/high thresholds, four-update growth patience, and a residency period longer than one ordinary compute interval. Then introduce a sudden critical budget drop and identify valid overrides.

Part 4 - Experimental Design and Instrumentation

1. Build a CPU scenario exposing the three-controller feedback loop and record the decision reason at every step.

2. Compare independent controllers, shared hysteresis, and shared hysteresis with bounded residency/cooldown.

3. Freeze policies before a held-out alternating-shape trace so thresholds are not fitted to one cycle.

4. Run a CUDA workload with versioned managed data and measure transfers, compute stalls, memory, and accepted throughput over the whole trace.

5. Add critical pressure and a newly urgent dependency. Verify stabilisation does not block required progress.

Record action duration and graph/placement transition costs; counting switches alone misses their severity.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate

measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class StorageActionHistory:
    storage_id: str
    version: int
    last_prefetch_time: object
    last_eviction_time: object
    next_required_use: object
    prior_action_reason: str

@dataclass
class UnifiedControlState:
    pressure_state: str
    growth_patience: int
    action_cooldowns: object
    storage_history: object
    current_batch: int

def identify_feedback_reversals(action_trace, dependency_trace):
    reversals = ...
    return reversals

def coordinate_controller_actions(state, proposals, resources):
    decision = ...
    return decision

def apply_hysteresis_and_residency_rules(state, decision, policy):
    filtered_decision = ...
    return filtered_decision

def quantify_excess_traffic(trace, necessary_transfer_baseline):
    metrics = ...
    return metrics

def E17(runtime, thrashing_scenarios, control_policies):
```

```
report = ...
return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify shared state prevents contradictory simultaneous decisions and records any safety override. Check that cooldown cannot permit stale-version use or premature storage release.

Measure excess traffic, lost compute time, batch switches, memory violations, and recovery delay. Include a trace where frequent switching is legitimately required. Report throughput gains only after including all transfer and transition work.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Thrashing is often a coordination failure among reasonable local policies. Explain the feedback path that created the observed repeated work and how the shared policy changed it.

Recommend stabilisation rules with explicit urgent exceptions. Wider hysteresis is not useful if it merely delays necessary work or hides an incorrect admission model.

19.26.19 Exercise 18

Exercise Title: Stress-Test the Scheduler with Variable Sequence Lengths, Random Memory Spikes, Concurrent Transfers, and Artificially Changing VRAM Budgets

Part 1 - Exercise Contract and Why It Matters

Build a seeded stress suite that exercises memory admission, dependencies, reservations, transfers, eviction, pressure states, and recovery together. Include variable lengths, temporary workspace spikes, concurrent copy activity, budget changes, stale observations, and delayed completion. Deliver scenario manifests, invariant audits, complete traces, and minimal reproducers for failures.

Use deterministic CPU event simulation for rare interleavings and representative CUDA integration tests for actual allocation and transfer behaviour. Clearly distinguish synthetic events from measured device failures.

Part 2 - System and Memory Mental Model

Dynamic shape changes demand; external pressure changes availability; concurrent transfers extend source and destination lifetimes. A budget drop can arrive while valid old commitments are still active. These mechanisms need different diagnoses and cannot all be labelled a reservation bug.

Stress completion ordering as well as resource size. Duplicate callbacks, stale generation IDs, failed producers, and delayed D2H readiness can corrupt a scheduler without generating OOM. Test such logic in simulation rather than deliberately racing GPU buffer reuse.

Recovery must not restore mutable state while submitted tasks still write to it. Stop new dependent admission, resolve managed in-flight work according to the supported context state,

and only then restore a logical transaction. Known context-fatal failures require a stopped process with preserved CPU evidence, not speculative new CUDA work.

Part 3 - Quantitative Prediction Before Execution

Represent a scenario by

$$\mathcal{S} = \{(u_i, p_i, e_i, m_i, g_i)\},$$

where u is logical update or scheduler epoch, p is phase, e event type, m magnitude/shape, and g the affected generation. Preserve the realised schedule, not only its random seed.

Define invariant violations by category: dependency, version, lifetime, reservation, budget, and accepted-work accounting. For each report count and first failing event. Measure retry amplification

$$A_{\text{retry}} = \frac{N_{\text{attempts}}}{N_{\text{accepted windows}}},$$

with explicit no-progress handling when the denominator is zero.

Predict behaviour for a length doubling, an extra 256 MiB workspace, a delayed copy completion, and a budget below current resident state. Distinguish preventable admission failure from an unavoidable mid-task cap reduction under the declared contract.

Part 4 - Experimental Design and Instrumentation

1. Define at least ten bounded scenarios covering normal work, shape spikes, workspace spikes, transfer contention, budget drops, stale observations, duplicate completion, failed producers, no-fit, and recovery.

2. Use a seeded CPU simulator to explore event order, including two simultaneous reservation requests.

3. Run representative CUDA cases with a controlled pressure worker on the same physical GPU, bounded by an explicit byte ceiling and cleanup protocol.

4. Audit every state transition and storage version. Compare accepted outputs/updates with a compatible serial reference.

5. Record host memory, diagnostic overhead, transfer volume, peak demand, waits, refusals, and completion status for all scenarios.

6. Minimise a failing schedule while preserving the original trace and environment metadata.

Terminate only experiment-created workers. Never clear unrelated application tensors to force a stress case to succeed.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import torch

@dataclass
class SchedulerStressEvent:
    epoch: int
    phase: str
    event_kind: str
    magnitude: object
    target_generation: object
    evidence_mode: str

def generate_bounded_scheduler_scenario(seed, workload, limits):
    scenario = ...
    return scenario

def replay_event_interleavings(simulator, scenario):
    traces = ...
    return traces

def execute_cuda_stress(runtime_factory, scenario, limits):
    result = ...
    return result

def audit_scheduler_invariants(trace, reference_manifest):
    violations = ...
    return violations

def reduce_failing_scenario(scenario, reproducible_replay):
    reduced = ...
    return reduced

def E18(runtime_factory, scenario_seeds, stress_limits):
    report = ...
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct dependencies, data versions, lifetime guards, atomic reservation accounting, and exact accepted sample/task coverage. Verify event duplication cannot refund memory twice.

Test stalled in-flight work, singleton no-fit, insufficient host staging, and exceptions during recovery. Preserve terminal outcomes and distinguish bounded deferral from deadlock. Check

cleanup returns managed live storage to the expected baseline, allowing documented allocator cache.

Report the tested envelope and sampling limits. Passing random scenarios does not prove safety against arbitrary external allocation or hidden operator workspaces.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

An integrated scheduler must remain correct across interacting disturbances, not just perform well in steady state. Explain the first broken invariant in each failing scenario.

Prioritise fixes by correctness and lost accepted work. Keep negative cases as evidence of the operating boundary rather than removing them from the benchmark.

19.26.20 Exercise 19

Exercise Title: Build and Benchmark a Unified PyTorch Memory-Aware Scheduler That Coordinates Compute, Prefetch, Placement, Eviction, Offloading, and OOM Prevention Under Dynamic Memory Budgets

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter into a unified scheduler with task dependencies, versioned placement, resource profiles, atomic reservations, compute/transfer priorities, prefetch control, eligible eviction, pressure states, configuration selection, and bounded OOM recovery. Deliver the learner-completed runtime, configuration schema, raw event logs, invariant audits, and benchmark comparison against simpler policies.

Use two explicit workload modes. In inference, manage immutable CPU-backed parameter copies and input/output placement. In training, retain optimizer-bound parameters and manage supported input, saved-activation offload, checkpoint, precision, and micro-batch policies. Parameter migration during training is a separate extension requiring proven gradient and version semantics.

Part 2 - System and Memory Mental Model

The task graph specifies required data versions and legal execution order. The placement registry records where valid copies live and which readers own them. The reservation ledger accounts for future additional demand. The policy ranks eligible work, and the executor submits calls with explicit stream dependencies and lifetime protection.

Every task progresses through planned, dependency-ready, reserved, submitted, completed, and retired states, with explicit failure/cancellation paths. A completed task may retain outputs; a retired reservation does not imply every related tensor is gone. Reconcile ownership and commitments using one consistent accounting model.

For training, a logical window is the unit of commit. Keep its sample IDs and loss denominator fixed, and perform the optimizer update only after all required gradient work completes. Avoid overlapping independent mutable optimizer updates in the base design. Restore a failed transaction only after safely resolving work that could still access or modify its storage.

Prevention means refusing predicted-inadmissible work and preserving margins inside a declared envelope. It cannot guarantee zero OOM against arbitrary external allocation or unbounded prediction error. Evaluate coordinated budget changes separately from asynchronous external pressure, and retain DMM23's terminal handling for context-fatal errors.

Part 3 - Quantitative Prediction Before Execution

For candidate schedule policy π, optimise accepted useful throughput over a finite validated policy set:

$$\pi^* = \arg\max_{\pi \in \Pi} \frac{N_{\text{accepted}}(\pi)}{T_{\text{full wall}}(\pi)}.$$

Use E16's cost function only when additional resource preferences are required and keep hard constraints:

$$\begin{aligned} M_{\text{accounted}}(t) + S_J(t) &\le J(t), \\ H_{\text{accounted}}(t) &\le H_{\max}(t), \\ \text{dependencies valid}(i) &= \text{true}, \\ E_{\text{numerical}}(\pi) &\le \varepsilon_{\max}. \end{aligned}$$

Also apply a conservative fresh device-availability check for additional allocations. Distinguish predicted admission constraints from post-execution observed peak audits.

Prepare a pre-run table for serial demand loading, first-fit, priority with fixed prefetch, and the unified policy. Predict peak GPU/host bytes, transfer volume, exposed stalls, accepted throughput, and recovery overhead. Include a case where scheduling overhead may make the simple baseline fastest.

Part 4 - Experimental Design and Instrumentation

1. Implement independent interfaces for the task DAG, storage registry, telemetry, cost profiles, reservation ledger, policy, stream executor, and incident recorder.
2. Validate CPU event transitions and ownership invariants before enabling CUDA overlap.
3. Establish serial references for inference and training separately. Check outputs, logical samples, gradients, parameters, buffers, and optimizer state where applicable.
4. Compare the four baselines under identical work, resource caps, candidate policies, and observation scope. Give each policy the same legal lookahead.
5. Evaluate steady shapes, variable lengths, coordinated budget changes, transfer contention, and asynchronous pressure. Use held-out traces after policy calibration.
6. Include initialization, calibration, pinned buffer preparation, policy switching, failed attempts, diagnostics, and recovery in total elapsed time.
7. Export accepted work, latency distribution, memory peaks, commitments, PCIe bytes, recomputation, queue wait, starvation, eviction/reload cycles, OOMs, margin violations, and terminal outcomes.

Record simulation and CUDA measurements separately. An offline future-aware schedule is a comparison bound, not evidence of the online scheduler's achievable policy.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier.

Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable training implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```

    return benchmark_report
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires valid dependencies and versions, protected source/destination lifetimes, no double-spent reservations, correct retained-output accounting, and bounded no-fit/recovery behaviour. Audit all of these at each transition, not only after the final output.

For inference, compare outputs with the resident reference. For training, verify logical sample coverage, loss weights, gradients, buffers, parameters, optimizer, scaler, and scheduler progress under declared tolerances. Test a delayed producer, stale version, duplicate completion, budget drop, unavailable host staging, and failure with other tasks in flight.

Distinguish application-margin violations from physical OOM and external pressure from accounting bugs. Report unsupported cases and all failed trials. Count accepted useful work once, excluding retries, redundant prefetch, and discarded speculative work. Performance improvement is a measured outcome, not a prerequisite for reporting a correct negative result.
Evidence format. Keep prediction, observation, and interpretation in separate columns. Each task or attempt needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The unified scheduler's value is coordinated progress: the right data version is available at the right time, memory promises remain consistent, and completed work preserves the intended computation.

Conclude with the strongest supported claim for the tested devices, allocators, workload modes, shapes, budgets, and policy set. Explain where simple serial scheduling remains preferable and where coordination earns its overhead. State the limits of OOM prevention and the conditions requiring deferral, rollback, or a fresh process.

19.27 DMM25

Chapter Title: Memory Pooling and Buffer Reuse
Specialization: Dynamic Memory Management and CUDA Systems

19.27.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Memory Pools, Reusable Buffers, Allocation Amortization, and Why Reuse Reduces Runtime Overhead

Part 1 - Exercise Contract and Why It Matters

Build a vocabulary and an accounting model before writing a pool. Your deliverables are a storage-lifetime diagram, an amortized-cost prediction, and a controlled comparison of repeated requests with retained-buffer reuse. Distinguish a tensor object, its underlying storage, an application-owned buffer, and a block managed by the PyTorch CUDA allocator. A successful exercise explains both a possible speedup and a workload where a custom pool loses. Repeated allocation requests are not evidence of repeated driver allocations.

Limit the initial experiment to contiguous tensors with one dtype on one CUDA device, outside autograd. Specify the requested element count, initialization rule, and maximum simultaneous borrowers. You must account for data initialization in both paths, preserve equal numerical work, and return a buffer only after its declared use ends. Do not begin by trying to replace internal cuBLAS workspaces or PyTorch's allocator.

Part 2 - System and Memory Mental Model

An application pool keeps tensor storage alive and lends it repeatedly. The caching allocator operates below this layer and can already recycle storage when ordinary tensors die. Thus a pool may reduce Python object creation, allocator bookkeeping, or host pinning calls, while adding lookup, ownership, and synchronization costs of its own. The name `torch.cuda.MemPool` refers to a separate allocator API; it is not the Python lease manager constructed in this chapter.

Use three disjoint capacity states: leased, pending completion, and free for application reuse. Their sum is retained pool capacity. Free pool buffers are still live tensors, so they contribute to allocated memory; allocator-reserved memory is a different level of accounting. A logical view can request fewer bytes than its backing buffer owns. That difference is internal waste, whereas an entirely idle buffer is retained idle capacity. Never count several views of one storage as separate backing allocations.

Uninitialized storage and reused storage both require a defined write before a read. Python scope ending does not prove that GPU work finished, and a returned tensor view can keep storage alive. The first implementation therefore uses a strict borrower contract and synchronized release. Later exercises relax synchronization through completion events, not through assumptions about the speed of the GPU.

Part 3 - Quantitative Prediction Before Execution

For request count N, new-storage count K, acquisition cost t_q, storage-creation cost t_a, release cost t_r, and useful work t_w, use the following explicitly simplified serial model:

$$T_{\text{pool}} \approx Kt_a + N(t_q + t_r + t_w), \qquad \bar{t}_{\text{creation}} = \frac{Kt_a}{N}.$$

Compare it with a measured baseline of warmed PyTorch allocations. Raw `cudaMalloc` latency is not that baseline. The model omits overlap, contention, variable allocation sizes, and occasional trimming.

Let c_j be unique buffer capacity and q_j the requested bytes of an active lease. Predict

$$C_{\text{pool}} = \sum_j c_j, \qquad W_{\text{live}} = \sum_{j \in \mathcal{L}} (c_j - q_j).$$

For a hypothetical request of 2^{20} float32 elements and three simultaneous borrowers, calculate the minimum backing capacity in MiB. Then predict what changes if one borrower releases while its GPU work is pending. State separately whether the pool can lend that capacity and whether the process still owns it. Use these predictions as hypotheses, not as measured GPU results.

Part 4 - Experimental Design and Instrumentation

1. Draw ownership timelines for ordinary allocation, synchronous reuse, and an attempted early release. Mark host return and device completion as separate instants.

2. Run a fixed-size request trace with one outstanding borrower, then repeat with three. Use the same initialization and checksum operation for the ordinary and pooled paths.

3. Sample allocated and reserved bytes before construction, after first acquisition, after safe release, and after dropping every pool reference. Record driver-visible free memory separately.

4. Measure a cold run and several warmed runs. Include pool construction in startup cost and exclude it only in a clearly labeled steady-state view.

5. Repeat with tiny and moderately sized buffers. Explain whether bookkeeping, initialization bandwidth, or useful computation dominates.

Keep a storage registry containing scalar IDs and sizes; evidence logging must not hold tensors. A data pointer may help explain a trace but cannot serve as a permanent identity across deallocation and reallocation.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class BufferRecord:
    buffer_id: int
    capacity_bytes: int
    state: str
    generation: int

def describe_storage(tensor):
    # Report logical bytes and unique backing-storage metadata.
    ...

def predict_costs(request_count, storage_count, cost_terms):
    # Declare units and the assumptions of the serial model.
    ...

def trace_ordinary_requests(spec, repetitions):
    # Allocate, initialize, consume, and release explicitly.
    ...
```

```
def trace_retained_reuse(spec, repetitions):
    # Keep storage alive and enforce one borrower per buffer.
    ...

def E00(config):
    # Record predictions before running either experiment.
    ...
    # Compare cold and warm costs using identical useful work.
    ...
    # Export scalar evidence and an ownership timeline.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Your report must reconcile requested bytes, backing capacity, allocated bytes, and reserved bytes without treating them as interchangeable. Show a row in which all leases have ended but retained capacity remains nonzero. Demonstrate that the contents of a previously used buffer are not a valid initialization guarantee. Validate checksums only after the corresponding CUDA work completes.

Acceptance requires one explanation of overhead amortization and one counterexample to unconditional speedup. A result dominated by initialization is valid if initialization was equivalent. Reject a comparison where the ordinary path allocates and fills but the pooled path only returns a tensor. Inspect lingering aliases when allocated memory fails to fall after pool destruction. Label allocator caching as a possible reason reserved memory does not fall with allocated memory.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Pooling exchanges recurring management work for retained resources and stronger lifetime obligations. A fast pointer lookup is only a small part of that exchange. The useful engineering question is whether explicit reuse improves the complete workload under a declared capacity limit.

Connect this model to DMM24: a scheduler needs to know when memory becomes reusable, not merely when a host function returns. Explain which state transitions your initial pool can prove and which require the later event protocol. Finish with a falsifiable statement describing when you expect pooling to help, including the request size distribution and concurrency assumptions.

19.27.2 Exercise 01

Exercise Title: Measure the Cost of Repeated CUDA Tensor Allocation and Deallocation in a Tight PyTorch Loop

Part 1 - Exercise Contract and Why It Matters

Establish an honest allocation baseline before claiming that reuse is faster. Produce request-latency distributions and complete-loop timings for repeated fixed-size CUDA tensors. Separate Python request overhead, initialization kernels, allocator cache reuse, and device allocation activity. The deliverable is a measurement protocol that another learner can replay without accidentally timing only queued GPU work.

Use several tensor sizes and two lifetime patterns: immediate release and a bounded set of simultaneously live tensors. Keep the largest experiment comfortably within an explicit VRAM allowance. This exercise studies allocation behavior, not deliberate OOM. A cold-start observation and a warmed steady-state observation must be reported separately.

Part 2 - System and Memory Mental Model

`torch.empty` creates an uninitialized tensor; its call need not launch a data-filling kernel or obtain a fresh device allocation. Releasing the last Python reference normally returns ownership to the allocator, whose cache can retain device memory. The cost of repeated empty tensors therefore differs from the cost of repeated filled tensors and from a loop that purges the allocator cache every iteration.

Host timing around a complete synchronized loop captures Python and allocator work as well as GPU completion. CUDA event timing describes positions on a stream timeline; it is not a direct measurement of Python allocation overhead and can include device idle time induced by host submission. Per-iteration synchronization changes the workload and must be a separate diagnostic variant. An empty-loop control estimates timer and iteration overhead but should not be blindly subtracted when it is comparable to the signal.

Allocator counters have distinct meanings. The cumulative allocation counter counts allocator requests, while segment counters describe allocator-managed segments. Available fields and interpretation depend on the backend. Record the backend and supported keys; do not rename a request counter as a driver allocation counter. Native-backend inactive split statistics are not a portable fragmentation metric for every backend.

Part 3 - Quantitative Prediction Before Execution

Let T_N be elapsed wall time for N requests and T_0 the matched empty-loop time. Report both

$$\bar{t}_{\text{raw}} = \frac{T_N}{N}, \qquad \bar{t}_{\text{adjusted}} = \frac{T_N - T_0}{N},$$

with uncertainty from repeated complete runs. If the adjusted estimate is unstable or negative, report insufficient resolution rather than claiming negative allocation cost.

For L simultaneous tensors of n elements and element size s, predict logical live bytes Lns. For a hypothetical 256 KiB request, calculate the expected logical increase when the live set changes from one tensor to 32. Predict why reserved bytes can exceed this amount. Before execution, state which cases should create new allocator segments, which may reuse cached capacity, and why those are hypotheses rather than guarantees about a specific allocator implementation.

Part 4 - Experimental Design and Instrumentation

1. Initialize CUDA outside the steady-state interval. Capture an optional fresh-process startup trace separately, with initialization costs identified.

2. Sweep small, medium, and large byte sizes using a fixed dtype. Generate shapes on CPU before timing and verify their byte counts.

3. Measure empty allocation and release, then allocation plus a full initialization write, using the same repetition counts and live-set limit.

4. Synchronize before and after each complete timed region. Collect per-request host timings only in a separate instrumented run to quantify the effect of timers and logging.

5. Record allocator statistics before and after each region. Warm each size intentionally; randomize comparison order across repeats.

6. Add a cache-purge diagnostic outside the main benchmark. If you also purge every iteration, label that a different allocator workload.

Hold CPU threads, background GPU load, dtype, and device constant. Report median and tail latency from sufficient samples, along with run-to-run variation. Do not present the minimum observation as the typical cost.

Useful measurement interfaces include:

- `time.perf_counter`: host wall-clock timing.
- `torch.cuda.synchronize`: a deliberate completion boundary.
- `torch.cuda.memory_stats`: allocator counter inspection.

Inspect the cumulative request key `allocation.all.allocated`. Inspect segment activity through `segment.all.allocated`. Check backend support before interpreting either counter. Use tensor `numel()` and `element_size()` to verify logical bytes, and storage-level size inspection when backing capacity differs.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
import time
import torch

def make_allocation_specs(byte_sizes, dtype):
    # Convert exact byte requests to supported tensor shapes.
    ...
```

```
def capture_allocator_counters(device):
    # Return scalar counters and identify unsupported fields.
    ...

def run_allocation_loop(spec, repeats, live_limit, initialize):
    live_tensors = []
    # Bound the live set and avoid tensor retention in logs.
    ...

def measure_region(operation, device):
    # Separate synchronized wall time from stream event time.
    ...

def E01(config):
    # Establish cold, warm, and empty-loop measurements.
    ...
    # Sweep sizes without changing unrelated conditions.
    ...
    # Export distributions and correctly named counter deltas.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report request size in bytes, simultaneous live count, repetitions, initialization mode, raw wall time, adjusted time, device elapsed time when meaningful, peak allocated bytes, and peak reserved bytes. Counter differences must use a matching measurement interval. Include missing-field status instead of silently replacing a missing counter with zero.

Check that tensor references do not accumulate in a list intended only for logging. Compare requested live bytes with observed allocated growth and explain allocator granularity. Investigate unexpectedly high variance with a fresh repeat and a smaller instrumentation footprint. A pointer reappearing proves address reuse in that trace, not a universal allocator policy. A near-zero CUDA event interval is not proof that allocation has no CPU cost.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The baseline determines the meaning of every later speedup. If ordinary PyTorch allocation already reuses storage efficiently, a Python pool must earn its complexity by reducing other costs or controlling lifetimes and capacity more effectively.

Explain how the benchmark changes when the workload is dominated by large memory writes, by tiny requests, or by many live buffers. Identify one measurement that would distinguish host bookkeeping from additional device allocation activity. Carry the baseline protocol

forward unchanged so that later pooling improvements are attributable to a specific design choice.

19.27.3 Exercise 02

Exercise Title: Build a Fixed-Size CUDA Buffer Pool That Reuses Previously Allocated Tensors Instead of Allocating New Storage

Part 1 - Exercise Contract and Why It Matters

Construct the smallest pool with a defensible ownership contract: a fixed number of identical contiguous CUDA buffers and at most one active lease per buffer. Produce acquisition and release interfaces, a registry of buffer states, and an experiment demonstrating reuse without reallocation after construction. The learner must implement the ownership checks and all CUDA operations.

Choose a fixed capacity and an exhaustion policy before running: bounded waiting or an explicit rejection. Silent growth is outside this exercise. Use a synchronized, single-stream consumer so that release can prove device completion. Require the caller to initialize the requested region and forbid use of any returned tensor or view after lease release.

Part 2 - System and Memory Mental Model

A lease is a temporary right to use storage, not a new storage allocation. Store a buffer ID and a monotonically advancing generation with each lease. A release must match the current owner and generation. These fields detect double release and stale handles, but cannot revoke a raw tensor alias that a caller deliberately retains. State that limitation as an API contract; Python objects do not become invalid merely because a registry changes their status.

Preallocated free buffers remain live CUDA tensors. They consume the full pool capacity even when no borrower exists. Acquiring a buffer should change ownership metadata, not storage size, dtype, or device. Avoid operations such as growing `resize_` that can allocate new storage behind a supposedly fixed-capacity record.

Correctness requires two separate conditions: no other lease owns the buffer, and all prior uses have finished. In this initial design, the caller performs an explicit completion step before release. Later exercises introduce pending states and asynchronous reclamation. Autograd-managed activations are excluded because their lifetime can extend through backward even after a forward function has returned.

Part 3 - Quantitative Prediction Before Execution

For m buffers of n elements and item size s, predict

$$C = mns, \qquad 0 \le L(t) \le m, \qquad F(t) + L(t) = m$$

for the synchronized two-state pool. F denotes free buffers and L leased buffers; an invalid release must not alter either count.

Use a hypothetical pool of four buffers, each with 2^{18} float32 elements. Calculate total capacity, then sketch the state sequence for four acquisitions, one rejected fifth request, two releases, and two new acquisitions. Predict the number of backing allocations and the number of successful leases separately. Explain why using one buffer 100 times should increase lease count without increasing pool capacity. Write the expected effect of an old-generation release before testing it.

Part 4 - Experimental Design and Instrumentation

1. Define a typed configuration and validate positive dimensions, device, dtype, and buffer count before construction.

2. Allocate all backing tensors outside the warmed acquisition interval. Record scalar storage identities and allocated memory growth.

3. Acquire every buffer, write a distinct pattern to each, run a deterministic consumer, and validate results after synchronization.

4. Exercise exhaustion without allocating an extra buffer. Release selected leases and confirm only those buffers become eligible.

5. Attempt a double release and a stale-generation release using metadata-only misuse tests. They must leave the registry unchanged.

6. Replay a long sequence with no more than the configured concurrency. Measure acquisition latency and prove no backing storage is added.

Do not deliberately race stale aliases with GPU execution. Demonstrate the alias limitation through a safe sequential example and document the borrower's responsibility.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass(frozen=True)
class Lease:
    buffer_id: int
    generation: int
    tensor: torch.Tensor

class FixedBufferPool:
    def __init__(self, shape, dtype, device, buffer_count):
        # Validate configuration and establish fixed storage.
        ...
```

```
    def acquire(self):
        # Grant an exclusive lease or report exhaustion.
        ...

    def release(self, lease, completion_proof):
        # Validate ownership and completed use before release.
        ...

    def audit(self):
        # Check unique ownership and constant capacity.
        ...

def E02(config):
    # Build the pool and preserve scalar storage identities.
    ...
    # Exercise reuse, exhaustion, and invalid lease release.
    ...
    # Compare numerical results with independent tensors.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires constant backing capacity after construction, unique ownership for every live buffer, correct output patterns, and explicit exhaustion behavior. Show registry snapshots before and after each misuse test. Invalid operations must not increase the free count or allow two borrowers to receive the same storage.

Check both logical shape and backing storage size. A correct-shaped tensor with replaced storage violates the intended fixed-pool experiment. Delete all experimental leases before studying destruction; their tensor fields are strong references. If capacity appears to remain after deleting the pool, inspect these references rather than assuming allocator leakage. Separate the pool's retained capacity from allocator-reserved bytes.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The fixed pool turns allocation into admission control. Exhaustion becomes an explicit condition the caller can wait for or handle, rather than unplanned growth. Its strongest advantage may be predictability rather than raw speed.

Explain the costs of preallocating for worst-case concurrency when typical concurrency is low. Identify what must change to support variable sizes and what must change to support asynchronous consumers. These are different extensions: size classes solve placement compatibility, while events solve completion. A reliable design keeps those obligations separate.

19.27.4 Exercise 03

Exercise Title: Compare Fresh Allocation Against Buffer Reuse by Latency, Peak VRAM, Reserved Memory, and Allocation Count

Part 1 - Exercise Contract and Why It Matters

Benchmark the fixed pool against ordinary per-request PyTorch allocation using identical useful work and request lifetimes. Deliver a comparison that distinguishes faster execution, lower memory consumption, and fewer management operations. None of these outcomes implies the others. The phrase fresh allocation means a new tensor request in this experiment, not necessarily a fresh driver allocation.

Use the E01 timing protocol and the E02 ownership contract. Include a startup-inclusive view and a warmed view, because preallocation moves cost rather than erasing it. Require numerical agreement before reporting a speedup. A pool that retains more memory or runs slower remains a valid experimental result.

Part 2 - System and Memory Mental Model

There are at least three relevant counters: application requests, new backing tensors created by the custom pool, and allocator activity. A high request count can coexist with few new allocator segments in the ordinary path. In the pooled path, a stable backing allocation count can coexist with substantial Python lease bookkeeping.

Peak allocated memory measures live tensor storage through PyTorch; peak reserved memory includes the allocator's retained segments. An application pool generally retains its free tensors, so its allocated baseline can be higher even if peak allocation churn is lower. Compare absolute peaks and increases above the mode's own baseline. Reporting only the increase can conceal a large preallocated pool.

The useful workload must initialize and consume the same bytes in each mode. If the consumer returns outputs, account for those separately and use identical output lifetimes. Pool capacity should match actual concurrency rather than the total number of requests. Cache purging, garbage collection, and synchronization inserted into only one path destroy the main comparison.

Part 3 - Quantitative Prediction Before Execution

For ordinary and pooled elapsed times T_o, T_p, define

$$S = \frac{T_o}{T_p}, \qquad \Delta M_{\text{peak}} = M_{p,\text{peak}} - M_{o,\text{peak}}.$$

Report uncertainty and both signs of the memory difference. If pool construction costs T_c and each completed request saves an assumed $\delta t > 0$, the simplified break-even request count is

$$N_{\text{break}} \approx \frac{T_c}{\delta t}.$$

This estimate is inapplicable when measured savings are nonpositive.

For a hypothetical construction cost of 2 ms and a hypothesized saving of 0.5 microseconds per request, predict the break-even scale. Then explain how a capacity of eight buffers can increase startup allocated memory relative to a trace with one simultaneous request. Record the prediction without presenting either hypothetical timing as a GPU measurement.

Part 4 - Experimental Design and Instrumentation

1. Build one request trace and replay it for both modes. Match byte sizes, simultaneous leases, initialization, consumer kernels, and outputs.

2. Use fresh processes for cold-start comparisons where practical. For warm comparisons, warm both modes and randomize their execution order.

3. Reset peak statistics at the same logical boundary. Sample mode baseline, complete-region peaks, and final allocated and reserved bytes.

4. Count requests explicitly. Count custom backing tensor creation inside the pool. Collect available allocator counter differences without claiming they all represent driver calls.

5. Repeat at multiple request sizes and concurrency levels. Compare medians, tail latencies, and total completed requests per second.

6. Run a minimally instrumented throughput pass and a detailed diagnostic pass to estimate logging overhead.

Keep pool construction and final cleanup visible in the startup-inclusive account. Use the same maximum in-flight work so overlap does not become an uncontrolled advantage for one mode.

Use these interfaces from `torch.cuda`:

- `memory_allocated` and `memory_reserved`: current allocator observations.
- `max_memory_allocated`: peak allocated bytes.
- `max_memory_reserved`: peak reserved bytes.
- `reset_peak_memory_stats`: reset at the declared boundary.
- `mem_get_info`: the separate device-free observation.

These interfaces provide different accounting views; their values must not be added together as disjoint memory components.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class TrialResult:
    mode: str
    request_count: int
    backing_creations: int
    elapsed_seconds: float
    peak_allocated_bytes: int
    peak_reserved_bytes: int

def replay_trace(trace, allocation_mode, consumer):
    # Match initialization, concurrency, and useful work.
    ...

def measure_trial(trace, allocation_mode, config):
    # Capture baseline, peaks, completion time, and counters.
    ...

def compare_trials(ordinary_rows, pooled_rows):
    # Calculate uncertainty and distinguish counter meanings.
    ...

def E03(config):
    # Validate numerical equivalence before timing.
    ...
    # Run cold and warm comparisons in balanced order.
    ...
    # Explain memory and latency results independently.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Provide columns for ordinary request count, custom backing creations, supported allocator counters, startup time, warmed time, throughput, absolute allocated peak, allocated increase, and reserved peak. Use not-applicable for a custom-pool counter in the ordinary mode instead of disguising it as zero storage activity.

Check output equivalence with dtype-appropriate tolerances declared before measurements; simple integer-pattern copy checks should be exact. Investigate suspiciously large speedups by confirming initialization and synchronization. Reject any run with differing completed work counts. Show at least one memory-versus-latency tradeoff, or report that none was observed within the measured range. Do not infer reduced allocator fragmentation from lower application request count alone.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use

an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Performance claims need a clearly defined counterfactual. Ordinary PyTorch allocation already benefits from caching, so the comparison measures the incremental value of an application pool over that existing machinery.

Use the results to decide whether a custom pool is justified for the tested workload. A small latency gain can be undesirable when it reserves capacity needed by a model, while a bounded pool can be valuable even without a speedup. State which constraint dominates your decision and what additional workload would most likely overturn it.

19.27.5 Exercise 04

Exercise Title: Implement a Pool Free List That Returns Released CUDA Buffers to Reusable Size Classes

Part 1 - Exercise Contract and Why It Matters

Extend the fixed pool into a registry of compatible size classes, each with a free list. Produce interfaces that distinguish requested shape, backing capacity, and lease identity. Demonstrate reuse across requests in one class without mixing incompatible dtypes or devices. The core deliverable is a set of invariants that remains true across acquisition, release, exhaustion, and invalid requests.

Keep the first implementation single-stream with synchronized release. Use typed contiguous one-dimensional backing tensors and shape views whose logical element count does not exceed capacity. Support a documented subset of layouts rather than claiming arbitrary-stride compatibility. Do not combine separate storages into one larger contiguous buffer.

Part 2 - System and Memory Mental Model

A free list is an index of eligible buffers, not the owner of a second copy of their storage. Maintain a canonical record per buffer; free-list entries refer to its ID. A record must appear in exactly one eligible list or be leased, never both. A release reestablishes eligibility only after ownership and completion checks pass.

The class key needs device identity, dtype, and a declared capacity unit. If the initial pool supports only contiguous tensors with no special alignment promise, say so. A float16 capacity in elements is not equivalent to the same float32 element count in bytes. Shape can be a view-level property when the storage and contiguous layout are compatible.

Returning a tensor view does not transfer the underlying allocation away from the pool. Every alias remains subject to the lease contract. An old handle with a reused buffer ID is rejected using its generation. When no eligible buffer exists, growing the pool creates a new record only after successful allocation; failed growth must not leave a ghost free-list entry. Pending asynchronous buffers will need a separate index in E11 and must never be counted as ready here.

Part 3 - Quantitative Prediction Before Execution

For class k, let n_k be its buffer count and c_k its capacity in bytes. Predict

$$C = \sum_k n_k c_k, \qquad n_k = f_k + \ell_k$$

for this synchronized design. Define a hit as finding an eligible compatible buffer at the first lookup; a later successful growth is a miss followed by creation.

Construct a hypothetical trace with class capacities 1 MiB and 2 MiB. Acquire two buffers from the first class, release one, acquire from the second class, then request the first class again. Predict list lengths, leased counts, total capacity, and hit status at each operation. Repeat the reasoning with the same element count in a different dtype. Explain which property prevents an incorrect cross-class reuse.

Part 4 - Experimental Design and Instrumentation

1. Write the compatibility key specification before coding. Reject unsupported layouts and nonintegral byte-to-element conversions.

2. Implement canonical records and free-list membership checks. Record each state transition using IDs and integer counts.

3. Replay a short hand-computable trace, validating the registry after every operation. Compare the trace against your Part 3 ledger.

4. Repeat with multiple shapes that share capacity and with dtypes that must remain in separate classes. Fully initialize each logical view.

5. Exercise double release, stale generation, wrong pool identity, and an allocation failure simulated before registry insertion.

6. Run a longer bounded trace and inspect acquisition latency as the number of classes grows.

Keep failure injection at a defined interface so metadata rollback can be tested without destabilizing the CUDA context. Use ordinary reference tensors to validate each supported view's result.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
```

```
@dataclass(frozen=True)
class ClassKey:
    device: str
    dtype: torch.dtype
    capacity_elements: int

class ClassedPool:
    def __init__(self, class_policy, device):
        # Establish canonical records and per-class indexes.
        ...

    def classify(self, shape, dtype):
        # Validate layout and derive a compatible key.
        ...

    def acquire(self, shape, dtype):
        # Remove one eligible ID or perform controlled growth.
        ...

    def release(self, lease, completion_proof):
        # Validate generation and restore unique membership.
        ...

    def audit_membership(self):
        # Reconcile every free-list entry with its record.
        ...

def E04(config):
    # Replay a deterministic trace and failure cases.
    ...
    # Validate view contents, membership, and byte accounting.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires one canonical record for every retained backing storage, no duplicate free-list entries, no leased record in a free list, and matching class capacity and dtype. Show the ledger before and after every rejected operation. Rejection must not consume a valid lease or increase available capacity.

Measure class count, successful acquisitions, initial hits, growth attempts, successful creations, and current capacity. Explain why a miss counter can exceed successful creations after an allocation failure. Check that reshaping a request does not unexpectedly clone storage. Verify byte accounting from actual element size and backing capacity, not from the logical shape of the smallest view.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use

an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The free list makes availability explicit, but correctness comes from the registry and ownership rules behind it. A very fast list can still be wrong if it admits incompatible storage or duplicates a release.

Explain why class design and search policy are separate decisions: classification defines compatibility and capacity, while selection chooses among eligible records. This separation allows later experiments to change rounding or fit policy without changing the lifetime contract. Identify the invariant most likely to fail when asynchronous release is introduced and state how a pending index would preserve it.

19.27.6 Exercise 05

Exercise Title: Build Exact-Size and Rounded-Size Allocation Policies and Compare Their Memory Waste and Reuse Rate

Part 1 - Exercise Contract and Why It Matters

Compare exact-size classes with a configurable rounding quantum using the same request and release trace. Quantify the tradeoff between fewer classes, more potential reuse, and unused capacity inside active buffers. Produce a policy comparison that includes total retained capacity and does not mistake internal waste for all memory overhead.

Use identical dtype, device, concurrency, capacity limits, and completion rules. Define rounding in elements or in aligned bytes, then use that definition consistently. The code must leave class calculation and selection to the learner. Include a held-out trace so a policy chosen on one distribution is evaluated on a different one.

Part 2 - System and Memory Mental Model

Exact-size policies minimize class slack for each request, but a sequence of nearby sizes may populate many rarely reused classes. Rounding can allow those requests to share capacity across time. It does not permit two overlapping leases to share one writable buffer and does not reduce the logical amount of data the computation needs.

Internal waste is capacity minus requested bytes for leased buffers. Idle retained buffers and pending buffers belong in separate categories. A rounded policy may have more slack per live lease yet less total retained capacity because it reuses a smaller collection of buffers. Alternatively, rounding can increase both waste and capacity.

Use an element-compatible quantum. For byte-based classes, the resulting capacity must be divisible by the element size, and any stronger alignment requirement must be specified. Do not reinterpret an arbitrary uint8 buffer as several dtypes without a validated alignment and layout design. The initial policy instead keeps typed storage classes separate. Define explicit behavior for zero-element tensors and requests above the configured maximum before measuring them.

Part 3 - Quantitative Prediction Before Execution

For positive requested bytes q and a compatible byte quantum a, an ideal rounded class has

$$c(q) = a \left\lceil \frac{q}{a} \right\rceil, \qquad w(q) = c(q) - q, \qquad 0 \le w(q) < a.$$

Exact-size application classes have $c(q) = q$, although the underlying allocator can still apply its own rounding.

For a hypothetical quantum of 256 KiB, predict class capacity and slack for requests of 513, 700, and 768 KiB. Then compare a sequential trace with a trace in which all three requests overlap. Calculate the minimum number of buffers in each case under exact-class matching. Predict how a repeated 513/700 KiB alternation differs from a stream of never-repeated sizes. State which conclusions depend on the trace's release order.

Part 4 - Experimental Design and Instrumentation

1. Generate three traces: one stable size, nearby jittered sizes, and a broad distribution. Preserve explicit acquire and release events.

2. Replay each trace with exact classes and several rounding quanta. Fix the cache-retention and growth rules across policies.

3. At every transition, record requested live bytes, live slack, idle capacity, pending capacity if supported, and unique retained storage.

4. Count class cardinality and initial lookup hits. Separate cold-start misses from steady-state misses.

5. Measure a CUDA workload using a subset of the trace, initializing only the complete logical region required by the consumer.

6. Choose one quantum from calibration traces and evaluate it on the held-out trace without retuning.

Do not read uninitialized class slack or include it in the output shape. If an implementation zeroes whole backing buffers, include those additional writes in its measured overhead and label the initialization policy.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class SizeDecision:
    requested_bytes: int
    capacity_bytes: int
    class_key: object

def exact_size_policy(request):
    # Validate the request and choose its exact class.
    ...

def rounded_size_policy(request, quantum_bytes):
    # Respect dtype element size and declared alignment.
    ...

def replay_policy(trace, policy, pool_config):
    # Keep lifetime, retention, and growth rules identical.
    ...

def summarize_waste(rows):
    # Separate live slack, idle retention, and total capacity.
    ...

def E05(config):
    # Predict classes for a hand-computable request sequence.
    ...
    # Calibrate on one trace and evaluate another unchanged.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check every class decision against the declared rounding rule. For positive supported requests, capacity must cover the logical bytes and obey element-size divisibility. Exact-size application slack should be zero; allocator rounding must appear in a different measurement.

Report hit rate, class count, time-weighted live slack, peak pool capacity, and complete workload time. Validate the time weighting: a large idle interval should not be treated as equal to one short transition merely because both produce one log row. Explain at least one case where better hit rate does not imply lower memory use. Reject comparisons that changed the request trace, live concurrency, or trimming policy while changing the rounding quantum.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Size classes are a prediction about which future requests can share storage. Rounding deliberately spends capacity to increase that sharing opportunity. The quality of the prediction depends on both sizes and lifetimes.

Discuss whether a globally fixed quantum is appropriate for the measured range or whether separate small and large regimes deserve investigation. Do not introduce a new policy solely because it improves the calibration trace. State the evidence that would justify the extra complexity and the memory cost of a mistaken prediction.

19.27.7 Exercise 06

Exercise Title: Design Power-of-Two Size Classes and Measure How Internal Fragmentation Changes Compared with Exact-Size Pools

Part 1 - Exercise Contract and Why It Matters

Implement and evaluate power-of-two size classes with a documented minimum class and maximum supported request. Derive their ideal slack bounds, then identify where minimum-class and alignment rules change those bounds. Compare against the exact-size pool on traces concentrated near class boundaries as well as ordinary variable workloads.

Produce a boundary table, an application-capacity ledger, and an empirical comparison. Use the term internal fragmentation specifically for unused space inside an assigned buffer. Do not equate it with the allocator's inability to satisfy a contiguous request or with idle cached capacity.

Part 2 - System and Memory Mental Model

Geometric classes reduce the number of class sizes needed across a wide range. Requests just above a power-of-two boundary can receive almost twice their requested capacity, while requests exactly on the boundary have no application-level slack. A single class can be reused by many different logical shapes when dtype and layout compatibility hold.

The mathematical rule is easy to state but still needs a robust implementation. Define whether rounding uses elements or bytes, handle zero explicitly, and reject negative or unsupported requests. Avoid floating-point logarithms for integer boundary decisions if their precision could select an undersized class; the learner must choose and justify an exact integer method. Verify multiplication into bytes before requesting storage.

A minimum class breaks the usual relative-waste bound for tiny requests. Likewise a maximum pool budget can reject a rounded class even when the unrounded request would have fit. Underlying allocator rounding introduces another layer that must be measured independently. The power-of-two policy has no authority over physical segment placement.

Part 3 - Quantitative Prediction Before Execution

For positive q with no extra minimum or alignment constraint, the ideal byte capacity is

$$c(q) = 2^{\lceil \log_2 q \rceil}, \qquad q \le c(q) < 2q.$$

Consequently, $w = c - q < q$ and $w/c < 1/2$. These strict bounds are for the ideal rule, not for all practical class configurations.

For requests $2^k - 1$, 2^k, and $2^k + 1$, predict capacity and both waste fractions w/q and w/c. Use byte requests representable by the selected dtype when constructing actual tensors. Then introduce a 4 KiB minimum class and a hypothetical 16-byte request: determine which relative

bound no longer holds. Predict the number of distinct classes for a chosen finite request interval and the effect of excluding zero from the logarithmic formula.

Part 4 - Experimental Design and Instrumentation

1. Build an integer-only boundary test table before touching CUDA. Include exact powers, adjacent representable requests, zero, and maxima.
2. Generate a sequential trace concentrated just above boundaries. Compare exact-size, fixed-quantum, and power-of-two class assignments.
3. Add overlapping lifetimes so the experiment cannot mistake temporal reuse for simultaneous sharing.
4. Replay bounded CUDA traces with identical initialization and consumers. Record live slack, idle capacity, pool peaks, hits, and acquisition time.
5. Test requests whose rounded capacity exceeds the limit. Report rejection without silently allocating outside the budget.
6. Repeat with a workload whose sizes naturally cluster near powers of two and compare the change in the tradeoff.

Keep the ordinary allocator backend fixed. If its reserved-memory behavior differs between policies, describe that as an observation requiring allocator evidence rather than as a direct consequence of the application slack formula.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
import torch

def choose_power_class(requested_elements, itemsize, limits):
    # Implement exact integer rounding and boundary handling.
    ...

def predict_boundary_rows(exponents, dtype, minimum_bytes):
```

```
    # Derive capacity and both definitions of waste fraction.
    ...

def build_boundary_trace(config):
    # Create valid requests with explicit overlap intervals.
    ...

def compare_class_policies(trace, policies, config):
    # Preserve identical lease and retention semantics.
    ...

def E06(config):
    # Validate class arithmetic before CUDA allocation.
    ...
    # Measure adversarial and naturally clustered traces.
    ...
    # Explain every exception to the ideal slack bound.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact boundary classification and no undersized buffers. Show the ideal bound separately from minimum-class cases. Include requested bytes, chosen class, slack bytes, slack divided by request, and slack divided by capacity in the table; the two percentages answer different questions.

Check that a rejected rounded request leaves accounting unchanged. Validate views and outputs for all accepted requests. Investigate a very high hit rate alongside high capacity: coarse classes may be reusable but expensive. Confirm that differences in reserved memory are not caused by running one policy immediately after another without controlling allocator history. Document cold and warm results instead of discarding an unfavorable startup cost.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A bounded number of class sizes simplifies metadata but can impose substantial slack near boundaries. The ideal bound is useful precisely because its assumptions are explicit and testable.

Use your results to explain whether power-of-two classes are appropriate for the chapter's target workload. A hybrid class scheme is a possible future experiment, not an automatic improvement. Describe the measurement that would justify finer classes and the extra bookkeeping or reduced reuse that finer granularity could introduce.

19.27.8 Exercise 07

Exercise Title: Implement Best-Fit Buffer Selection and Compare It Against First-Fit Reuse Under Variable Tensor Sizes

Part 1 - Exercise Contract and Why It Matters

Compare first-fit and best-fit selection among compatible, safely reusable buffers. Keep class construction, pool growth, request order, and release order fixed. Deliver a hand-worked trace and a measured comparison showing selection overhead, live slack, misses, and retained capacity. The implementation must distinguish choosing a candidate from deciding whether growing the pool is allowed.

Allow a request to use an oversized compatible buffer when the policy permits it. Require the learner to define deterministic iteration and tie-breaking rules. An unavailable or pending buffer must never become a candidate solely because its size is attractive.

Part 2 - System and Memory Mental Model

First-fit chooses the first eligible buffer large enough in a specified order; best-fit chooses the smallest eligible capacity that covers the request. Best-fit minimizes immediate slack within the candidate set. It does not generally minimize future allocations, latency, or allocator fragmentation over the whole trace.

A best-fit search over an unsorted list can inspect every candidate, while an indexed structure changes both lookup and update costs. Measure those costs instead of attributing all differences to memory. First-fit results depend on list order, so insertion order, size order, and recency order are different policies and must not be mixed.

Application buffers are separate storages. Unused tails are not reusable suballocations unless a separate arena allocator with offsets and alias rules is implemented. That extension is outside this exercise. Two free 4 MiB tensors do not form one contiguous 8 MiB tensor. Describe fragmentation at the application inventory level before attempting to infer anything about allocator segments.

Part 3 - Quantitative Prediction Before Execution

For eligible set $\mathcal{F}$ and request q, best-fit targets

$$c^* = \min\{c_j : j \in \mathcal{F},\ c_j \geq q,\ j \text{ compatible}\}.$$

The immediate slack is $c^* - q$. If the set is empty, the selection result is no fit; growth or waiting is a separate decision.

Consider free buffers in order 16, 8, and 12 MiB, followed by overlapping requests of 7 and 15 MiB. Predict each policy's choices and whether a second allocation is needed. Then devise a different trace where both policies use the same capacity but best-fit performs more comparisons. For a linear scan of F free records, state a worst-case comparison bound and distinguish it from measured average search work.

Part 4 - Experimental Design and Instrumentation

1. Implement one candidate-compatibility predicate shared by both policies. Include device, dtype, capacity, layout, and readiness.

2. Verify the hand-worked trace with scalar simulated records. Log candidate order and selected buffer ID for every request.

3. Replay identical seeded size-and-lifetime traces in separate pools. Preserve the same growth limit and eviction policy.

4. Measure lookup time and comparison count separately from total workload time, where CUDA completion is included.

5. Include traces with many small requests followed by a large request, and traces with a narrow range of sizes.

6. Compare application slack and retained capacity with allocator statistics, keeping the accounting layers distinct.

Do not reorder first-fit's free list between runs without labeling the policy change. When there is no fit, log why each plausible buffer failed eligibility rather than calling every failure a size shortage.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class Candidate:
    buffer_id: int
    capacity_bytes: int
    compatible: bool
    ready: bool

def eligible_candidates(records, request):
    # Apply one shared compatibility and readiness contract.
    ...

def select_first_fit(candidates, requested_bytes):
    # Preserve the declared deterministic iteration order.
    ...
```

```
def select_best_fit(candidates, requested_bytes):
    # Choose by capacity and an explicit tie-break rule.
    ...

def replay_selection(trace, selection_policy, pool_config):
    # Separate no-fit selection from admission and growth.
    ...

def E07(config):
    # Verify the hand trace, then compare seeded workloads.
    ...
    # Export slack, comparisons, misses, and complete latency.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that selected candidates are ready, compatible, and large enough. For best-fit, audit the complete candidate set in a diagnostic pass to prove no smaller eligible capacity was skipped. For first-fit, audit that no earlier eligible record was skipped. Keep these expensive audits out of the primary throughput interval and report their overhead.

Use a results table containing policy order, live slack, pool peak, growth count, mean comparisons, lookup tail latency, and complete throughput. Include a no-fit event despite sufficient total free bytes spread across separate buffers. Do not label that evidence as physical allocator fragmentation without a separate allocator-level investigation. Numerical outputs and completed request counts must match across policies.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Selection is an online decision with incomplete knowledge of future requests. Minimizing immediate slack can preserve large buffers, but the benefit depends on the future trace and may cost additional search work.

State whether the observed gain comes from better inventory use, lower search overhead, or neither. Explain how stronger workload predictability might favor static preallocation instead. The experiment should leave the reader with a conditional policy choice grounded in evidence, not a universal ranking of fit algorithms.

19.27.9 Exercise 08

Exercise Title: Track Pool Hit Rate, Miss Rate, Reuse Count, Wasted Bytes, and Peak Pool Capacity During a Real PyTorch Workload

Part 1 - Exercise Contract and Why It Matters

Instrument the pool with metrics that remain interpretable under growth, waiting, rejection, and repeated reuse. Integrate it into a real PyTorch inference or input-staging workload with supported buffers, rather than claiming control over every allocation made inside a model. Deliver a scalar event log, a reconciled summary, and a measured instrumentation overhead comparison.

Define every denominator before collecting results. Track application requests separately from retry attempts and count unique storage rather than tensor views. Include a period with no active leases and a period with several in-flight leases. The report must explain why a high hit rate does not by itself imply an efficient memory system.

Part 2 - System and Memory Mental Model

A request can miss at its first lookup, wait, and eventually receive an existing buffer. It can also miss and grow the pool, or be rejected. Choose a mutually exclusive first-lookup classification, then record the terminal outcome separately. This avoids counting one request as both a hit and a miss when it is retried. Repeated internal polls are attempts, not new application requests.

Reuse count describes repeated successful loans of a backing buffer after its first successful loan. It is not identical to hit count when the pool was preallocated before any request. Report that convention. Live slack, free capacity, pending capacity, and total retained capacity have distinct meanings and must be tracked at transitions that can change them.

Metrics themselves can change performance. GPU scalar extraction can synchronize, and retaining tensors in a log changes their lifetime. Prefer host metadata for ownership events and periodic scalar CUDA memory observations at deliberate boundaries. Pool misses do not describe allocations inside opaque operators, so measure whole-process peaks alongside the managed subset.

Part 3 - Quantitative Prediction Before Execution

Let R be distinct application requests, H first-lookup hits, and M first-lookup misses:

$$R = H + M, \qquad h = H/R \quad (R > 0).$$

If buffer j has u_j successful loans, define total reuse as

$$U = \sum_j \max(u_j - 1, 0).$$

For time-varying slack $W(t)$, compare its peak with its time average

$$\overline{W} = \frac{1}{T} \int_0^T W(t)\, dt.$$

State how event timestamps approximate that integral.

For a hypothetical ten-request trace containing three initial misses, two waits, one rejection, and seven first-lookup hits, determine which facts are insufficient to calculate reuse. Explain why terminal outcomes must be linked to request IDs. Predict the difference between a large slack spike lasting one millisecond and the same slack lasting one second.

Part 4 - Experimental Design and Instrumentation

1. Write a metric schema with units, counting scope, reset behavior, and zero-denominator conventions. Validate it on a small simulated trace.

2. Integrate the pool into repeated inference input staging or explicit temporary tensors whose lifetimes you control.

3. Run stable shapes, variable shapes, and a short burst of increased concurrency. Keep model parameters and numerical settings fixed.

4. Log request and buffer IDs, state transitions, requested and capacity bytes, first-lookup result, terminal outcome, and completion time.

5. Reconstruct summary metrics from the raw log and compare them with live counters.

6. Repeat with detailed logging disabled to quantify overhead.

Store tensor-free records. If whole-process allocation rises while pool capacity is stable, inspect unmanaged model outputs or activations instead of blaming the pool's class policy.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PoolEvent:
    timestamp_seconds: float
    request_id: int
    buffer_id: int
    event_kind: str
    requested_bytes: int
    capacity_bytes: int

class PoolMetrics:
    def __init__(self):
        # Establish explicit counters and empty-log semantics.
```

```
        ...

    def observe(self, event):
        # Count requests, attempts, and outcomes separately.
        ...

    def reconcile(self, registry):
        # Compare live counters with unique storage records.
        ...

    def summarize(self):
        # Derive rates, peaks, and time-weighted quantities.
        ...

def E08(model, request_trace, config):
    # Run a supported workload and verify output equivalence.
    ...
    # Reconstruct metrics independently from scalar events.
    ...
    # Measure the cost of instrumentation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires $R = H + M$, one terminal outcome per completed request, and agreement between reconstructed and live capacity metrics. Pending requests at shutdown must be labeled unfinished until drained or cancelled under a defined protocol. Zero-request intervals should have undefined rates, not misleading perfect hit rates.

Report median and tail acquisition latency, wait duration, hit rate, successful creations, reuse count, live slack, idle capacity, pool peak, and process memory peaks. Verify that the metrics logger contains no tensor objects or autograd graphs. If instrumentation changes throughput, present both measurements and use the minimally instrumented run for performance claims. Show a high-hit-rate case with substantial retention or explain why your measured trace did not produce one.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Observability is part of the pool design because incorrect metrics can reward unsafe or wasteful behavior. A request that waits for an in-flight buffer may be memory-efficient yet have poor tail latency; one number cannot capture both effects.

Use the evidence to identify the current limiting factor: insufficient capacity, poor size matching, overly long ownership, or instrumentation. Propose the smallest experiment that

distinguishes your leading explanation from an alternative. Carry the same event schema into later asynchronous and budgeted pools so comparisons remain meaningful.

19.27.10 Exercise 09

Exercise Title: Build Separate CPU Pinned-Memory and GPU VRAM Buffer Pools for Repeated Host-to-Device Transfers

Part 1 - Exercise Contract and Why It Matters

Build separate pools for pinned CPU staging buffers and CUDA destination buffers. Demonstrate repeated host-to-device transfers with explicit ownership on both sides and independent RAM and VRAM accounting. Compare against an ordinary allocation-and-transfer path using equivalent CPU preparation and GPU consumption.

The initial implementation may use conservative completion barriers. Its purpose is to establish correct paired lifetimes and budgets before E10 introduces overlap. Do not assume pinned memory is free or that pinning every iteration is cheaper than retaining a bounded pinned pool. Measure construction and warmed reuse separately.

Part 2 - System and Memory Mental Model

A pinned source buffer occupies host memory and supports transfer behavior different from ordinary pageable storage. The GPU destination occupies device memory. These allocations are not one interchangeable pool, even when they represent the same logical batch. Their dtypes, capacities, and initialization regions must match the transfer contract.

For an H2D transfer, the CPU source must remain unchanged until the copy finishes. The destination cannot be consumed before the copy completes and cannot be overwritten until its last GPU consumer finishes. Those are separate completion points. In the conservative baseline, synchronize at defined boundaries and release only when the corresponding condition is established.

Pinned memory is a subset of host memory, so avoid summing a process RAM metric and pinned bytes as though they were disjoint. The process may also have dataset pages, Python objects, and pageable staging allocations. Likewise the GPU process contains model storage outside the destination pool. A pool cap controls managed capacity, not all memory on the machine. Host and device allocator caching can persist after application records are dropped, so retain both application and process-level observations.

Part 3 - Quantitative Prediction Before Execution

For n_h host buffers and n_d device buffers of capacity c, predict

$$C_{\text{pinned}} = n_h c, \qquad C_{\text{device}} = n_d c.$$

These are separate resource requirements. A simplified serial transfer model is

$$T_{\text{batch}} = t_{\text{fill}} + t_{\text{H2D}} + t_{\text{compute}}.$$

Pooling changes preparation and allocation costs; it does not make the transfer payload disappear.

For a hypothetical 8 MiB payload, three pinned buffers, and two device buffers, calculate each pool's capacity and the total logical bytes copied over 100 batches. Predict why the two pools need not have equal depth. Explain what extra measurement is needed before using a bandwidth estimate to predict transfer time for the chosen payload size.

Part 4 - Experimental Design and Instrumentation

1. Specify independent pinned-RAM and VRAM caps and leave room for the dataset, model, and runtime outside the pools.
2. Allocate typed pinned CPU buffers and typed CUDA buffers with matching transfer layouts. Verify pinning and device properties.
3. Fill a host lease with a request-specific pattern, copy it to a device lease, and validate a deterministic GPU consumer.
4. Release the source only after copy completion and the destination only after consumer completion.
5. Compare ordinary pageable transfer, repeated pinning if supported, and reused pinned staging as separate labeled modes.
6. Measure CPU fill time, transfer time, complete batch time, host retention, device retention, and startup cost.

Include the cost of copying dataset data into the pinned staging buffer. Do not compare a prepared pooled source with an unprepared baseline and attribute the difference solely to allocation reuse.

Investigate `torch.empty` with CPU placement and `pin_memory=True`, tensor `is_pinned()`, and a destination tensor's `copy_` interface. A conversion such as `to()` can create a new destination; verify that your chosen operation actually uses the acquired destination storage.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class TransferLeases:
    request_id: int
    host_lease: object
    device_lease: object
```

```
def acquire_transfer_pair(host_pool, device_pool, request):
    # Acquire compatible leases with rollback on failure.
    ...

def prepare_host_payload(host_lease, batch):
    # Initialize the complete logical transfer region.
    ...

def copy_and_consume(pair, consumer, device):
    # Establish distinct copy and compute completion points.
    ...

def release_transfer_pair(pair, completion):
    # Respect host-source and device-destination lifetimes.
    ...

def E09(config):
    # Compare startup and warmed transfer modes fairly.
    ...
    # Validate payload identity and both resource ledgers.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct device contents for every transferred request, no premature source mutation, and no destination reuse before consumption. Verify that failure to acquire the second lease returns the first safely without leaking capacity. A metadata rollback cannot cancel an already submitted CUDA copy; submitted work needs its completion protocol.

Report host and device capacities in separate columns and distinguish pinned bytes from total process RAM. Show a shutdown procedure that drains work before discarding buffers. If a transfer is slower than the pageable baseline, inspect CPU fill cost, small-payload overhead, and measurement boundaries. Treat the result as evidence rather than assuming pinned reuse must always win.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Transfer pooling is a two-resource scheduling problem. The host buffer and device buffer can become reusable at different times, so coupling their lifetimes unnecessarily can retain memory

and reduce throughput.

Explain which pool is the bottleneck in your experiment and whether adding capacity to the other pool would help. Relate the answer to the measured fill, copy, and compute durations. This reasoning provides the basis for a pipelined design whose depth is justified by service times and memory budgets.

19.27.11 Exercise 10

Exercise Title: Reuse Staging Buffers Across Non-Blocking Transfers Without Overwriting Data Still Used by an In-Flight CUDA Operation

Part 1 - Exercise Contract and Why It Matters

Turn the transfer baseline into a bounded pipeline with non-blocking copies and request-specific completion tracking. The objective is to overlap independent work while preserving data identity. Produce a timeline showing host fill, H2D copy, GPU consumption, and the two different release points.

Use a configurable ring depth and compare depth one with deeper pipelines. A correct implementation may wait when the next slot is still busy. Never make an occupied slot appear free merely because the Python copy call has returned.

Part 2 - System and Memory Mental Model

Non-blocking submission means the host can continue before the transfer finishes; it does not authorize mutation of the pinned source. A GPU wait can order device work, but it does not stop the CPU from overwriting a host buffer. Host reuse needs proof that the copy has completed, such as an appropriate event query or synchronization.

The GPU destination has a longer possible lifetime. Copy completion permits its consumer to begin, while the final consumer's completion permits another producer to overwrite it. If several consumers read the destination, all relevant uses must be covered. For D2H extensions, the host destination must not be read before transfer completion or reused before the host consumer releases it.

Separate streams can permit overlap when hardware and dependencies allow it, but do not guarantee it. Pinned source storage, sufficient independent work, copy-engine capability, and scheduling all matter. A ring index is only a location selector; its generation and completion state determine whether that slot is eligible.

Part 3 - Quantitative Prediction Before Execution

Let τ be the production interval and L_h, L_d the host and device lease lifetimes. Under a regular ideal pipeline, useful depth estimates are

$$n_h \gtrsim \lceil L_h/\tau \rceil , \qquad n_d \gtrsim \lceil L_d/\tau \rceil .$$

These are planning estimates, not guarantees under jitter or contention. An ideal steady-state lower bound on batch interval is

$$\tau \geq \max(t_{\text{fill}}, t_{\text{copy}}, t_{\text{compute}})$$

only when the stages can overlap as modeled.

For hypothetical fill, copy, and compute durations of 1, 2, and 5 ms, sketch a depth-one serial timeline and a feasible deeper timeline. Identify when each host and device slot can

be reused. Predict how extra depth changes memory capacity even after throughput stops improving.

Part 4 - Experimental Design and Instrumentation

1. Create a safe depth-one reference and verify its outputs exactly for copied integer patterns.
2. Add a copy stream and compute stream with explicit producer-to-consumer dependencies. Associate events with request and slot generations.
3. Refill a host slot only after its copy event is complete. Reassign a device slot only after its last consumer completes.
4. Sweep pipeline depth within fixed RAM and VRAM caps. Measure complete throughput, wait time, and retained capacity.
5. Vary CPU preparation and GPU consumer duration so either side can become the bottleneck.
6. Add a safe simulator that rejects an attempted early refill. Use it as the negative control instead of intentionally racing live DMA.

Do not synchronize every iteration in the overlapped benchmark. Drain the pipeline before the final wall-clock timestamp and before validating results or destroying its buffers.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class StagingSlot:
    generation: int
    host_lease: object
    device_lease: object
    copy_done: object
    consumers_done: object
```

```
def slot_host_ready(slot):
    # Establish CPU-safe source reuse for this generation.
    ...

def slot_device_ready(slot):
    # Cover every previous GPU consumer.
    ...

def submit_pipeline_stage(slot, payload, streams):
    # Fill, copy, order consumption, and record completions.
    ...

def drain_pipeline(slots, device):
    # Finish submitted work before validation or shutdown.
    ...

def E10(config):
    # Compare ring depths with identical complete workloads.
    ...
    # Export ownership intervals and producer wait times.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Every consumed payload must match its request ID and expected contents. Log the generation occupying each slot so a correct value from a previous batch cannot pass unnoticed. Check that slot reuse timestamps follow the relevant completion evidence; host function return is not sufficient.

Report pipeline depth, completed batches, total time, host wait time, device wait time, transfer bytes, and both pool capacities. Inspect the timeline if throughput fails to improve: the workload may lack independent work or may already saturate one stage. A depth increase that only grows memory is an important result. Require bounded waiting and an explicit timeout outcome for injected missing-completion cases.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Safe overlap is a lifetime transformation, not just a non-blocking flag. The pipeline gains freedom by keeping multiple generations alive, and that freedom consumes capacity.

Explain the smallest depth that achieves the observed throughput within measurement uncertainty. Compare the cost of waiting with the cost of holding another buffer. Carry forward the distinction between host-safe and device-safe reuse: later multi-stream pooling must preserve both, even when the physical buffer selection becomes more dynamic.

19.27.12 Exercise 11

Exercise Title: Add CUDA Event Tracking So Buffers Return to the Pool Only After Their Last Asynchronous Consumer Has Completed

Part 1 - Exercise Contract and Why It Matters

Introduce an explicit pending-completion state between lease release and reusable availability. Build an event-aware reclamation interface that returns buffers to free lists only after every declared asynchronous consumer has finished. Deliver a state-transition audit and a comparison against globally synchronized release.

Specify who registers consumers, who closes the lease to new consumers, and who polls completion. A buffer cannot be safely reclaimed if new users may still be registered after the final event is chosen. The learner must implement this protocol and its validation.

Part 2 - System and Memory Mental Model

Use the state sequence free, leased, pending, free. Releasing a lease closes its ownership generation but may only move the record to pending. Capacity remains retained and unavailable until the completion proof passes. A successful event query establishes completion of work covered by that event; it does not cover commands submitted later.

For multiple consumers, retain a set of completion events or construct a join on a stream that waits for all consumers before recording one final event. An event recorded after only one consumer is insufficient. Avoid re-recording an event for a new generation while old pool records still depend on its meaning.

`record_stream` informs the allocator about uses when tensor storage is eventually deallocated. It does not prevent an application pool from overwriting the same still-live tensor. This pool therefore needs its own lease and completion protocol even if allocator lifetime tracking is also used. Completion polling should be bounded and must not turn a CUDA error into a false claim of readiness.

Part 3 - Quantitative Prediction Before Execution

For a closed lease with consumer event set $\mathcal{E}_j$, the eligibility condition is conceptually

$$\text{ready}(j) = \text{closed}(j) \ \wedge \bigwedge_{e \in \mathcal{E}_j} \text{complete}(e).$$

Predict the capacity conservation relation

$$C = C_{\text{free}} + C_{\text{leased}} + C_{\text{pending}}.$$

No capacity is removed merely by moving from leased to pending.

For a hypothetical 16 MiB buffer with consumers completing at 3 and 7 ms, identify the earliest globally safe return time. If polling occurs at 4 and 8 ms, distinguish actual completion from observed reclamation. Predict how a longer polling interval can increase required capacity without changing useful GPU work.

Part 4 - Experimental Design and Instrumentation

1. Implement a metadata-only completion simulator and prove all state transitions before connecting real CUDA events.

2. Run one-consumer and two-consumer CUDA cases with request-specific patterns and explicit data dependencies.

3. Close the lease, record the relevant completion evidence, and place the record in pending without putting it in a free list.

4. Poll at configurable intervals; measure pending bytes, polling cost, and delay between completion and observed reclamation.

5. Compare with a synchronized-release baseline under equal maximum capacity and useful work.

6. Inject stale-generation callbacks, duplicate completion processing, and missing consumer registration in the simulator.

Ensure diagnostics do not reuse event objects prematurely. At shutdown, drain pending work or report an explicit incomplete state; do not label undrained buffers as free.

Inspect `torch.cuda.Event`, its `record` and `query` methods, and stream `wait_event`. Distinguish a host completion query from inserting a dependency into another stream. Events used only for completion do not require timing measurements to be enabled.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class PendingLease:
    buffer_id: int
    generation: int
    completion_events: tuple
    closed: bool
```

```
class EventReclaimer:
    def __init__(self, pool):
        # Track pending records independently of free lists.
        ...

    def close_lease(self, lease, consumer_events):
        # Reject future consumers and capture this generation.
        ...

    def poll(self, limit):
        # Reclaim only records whose complete proof is ready.
        ...

    def audit(self):
        # Prevent duplicate refunds and stale-event reuse.
        ...

def E11(config):
    # Compare one consumer, multiple consumers, and a join.
    ...
    # Measure polling overhead and delayed reclamation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require that pending records never appear in free lists and that every reclaimed record corresponds to the current closed generation. Repeated polls after completion must not refund capacity twice. Validate the two-consumer case against a synchronized reference and show that the earlier event alone cannot authorize reuse.

Report pending peak bytes, completion-observation delay, poll count, acquisition stalls, and complete throughput. Keep true GPU completion and host observation timestamps conceptually separate. A timeout or CUDA failure must produce a diagnosable terminal status, not silently release the buffer. Explain how an incomplete consumer-registration contract could invalidate otherwise correct event code.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Asynchronous reclamation separates logical release from physical reuse. That distinction lets the host continue without globally synchronizing, but it requires a proof that covers all users of each generation.

Discuss how polling frequency trades CPU overhead against retained pending capacity. Identify whether your workload benefits more from frequent polling, larger capacity, or shorter

consumer lifetimes. The resulting policy should be justified by measured delay and throughput rather than by assuming events are free.

19.27.13 Exercise 12

Exercise Title: Build a Multi-Stream Buffer Pool and Prevent Two CUDA Streams from Reusing the Same Storage Unsafely

Part 1 - Exercise Contract and Why It Matters

Extend the event-aware pool to several CUDA streams and, optionally, several host submitters. Preserve exclusive write ownership and explicit producer-to-consumer ordering. Deliver a stream-use registry, a contention trace, and correctness evidence under deliberately varied completion orders.

Begin with the conservative rule that a free buffer is globally reusable only after all previous consumers finish. A more aggressive stream-ordered reuse policy is an optional extension requiring its own proof. Keep host-buffer reuse rules separate because GPU waits cannot prevent a CPU producer from overwriting pinned storage.

Part 2 - System and Memory Mental Model

Two kinds of ordering are required. Data dependencies ensure that a consumer reads results after their producer writes them. Lifetime dependencies ensure that a future borrower does not overwrite storage while an earlier consumer still uses it. Satisfying one does not automatically satisfy the other.

The host registry must also allocate ownership atomically. Two threads cannot both observe the same free record and then independently lease it. Use an explicit synchronization design rather than relying on the Python GIL as the ownership protocol. Metadata locks should not be held while performing an unbounded CUDA wait; define how to wait and then revalidate the state.

Allocator stream tracking concerns deallocation and later allocator reuse. An application pool retains the same tensor, so its manual overwrite must be governed by its own events and generations. If storage is evicted while side-stream work is still outstanding, the design is already violating the conservative pool contract. For permitted deallocation paths, also honor the allocator's stream lifetime requirements. An event on the default stream does not automatically describe work on every other stream.

Part 3 - Quantitative Prediction Before Execution

For buffer j, define owner count o_j and outstanding closed-generation consumer count u_j. Require

$$o_j \in \{0, 1\}, \qquad j \in \mathcal{F} \Rightarrow o_j = 0 \ \wedge \ u_j = 0.$$

These are metadata invariants; correct data ordering requires additional producer dependencies.

With three streams and two buffers, predict the outcome when each stream requests a writable lease before any release. Then consider one producer whose output is read by two streams: distinguish one shared read phase under a closed ownership protocol from two independent writable leases. Draw the event dependencies and identify which event or join permits the next writer. Predict how conservative global readiness can reduce overlap relative to a proven stream-ordered design.

Part 4 - Experimental Design and Instrumentation

1. Implement the ownership transition logic in a host-only simulator. Force two submitters to contend for the same free record.

2. Run a single-stream reference, then the same request trace across multiple streams with explicit producer dependencies.

3. Register all consumers before closing each lease. Reclaim through the E11 completion protocol.

4. Vary consumer duration and submission order while keeping the numerical workload fixed. Record request, stream, buffer, and generation.

5. Validate unique ownership and output patterns after draining. Measure waits caused by both capacity shortage and incomplete consumers.

6. If adding stream-ordered reuse, state its stronger assumptions and compare it separately with globally ready reuse.

Use bounded metadata misuse tests rather than intentionally submitting conflicting writes. A safety checker should reject an invalid transition before it becomes a real CUDA data race.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import threading
import torch

@dataclass
class StreamUse:
    stream_id: int
    generation: int
    completion_event: object

class MultiStreamPool:
    def __init__(self, config):
        # Establish records, locks, and completion tracking.
```

```
        ...

    def acquire(self, request, producer_stream):
        # Atomically reserve one compatible globally ready record.
        ...

    def register_consumer(self, lease, stream, ready_event):
        # Enforce data ordering and record the consumer lifetime.
        ...

    def close(self, lease):
        # Seal registration before forming completion evidence.
        ...

    def reclaim(self):
        # Revalidate generations without unbounded locked waits.
        ...

def E12(config):
    # Exercise contention and out-of-order stream completion.
    ...
    # Audit ownership separately from numerical correctness.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no duplicate writable ownership, no reuse of pending storage, and correct output for every request. A test that only checks final outputs can miss a race that happened not to corrupt data, so also audit the event and ownership graph. A graph with correct ordering but a forgotten consumer must fail the lifetime audit.

Report per-stream completed requests, acquisition stalls, pending capacity, metadata contention time, and complete throughput. Check shutdown while streams have unequal outstanding work. Validate that one submitter timing out cannot release another submitter's lease. Document any unsupported cross-device or external-stream use rather than assuming the single-device proof extends automatically.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Concurrency changes the pool from a container into a coordination system. The central requirement is a consistent ownership decision across host threads and device streams.

Explain where the conservative protocol spends performance to gain simpler reasoning. Consider relaxing it only when measurements identify that restriction as a significant bottleneck.

An optimization that depends on undocumented stream behavior is weaker than a slower design with explicit dependencies and reproducible evidence.

19.27.14 Exercise 13

Exercise Title: Add Maximum Pool Capacity and Evict Cached Buffers When the Pool Exceeds a Fixed VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Add a hard limit on application-managed GPU buffer capacity. Before growing the pool, account for existing storage and outstanding growth reservations; evict only eligible free buffers when policy allows it. Demonstrate bounded behavior under concurrent growth attempts, allocation failure, and a runtime reduction of the configured cap.

Define the limit in bytes and include leased, pending, and free buffers. The cap applies to this pool, while model storage and other allocations remain outside it. A pool cap is not a guarantee that the entire process or GPU cannot run out of memory.

Part 2 - System and Memory Mental Model

Admission must occur before allocation. If two requests each check the same remaining capacity, both can overcommit unless the decision and growth reservation are atomic. When storage is materialized, replace its reservation with actual capacity rather than counting both. On allocation failure, remove the reservation exactly once.

Eviction means removing the pool's ownership of a free buffer. It cannot reclaim a leased or pending buffer without violating the lifetime contract. Dropping the last application tensor reference can reduce allocated bytes, but the CUDA allocator may retain the freed block. `empty_cache()` affects unused allocator cache, not live tensors that still belong to the pool.

If the configured cap shrinks below unavoidable live and pending capacity, the pool is temporarily over the new limit. Stop growth and new unsafe admissions, drain work, and report the condition. Do not retroactively claim the smaller cap was honored. Requests larger than the cap need an explicit rejection or a separately specified fallback that is still charged to the relevant budget.

Part 3 - Quantitative Prediction Before Execution

Let C be materialized unique capacity, G outstanding growth reservations, c a proposed buffer, and B the cap. Admission needs

$$C + G + c \leq B$$

after eligible eviction and before materialization. During successful creation, the increase in C must match the decrease in G.

For a hypothetical 64 MiB cap, 40 MiB leased, 8 MiB pending, and 16 MiB free, analyze a new 24 MiB request. Determine whether evicting all free buffers is sufficient. Then analyze a cap reduction to 32 MiB and state what can and cannot be reclaimed immediately. Distinguish admitted capacity from driver-visible free VRAM in both examples.

Part 4 - Experimental Design and Instrumentation

1. Implement an atomic capacity ledger and validate it with concurrent host-only growth simulations.

2. Use a deterministic victim policy over free records, recording evicted capacity and expected future reuse cost.

3. Replay a CUDA trace with alternating small and large requests. Compare unlimited retention with several bounded capacities.

4. Inject allocation failure after reservation but before record publication. Confirm exact rollback and unchanged existing leases.

5. Reduce the cap while work is pending. Record oversubscription, blocked growth, completion, and eventual compliance.

6. Observe allocated, reserved, and driver-free memory before and after dropping eligible buffers; treat cache release as a separate action.

Keep a reserve for unmanaged GPU allocations. A favorable free-memory sample does not lock out another process, so report allocation failures even when the pool's internal ledger was valid. **Reproducibility record.** Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class CapacityLedger:
    limit_bytes: int
    materialized_bytes: int
    reserved_growth_bytes: int

class BudgetedPool:
    def __init__(self, config):
        # Establish atomic accounting and free-only eviction.
        ...

    def reserve_growth(self, request):
        # Select eligible victims and reserve before allocating.
```

```
        ...

    def materialize(self, reservation):
        # Publish storage or roll back a failed reservation.
        ...

    def set_limit(self, new_limit_bytes):
        # Handle limits below current non-evictable capacity.
        ...

    def audit_capacity(self):
        # Reconcile actual storage and unmaterialized promises.
        ...

def E13(config):
    # Exercise concurrent growth, failure, and cap reduction.
    ...
    # Compare application capacity with allocator observations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require capacity conservation and no uncharged allocation path. At a fixed cap, every admitted growth must satisfy the ledger inequality. Under cap reduction, explicitly identify the interval in which previously admitted storage exceeds the new limit. Free-only eviction must preserve all active and pending generations.

Report rejection count, waiting time, eviction count, growth retries, pool peak, and allocated/reserved peaks. Verify that stale aliases are not silently counted as freed storage; the borrower contract must be honored before physical-release claims. Test a request exactly at the cap and one whose rounded capacity exceeds it. Explain any difference between reduced application capacity and unchanged driver-visible usage.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A capacity limit turns cache growth into an admission decision. Its meaning is strongest when the accounting boundary is explicit: this pool can control its own buffers, while the surrounding runtime must manage the rest of the process.

Discuss the throughput cost of a smaller cap and whether evictions mostly remove cold buffers or force repeated recreation of hot ones. Identify when waiting for pending work is cheaper than eviction and growth. This prepares the pressure-aware trimming policy without weakening the hard accounting invariant.

19.27.15 Exercise 14

Exercise Title: Implement Pool Trimming That Releases Long-Unused Buffers When Runtime Memory Pressure Crosses a High Watermark

Part 1 - Exercise Contract and Why It Matters

Implement pressure-triggered trimming of safely free buffers using idle age and a declared target. Add separate high and low watermarks so small fluctuations do not trigger repeated trimming and regrowth. Deliver a trace connecting pressure samples, victim selection, capacity reduction, and later misses.

Keep the hard cap from E13 independent of this policy. Trimming is a proactive retention decision; it cannot reclaim leased or pending storage. Use an explicit simulated-budget trace before introducing bounded real memory pressure.

Part 2 - System and Memory Mental Model

Choose the pressure signal deliberately. Pool occupancy, process allocated memory, allocator-reserved memory, and device free memory answer different questions. A reserved-memory ratio may remain high after pool trimming because the allocator caches freed blocks. A device-free signal also reflects other processes and can change between measurement and action.

Idle age begins when a buffer becomes safely free, not when its lease was acquired or when a host release moved it to pending. Track last use and free-since timestamps separately. A recently completed long operation is not necessarily a long-idle buffer.

Use hysteresis for policy state and a cooldown or minimum retention rule only when compatible with the hard cap. Under severe pressure, keeping a hot free buffer may be unaffordable, so document which constraints take precedence. Dropping references and releasing allocator cache are distinct interventions and should be timed separately. If no free victims exist, the correct response is waiting, admission restriction, or explicit failure, not eviction of active storage.

Part 3 - Quantitative Prediction Before Execution

For a declared byte-pressure measure $M(t)$ and budget $B(t) > 0$, define $p(t) = M(t)/B(t)$. Choose

$$0 < p_{\text{low}} < p_{\text{high}} < 1.$$

Enter trimming mode at the high watermark and leave it only after the low-watermark condition and any declared stability interval hold. Do not mix a numerator from one accounting layer with a budget from another.

For an idle-age threshold a, eligible victims satisfy

$$t - t_{j,\text{free}} \geq a, \qquad j \in \mathcal{F}.$$

Given hypothetical free buffers of 8, 16, and 32 MiB with idle ages 10, 2, and 20 seconds, predict which are eligible at a 5-second threshold. Select a declared policy to release at least 24 MiB and calculate its overshoot. Explain why eligibility alone does not determine victim order.

Part 4 - Experimental Design and Instrumentation

1. Define pressure units, watermarks, age threshold, polling interval, and trim target before implementation.

2. Replay a synthetic pressure trace crossing the high threshold once, oscillating near it, and later staying below the low threshold.

3. Populate the pool with hot and cold size classes, including pending buffers that must remain ineligible.

4. Measure trimming time, removed capacity, later misses, and changes in the pressure state.

5. Run a bounded CUDA pressure experiment using a declared managed allocation or controlled budget change. Record the mechanism explicitly.

6. Compare age-based trimming with an equally budgeted no-age policy and with no proactive trimming.

Use a monotonic host clock for age. Sample pressure at controlled points and log its age, since delayed observations can explain late reactions.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class TrimConfig:
    high_ratio: float
    low_ratio: float
    minimum_idle_seconds: float
    cooldown_seconds: float

def pressure_observation(device, pool, budget):
    # Name the accounting layer and timestamp the observation.
    ...

def eligible_trim_victims(records, now, config):
    # Include only safely free records with sufficient age.
    ...
```

```
def choose_trim_target(observation, config):
    # Apply hysteresis without overriding the hard cap.
    ...

def apply_trim(pool, victim_ids):
    # Retire eligible records and reconcile released ownership.
    ...

def E14(config):
    # Replay threshold crossings and measure regrowth cost.
    ...
    # Explain allocated, reserved, and free-memory responses.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require that no leased or pending buffer is selected, that free-since age is measured correctly, and that repeated noisy pressure samples do not cause uncontrolled state changes. Show one trace in which trimming removes application capacity without immediately reducing reserved bytes.

Report bytes requested for trimming, bytes actually retired, overshoot, trim latency, state transitions, later growth count, and complete workload throughput. Inspect a no-victim case explicitly. A policy that reports success despite freeing nothing must distinguish target unmet from successful pressure relief. Verify that hard-cap enforcement still works during cooldown and that logging retains no evicted tensors.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Trimming is a prediction that idle capacity will be less valuable than the headroom it releases. Idle age is evidence for that prediction, not a proof about future demand.

Use the measured regrowth cost to judge the threshold. If trimming repeatedly removes hot capacity, a lower retention target may be too aggressive or the pressure signal may be mismatched to the goal. Explain how hysteresis stabilizes decisions while preserving a prompt response to a real shortage.

19.27.16 Exercise 15

Exercise Title: Detect Pool Bloat Where Cached Buffers Consume Far More VRAM Than the Active Working Set Requires

Part 1 - Exercise Contract and Why It Matters

Build diagnostics that distinguish legitimate warm capacity from sustained pool bloat. Analyze live demand, retained idle classes, pending lifetimes, and storage that remains alive through escaped references. Deliver a time-series report and a targeted mitigation supported by a before-and-after comparison.

Use a workload with a temporary large-shape phase followed by a smaller steady phase. Include a short quiet interval so ratio definitions must handle zero active bytes explicitly. Do not declare every cache above the instantaneous working set wasteful.

Part 2 - System and Memory Mental Model

Retaining capacity can prevent future allocation cost, but a pool may continue holding many obsolete classes after demand changes. A high hit rate during the smaller phase can coexist with a large idle inventory left by the earlier phase. Hit rate alone cannot detect this.

Separate four causes: active class slack, free cold buffers, long-pending buffers, and storage outside the pool's current registry that remains alive through references. The last case is an ownership or observability problem, not ordinary cache retention. Pending capacity may reflect legitimate slow consumers or a missing completion transition.

Instantaneous demand is too narrow a denominator for every diagnosis. Compare retained capacity with a recent demand window and with a known replay of future requests when evaluating offline. During zero demand, report retained bytes and quiet duration rather than dividing by zero or hiding the interval with an arbitrary denominator. Pool bloat also differs from allocator cache retention after tensors are released; keep application and allocator measurements separate.

Part 3 - Quantitative Prediction Before Execution

For positive requested live bytes $Q(t)$, define the diagnostic ratio

$$\beta(t) = \frac{C_{\text{pool}}(t)}{Q(t)}.$$

It is undefined at $Q(t) = 0$. A complementary time-window measure is

$$I_{\text{idle}} = \int_{t_0}^{t_1} C_{\text{free}}(t)\, dt,$$

with units byte-seconds. Compare it with latency saved by future hits, not with an unrelated count.

For a hypothetical pool retaining 512 MiB while live demand is 32 MiB, calculate the ratio. Then distinguish a one-millisecond dip in demand from a ten-minute low-demand phase. Construct a ledger separating 64 MiB pending, 384 MiB free, and the remaining materialized capacity. Explain what additional information is needed to calculate active slack and to classify the pending bytes as suspicious.

Part 4 - Experimental Design and Instrumentation

1. Run a three-phase trace: small steady requests, a large-shape burst, then the original small requests for a sustained interval.

2. Collect per-class capacity, free-since age, loan count, recent hits, pending duration, and requested live bytes.

3. Add a safe reference-retention diagnostic: retain one known tensor alias, retire its pool record after completed use, and observe storage lifetime until that alias is removed.

4. Compare unlimited retention, hard-cap-only retention, and age-based trimming under the same request trace.

5. Evaluate future miss cost and throughput after mitigation, so capacity reduction is not treated as the only objective.

6. Replay the trace with a later return to large shapes and measure whether the chosen mitigation was too aggressive.

Keep the deliberate alias confined to this diagnostic and document that it violates the normal no-use-after-release contract.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ClassHealth:
    class_key: object
    requested_live_bytes: int
    free_bytes: int
    pending_bytes: int
    retained_bytes: int

def collect_class_health(pool, now):
    # Reconcile unique storage and ownership durations.
    ...

def diagnose_bloat(history, quiet_interval):
    # Separate ratios, idle retention, and pending anomalies.
    ...
```

```
def recommend_retention_change(diagnostics, config):
    # State expected capacity gain and future miss penalty.
    ...

def E15(config):
    # Replay demand shifts and a bounded alias diagnostic.
    ...
    # Compare memory relief with later recreation cost.
    ...
    # Explain zero-demand intervals without invalid ratios.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

The report must identify which category dominates retention and show evidence for the proposed cause. High capacity by itself is insufficient to claim a leak. A missing pending-to-free transition needs a completion and generation trace; an escaped reference needs an ownership trace.

Report retained bytes during quiet intervals, time-weighted idle capacity, recent demand, pending-age tails, hit rate, and later growth latency. Verify that mitigation preserves outputs and does not evict live storage. After releasing the diagnostic alias, compare allocated and reserved memory separately. Confirm that a lower bloat ratio is not merely the result of increasing active batch size and consuming more memory.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Useful caching is a bet on reuse, while bloat is retained capacity whose expected value no longer justifies its cost. The distinction depends on workload phases and the resource pressure faced by the surrounding runtime.

Explain whether a fixed age threshold, a capacity cap, or a demand window best addresses the measured cause. Avoid adding a complex retention policy to conceal a broken ownership transition. First prove the accounting and lifetimes, then optimize the cache's economic tradeoff between capacity and recreation cost.

19.27.17 Exercise 16

Exercise Title: Build a Shape-Aware Temporary Tensor Pool for Repeated Attention or Matrix-Multiplication Workspaces

Part 1 - Exercise Contract and Why It Matters

Adapt the pool to explicitly managed temporary tensors for repeated matrix multiplication or a transparent attention implementation. Define supported shapes, dtypes, layouts, and lifetimes, then compare pooled scratch with ordinary temporary allocation under identical mathematics. Deliver numerical validation and a breakdown of which allocations the pool actually controls.

Start in inference or a no-gradient region using operations whose documented output-buffer behavior is suitable. This pool cannot supply arbitrary internal workspaces to opaque cuBLAS, cuDNN, or fused attention operators through ordinary tensor reuse. A training extension must separately prove autograd compatibility and saved-tensor lifetime.

Part 2 - System and Memory Mental Model

A shape-aware key can include dtype, device, capacity, contiguous layout, and the operation's output contract. Shape equality is sufficient for some reuse but not necessary when a larger typed contiguous buffer can provide an appropriate view. Conversely, equal element count is insufficient if an operator requires a different stride or layout.

Operations with an `out=` argument must be checked individually for supported shape, dtype, aliasing, and autograd behavior. Many such operations do not support automatic differentiation when participating inputs require gradients. Pre-size supported outputs so implicit resizing does not invalidate the pool's capacity accounting. Never use `.data` or bypass version checks to force unsafe reuse.

Autograd may save an input or intermediate for backward even when the forward computation is complete. Overwriting it can trigger a version-counter error or invalidate differentiation if checks are bypassed. A scratch buffer is reusable only after its last semantic consumer, not simply after the kernel that wrote it.

Explicit attention materializes tensors that a fused backend may avoid. Comparing those two implementations confounds pooling with algorithm and backend selection. The primary pooling comparison must use the same operator structure and materialization policy.

Part 3 - Quantitative Prediction Before Execution

For a matrix product with output $M \times N$ and element size s, predict output bytes

$$q_{\text{out}} = MNs.$$

For explicitly materialized attention scores with batch B, heads H, and sequence length S, predict

$$q_{\text{scores}} = BHS^2 s.$$

This describes that explicit score tensor, not the peak of every attention backend. Peak scratch depends on overlapping lifetimes of scores, probabilities, outputs, and any other temporary storage.

For hypothetical $B = 2$, $H = 8$, $S = 512$, and float32 scores, calculate score bytes and the increase when S doubles. Draw a lifetime chart to determine whether two equally sized intermediates can share one buffer under the chosen operations. Explain what changes if backward still requires the earlier intermediate.

Part 4 - Experimental Design and Instrumentation

1. Choose an explicit matrix-product or attention computation and document which tensors are pooled and which remain operator-owned.

2. Build a reference with ordinary allocation and a pooled variant using the same operations, precision settings, and initialization.

3. Validate supported output-buffer behavior and reject unsupported gradient-enabled or layout cases before execution.

4. Sweep repeated shapes and variable shapes, recording logical scratch bytes, backing capacity, process peaks, and complete latency.

5. Keep all scratch leases until their last consumer completes. Check aliases before using an output as another operation's input.

6. As an optional training study, use a separate supported design and compare gradients with a reference; do not assume inference scratch rules extend to backward.

If comparing fused attention separately, label it an algorithm/backend comparison and report its different materialization behavior.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass(frozen=True)
class WorkspaceSpec:
    operation: str
    shape: tuple
    dtype: torch.dtype
    device: str
    layout: str

def validate_workspace_contract(spec, inputs, grad_enabled):
    # Reject unsupported output, alias, layout, or grad cases.
    ...
```

```
def plan_workspace_lifetimes(operation_graph):
    # Identify last consumers and overlapping storage needs.
    ...

def run_reference(inputs, config):
    # Use ordinary allocation with the chosen operator graph.
    ...

def run_with_workspaces(inputs, pool, config):
    # Acquire compatible views and preserve their lifetimes.
    ...

def E16(config):
    # Validate outputs before comparing shapes and latency.
    ...
    # Distinguish managed scratch from hidden operator memory.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require numerical agreement with predeclared absolute and relative tolerances appropriate to dtype and operation. Report maximum error and non-finite values, not just a pass flag. The primary comparison must use identical backend and precision settings.

Audit actual backing storage before and after output operations to detect implicit reallocation. Reject unsupported layouts instead of silently cloning them and omitting the extra allocation from accounting. For any training extension, validate gradients and parameter updates while preserving saved tensors until backward completes.

Report requested scratch, retained capacity, unmanaged peak contribution where measurable, and complete workload latency. State that a reduction in application scratch requests does not prove elimination of internal library workspaces. Include the largest tested shape and all rejected or unsupported cases.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Shape-aware pooling is most effective where the application owns both the temporary storage and its lifetime. Opaque operators may already use specialized memory strategies that a Python-level pool cannot replace.

Explain whether the measured opportunity comes from repeated output storage, staging, or explicit intermediates. If a fused implementation uses less memory, that does not invalidate the pooling experiment; it changes the best engineering choice for the application. Keep algorithm selection, precision, and storage reuse as separately measured decisions.

19.27.18 Exercise 17

Exercise Title: Compare Static Preallocation, Dynamic Pooling, and Ordinary PyTorch Allocation Under Stable and Variable Workloads

Part 1 - Exercise Contract and Why It Matters

Benchmark three complete allocation strategies: fixed static buffers, dynamic pooling, and ordinary PyTorch tensor allocation. Compare stable shapes, variable shapes, and phase changes under matched resource limits and useful work. Deliver a decision table describing where each strategy is feasible and where it is competitive.

Specify static capacity before running. If a later request exceeds that capacity, record rejection or a declared fallback and charge its cost. Dynamic pooling must include growth, lookup, event management, and trimming overhead. Ordinary allocation retains the normal caching allocator behavior unless a separate experiment explicitly changes it.

Part 2 - System and Memory Mental Model

Static preallocation offers predictable application capacity and low management work when shapes and concurrency are known. It can waste memory when provisioned for rare maxima or fail when an unseen shape exceeds the contract. Dynamic pooling adapts its inventory but can accumulate classes, introduce search overhead, and require complex ownership tracking.

Ordinary allocation delegates reuse to PyTorch's allocator and keeps the application simpler. It may already perform well enough that a custom pool has no practical benefit. The three strategies operate above the same CUDA hardware but expose different application-level lifetimes and metadata costs.

Fairness requires matching peak in-flight work, initialization, output retention, and stream synchronization. A static buffer reused by one serialized consumer is not directly comparable to a dynamic pool supporting four overlapping consumers. Likewise, a strategy that rejects difficult requests cannot claim higher throughput by counting only the requests it happened to accept.

Part 3 - Quantitative Prediction Before Execution

For strategy s, decompose startup-inclusive time as

$$T_s = T_{s,\text{setup}} + T_{s,\text{useful}} + T_{s,\text{management}} + T_{s,\text{waits}} + T_{s,\text{cleanup}}.$$

This is an accounting decomposition of non-overlapping wall-time categories; do not add overlapping stage timings as though they were serial costs.

For a static design with m slots of maximum capacity $c_{\max}$, predict $C_{\text{static}} = mc_{\max}$. Compare it with the dynamic inventory required by a specific trace, including retained old classes. Use a hypothetical workload with 95 requests of 1 MiB and five requests of 32 MiB. Explain why frequencies alone are insufficient to determine peak capacity: request overlap and release order are also needed. Predict which strategy is favored under a 16 MiB cap if every request must be completed unchanged.

Part 4 - Experimental Design and Instrumentation

1. Define one supported consumer and one request-trace format for all strategies. Include explicit concurrency and completion events.

2. Create stable, jittered, broad-size, and phase-shift traces. Reserve one trace for evaluation after policy calibration.

3. Set equal application resource limits and disclose unmanaged process memory. Define feasibility and rejection rules consistently.

4. Measure startup-inclusive and warmed complete execution, plus management-only diagnostics in separate runs.

5. Validate outputs and request coverage before comparing throughput. Report incomplete or infeasible runs with their failure point.

6. Compare latency distributions, pool or static capacity, allocated and reserved peaks, and implementation complexity.

Use fresh processes or a documented balanced warmup strategy to control allocator history. Do not clear the cache inside only the ordinary path.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class StrategyOutcome:
    name: str
    accepted_requests: int
    completed_requests: int
    rejected_requests: int
    elapsed_seconds: float
    capacity_bytes: int

def build_strategy(name, specification):
    # Establish static, dynamic, or ordinary allocation rules.
    ...

def replay_common_workload(strategy, trace, consumer):
    # Preserve concurrency, initialization, and request coverage.
```

```
    ...

def evaluate_feasibility(outcome, trace):
    # Keep rejection and incomplete work visible.
    ...

def E17(config):
    # Calibrate on one trace and evaluate held-out workloads.
    ...
    # Compare startup-inclusive and steady-state outcomes.
    ...
    # Produce a conditional strategy decision table.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires matching numerical results for completed requests and full accounting for every rejected or unfinished request. Report throughput using a clearly defined workload boundary; never compare successful-only subsets with complete-trace execution without labeling the difference.

Include strategy, trace, budget, startup time, complete elapsed time, median and tail request latency, completed coverage, capacity peak, allocated peak, and reserved peak. Show at least one capacity or shape-contract limitation of static preallocation. Investigate dynamic pool results that improve hits but worsen latency. A finding that ordinary allocation is best is acceptable when the comparison is fair and repeatable.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The best storage strategy depends on predictability, concurrency, capacity pressure, and maintenance cost. Static allocation moves decisions to configuration time; dynamic pooling makes them online; ordinary allocation delegates more of them to the framework.

Choose a strategy for each measured workload regime and state the constraint that drives the choice. Include a condition that would change your recommendation, such as a tighter cap or an altered shape distribution. Engineering judgment here is the ability to select an appropriately simple mechanism from evidence.

19.27.19 Exercise 18

Exercise Title: Stress-Test the Pool with Thousands of Random Tensor Sizes and Diagnose Excessive Misses, Internal Waste, Stale Buffers, and Synchronization Hazards

Part 1 - Exercise Contract and Why It Matters

Build a reproducible stress harness that generates thousands of requests with explicit sizes, dtypes, lifetimes, and consumer patterns. Exercise the pool's invariants under bounded capacity rather than allocating thousands of simultaneously live tensors indiscriminately. Deliver replayable seeds, minimized failure traces, and a diagnosis for every observed violation.

Separate host-only adversarial metadata tests from CUDA correctness tests. The simulator should reject unsafe transitions before they become real races. Test both ordinary randomized traces and targeted adversarial sequences; randomness alone is unlikely to cover all generation and completion bugs.

Part 2 - System and Memory Mental Model

Stress dimensions interact. A broad size distribution increases class diversity; overlapping lifetimes increase required concurrency; delayed completion increases pending capacity; and bursty demand exposes growth-reservation races. Stale handles and double releases attack ownership invariants even when sizes are constant.

Generate request IDs and buffer generations independently. Data patterns should identify the request that wrote the logical region so stale contents cannot pass a shape-only check. Every read region must be initialized in the valid implementation. An intentionally omitted initialization can be demonstrated sequentially as a safe negative control, not by racing a real writer against a reader.

Use bounded event deadlines and distinguish a slow workload from a missing completion transition. After each phase, drain and audit capacity, then compare against the pool's documented retention policy. Reserved memory remaining after drain is not by itself evidence of stale live tensors. A useful failure report identifies whether the problem is class selection, ownership, completion, capacity accounting, or an external allocation failure.

Part 3 - Quantitative Prediction Before Execution

For N requests and state transitions indexed by t, define

$$V = \sum_{t} \mathbf{1}\{\text{an invariant fails at } t\}.$$

The correctness target is $V = 0$, not merely a high successful-request percentage. Budget rejection is a valid outcome when policy requires it.

Predict peak live demand from an explicit lifetime trace:

$$Q_{\text{peak}} = \max_{t} \sum_{i \in \mathcal{L}(t)} q_i.$$

This is a lower bound on required application capacity before class slack, pending storage, and retained free buffers.

Design a hypothetical 10,000-request campaign with a bounded live set, a rare large-size burst, and delayed consumers. State expected failure signals for a deliberately broken double-release checker, a missing consumer event, and a too-coarse class policy. Only the first two necessarily violate correctness; excessive waste is a policy outcome.

Part 4 - Experimental Design and Instrumentation

1. Create a seeded CPU trace generator with explicit acquire, use, close, completion, and invalid-operation events.

2. Run a reference state model and the pool's metadata logic against the same trace. Stop on the first invariant divergence.

3. Add targeted cases: boundary sizes, zero requests, oversize requests, stale generations, duplicate callbacks, growth failure, and cap shrink.

4. Run supported CUDA traces with bounded simultaneous bytes and request-specific content checks after completion.

5. Vary stream count, polling interval, size distribution, and pressure independently before combining them in a final campaign.

6. Reduce any failure to a smaller replay trace while preserving the original seed, configuration, and first failing event.

Keep diagnostic logging bounded and tensor-free. Capture allocator statistics or a memory snapshot only in a designated diagnostic run, with installed-version API support recorded.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import torch

@dataclass
class StressAction:
    action_id: int
    request_id: int
    kind: str
    requested_bytes: int
    generation: int

def generate_trace(seed, request_count, constraints):
    # Bound live demand and include targeted corner cases.
    ...
```

```
def reference_transition(state, action):
    # Implement the independent ownership and budget model.
    ...

def run_metadata_campaign(pool, trace):
    # Reject unsafe actions before any CUDA submission.
    ...

def run_cuda_campaign(pool, trace, config):
    # Validate initialized payloads and completion ordering.
    ...

def minimize_failure(trace, failure_predicate):
    # Preserve the first reproducible invariant violation.
    ...

def E18(config):
    # Execute seeded campaigns and export replay artifacts.
    ...
    # Classify correctness failures separately from poor policy.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, request count, accepted and rejected counts, invariant violations, output mismatches, peak capacity, pending-age tails, hit rate, waste, and total runtime. A passing run must also drain cleanly and reconcile the final registry. Zero observed failures means only that the tested campaign passed, not that all possible schedules are proven safe.

For each injected metadata bug, demonstrate that the harness detects it without relying on random GPU corruption. For poor-policy cases, show measurable excess misses or waste rather than labeling them memory safety failures. Preserve the smallest failing trace and the last valid ledger. Explicitly distinguish pool-cap rejection, allocator OOM, unsupported requests, and synchronization errors.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Stress testing is strongest when randomness explores a space defined by precise invariants. A large request count is less valuable than a smaller campaign that can reproduce and explain its failures.

Use the results to prioritize fixes by correctness, capacity compliance, and performance. Repair ownership and completion defects before tuning hit rate. Identify a remaining untested dimension, such as external libraries or cross-device transfers, and keep it outside the manager's claimed support contract until it receives its own evidence.

19.27.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Memory Pool Manager That Reuses CPU and CUDA Buffers Safely Across Dynamic Workloads Under Fixed RAM and VRAM Budgets

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter's components into a single manager with typed requests, exclusive leases, compatible size classes, event-aware release, independent host and device budgets, bounded growth, trimming, and replayable diagnostics. The deliverable is a student-completed runtime and a benchmark dossier; the scaffold below intentionally leaves all policy and execution logic unfinished.

Define the support contract before implementation: devices, dtypes, layouts, inference or training-safe buffer roles, host pinning, stream registration, maximum request size, timeout behavior, and shutdown. Require correct outputs and capacity accounting before optimizing throughput. The runtime must explicitly reject unsupported requests instead of silently allocating untracked fallback storage.

Part 2 - System and Memory Mental Model

Separate the manager into request validation, class selection, admission, storage ownership, completion tracking, retention policy, and observation. These modules share a canonical ledger but answer different questions. A suitable-size buffer is not necessarily ready; a ready buffer may belong to the wrong device; a new compatible buffer may exceed the cap.

Track pageable host capacity and pinned host capacity as components of the manager's total host budget, with an optional additional pinned sub-limit. Track CUDA capacity separately for each supported device. Do not double-count pinned capacity in total host use. Process RSS and device free-memory observations remain external signals because datasets, model state, operator temporaries, and other processes are outside the manager's ownership boundary.

Acquisition must publish exactly one valid lease or a well-defined failure. Growth reservations are atomic and become materialized capacity only after successful creation. Release closes consumer registration, then waits through a pending state until the completion proof is valid. Eviction can retire only safely free records. Generation IDs protect metadata against stale releases but do not revoke escaped tensor aliases.

For training, manage only buffers whose autograd lifetime is explicitly supported; do not overwrite saved tensors or assume output-buffer operators are differentiable. OOM handling must preserve submitted work and ledgers. Some CUDA errors require terminating the experiment; the manager must not turn every runtime error into a retry. Dynamic external pressure cannot be eliminated by an internal pool cap.

Part 3 - Quantitative Prediction Before Execution

For resource r, require the fixed-cap admission invariant

$$C_{r,\text{leased}} + C_{r,\text{pending}} + C_{r,\text{free}} + G_r \leq B_r.$$

Here G_r counts only unmaterialized growth promises. Define host capacity without double counting:

$$C_{\text{host}} = C_{\text{pageable}} + C_{\text{pinned}}.$$

For a declared useful unit such as completed batches or valid tokens, measure

$$\text{throughput} = \frac{\text{completed useful units}}{\text{complete elapsed seconds}}.$$

Report request latency and byte traffic separately.

Before execution, construct a capacity plan for a hypothetical pipeline with 16 MiB payloads, three pinned source slots, two CUDA destination slots, and two additional 8 MiB scratch buffers. Allocate scratch to the appropriate resource and state all outside-manager memory. Predict feasibility under several independent host and device caps. Add delayed consumers and explain why lower nominal request size need not reduce pending capacity immediately.

Part 4 - Experimental Design and Instrumentation

1. Write a support matrix and invariants, then connect the components through typed requests and generation-bearing leases.

2. Validate capacity and ownership in the host simulator before CUDA integration. Inject reservation failure and duplicate callbacks.

3. Integrate a pinned-to-CUDA staging pipeline and a supported explicit scratch workload. Preserve complete consumer registration.

4. Benchmark ordinary allocation, static preallocation, and the manager on stable, variable, phase-shift, and bursty traces.

5. Sweep host and device caps independently. Record infeasible configurations and exact refusal reasons.

6. Add delayed completion, bounded pressure, and repeated growth/trim cycles. Measure tail latency and useful throughput after warmup as well as startup-inclusive cost.

7. Run ablations for rounding, fit policy, event polling, and trimming. Change one mechanism at a time on the same trace.

8. Perform graceful shutdown: stop admission, close or reject remaining registrations, drain submitted work, reconcile ledgers, and retire eligible storage.

Calibrate policies on one trace and evaluate them on held-out traces. Keep numerical precision and operator backend fixed during pooling comparisons. Publish the completed-request count and failure ledger with every timing result.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import threading
import torch

@dataclass(frozen=True)
class BufferRequest:
    request_id: int
    shape: tuple
    dtype: torch.dtype
    device: str
    pinned: bool
    role: str

@dataclass
class ResourceBudget:
    host_bytes: int
    pinned_limit_bytes: int
    device_limits: dict

class MemoryPoolManager:
    def __init__(self, budgets, policy, support_contract):
        # Establish registries, counters, locks, and resource caps.
        ...

    def validate_request(self, request):
        # Check supported layout, dtype, role, and capacity.
        ...

    def acquire(self, request, producer_stream=None):
        # Select ready storage or reserve budgeted growth.
        ...

    def register_consumer(self, lease, consumer, ready_event):
        # Register host or device use under the lease contract.
        ...

    def close_lease(self, lease):
        # Seal registration and establish pending completion.
        ...
```

```
    def poll_completions(self, work_limit):
        # Reclaim completed generations without duplicate refunds.
        ...

    def trim(self, pressure_observation):
        # Retire only eligible free storage under declared policy.
        ...

    def handle_creation_failure(self, reservation, error):
        # Roll back accounting and classify the failure.
        ...

    def audit(self):
        # Verify ledgers and declared ownership/completion records.
        ...

    def shutdown(self, deadline):
        # Stop admission, drain work, and report incomplete cases.
        ...

def benchmark_manager(manager_factory, traces, references):
    # Preserve useful work and compare all allocation strategies.
    ...

def E19(config):
    # Validate support contracts and simulator invariants first.
    ...
    # Run CUDA correctness, benchmark, ablation, and stress phases.
    ...
    # Export evidence, limitations, and a justified policy choice.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance has four independent gates. First, every accepted request must produce correct data under its supported operation contract. Second, ownership must remain exclusive and reuse must follow all declared completion evidence. Third, each fixed resource cap must hold for materialized capacity plus growth reservations. Fourth, the benchmark must account for all requested work, refusals, waits, and failures. A faster result cannot compensate for failure of another gate.

Provide a dossier containing environment metadata, support matrix, policy configuration, request traces, seed list, per-resource capacity timeline, latency distributions, useful throughput, transfer bytes, hit/miss definitions, live slack, pending ages, trimming cost, and allocator observations. Include numerical error summaries for floating point workloads and exact request-identity checks for staging.

Inspect shutdown with active work, missing completion evidence, stale leases, and growth failure. Report any remaining references that keep storage alive after manager retirement.

Distinguish application release, allocator cache retention, and device-visible memory relief. Preserve negative results and identify the smallest configuration in which the manager fails to improve on ordinary allocation.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use an explicit not-measured value instead of inventing hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The completed manager should make a precise promise: it controls the storage it owns under a documented lifetime and budget contract. That promise is more useful than an unsupported claim to eliminate all allocation overhead or all CUDA OOM events.

Use the benchmark to decide which components justify their cost for the target workload. Some applications need only static staging, while others benefit from event-aware dynamic reuse and proactive trimming. Explain the tradeoff among retained capacity, tail latency, CPU bookkeeping, and implementation complexity. End with an evidence-based deployment recommendation and the next unsupported condition that would need validation before broadening the manager's contract.

19.28 DMM26

Chapter Title: Memory Fragmentation Management
Specialization: Dynamic Memory Management and CUDA Systems

19.28.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Internal Fragmentation, External Fragmentation, Contiguous Allocation Requirements, and CUDA Memory Waste

Part 1 - Exercise Contract and Why It Matters

Build an accounting and lifetime model that distinguishes internal fragmentation, external fragmentation, reusable cache, and genuinely live demand. Deliver a labeled segment diagram, a quantitative example, and a small PyTorch observation that tests the model. Your explanation must identify the layer at which each claim is made: application buffer, PyTorch allocator block, allocator segment, or CUDA virtual memory.

Use one CUDA device and a documented allocator backend. Begin outside autograd with bounded contiguous tensors. Explain a case with substantial reserved memory that is harmless and a case where scattered inactive space can obstruct reuse. Do not define all unused memory as fragmentation.

Part 2 - System and Memory Mental Model

Internal fragmentation is unused capacity inside an assigned allocation: an application may request q useful bytes while a rounded buffer or allocator block occupies $c > q$. External fragmentation concerns free regions whose placement or eligibility prevents satisfying a particular request, despite an apparently adequate aggregate. Both definitions need an explicit allocation layer and request.

The native CUDA caching allocator can split segments into blocks and reuse inactive blocks. Live neighbors can prevent separate holes from coalescing into a larger reusable block. Entire inactive ordinary segments may be releasable, whereas a partially occupied segment can retain inactive space. Stream dependencies can also delay reuse after Python releases a tensor; delayed completion is not automatically structural fragmentation.

A contiguous tensor has a layout and backing storage contract. This does not require physically adjacent VRAM chips or a single run of physical pages. CUDA addresses are virtual, and allocation backends can obtain new segments or use virtual-memory mechanisms. Therefore the largest cached inactive block is not a universal upper bound on the next successful allocation.

Reserved minus allocated bytes can include reusable cache, split holes, and pending activity. A pool from DMM25 keeps idle tensors alive, so its free buffers may still count as allocated at the PyTorch layer. Do not add overlapping accounting categories or identify a leak from a single large reserved-memory observation.

Part 3 - Quantitative Prediction Before Execution

For allocated blocks in a declared set, define internal slack

$$W_{\text{int}} = \sum_i (c_i - q_i), \qquad \eta = \frac{\sum_i q_i}{\sum_i c_i}.$$

For a simplified fixed arena with eligible free holes h_j, define

$$F = \sum_j h_j, \qquad L = \max_j h_j.$$

A request with $L < q \leq F$ cannot fit in one existing hole in that arena. The conclusion assumes no growth, remapping, or live relocation. It is not a complete model of PyTorch's allocation path.

Draw a hypothetical 64 MiB arena with live blocks separating free holes of 8, 12, and 4 MiB. Test a 16 MiB request and explain the difference between aggregate capacity and immediate placement. Then allow a new segment and reconsider the prediction. For an independent 10 MiB logical request placed in a 16 MiB application buffer, calculate internal slack and state why it should not be added to the arena's free holes.

Part 4 - Experimental Design and Instrumentation

1. Construct a paper ledger with requested, assigned, live, pending, inactive, and reserved categories. Mark which categories overlap.

2. Inspect bounded PyTorch allocations before creation, while live, after completed release, and after a separate cache-release intervention.

3. Collect current allocated and reserved bytes plus device-free bytes. Compare these with a native allocator snapshot when supported.

4. Classify the largest inactive block as an observation with device, stream, pool, and timestamp scope, not as guaranteed allocation capacity.

5. Explain the difference between a noncontiguous tensor view and fragmented allocator free space using two independent examples.

6. Record what evidence would distinguish capacity shortage, long-lived references, and split-block trapping.

Preserve the exact backend and version. If snapshot semantics differ from the simplified arena, revise the mapping rather than forcing the observation to match the diagram.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class MemoryView:
    allocated_bytes: int
    reserved_bytes: int
    driver_free_bytes: int
    backend: str
    observation_time: float

def explain_arena(blocks, requested_bytes):
    # Compute layer-specific capacity and placement quantities.
    ...

def capture_memory_view(device):
    # Keep allocator and driver observations separate.
    ...

def classify_snapshot_blocks(snapshot, scope):
    # Identify live, pending, and inactive records.
    ...

def E00(config):
```

```
# Write predictions before observing PyTorch behavior.
...
# Compare the fixed-arena model with real allocator growth.
...
# Export a diagram and a reconciled accounting ledger.
...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires a correct distinction between virtual contiguity, tensor layout, and physical placement. Show why reserved bytes are not equivalent to currently free bytes. Include a counterexample to the claim that a large reserved-minus-allocated gap always signals damage.

Validate the arithmetic of the hypothetical arena independently of CUDA. For real observations, record whether uses have completed and whether references remain. Explain any unknown category instead of forcing a false conservation identity. No conclusion about unseen physical pages or allocations made directly by another library can be established from a PyTorch snapshot alone.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Fragmentation is a relationship between a request and the organization of available memory. A scalar utilization percentage cannot describe that relationship completely.

Use the model to state a testable diagnosis rather than a slogan: which request, which existing blocks, which live neighbors, and which growth constraint matter? This discipline connects DMM25's explicit buffer ownership to the allocator behavior below it and prevents later mitigation policies from optimizing a misleading metric.

19.28.2 Exercise 01

Exercise Title: Create a Controlled CUDA Allocation Pattern That Leaves Free Memory Split Across Noncontiguous Blocks

Part 1 - Exercise Contract and Why It Matters

Design an allocation-and-release trace intended to leave inactive blocks separated by live blocks within native allocator segments. Verify the result using allocator evidence rather than assuming that alternating Python list entries correspond to neighboring storage. Deliver the request trace, segment maps before and after selected releases, and a statement of whether the intended pattern actually formed.

Run the experiment in a fresh worker process with a bounded memory allowance. Keep initial experiments on one stream with completed uses. Use a host-only fixed-arena simulator as a deterministic conceptual control, labeled separately from real CUDA allocator behavior.

Part 2 - System and Memory Mental Model

Allocation order is not a promise about address order or segment membership. PyTorch may reuse older blocks, choose different pools, split a larger cached block, or obtain a new segment. If each tensor receives its own segment, releasing alternating tensors can simply produce independently releasable segments rather than trapped holes.

One candidate construction is to seed reusable capacity, then issue smaller requests and retain selected neighbors. Whether the allocator actually subdivides that capacity must be confirmed from the snapshot. Use sizes calibrated to the installed backend and a fresh allocator history. Do not hard-code an implementation threshold as an eternal property of CUDA.

Dropping a list entry removes only one reference. Views, temporary variables, closures, or exception tracebacks may keep storage live. After all relevant uses complete, inactive blocks adjacent inside the same compatible segment can coalesce; holes separated by live blocks cannot be assumed to merge. Separate segments do not become one tensor merely because their sizes add up.

Part 3 - Quantitative Prediction Before Execution

For a known segment of size S, construct a predicted map with alternating live capacities a_i and holes h_j:

$$S = \sum_i a_i + \sum_j h_j$$

for a fully represented fixed-arena model. Predict total inactive bytes, largest hole, and releasability before touching CUDA.

Use a hypothetical 48 MiB segment divided into six equal blocks. Release the second, fourth, and sixth blocks while retaining the others. Calculate inactive total and largest hole, then predict the effect of releasing the third block. State the adjacency and coalescing assumptions behind the result. In the real experiment, compare segment IDs and block addresses before using the same arithmetic.

Predict a contrasting outcome when the six requests occupy six separate segments. This control demonstrates why identical Python lifetime patterns can lead to different allocator states.

Part 4 - Experimental Design and Instrumentation

1. Implement the trace in a fixed-arena simulator and verify the expected holes and coalescing transitions.

2. Launch a fresh native-backend CUDA worker. Warm initialization outside the trace and record the initial allocator state.

3. Try a bounded seed-and-subdivide pattern. Capture a snapshot after allocation and check actual segment membership.

4. Release selected tensors after completed use, clearing every intended reference. Capture the resulting block map.

5. Release one separating live neighbor and inspect whether inactive regions merge as predicted.

6. Repeat with a few calibrated request scales and record both successful and unsuccessful constructions.

Keep addresses as diagnostic labels, not permanent storage identities. Record allocation generations because the same address can be reused. Stop the bounded search if the intended pattern does not reproduce.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class AllocationAction:
    action_id: int
    operation: str
    tensor_id: int
    requested_bytes: int

def build_candidate_trace(scale_bytes, live_pattern):
    # Specify allocations and complete reference releases.
    ...

def simulate_fixed_arena(trace, arena_bytes):
    # Model adjacency and coalescing with explicit assumptions.
    ...

def replay_cuda_trace(trace, config):
    # Capture actual segment membership at chosen boundaries.
    ...

def verify_split_pattern(snapshot, expected_roles):
    # Prove separation by live neighbors in observed segments.
    ...
```

```
def E01(config):
    # Calibrate within a bounded allowance and attempt count.
    ...
    # Report reproduced, not reproduced, or unsupported.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a segment map showing at least two inactive regions separated by live storage before claiming success. A list of tensor addresses without segment membership is insufficient. Distinguish a block still awaiting stream completion from a truly inactive hole.

Show requested sizes, actual block capacities, segment size, retained neighbors, inactive total, and largest observed inactive block at each boundary. If the allocator obtained separate segments or immediately coalesced the holes, report that outcome and explain it. Do not label the simulator's deterministic result a measured PyTorch fragmentation result. Confirm that final cleanup releases all intended tensor references.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Controlled experiments require control over the variable being claimed. Python allocation order alone gives less placement control than a fixed-arena model suggests.

Explain which parts of the trace were deterministic and which depended on allocator policy. The verified pattern becomes a useful fixture for subsequent diagnostics. An unsuccessful construction is also valuable evidence about the allocator's reuse and coalescing behavior on the tested configuration.

19.28.3 Exercise 02

Exercise Title: Trigger an Allocation Failure Even When Total Free or Reserved Memory Appears Sufficient and Explain the Fragmentation Mechanism

Part 1 - Exercise Contract and Why It Matters

Attempt a bounded fragmentation-related allocation failure and build an evidence chain distinguishing it from ordinary capacity exhaustion. Capture the requested size, pre-attempt block map, live references, growth conditions, allocator retries, and final outcome. A successful large allocation is a valid outcome if the allocator can grow or reclaim capacity; the exercise must explain that result rather than hide it.

Use the verified pattern from E01, a fresh worker, and an explicit attempt limit. Include a capacity-only control. Any imposed process allocation limit or pressure allocation must be recorded as part of the cause, not presented as physical VRAM fragmentation.

Part 2 - System and Memory Mental Model

An apparent contradiction often comes from comparing unlike quantities. Reserved bytes include live tensors; driver-free bytes exclude allocator cache; and total inactive bytes may be split across unsuitable blocks. No one of these scalars guarantees that the next request can succeed.

If no cached block fits, the allocator may request another segment, release eligible cached segments, and retry. Thus a request larger than every cached hole can still succeed. Conversely, live neighbors can trap free regions while growth is constrained by actual capacity, an explicit allocator limit, or external pressure. A post-failure snapshot may already reflect reclamation and differ from the state that motivated the attempt.

Catch the specific CUDA OOM exception supported by the installed PyTorch version. Do not convert unrelated runtime failures into OOM. Preserve scalar diagnostics without retaining traceback frames and their tensor references. An OOM is not proof that the CUDA context is unusable, but illegal memory accesses and other device errors need different handling. This isolated experiment performs no optimizer update, so it avoids partial training-state recovery.

Part 3 - Quantitative Prediction Before Execution

For the simplified non-growing arena, choose a request satisfying

$$L_{\text{cached}} < q \leq F_{\text{cached}}.$$

This establishes lack of a single fitting cached hole only within the declared eligibility model. Real failure additionally needs an explanation for unsuccessful growth and reclamation.

For hypothetical cached holes of 24 and 24 MiB, separated by live neighbors, analyze a 40 MiB request. Consider three independent cases: sufficient driver headroom for a new segment, insufficient headroom, and a lower configured allocator cap. Predict the likely outcome under each set of assumptions and list the observations needed to test it. Calculate why quoting the entire reserved total would overstate reusable capacity.

Part 4 - Experimental Design and Instrumentation

1. Reproduce and verify the split-block fixture before attempting the larger request. Record all live holders and inactive candidates.

2. Sample allocator counters and device-free bytes immediately before the attempt. Preserve an event-history window if supported.

3. Attempt one declared allocation. Record success or typed OOM and the complete exception text as evidence.

4. Capture post-attempt counters and state. Identify changes caused by allocator reclamation or retry.

5. Repeat in a fresh worker with the same live demand but a less fragmented construction, then with an intentionally impossible capacity-only request.

6. Compare outcomes without increasing memory pressure indefinitely just to force an OOM.

If using an allocator memory-fraction limit, document its accounting scope and supported backend. A refusal under that limit is not equivalent to exhausting every free byte on the device.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class AttemptEvidence:
    attempt_id: int
    requested_bytes: int
    outcome: str
    exception_text: str
    pre_state: object
    post_state: object

def establish_verified_pattern(config):
    # Reuse E01 evidence rather than assuming placement.
    ...

def attempt_large_request(request, diagnostics):
    # Catch only the supported CUDA OOM exception.
    ...

def compare_failure_mechanisms(evidence, controls):
    # Separate placement limits, capacity, and imposed caps.
    ...

def cleanup_attempt(handles):
    # Release dead references without discarding evidence.
    ...
```

```
def E02(config):
    # Execute bounded attempts in fresh isolated workers.
    ...
    # Explain successful allocations as well as failures.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Claim fragmentation-related failure only when the evidence links unsuitable cached regions, live separators, and a failed path to additional usable capacity. A large reserved-minus-allocated gap plus an exception is insufficient by itself. Use supported, inconclusive, and contradicted classifications for the diagnosis.

Report pre- and post-attempt states separately, with requested bytes, driver-free observation age, live bytes, inactive split bytes, candidate hole sizes, retry deltas, and exception category. The capacity-only control should fail for an independently explainable reason. If no real OOM reproduces, retain the fixed-arena demonstration and explain how the actual allocator avoided the predicted obstruction.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Failure analysis is strongest when it explains why an apparent solution was unavailable. In this case the missing explanation is often the allocator's ability to grow, reclaim, or remap memory.

Use the controls to state the narrowest supported claim. An allocation limit can create a useful controlled experiment, but it becomes part of the mechanism. The goal is a reproducible diagnosis that guides mitigation, not an impressive OOM message without a causal account.

19.28.4 Exercise 03

Exercise Title: Use torch.cuda.memory_stats() to Track Inactive Split Bytes, Segment Count, Allocation Retries, and Other Fragmentation Signals

Part 1 - Exercise Contract and Why It Matters

Build a backend-aware statistics collector and interpret its fields without turning every counter into a fragmentation score. Produce a time series aligned with allocation and release phases, a dictionary of metric meanings, and a reconciled comparison with one snapshot. The collector must preserve missing or unsupported fields explicitly.

Use native-backend traces first, then inspect what changes when a different backend is selected. Separate current values, peaks, and cumulative counters. Resetting peak memory statistics is not a substitute for recording the beginning value of every cumulative counter.

Part 2 - System and Memory Mental Model

`memory_stats()` provides allocator-specific counters. Inactive split bytes describe inactive, non-releasable split blocks in the documented native accounting; they are not all free device memory and are not universally comparable across backends. Active bytes can include blocks awaiting stream completion, while allocated bytes track a different ownership boundary.

Segment count describes allocator-managed segments, not tensor count. Allocation retry counters indicate failed device-allocation paths that lead to cache release and retry under the documented implementation. They can rise because of capacity pressure, not only fragmentation. OOM count records errors already encountered; it is a lagging signal rather than an early prediction.

Requested bytes and assigned allocation bytes can help study allocator rounding when sampled over matching scopes. Application pool slack can remain invisible to that comparison because the allocator sees the larger backing request. Some statistics are reported as zero or have no meaningful equivalent with `cudaMallocAsync`. Preserve the backend and field-support status alongside every value.

Part 3 - Quantitative Prediction Before Execution

For a cumulative counter C, report interval change

$$\Delta C = C(t_1) - C(t_0).$$

For current native inactive split bytes I_s and reserved bytes $R > 0$, define a descriptive ratio

$$f_s = I_s/R.$$

This is a trapped-split share under the chosen accounting, not an OOM probability or a universal fragmentation percentage.

For a hypothetical interval with retries changing from 3 to 5, reserved bytes of 256 MiB, and inactive split bytes of 64 MiB, calculate the interval retry count and ratio. Explain why the same ratio with 16 GiB of driver headroom has a different practical meaning. Predict which counters should remain monotonic unless explicitly reset, and which current quantities can decrease.

Part 4 - Experimental Design and Instrumentation

1. Enumerate supported keys on the installed backend and record the allocator configuration before collecting measurements.

2. Sample before allocation, at peak live demand, after selected reference releases, after completion, and after optional cache release.

3. Track these native keys when supported:

   - `inactive_split_bytes.all.current`.
   - `segment.all.current`.
   - `active_bytes.all.current`.
   - `reserved_bytes.all.current`.
   - `num_alloc_retries` and `num_ooms`.

4. Add requested and allocated byte counters with clearly matched current or cumulative semantics.

5. Compare an ordinary reusable-cache trace, a verified split pattern, and a capacity-pressure control.

6. Reconstruct interval deltas from the raw samples and validate them against the exported summary.

Keep observation overhead outside the primary timing run when possible. Use one timestamp convention and record whether a sample synchronized.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import time
import torch

@dataclass
class MetricValue:
    name: str
    value: object
    supported: bool
    scope: str

def discover_metric_support(device, backend):
    # Preserve missing and backend-inapplicable distinctions.
    ...

def capture_stats(device, phase, support):
    # Read scalar counters with a timestamp and phase ID.
    ...

def calculate_interval_deltas(before, after):
    # Handle cumulative counters and explicit reset boundaries.
    ...
```

```
def reconcile_with_snapshot(stats, snapshot):
    # Match device, time, block states, and accounting scope.
    ...

def E03(config):
    # Compare cache, split-block, and capacity-pressure traces.
    ...
    # Export raw samples and a metric interpretation table.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative interval deltas only where no reset occurred. Flag mismatched reset epochs rather than silently clipping a negative result. Confirm that the collector never treats an unsupported zero as proof of no fragmentation. Do not require two asynchronously sampled accounting sources to match exactly without a controlled observation boundary.

Report units and semantics for each field, plus a plot of current bytes and a separate plot of interval retry counts. Investigate counter changes against the request trace and snapshot. A retry without increasing inactive split bytes is an important counterexample to a single-cause interpretation. Preserve it in the report.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Counters are evidence about an allocator's internal state transitions, not self-explanatory diagnoses. Their value increases when they are aligned with the exact workload phase and backend.

Choose a small set of signals sufficient to distinguish your controls. Explain why adding more counters can create confusion if their scopes differ. This collector becomes the observation layer for later predictors and controllers, so its missing-data and reset semantics must be as precise as its arithmetic.

19.28.5 Exercise 04

Exercise Title: Capture a CUDA Memory Snapshot and Visually Identify Partially Used Segments and Trapped Free Blocks

Part 1 - Exercise Contract and Why It Matters

Capture allocator snapshots and use their visual representation to identify live blocks, pending frees, inactive holes, and completely inactive segments. Deliver annotated views at selected

workload events and a table connecting each visible region to scalar accounting. The exercise is about explaining an observed allocator state, not merely producing a colorful timeline.

Use a bounded history window and a native-backend trace with known allocation roles. Record the exact PyTorch version and snapshot API. Treat unsupported schemas or backends as explicit limitations. Do not invent block information when the chosen backend does not expose it.

Part 2 - System and Memory Mental Model

A snapshot describes memory visible to the PyTorch allocator. It does not enumerate every GPU allocation made directly by CUDA libraries, other processes, or communication runtimes. Segment addresses are virtual-address labels and reveal no physical-page layout.

The documented native schema distinguishes these block states:

- `active_allocated`: owned by a live allocation.
- `active_awaiting_free`: awaiting stream completion.
- `inactive`: cached without an active allocation.

The second state is particularly important: a host reference can be released while a stream still has outstanding uses. A plot that colors both inactive and awaiting-free regions as available exaggerates immediate reuse.

A current-state snapshot and an allocation-history snapshot answer different questions. History can associate allocation and free events with stacks and earlier allocator states. If a history buffer wraps, older causal events may be absent. Capturing only after OOM recovery can miss the original arrangement because retries may have changed the cache.

Ordinary partially occupied segments can contain inactive blocks that are not individually releasable to the driver. Expandable segments and other allocator modes require their own schema and release interpretation. Do not extend the ordinary-segment model without checking.

Part 3 - Quantitative Prediction Before Execution

For an ordinary fully represented segment s, reconcile its block capacities as

$$S_s = A_s + P_s + I_s,$$

where A_s is allocated-block capacity, P_s awaiting-free capacity, and I_s inactive capacity. Verify this identity against the actual schema; report any unrepresented range explicitly.

For a hypothetical 32 MiB segment containing 12 MiB allocated, 4 MiB awaiting completion, and 16 MiB inactive, calculate state shares. Explain why 20 MiB must not automatically be called immediately reusable. If the inactive portion consists of holes of 6 and 10 MiB, predict the largest observed hole and distinguish that from the size of a potential new allocation.

Sketch the expected visual change after the pending work completes and after a separating allocation is released.

Part 4 - Experimental Design and Instrumentation

1. Inspect installed signatures for the snapshot interfaces. The public state snapshot and the history-oriented private helpers have different output and stability contracts.
2. When available, use bounded history recording through the `torch.cuda.memory` helper named `_record_memory_history`. Save evidence with the supported `_dump_snapshot` interface.

3. Capture initial, partially released, post-completion, and post-cleanup states. Use identical event labels in the trace.

4. Inspect the files with the official PyTorch memory visualizer or parse the documented schema into your own segment plot.

5. Annotate axes in bytes or MiB, segment IDs, block states, event times, and the live allocations that separate inactive holes.

6. Compare the visual totals with statistics collected at a matching controlled boundary.

Use snapshots you generated or otherwise trust; serialized diagnostic files are not arbitrary data to execute. Measure history overhead separately from the primary throughput experiment.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class SnapshotPlan:
    phases: tuple
    maximum_history_entries: int
    output_directory: str

def verify_snapshot_support():
    # Record version, supported signatures, and schema.
    ...

def capture_phase_snapshot(phase, plan):
    # Bound history and associate the artifact with an event.
    ...

def summarize_segments(snapshot, device):
```

```
    # Keep allocated, pending, and inactive states distinct.
    ...

def annotate_segment_view(summary, request_trace):
    # Label units, live separators, and missing history.
    ...

def E04(config):
    # Capture and inspect controlled allocator transitions.
    ...
    # Reconcile visual block totals with scalar evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Provide at least one annotated partially occupied segment, or explain why the intended pattern did not occur. Every claimed trapped hole must be linked to its containing segment and live or pending neighbors. Show a completely inactive ordinary segment as a contrasting case.

Check state totals, byte units, device identity, and snapshot timestamps. Do not compare a pre-synchronization snapshot with post-synchronization statistics as though they were simultaneous. Record missing stack history and unknown allocations rather than guessing their owners. Preserve the original snapshot alongside the annotated interpretation so another learner can challenge the diagnosis.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Visualization exposes structure that aggregate counters hide: which objects prevent coalescing and when those objects were created. Its usefulness depends on correct state semantics and a clear event boundary.

Explain one inference supported by the picture and one claim the picture cannot establish. A rigorous visual diagnosis connects the allocation pattern to a specific request and then tests a counterfactual change, rather than assuming that visible empty regions are necessarily harmful.

19.28.6 Exercise 05

Exercise Title: Build a Fragmentation Metric from Reserved Bytes, Active Bytes, Inactive Split Bytes, and Largest Reusable Block

Part 1 - Exercise Contract and Why It Matters

Build a small family of fragmentation indicators with explicit scopes, instead of presenting one ratio as a complete allocator diagnosis. Combine retained capacity, active occupancy, native split-block signals, and request-specific block-fit evidence. Deliver definitions, synthetic counterexamples, and a comparison with observed allocation outcomes.

The largest reusable block must be defined carefully. In a controlled application arena it can be exact. In a PyTorch snapshot it is usually the largest observed inactive candidate under known filters, with incomplete knowledge of actual allocator eligibility and growth.

Part 2 - System and Memory Mental Model

Reserved and active bytes describe occupancy at an allocator boundary. Native inactive split bytes identify one kind of retained inactive space. A large inactive block describes local fit opportunity. These quantities overlap and must not be summed into an invented total waste.

Let the eligible-set definition include device, known stream constraints, pool identity, capture mode if relevant, and completion state. If the snapshot does not expose enough information to verify eligibility, call the result a candidate metric and record the unknowns. Do not assume there is a public API returning the maximum CUDA allocation that would succeed now.

A request can succeed by growing the allocator despite a small largest cached candidate. A request can fail despite a large apparent candidate because of restrictions omitted from the filter. Snapshot age also matters: another allocation or completion can change the set immediately. Use the metric to guide investigation and prediction, not as a reservation or a mathematical guarantee about the real allocator.

Part 3 - Quantitative Prediction Before Execution

For $R > 0$, active capacity A_{act}, and native inactive split bytes I_s, define

$$f_{\text{idle}} = \frac{R - A_{\text{act}}}{R}, \qquad f_s = \frac{I_s}{R}.$$

The first is a scoped inactive share, not pure fragmentation. For a declared candidate set with total $F > 0$ and largest L, define dispersion and request coverage:

$$d = 1 - \frac{L}{F}, \qquad k(q) = \frac{L}{q} \quad (q > 0).$$

Undefined denominators must remain undefined.

Compare hypothetical free sets $\{32, 32\}$ MiB and $\{64\}$ MiB. Compute d and coverage for a 48 MiB request. Then consider a 1 MiB request and explain why a high dispersion score may be irrelevant to it. Add driver headroom as separate context rather than inserting it into the candidate-block formula.

Part 4 - Experimental Design and Instrumentation

1. Define each metric's accounting layer, units, eligibility filters, missing-data status, and timestamp.

2. Validate formulas on synthetic block lists with one hole, many holes, no holes, and pending-only space.

3. Collect matching statistics and native snapshots for the E01 trace and a harmless cache-retention control.

4. Compare metric values with later request outcomes from separate replays. Probing changes allocator state, so do not reuse a mutated state as the original observation.

5. Test a case with a small cached candidate but ample growth headroom and a case with insufficient total live-capacity allowance.

6. Report which metric distinguishes the cases and which produces a misleading ranking.

Do not merge inactive blocks across separate segments simply because their addresses appear numerically adjacent. Coalescing requires the allocator's actual ownership and compatibility conditions.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every `...` marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class FragmentationIndicators:
    inactive_share: object
    split_share: object
    candidate_dispersion: object
    request_coverage: object
    observation_age_seconds: float
    limitations: tuple

def select_inactive_candidates(snapshot, request_scope):
    # Preserve unknown eligibility rather than fabricating fit.
    ...

def calculate_indicators(stats, candidates, request):
    # Apply scoped formulas and explicit undefined cases.
    ...
```

```
def compare_with_outcomes(indicator_rows, replay_results):
    # Evaluate candidate fit separately from growth success.
    ...

def E05(config):
    # Validate synthetic counterexamples first.
    ...
    # Assess which indicators explain the controlled traces.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a counterexample to each proposed universal interpretation. Examples include a high inactive share with healthy reuse, a small cached block followed by successful growth, and a high dispersion score with requests small enough to fit existing holes.

Report raw $R, A_{\text{act}}, I_s, F, L, q$ beside derived values so the result can be audited. Flag observations where sampling time or unsupported fields invalidate a formula. A predictor must not silently substitute zero for unknown candidate capacity. Separate diagnostic usefulness from predictive accuracy, and do not call a correlation a causal fragmentation proof.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A useful metric compresses information while preserving the distinction needed for a decision. Fragmentation requires more than a global percentage because request size and allocator capabilities matter.

Choose a minimal indicator set for the later warning detector. Explain which remaining uncertainty belongs to the allocator and which can be reduced through better workload instrumentation. The strongest outcome is an honest, request-aware signal with known failure cases.

19.28.7 Exercise 06

Exercise Title: Compare Fixed-Shape and Variable-Shape Tensor Workloads and Quantify Their Impact on Fragmentation Over Time

Part 1 - Exercise Contract and Why It Matters

Compare fixed and changing tensor shapes while controlling useful work, live-demand envelopes, and lifetime structure as far as the experiment allows. Deliver a longitudinal allocator trace and an explanation of whether shape variability changed reuse, internal slack, or trapped inactive space.

Use both an allocation-only experiment and a supported PyTorch workload. The allocation-only trace isolates allocator behavior; the workload reveals operator workspace and activation effects. Do not assume variable shapes must cause fragmentation or that rising reserved memory proves degradation.

Part 2 - System and Memory Mental Model

Stable repeated shapes can reuse a warmed inventory. Changing shapes can introduce nearby or dissimilar allocation requests that fit existing blocks differently. Yet the effect depends on lifetime overlap, rounding policy, segment growth, and operator behavior. A variable trace may still reuse memory efficiently.

Training introduces confounders: optimizer state may be allocated lazily, gradient buffers can appear on the first backward pass, and kernels may select different workspaces for different shapes. Warm these states or report their startup contribution separately. Keep precision, checkpointing, optimizer, and backend fixed during the primary comparison.

For padded sequence workloads, fixed physical shape can perform more work on padding even when useful token count is unchanged. Measure both physical and useful work. Allocator-only controls can match total requested bytes and maximum live bytes more closely than full model workloads, but they lack realistic operator temporaries. Use both experiments to narrow the interpretation.

Part 3 - Quantitative Prediction Before Execution

Let Q_t be requested live bytes at step t, and let R_t and $I_{s,t}$ be reserved and native inactive split bytes at a matched phase. Predict time series rather than only final values:

$$Q_{\text{peak}} = \max_t Q_t, \qquad \Delta R = R_{\text{end}} - R_{\text{warm}}.$$

Growth in R is retained capacity, whose cause still needs inspection.

For a hypothetical trace alternating 8 and 12 MiB requests, compare it with a 10 MiB fixed-request trace over equal request counts. Calculate total requested bytes, then explain why equal totals do not imply equal peak live demand or equal allocator placement. Specify lifetimes that make the comparison informative. Predict how a fixed maximum-size padded workload changes useful-byte efficiency relative to those two traces.

Part 4 - Experimental Design and Instrumentation

1. Prepare fixed, alternating-nearby, and broad-variable shape sequences with explicit allocation lifetimes.

2. Match request count, dtype, device, and release rules. Report any unavoidable difference in peak demand.

3. Run each trace in a fresh worker, with a declared warmup. Sample statistics at the same lifecycle phase.

4. Repeat using a small model or explicit operator workload. Record shapes, useful units, padding, and workspace-sensitive choices.

5. Capture snapshots only at selected early and late windows to inspect whether retained capacity forms reusable blocks or partially occupied segments.

6. Repeat the comparison with several seeds and reversed phase order to expose history dependence.

Keep primary timing separate from detailed history recording. End each run with a complete drain so pending activity can be distinguished from persistent retained capacity.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class WorkloadShape:
    step_id: int
    shape: tuple
    useful_units: int
    lifetime_group: int

def build_matched_shape_traces(config):
    # Document matched quantities and remaining confounders.
    ...

def run_allocation_control(trace, config):
    # Replay explicit live intervals without model changes.
    ...

def run_operator_workload(trace, model, config):
    # Preserve precision, backend, and numerical semantics.
    ...

def compare_longitudinal_rows(rows):
    # Separate startup growth, demand, and split-block changes.
```

```
    ...

def E06(config):
    # Compare controlled allocation traces and real workloads.
    ...
    # Export useful-work-normalized results and snapshots.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report request count, useful work, physical work, live-demand peak, allocated and reserved peaks, split-byte trajectory, retry count, and complete throughput. Verify that apparent fragmentation growth is not simply the larger trace requiring more simultaneous memory.

Show early and late segment evidence when claiming worsening block organization. If reserved capacity plateaus and reuse is healthy, report stabilization rather than degradation. Validate model outputs under shape changes with the intended masks and semantics. Do not compare different useful workloads using raw steps per second as the only performance metric. **Evidence format.** Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Shape diversity is one contributor to allocation diversity, not a standalone diagnosis. The value of this experiment lies in separating size changes from increased live demand and backend workspace changes.

Explain whether the measured problem is best addressed by bucketing, reuse, lifetime management, or no intervention. State which control supports that decision and what additional trace would most strongly challenge it.

19.28.8 Exercise 07

Exercise Title: Generate Random Tensor Sizes and Measure How Allocation Size Variability Changes Reuse Efficiency and Fragmentation

Part 1 - Exercise Contract and Why It Matters

Generate reproducible random size traces and measure how their distribution interacts with reuse and fragmentation. Vary size variability while holding request count, live concurrency, and total or mean demand under a declared matching scheme. Deliver seeds, trace files, distributions, and allocator observations.

Include bounded uniform, clustered, and heavy-tail-like distributions. Truncate every distribution at a documented request limit and enforce a simultaneous-memory allowance. Do not create an uncontrolled OOM campaign by drawing arbitrary large sizes.

Part 2 - System and Memory Mental Model

Variance describes size dispersion but not temporal locality. Two traces with identical size histograms can have different allocator behavior if one clusters similar requests and the other alternates them. Lifetimes matter as well: sequential requests can reuse the same storage while overlapping requests require separate capacity.

A large rare request can establish a reusable cache that helps later work, or it can introduce partially occupied segments depending on subsequent allocation patterns. Neither high variance nor a heavy tail guarantees fragmentation. Keep the request distribution and temporal order as separate experimental factors.

Random trials need replayability. Generate the trace on CPU before timing and store exact integer byte or element requests, not just the seed. Library versions can change random sampling behavior. The evidence should also preserve release events, stream assignment, and any rounding applied before the allocator sees the request.

Part 3 - Quantitative Prediction Before Execution

For request sizes q_i, define

$$\mu = \frac{1}{N}\sum_i q_i, \qquad \sigma^2 = \frac{1}{N}\sum_i (q_i - \mu)^2, \qquad \mathrm{CV} = \sigma/\mu \quad (\mu > 0).$$

These characterize the generated finite trace. They are not fragmentation metrics.

Compare hypothetical sequences containing equal counts of 4 and 12 MiB requests: one groups equal sizes, another alternates them. Calculate their shared mean and variance, then predict why their reuse may differ under an overlapping lifetime pattern. Define the overlap explicitly. Add one rare 64 MiB request and predict how it changes both the statistical summary and the required bounded-memory plan.

Part 4 - Experimental Design and Instrumentation

1. Create a trace generator with seed, dtype-compatible size limits, request count, and maximum live demand.

2. Match finite-sample means or total bytes across chosen distributions where feasible; report residual mismatch exactly.

3. Compare original, shuffled, and size-clustered orders of the same request multiset.

4. Replay each trace in a fresh process under identical allocator settings and completion rules.

5. Collect request-size histograms, size transitions, native split bytes, segment growth, retries, and timing.

6. Inspect a few snapshots at equal completed-request counts to connect statistical differences with actual block organization.

If estimating allocator reuse from traces, distinguish reuse without new segments from exact reuse of one backing address. Pointer equality alone is not a complete allocation history.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need

an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import torch

@dataclass
class DistributionSpec:
    name: str
    seed: int
    request_count: int
    minimum_bytes: int
    maximum_bytes: int

def generate_size_trace(spec, lifetime_rules):
    # Enforce dtype alignment and bounded live demand.
    ...

def describe_trace(trace):
    # Compute finite-trace size and temporal statistics.
    ...

def reorder_same_multiset(trace, order_policy):
    # Preserve declared workload and lifetime constraints.
    ...

def replay_random_trace(trace, allocator_config):
    # Capture allocator changes without sampling in the loop.
    ...

def E07(config):
    # Compare variability and ordering as separate factors.
    ...
    # Preserve exact traces and analyze repeated seeds.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Require matching trace counts and documented demand differences before interpreting results. Check that all requests satisfy the configured bounds and that the live set never exceeds the intended test allowance through a generator bug.

Report distribution statistics alongside temporal-locality measures, allocator metrics, and complete runtime. Show at least one pair with identical size statistics but different ordering. If allocator behavior is indistinguishable, report that finding within measurement uncertainty. Do not attribute a single unlucky random run to a universal property of the distribution.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Randomness is a tool for exploring workload diversity, not a replacement for an explanatory model. Size histograms need lifetime and ordering information before they can predict reuse.

Use the results to identify which workload property deserves management. A policy aimed at variance may be ineffective when the real problem is overlap or a long-lived separator. Preserve the exact traces so subsequent mitigation experiments can test that diagnosis fairly.

19.28.9 Exercise 08

Exercise Title: Bucket Variable Tensor Shapes into Size Classes and Measure Whether Reduced Shape Diversity Lowers Fragmentation

Part 1 - Exercise Contract and Why It Matters

Bucket variable shapes into a smaller set of physical allocation shapes and test whether that improves reuse under the same useful workload. Deliver a bucketing policy, a useful-versus-padded work ledger, and allocator evidence before and after bucketing. The learner must implement classification, masks, trace replay, and measurements.

Start with sequences or matrices whose padding semantics can be validated against a reference. Distinguish shape bucketing from allocator rounding: bucketing changes the physical tensor shape seen by operators, whereas allocator rounding can preserve the original logical shape.

Part 2 - System and Memory Mental Model

Fewer physical shapes can stabilize allocation requests, but padding increases tensor size and may increase arithmetic. A policy that reduces split blocks while raising peak live memory can still be undesirable. Different physical shapes can also select different kernels or attention backends, so record those changes.

Reordering samples into buckets changes temporal locality and possibly training order. To isolate physical shape diversity, first preserve request order while padding to class boundaries.

Then evaluate reordering as a separate experiment with the same sample multiset and clearly stated update semantics.

Masking must preserve the intended computation. Attention masks, loss masks, and output cropping are distinct operations. Padding tokens must not alter the loss denominator or leak into meaningful attention positions. For a numerical comparison, disable uncontrolled stochastic differences or explain their effect. Reduced shape cardinality does not itself prove reduced allocator fragmentation.

Part 3 - Quantitative Prediction Before Execution

For sequence lengths l_i and bucketed physical lengths $b_i \geq l_i$, define token padding fraction

$$p = 1 - \frac{\sum_i l_i}{\sum_i b_i}.$$

For explicitly materialized attention, a rough score-storage ratio is

$$\rho_{\text{scores}} = \frac{\sum_i b_i^2}{\sum_i l_i^2}$$

under otherwise equal independent sequence computations. This is not a universal fused-attention cost model.

Assign hypothetical lengths 129, 190, and 257 to bucket ceilings 128, 256, and 512, with an explicit oversize rule. Predict the physical lengths, padding fraction, and shape count. Explain why the 257-token request can be costly under this policy. Compare with a finer ceiling and predict the additional class count.

Part 4 - Experimental Design and Instrumentation

1. Choose bucket boundaries from a calibration length distribution and freeze them before evaluation.

2. Replay original-order requests with exact shapes and with padded bucket shapes under the same backend and precision.

3. Validate masks, loss normalization, and cropped outputs against the exact-shape reference.

4. Measure physical bytes, useful tokens, padding, complete latency, split-byte trajectory, and allocator growth.

5. Add a separate sorted-bucket experiment and disclose its ordering change.

6. Evaluate held-out lengths near bucket boundaries and requests above the largest configured class.

Do not silently truncate oversize sequences. Reject, use a declared larger class, or apply a separately authorized semantic transformation. Keep allocator settings fixed so the experiment tests shape bucketing.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need

an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class BucketedRequest:
    request_id: int
    logical_shape: tuple
    physical_shape: tuple
    useful_units: int

def choose_bucket(logical_shape, boundaries):
    # Cover the request and handle oversize inputs explicitly.
    ...

def prepare_padded_input(request, source):
    # Construct data and masks without changing useful content.
    ...

def validate_bucket_semantics(reference, candidate, masks):
    # Compare outputs and the intended loss denominator.
    ...

def compare_bucket_traces(trace, policies, config):
    # Separate physical-shape changes from order changes.
    ...

def E08(config):
    # Calibrate boundaries, then freeze them for evaluation.
    ...
    # Compare allocator behavior and useful-work throughput.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires preserved useful inputs, correct masks, and no hidden truncation. Report the sample multiset and order for every mode. Validate a boundary case where padding almost doubles physical sequence length.

Include physical-shape count, padding fraction, useful tokens per second, allocated and reserved peaks, native split bytes, retries, and snapshot evidence. If the allocator metric improves but useful throughput or feasibility worsens, retain the tradeoff. Do not call the policy successful solely because fewer shapes reached the allocator. Separate changed kernel selection from improved storage reuse where the evidence permits.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Bucketing spends extra physical work to make demand more predictable. Its value depends on whether the resulting reuse and kernel behavior outweigh padding costs.

Choose boundaries from measured workloads and state where they fail. A useful recommendation may favor bucketing only a subset of the length range. Explain why fewer classes is not an objective by itself and how useful-work throughput keeps the decision tied to the application.

19.28.10 Exercise 09

Exercise Title: Compare Exact-Size Allocation Against Rounded Allocation Classes and Quantify the Trade-Off Between Internal and External Fragmentation

Part 1 - Exercise Contract and Why It Matters

Compare exact requested sizes with explicit rounded backing capacities while preserving logical tensor shapes and useful computation. Quantify internal slack and allocator-level placement evidence separately. Deliver a capacity ledger showing whether the policy trades one form of waste for another.

Use one rounding layer at a time. The primary experiment can use application-managed typed buffers; allocator configuration changes belong in a separate controlled variant. Ordinary exact-size tensor requests can still be rounded by the underlying allocator, so the label exact refers to the application request.

Part 2 - System and Memory Mental Model

Application rounding asks PyTorch for a larger backing tensor and exposes a logical view. The allocator sees the backing request, not the smaller useful region. Therefore its requested-versus-allocated statistics do not include all application slack.

Track three byte quantities: useful logical demand q, application backing request c, and allocator-assigned block capacity a. Internal slack can occur at both boundaries. External placement signals concern separate inactive regions and cannot be obtained by subtracting only these three numbers.

Rounded classes may improve future fit and reuse, but they can consume the very headroom needed for a large request. The result depends on size distribution and overlapping lifetimes. Buffer views must remain within capacity, preserve dtype and layout, and avoid exposing uninitialized slack. A hidden clone or resize would invalidate the claimed accounting.

Part 3 - Quantitative Prediction Before Execution

For matching live allocations, decompose internal slack as

$$W_{\text{app}} = \sum_i (c_i - q_i), \qquad W_{\text{alloc}} = \sum_i (a_i - c_i).$$

Their sum equals $\sum_i (a_i - q_i)$ only when the same allocations, states, and time boundary are used. Idle retained buffers are accounted separately.

For a compatible byte quantum u, predict

$$c(q) = u \left\lceil q/u \right\rceil .$$

Use hypothetical requests 5, 6, and 7 MiB with an 8 MiB class. Calculate application slack for sequential and simultaneously live requests, making the buffer-retention policy explicit. Predict why sequential reuse can require one backing buffer while overlapping requests cannot. State what snapshot evidence would be needed to claim reduced external fragmentation.

Part 4 - Experimental Design and Instrumentation

1. Fix dtype, device, logical shapes, lifetime trace, and allocator configuration.
2. Implement exact backing requests and several rounded application policies with the same retention rules.
3. Log useful bytes, backing requests, actual storage capacity, and observed allocator block capacity where available.
4. Compare size-jittered and boundary-heavy traces under matched useful work and maximum concurrency.
5. Capture selected native snapshots and compute only scoped candidate-fit or split-block indicators.
6. Evaluate total process peaks and request success under several budgets, including cases where rounding causes rejection.

Avoid merging allocator-level rounding and application-level rounding into one unlabeled policy. Initialize the entire logical read region and record any extra writes made to slack.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class CapacityLayers:
    useful_bytes: int
    backing_request_bytes: int
    assigned_block_bytes: object
    allocation_id: int

def choose_backing_capacity(request, rounding_policy):
    # Preserve dtype compatibility and the logical shape.
    ...

def match_allocation_layers(request_log, snapshot):
    # Match identities, generations, and observation states.
    ...

def calculate_internal_slack(layer_rows):
    # Keep application and allocator contributions distinct.
    ...

def compare_placement_evidence(snapshot_rows, next_requests):
    # Assess request-specific fit without claiming global capacity.
    ...

def E09(config):
    # Replay exact and rounded backing policies fairly.
    ...
    # Report internal costs and external-placement evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct logical outputs and complete byte accounting for every live backing allocation. Do not add idle capacity to active slack twice. If allocator block matching is unavailable, mark that layer unknown instead of substituting the tensor's logical byte size.

Report internal slack by layer, retained idle capacity, native split bytes, candidate-fit evidence, peak VRAM, and complete throughput. Include a case where rounding improves reuse and one where it imposes a significant cost, or state which case was not observed. A lower split-byte ratio caused only by a larger reserved denominator is not sufficient evidence of reduced absolute fragmentation.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Rounding is an explicit exchange: capacity is spent inside allocations in the hope of improving reuse between allocations. Only the complete memory and runtime ledger reveals whether that exchange was favorable.

Choose a policy for the tested distribution and explain how a change in overlap or budget could reverse the decision. The goal is a measured tradeoff rather than a promise that coarser classes always improve memory efficiency.

19.28.11 Exercise 10

Exercise Title: Use Buffer Reuse to Replace Repeated Allocate-Free Cycles and Measure the Reduction in Fragmentation Growth

Part 1 - Exercise Contract and Why It Matters

Apply a bounded DMM25-style buffer pool to an allocation-heavy workload and measure whether it stabilizes allocator behavior. Compare ordinary tensor requests with retained backing reuse under identical logical work, shapes, and concurrency. Deliver a longitudinal comparison of allocator activity, retained capacity, and useful throughput.

Restrict pooled storage to lifetimes you can control, such as input staging or explicit inference scratch. Do not overwrite autograd-saved tensors or claim that a Python pool replaces opaque operator workspaces. A result showing no fragmentation reduction remains valid.

Part 2 - System and Memory Mental Model

Ordinary PyTorch allocation already uses a caching allocator. Replacing Python tensor creation with application reuse may reduce allocator requests, but it does not automatically reduce device allocation calls or fragmentation. The custom pool can also retain obsolete classes and increase live allocated memory.

Free application buffers remain live backing tensors. As a result, allocator inactive split bytes may decrease simply because more capacity is held as active allocations. That metric change can be a reclassification rather than actual memory relief. Account for useful demand, pool slack, idle pool capacity, and whole-process memory.

Reuse requires completed consumers and exclusive ownership. `record_stream` protects allocator lifetime when storage is deallocated; it does not authorize early manual overwrite of the same live pooled tensor. Use the event and generation protocol from DMM25 when asynchronous consumers are involved. Reference logs must not keep supposedly released tensors alive.

Part 3 - Quantitative Prediction Before Execution

Let N be logical requests and K new application backing allocations. Define a creation-avoidance measure

$$r_{\text{avoid}} = 1 - K/N \quad (N > 0),$$

with startup allocations and successful requests counted by a stated convention. This is not allocator fragmentation.

Decompose retained pool capacity as

$$C_{\text{pool}} = C_{\text{leased}} + C_{\text{pending}} + C_{\text{free}}.$$

For a hypothetical repeating trace requiring at most three simultaneous 8 MiB buffers, predict the minimum fixed inventory and backing-creation count after warmup. Then add a one-time 32 MiB request and predict how unrestricted retention can increase the pool baseline. Explain how inactive split bytes could fall while total live allocated bytes rise.

Part 4 - Experimental Design and Instrumentation

1. Select one supported workload and implement equivalent ordinary-allocation and pooled paths.
2. Match initialization, output lifetimes, concurrent work, precision, and completion boundaries.
3. Compare startup-inclusive and warmed execution, preserving the same exact request trace.
4. Record pool capacity by state together with allocator statistics and selected snapshots.
5. Add a phase shift from large requests to smaller requests and compare bounded trimming with unrestricted retention.
6. Measure useful throughput and request tail latency with minimal logging, then use a separate detailed diagnostic pass.

Count application requests, backing creations, and supported device-allocation counters separately. Do not call every `torch.empty` request a fresh device allocation.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ReuseObservation:
    request_id: int
    useful_bytes: int
    pool_capacity_bytes: int
    idle_pool_bytes: int
    new_backing_created: bool

def run_ordinary_path(trace, consumer, config):
    # Preserve normal allocator caching and equal useful work.
    ...

def run_pooled_path(trace, pool, consumer, config):
    # Enforce exclusive leases and complete consumer lifetimes.
    ...

def reconcile_pool_and_allocator(pool_rows, allocator_rows):
    # Detect reclassification rather than real capacity relief.
    ...

def E10(config):
    # Validate numerical equivalence before timing.
    ...
    # Compare stable, phase-shifted, and trimmed runs.
    ...
    # Explain both memory and runtime tradeoffs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires equal completed work, correct outputs, no premature reuse, and a reconciled pool ledger. Show absolute allocated and reserved peaks, not only increases above a larger pooled baseline.

Report backing creations, allocator activity, inactive split trajectory, free pool capacity, useful throughput, and trimming cost. Investigate lower split bytes accompanied by higher active occupancy before claiming less waste. If ordinary allocation already stabilizes, report the small or absent incremental benefit of the custom pool. Include the memory cost of retaining rare large buffers.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use

explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Buffer reuse moves lifetime management upward into the application. That can improve predictability while making more memory appear permanently live to the allocator.

Explain whether the measured benefit comes from lower bookkeeping, fewer new segments, or better shape predictability. Choose reuse only where its ownership complexity and retained capacity are justified by the complete workload results.

19.28.12 Exercise 11

Exercise Title: Compare Long-Lived and Short-Lived CUDA Tensors and Show How Interleaving Their Lifetimes Can Trap Free Memory Inside Segments

Part 1 - Exercise Contract and Why It Matters

Study how persistent tensor lifetimes interact with transient allocations. Construct grouped and interleaved lifetime traces, verify actual segment placement, and identify live allocations that prevent inactive regions from becoming fully reclaimable. Deliver a lifetime diagram and a segment-level explanation.

Use explicit synthetic tensors before a model-based example. Keep persistent byte count and transient demand comparable. Do not mistake a tensor retained accidentally by a logger for an intended persistent object.

Part 2 - System and Memory Mental Model

A long-lived tensor can keep an ordinary segment partially occupied after neighboring transient tensors are released. Inactive pieces may remain reusable for suitably sized requests but unavailable as one large hole or as a fully releasable segment. The harm is request-dependent.

Interleaving lifetime classes in Python does not guarantee that they share segments. Allocation size, pool selection, history, and stream use can separate them. Verify the placement before claiming a trapped-region mechanism. A small view can retain an entire backing storage, so logical view size is not necessarily the persistent footprint.

GPU completion creates another lifetime boundary. A tensor released on the host may still await work on a stream. Compare completed-release and pending-release observations separately. Releasing a live separator is only valid when the program no longer needs its data and all consumers have finished; moving or destroying live model state is not a general defragmentation operation.

Part 3 - Quantitative Prediction Before Execution

Define lifetime duration $d_i = t_{i,\text{release}} - t_{i,\text{acquire}}$ using a declared release meaning. For ordinary segment s, define a snapshot retention indicator

$$z_s = \mathbf{1}\{A_s + P_s > 0\},$$

where A_s and P_s represent allocated and pending block capacities. Inactive bytes inside such segments are candidates for trapped retention, subject to backend semantics.

For a hypothetical 32 MiB segment with one 4 MiB persistent block and 28 MiB of transient blocks, predict the state after all transient uses finish. Determine what additional information is required to know the largest inactive hole. Compare a persistent block at one end with one in the middle, then predict the effect of its legitimate final release.

Part 4 - Experimental Design and Instrumentation

1. Build two traces with the same persistent and transient sizes: one groups lifetime classes, another interleaves them.
2. Replay in fresh native-backend workers using bounded memory and completed single-stream uses.
3. Capture snapshots during the transient peak and after transient release. Confirm segment membership and adjacency.
4. Retain a small view of a larger backing tensor in a separate control to demonstrate storage-level lifetime.
5. Release persistent objects only at their declared last use, then observe coalescing and possible segment release.
6. Repeat with a pending stream consumer to distinguish asynchronous retention from structural trapping.

Keep all evidence tensor-free. Use allocation IDs and generation-aware address labels when matching lifetime records to snapshots.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class LifetimeSpec:
    tensor_id: int
    requested_bytes: int
```

```
    acquire_event: int
    last_use_event: int
    release_event: int
    lifetime_class: str

def build_lifetime_variants(config):
    # Preserve demand while changing lifetime interleaving.
    ...

def replay_lifetime_trace(trace, config):
    # Release only after semantic use and CUDA completion.
    ...

def identify_live_separators(snapshot, lifetime_log):
    # Match actual segment placement to persistent holders.
    ...

def E11(config):
    # Compare grouped, interleaved, view, and pending controls.
    ...
    # Explain segment retention through specific allocations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Claim trapping only when the snapshot shows inactive space retained within a segment containing the identified live or pending allocation. Distinguish a large reusable inactive block from several small holes. If persistent and transient objects occupy separate segments, report that counterexample.

Report persistent logical bytes, persistent backing bytes, transient peak, retained inactive bytes, largest candidates, and complete runtime. Validate that the small-view control retains backing storage without attributing that effect to allocator fragmentation alone. Show how legitimate final release changes the map and whether reserved memory remains cached afterward.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Lifetime structure can matter as much as allocation size. The allocator cannot freely repack arbitrary live tensors while preserving all pointers, aliases, and asynchronous users.

Use the evidence to identify a scheduling opportunity: which objects could be allocated together or released earlier without changing semantics? Do not recommend moving live model state merely to improve a diagram. The next exercise tests legal lifetime reordering as a measured intervention.

19.28.13 Exercise 12

Exercise Title: Reorder Tensor Allocation Lifetimes to Group Similar-Lived Buffers and Measure the Effect on Allocator Reuse

Part 1 - Exercise Contract and Why It Matters

Test whether legal changes to allocation timing and release timing improve allocator reuse. Group persistent buffers and transient buffers where program dependencies permit it, then compare with an interleaved baseline. Deliver a dependency-preserving schedule, a live-demand ledger, and allocator evidence for the resulting memory layout.

The experiment changes future allocation behavior; it does not magically compact existing live tensors. Any explicit copy or relocation must be a separate variant with its own transient memory cost and alias correctness proof.

Part 2 - System and Memory Mental Model

Allocation can sometimes be moved earlier without changing values, while release can move earlier only after the last semantic consumer and required CUDA completion. Moving allocation earlier may increase overlap and peak live demand. A schedule that reduces fragmentation but increases true memory demand can be a poor tradeoff.

Group persistent model-independent buffers before transient work when their construction permits it. Do not assume optimizer state, lazy module state, and backend workspaces all exist before the first training step. Include their initialization phase in the model or warm it separately.

The allocator may still place lifetime classes in unexpected segments, so verify actual maps. Preserving the dependency graph is necessary but not always sufficient for numerical equivalence: changing stochastic execution order can change random draws, and in-place aliases can impose additional ordering constraints. Keep the initial comparison deterministic and treat concurrent scheduling as a later extension.

Part 3 - Quantitative Prediction Before Execution

For allocation i with capacity c_i, define the live interval $[a_i, r_i)$ under one schedule:

$$M(t) = \sum_i c_i \mathbf{1}\{a_i \le t < r_i\}, \qquad M_{\text{peak}} = \max_t M(t).$$

This counts declared capacity before hidden operator temporaries. For every dependency $u \to v$, require the chosen execution order to preserve the required producer completion.

Create a hypothetical trace containing two persistent 8 MiB buffers and four transient 4 MiB buffers used in pairs. Calculate peak live capacity before and after moving all transient allocations to startup. Explain why that apparently simple grouping can be counterproductive. Propose a different legal ordering that keeps transient overlap bounded and predict its segment-reuse opportunity.

Part 4 - Experimental Design and Instrumentation

1. Write a dependency graph and identify each tensor's first and last semantic use.
2. Construct an interleaved schedule, a grouped persistent schedule, and an intentionally over-eager preallocation control.
3. Verify live-demand peaks in a host simulator before running CUDA.
4. Replay each schedule in a fresh worker with identical sizes, values, backend, and complete useful work.
5. Compare native snapshots at matched logical milestones, not merely equal wall-clock times.
6. Measure allocated and reserved peaks, split bytes, growth events, stalls, and complete latency.

For training-related variants, validate gradients and parameter updates under a declared deterministic reference. Do not release an activation merely because its forward consumer has completed if backward still needs it.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ScheduledLifetime:
    tensor_id: int
    allocate_event: int
    last_consumer_event: int
    release_event: int
    capacity_bytes: int

def derive_lifetime_constraints(operation_graph):
    # Include aliases, backward uses, and stream completion.
    ...
```

```
def propose_grouped_schedule(constraints, policy):
    # Reorder only operations allowed by the support contract.
    ...

def predict_live_peak(schedule):
    # Account for overlap introduced by earlier allocation.
    ...

def validate_schedule(reference, candidate, config):
    # Compare dependencies, outputs, and supported gradients.
    ...

def E12(config):
    # Replay schedules and compare allocator placement.
    ...
    # Separate reduced live demand from improved reuse.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires preserved dependencies and correct numerical results, with no premature release. Report the predicted and observed live-demand peaks for every schedule. A reduction in reserved memory caused by lower true live demand must be distinguished from reduced fragmentation.

Show actual segment membership when claiming improved lifetime grouping. Include the preallocation control to demonstrate that grouping can increase overlap. If a copy-based relocation variant is attempted, account for both source and destination being live during the copy, all aliases, and transfer completion. Do not present it as a free allocator compaction operation. **Evidence format.** Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Good lifetime scheduling reduces unnecessary overlap and may improve future allocator placement. Those benefits come from understanding program dependencies, not from rearranging Python statements blindly.

Use the results to identify a legal, maintainable scheduling change. Explain whether its benefit is robust across traces or relies on a specific allocator history. Prefer a simple schedule with clear ownership over a fragile placement trick that fails under a nearby shape change.

19.28.14 Exercise 13

Exercise Title: Experiment with PyTorch CUDA Allocator Configuration and Measure How Split-Size or Backend Choices Affect a Fragmentation-Prone Workload

Part 1 - Exercise Contract and Why It Matters

Run a controlled allocator-configuration study using a verified fragmentation-prone trace. Compare the default native behavior with selected split or rounding settings, and optionally a supported alternative backend. Deliver a configuration matrix with measured outcomes and explicit unsupported cases.

Each configuration must run in a fresh process with its environment set before CUDA allocator initialization. Do not attempt to switch allocator backends halfway through a training process. The scaffold leaves configuration validation, worker launch, and interpretation to the learner.

Part 2 - System and Memory Mental Model

Allocator settings change reuse and growth policy; they do not reduce the bytes genuinely needed by live tensors. A split-size restriction can preserve larger blocks but reduce flexibility and increase runtime or internal waste. It is appropriate to investigate when native split-block evidence supports the diagnosis, not as an automatic first response to every OOM.

Current documentation names `PYTORCH_ALLOC_CONF`; `PYTORCH_CUDA_ALLOC_CONF` is the compatibility name documented in older releases such as PyTorch 2.9. Check the installed version and set one supported variable consistently. Do not define conflicting values under both names. Preserve the exact configuration string and verify the effective backend in the worker.

Native-only options include split-size and rounding policies whose effects do not carry over to `cudaMallocAsync`. Some are ignored on that backend. Experimental expandable segments are a separate feature with platform and version constraints, not a guaranteed improvement. Keep unsupported or ignored settings out of the efficacy comparison.

Part 3 - Quantitative Prediction Before Execution

For configuration j, compare a vector rather than one score:

$$\mathbf{v}_j = (T_j, M_{\text{alloc},j}, M_{\text{reserve},j}, I_{s,j}, N_{\text{retry},j}, N_{\text{fail},j}).$$

Fields without meaningful backend support remain unavailable. Define speed ratio T_{base}/T_j only for equivalent completed work.

For a hypothetical native cache containing a 128 MiB inactive block and recurring 48 MiB requests, predict how preventing certain large-block splits might change reuse. List possible outcomes rather than assuming it must help. Explain why the raw setting's documented unit and observed byte capacities should both be recorded. Predict which measurements would distinguish preserved large-block fit from increased internal waste.

Part 4 - Experimental Design and Instrumentation

1. Confirm the baseline pattern and select a small, justified configuration matrix.
2. Inspect the installed documentation for native split-size configuration. Test one change at a time.

3. Evaluate power-of-two division rounding as a separate native configuration.
4. Launch sequential fresh workers with structured argument lists and an explicit environment. Record startup failures and effective backend.
5. Replay the exact same trace and useful work for every supported configuration.
6. Collect comparable timing and peak metrics plus native diagnostics where meaningful.
7. Evaluate the best calibration candidates on held-out traces without retuning.

Backend selection is process-wide in the documented allocator configuration. Avoid simultaneous benchmark workers competing for the same GPU. Treat optional expandable segments as a separately labeled experiment.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import os
import subprocess
import sys

@dataclass
class AllocatorTrial:
    trial_id: str
    environment_name: str
    configuration: str
    trace_path: str

def validate_trial_support(trial, version_information):
    # Reject unsupported options and record ignored settings.
    ...

def build_worker_environment(trial, base_environment):
    # Set one supported allocator variable before child startup.
```

```
    ...

def launch_fresh_worker(trial, worker_path):
    # Use an argument list and capture exit status and evidence.
    ...

def compare_configuration_trials(results):
    # Compare only equivalent completed work and supported metrics.
    ...

def E13(config):
    # Run a small calibration matrix and held-out evaluation.
    ...
    # Export effective settings, failures, and tradeoffs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require proof that every worker used the intended backend and configuration. Mark invalid startup, unsupported feature, ignored setting, successful execution, and OOM as different outcomes. A worker that failed to start is not a fast run.

Report startup-inclusive and warmed time, completed work, peak memory, native split bytes where supported, retries, and output correctness. Explain a setting that helps one trace and harms another, or state that no such reversal was observed. Do not claim that a native-only option improved an asynchronous-backend run when the option was ignored.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Allocator tuning is workload-specific policy selection. Its credibility comes from reproducing the original problem, changing a defined mechanism, and evaluating the result outside the calibration trace.

Recommend a setting only with its version, backend, workload, and measured cost. A complicated configuration that marginally improves one trace may be less valuable than a simple workload-level change. Preserve the default baseline so future PyTorch upgrades can be assessed fairly.

19.28.15 Exercise 14

Exercise Title: Compare Native CUDA Caching Allocation Behavior Against cudaMallocAsync Backend Behavior Under Variable-Size Workloads

Part 1 - Exercise Contract and Why It Matters

Compare native and CUDA asynchronous allocator backends on identical variable-size workloads in isolated processes. Measure feasibility, useful throughput, latency, and comparable memory observations. Deliver a support matrix showing which diagnostics can and cannot be compared across backends.

Verify runtime, driver, device, and PyTorch support before running. PyTorch documentation specifies CUDA 11.4 or newer for the asynchronous backend, but that version requirement alone does not establish every feature's availability. Do not replace unavailable diagnostics with zeros.

Part 2 - System and Memory Mental Model

The native backend manages its own cached block and segment organization. The asynchronous backend uses CUDA's stream-ordered allocation mechanisms and driver-managed pools. Their reuse, release, and diagnostic behavior can differ even when the application issues identical tensor requests.

CUDA pool mechanisms can use virtual-memory management to improve reuse under some fragmentation patterns. This is not a guarantee that every large allocation succeeds or that all forms of fragmentation disappear. Live demand, pool growth requirements, external pressure, and supported implementation behavior still constrain allocations.

Native inactive-split statistics and some retry counters may be meaningless or always zero with the asynchronous backend. A zero therefore cannot prove superior fragmentation. Snapshot support and granularity must also be verified. Compare common application outcomes first, then interpret backend-specific diagnostics within their own scope.

Synchronization can affect both timing and memory reclamation. Use matched boundaries and distinguish a serial diagnostic run from a pipelined workload. Do not assume the CUDA driver's default pool release configuration is identical to the configuration used internally by a given PyTorch release.

Part 3 - Quantitative Prediction Before Execution

Define useful throughput for each backend as

$$U_b = \frac{W_{\text{completed}}}{T_b}.$$

For a common supported memory quantity M_b, compare absolute peak and final retention separately. Do not subtract unlike native and driver pool counters.

Using a hypothetical trace with a 64 MiB request followed by repeated 40 and 48 MiB requests, predict which questions must be measured: additional pool growth, reuse latency, retained capacity, and later large-request success. Explain why no native split-byte formula alone predicts the asynchronous backend's answer. Plan a matched single-stream control and a multi-stream variant with correct producer and consumer ordering.

Part 4 - Experimental Design and Instrumentation

1. Launch fresh workers with explicit native and asynchronous backend selection before allocator initialization.

2. Verify effective backend, supported APIs, and device identity. Record unavailable features as unsupported.

3. Replay stable, nearby-variable, broad-variable, and mixed-lifetime traces with identical useful work.

4. Measure complete wall time, request latency, application live bytes, and documented comparable memory observations.

5. Add native-specific statistics only to the native diagnostic view. Use supported driver or backend diagnostics for the other view without renaming them as equivalent.

6. Repeat with a correctly ordered multi-stream workload and with selected synchronization frequencies.

Catch and classify typed OOM outcomes. Do not keep retrying arbitrary device errors or infer a universal backend ranking from one trace.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class BackendCapabilities:
    backend: str
    supported_metrics: tuple
    snapshot_support: str
    environment_description: str

def inspect_backend_capabilities(device):
    # Verify support rather than assuming native diagnostics.
    ...

def run_common_trace(trace, capabilities, config):
    # Preserve useful work, lifetimes, and stream ordering.
    ...

    ...

def compare_backends(native_result, async_result):
    # Keep unsupported fields out of numerical rankings.
    ...

def E14(config):
    # Coordinate isolated workers and matched trace replays.
    ...
    # Explain feasibility, retention, and latency differences.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equivalent completed work and correct outputs. Backend selection must be confirmed from inside each worker. Show the diagnostic support matrix next to the results so missing values cannot be mistaken for perfect allocator behavior.

Report whole-trace success, useful throughput, latency tails, application peak demand, supported memory peaks, and final retention. Investigate performance changes caused by synchronization or different release behavior. If one backend fails a trace the other completes, preserve the request and environment evidence without claiming that the successful backend can never fragment.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Backend choice changes mechanisms and observability. A fair comparison begins with what the application needs to accomplish and uses internal statistics to explain those outcomes.

Recommend a backend for the tested workload and document its support constraints. Explain when simpler native diagnostics might be useful even if another backend performs better, and why a future runtime upgrade requires re-evaluation rather than blind reuse of an old conclusion.

19.28.16 Exercise 15

Exercise Title: Build an Early-Warning Detector That Predicts Fragmentation Risk Before the First Allocation Retry or OOM

Part 1 - Exercise Contract and Why It Matters

Build a detector that uses only information available before a defined allocation event to warn of fragmentation risk. Evaluate it against healthy cache retention, capacity pressure, and verified split-block patterns. Deliver warning traces, lead-time measurements, false-alarm rates, and clearly stated diagnostic uncertainty.

Define the target event and prediction horizon before calibration. The first retry or OOM is measured relative to a declared warmed baseline and counter epoch. An event already visible in a post-failure counter must not be used as an early predictor of itself.

Part 2 - System and Memory Mental Model

A useful warning can combine increasing native split bytes, deteriorating candidate coverage for a known queued request, low driver headroom, and persistent live separators. Each signal has alternative explanations: healthy cache can raise inactive bytes, pending work can temporarily reduce availability, and new shapes can legitimately increase live demand.

Use known queued request sizes only when the scheduler actually has them at decision time. Otherwise forecast them from past data and record uncertainty. A snapshot is an observation, not a reservation; its age and scope limit the warning's confidence.

Retries and OOM events are outcomes, while fragmentation attribution requires additional evidence. Maintain separate labels for event prediction and mechanism diagnosis. Some backends lack meaningful retry metrics, so do not transfer a native label definition silently. No positive events in an evaluation set means detection recall cannot be estimated, not that recall is perfect.

Part 3 - Quantitative Prediction Before Execution

For warning time t_w and later event time t_e, define positive lead time

$$\ell = t_e - t_w.$$

For predeclared event windows, calculate precision and recall:

$$\text{precision} = \frac{TP}{TP + FP}, \qquad \text{recall} = \frac{TP}{TP + FN}.$$

Undefined denominators remain undefined. Also report false alarms per unit runtime and time spent in warning state.

Use a hypothetical sequence with warnings at steps 10 and 40, a retry at 14, and no later event through step 60. Under a five-step horizon, classify the warnings and calculate lead time for the matched event. Explain how changing the horizon changes the evaluation. Predict a healthy-cache false positive for a detector using only reserved-minus-allocated bytes.

Part 4 - Experimental Design and Instrumentation

1. Define causal features, observation cadence, target event, warning horizon, and matching rules.

2. Split traces chronologically or by independent workload family into calibration and evaluation sets.

3. Build a simple threshold-based detector before considering a learned model.

4. Replay observations in order and prohibit access to future snapshots, outcome counters, or future shapes not present in the actual queue.

5. Measure event prediction and fragmentation attribution separately against controlled traces.

6. Add noisy headroom, missing metrics, stale snapshots, and long stable periods.

Bound monitoring overhead and compare monitored with unmonitored throughput. Mark incomplete event windows near the end of a run as censored or apply a declared evaluation rule.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class WarningDecision:
    step_id: int
    risk_level: str
    reason_codes: tuple
    observation_age_seconds: float
    predicted_request_bytes: object

def build_causal_features(history, known_queue, capabilities):
    # Exclude future outcomes and unsupported diagnostics.
    ...

def decide_warning(features, calibrated_policy):
    # Apply a declared horizon and uncertainty handling.
    ...

def match_warnings_to_events(warnings, events, horizon):
    # Handle repeated warnings and censored final windows.
    ...
```

```
def E15(config):
    # Calibrate on separate traces and freeze the detector.
    ...
    # Report event prediction, attribution, and overhead.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require positive lead time for a true early warning. Audit feature timestamps to detect leakage from post-retry counters or future allocation history. Include healthy-cache and capacity-only controls in the evaluation.

Report precision, recall where defined, false alarms, missed events, lead-time distribution, warning duration, and monitoring cost. Present a mechanism-confidence label separately from the event alarm. If no retry or OOM occurs, report the detector's warning behavior and leave event-recall claims unsupported. Explain how missing native metrics change behavior instead of treating their absence as low risk.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Prediction is useful only if it gives time for a valid intervention and avoids excessive false alarms. A detector that recognizes an OOM after it happens is a reporter, not an early-warning system.

Use the evaluation to choose an operating point appropriate to the measured cost of waiting or reshaping. Preserve uncertainty in the diagnosis so the later scheduler can choose a bounded action without pretending the allocator's future is known.

19.28.17 Exercise 16

Exercise Title: Trigger Fragmentation During a Long Transformer Training Run and Diagnose the Exact Allocation Pattern Responsible for Memory Degradation

Part 1 - Exercise Contract and Why It Matters

Run a bounded long-duration Transformer training experiment with variable sequence lengths and investigate any memory degradation. Attempt to create a reproducible fragmentation-prone pattern, then identify the responsible allocation sizes, lifetimes, and call sites through history and controlled replay. Deliver a training timeline, incident dossier, and minimized allocation trace. If fragmentation does not appear, report that outcome and explain the observed stabilization.

Keep model dimensions, optimizer, precision, checkpointing, and attention backend fixed in the primary study. Distinguish fragmentation from legitimate activation growth, optimizer initialization, retained autograd graphs, and temporary operator workspaces. The title's proposed failure is a hypothesis to test, not a required fabricated result.

Part 2 - System and Memory Mental Model

Sequence-length changes alter multiple allocation families: embeddings, projections, saved activations, masks, attention temporaries, and outputs. Some sizes scale linearly with length; explicitly materialized attention scores scale quadratically. Fused attention may avoid those score tensors, so record the actual backend rather than applying one universal formula.

Optimizer state and gradient buffers can create startup growth unrelated to fragmentation. A logger that stores loss tensors with their graphs can produce increasing live demand, while a logger of detached CPU scalars does not preserve those graphs. Include a bounded, separately labeled retention control to distinguish this mechanism from allocator trapping.

A credible diagnosis links a size-and-lifetime sequence to partially occupied segments and subsequent allocation pressure. Stack traces identify candidate call sites, but causal attribution needs a counterfactual replay. Change one suspected allocation pattern while preserving useful work as closely as possible, and disclose changes to arithmetic, shape, or peak live demand.

Do not restore training state by simply clearing gradients after an arbitrary failed update. Place diagnostic replays in separate workers with known model and optimizer state. Recovery during training requires the transactional discipline developed in DMM23.

Part 3 - Quantitative Prediction Before Execution

For batch B, length S, hidden width D, and element size s, a single activation family may require

$$q_{\text{linear}} = BSDs.$$

For explicitly materialized attention scores with H heads, the corresponding family requires

$$q_{\text{score}} = BHS^2s.$$

Neither equation is total training memory.

For hypothetical $B = 2, D = 512, H = 8$, compare lengths 256 and 384 at a declared dtype. Predict the relative growth of these two families and explain why the measured peak can differ. Add a persistent 64 MiB allocation family to the lifetime model and predict how it could separate transient blocks if they share segments.

Before running, sketch expected startup, steady-state, shape-shift, and possible degradation phases. State what stable active bytes with rising split bytes would suggest, and what rising active bytes would require you to investigate first.

Part 4 - Experimental Design and Instrumentation

1. Build a small Transformer training workload with bounded lengths and reproducible useful-token traces. Record attention implementation and optimizer settings.

2. Establish a fixed-length baseline including complete forward, backward, and optimizer steps.

3. Run a nearby-length oscillation trace and a phase-shift trace after a declared warmup.

4. Log pre-forward, post-forward, post-backward, post-update, and completed-cleanup memory at selected steps. Use scalar-only training logs.

5. Enable bounded history in targeted windows or a separate diagnostic replay. Capture before suspected degradation and near a retry or OOM if one occurs.

6. Match problematic blocks to allocation stacks, sizes, generations, and persistent neighbors.

7. Minimize the suspected trace and test one counterfactual mitigation while preserving workload semantics or explicitly documenting differences.

Compare losses and gradients for short deterministic reference windows. Keep lengthy numerical validation and CPU state snapshots outside the primary timing run.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class TrainingObservation:
    step_id: int
    phase: str
    sequence_length: int
    useful_tokens: int
    loss_scalar: float
    allocator_state: object

def build_training_reference(config):
    # Establish model, optimizer, precision, and backend.
    ...

def run_training_phase(model, optimizer, batch, observer):
    # Expose full lifecycle phases without retaining graphs.
    ...

def capture_diagnostic_window(window, config):
    # Bound history and preserve pre-incident evidence.
```

```
    ...

def trace_block_to_operation(snapshot, training_log):
    # Match call sites, sizes, generations, and live neighbors.
    ...

def replay_suspected_pattern(pattern, counterfactual, config):
    # Isolate one mechanism in a fresh known-state worker.
    ...

def E16(config):
    # Compare stable, variable, and bounded retention controls.
    ...
    # Diagnose only mechanisms supported by replay evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require complete-step measurement and a clear startup boundary. Report useful tokens, physical tokens, loss, allocated and reserved peaks, native split trajectory, retries, and history-window coverage. Label missing or overwritten history explicitly.

An exact-pattern claim needs a reproducible minimized trace and a counterfactual that changes the suspected mechanism. If several mechanisms remain plausible, report a candidate diagnosis. A growing list of live loss graphs is a retention defect even if fragmentation also exists. A larger sequence requiring more activations is increased demand, not evidence of allocator degradation.

Preserve every OOM or unsupported-shape outcome and verify that successful runs complete the intended updates. Do not call a shorter or truncated workload a recovery of the same training experiment.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

Long training runs make allocator history important, but they also create many confounding state changes. The strongest investigation reduces a complex incident to a small, explainable allocation and lifetime pattern.

Explain which part of the diagnosis is directly observed, which is inferred, and which is tested by intervention. Recommend a mitigation only for the supported cause. If the allocator remains stable, describe the conditions that enabled that stability rather than forcing a fragmentation narrative.

19.28.18 Exercise 17

Exercise Title: Build a Fragmentation-Aware Scheduler That Delays, Reuses, or Reshapes Allocations When the Largest Contiguous Free Block Becomes Too Small

Part 1 - Exercise Contract and Why It Matters

Build a scheduler that uses request-aware fragmentation evidence to choose among waiting, reusing owned buffers, or applying a semantics-preserving shape policy. Deliver decision traces, ownership checks, and a comparison with a scheduler using only aggregate headroom.

Interpret largest contiguous free block at the correct layer. An application-owned pool can expose exact eligible buffers; a native allocator snapshot provides observed inactive candidates and cannot reserve them for the scheduler. The implementation must preserve this distinction.

Part 2 - System and Memory Mental Model

A pending request can be delayed until known consumers finish, provided the schedule still makes progress. Waiting is ineffective when no scheduled release can improve the state. Add deadlines or bounded retries and identify infeasible requests explicitly.

Explicit reuse requires a compatible, owned buffer and a valid completed lease. A snapshot address is not a tensor handle and does not grant permission to select or overwrite an allocator block. For ordinary PyTorch allocations, the allocator still chooses the actual block.

Reshaping by a view does not reduce backing bytes. Bucketing or padding can improve future reuse while increasing immediate demand; token or micro-batch splitting can change execution and requires correct normalization and effective-batch semantics. Do not truncate content to make the scheduler appear feasible.

Cached candidate size below the request is a warning, not a universal refusal condition, because new segments may be obtained. Conversely, an apparently large candidate is not an allocation guarantee. Combine evidence with live-demand estimates, known release events, observation age, and explicit uncertainty.

Part 3 - Quantitative Prediction Before Execution

For action a, define an estimated completion cost

$$\widehat{J}(a) = \widehat{T}_{\text{wait}}(a) + \widehat{T}_{\text{execute}}(a) + \widehat{T}_{\text{transform}}(a).$$

Minimize over actions that preserve semantics and satisfy the scheduler's declared admission model. Estimated capacity is not a physical reservation.

For a hypothetical 40 MiB request, a 24 MiB largest cached candidate, and a 48 MiB owned buffer becoming free after 3 ms, compare waiting with a fresh allocation when driver headroom is uncertain. State the information needed to choose responsibly. Then analyze a proposed padded class of 64 MiB: explain why it may aid future reuse yet fail the current budget. Identify a starvation case for always favoring small requests.

Part 4 - Experimental Design and Instrumentation

1. Define typed request metadata, owned-buffer eligibility, dependencies, deadlines, and known future release events.

2. Build a host simulator for wait, reuse, bounded allocation attempt, and supported shape transformations.

3. Compare an aggregate-headroom scheduler with a request-aware policy on identical traces.
4. Integrate CUDA only after ownership and progress invariants pass.
5. Measure wait time, tail latency, completed work, rejected requests, process peaks, and allocator-specific diagnostics.
6. Add stale snapshots, delayed completions, and requests that cannot fit any supported strategy.

Apply hysteresis or cooldown to avoid immediate reversal of costly shape decisions. Keep backend switching out of the live scheduler; that belongs to process startup experiments.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class ScheduledRequest:
    request_id: int
    required_bytes: int
    logical_shape: tuple
    deadline_seconds: float
    dependencies: tuple

def observe_request_context(request, allocator, owned_pool):
    # Separate exact owned capacity from snapshot candidates.
    ...

def enumerate_legal_actions(request, context, policy):
    # Preserve data, normalization, ownership, and progress.
    ...
```

```
def estimate_action_cost(action, calibrated_costs):
    # Include wait and transformation costs with uncertainty.
    ...

def execute_scheduled_action(action, runtime):
    # Enforce real dependencies and bounded failure handling.
    ...

def E17(config):
    # Compare schedulers on the same request and release trace.
    ...
    # Audit starvation, stale evidence, and useful work.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires no early reuse, no hidden data truncation, and bounded behavior for infeasible requests. Show that the scheduler cannot obtain ownership merely by reading a snapshot address. Validate every shape transformation against a numerical reference.

Report action counts, wait duration, transformation cost, completed useful work, starvation indicators, OOM outcomes, and memory peaks. Include a case where new allocation succeeds despite a small cached candidate and a case where waiting fails to improve feasibility. These prevent the policy from treating one diagnostic as an infallible oracle.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A fragmentation-aware scheduler should use incomplete information to make better bounded decisions. It cannot turn allocator observations into ownership or make live memory disappear.

Explain which action produced the measured benefit and what correctness assumptions it required. Prefer a policy that admits uncertainty, preserves progress, and handles failure cleanly over one that reports perfect prevention by rejecting all difficult work.

19.28.19 Exercise 18

Exercise Title: Stress-Test Fragmentation Management with Thousands of Mixed-Lifetime, Mixed-Size CUDA Allocations and Compare Multiple Mitigation Strategies

Part 1 - Exercise Contract and Why It Matters

Build a reproducible stress suite combining size variability, long-lived separators, delayed completion, and changing demand. Compare multiple mitigations on the same exact traces and resource limits. Deliver a benchmark matrix, replay artifacts, and minimized failures.

Generate thousands of requests while bounding simultaneous live bytes and total experiment duration. Separate simulator failures, application budget refusals, allocator OOM, and unrelated CUDA errors. The suite should expose weak diagnoses as well as weak policies.

Part 2 - System and Memory Mental Model

Mixed-size and mixed-lifetime traces can create more challenging histories than either factor alone. Yet some traces will stabilize, and some failures will be ordinary capacity limits. Keep healthy and capacity-only controls in the suite so a detector cannot succeed by labeling every pressure event fragmentation.

Compare default allocation, bucketing, rounded buffers, bounded reuse, legal lifetime grouping, and justified allocator settings. Backend variants need separate workers and capability-aware diagnostics. Changing a mitigation must not silently change the amount of useful work.

Stress correctness as well as memory efficiency. Delayed consumer events, stale leases, and missing references can produce hazards unrelated to fragmentation. Test invalid transitions in a host simulator before they reach CUDA. Use request-specific patterns and controlled completion to validate accepted work.

Keep diagnostic overhead bounded. A huge history buffer or tensor-retaining log can create the very memory growth being investigated. Preserve raw traces and short targeted snapshots instead of recording every detail indefinitely.

Part 3 - Quantitative Prediction Before Execution

For each exact trace, calculate a logical live-demand lower bound

$$Q_{\text{peak}} = \max_{t} \sum_{i \in \mathcal{L}(t)} q_i.$$

Compare measured peak capacity with that bound while accounting for rounding, pending work, and operator temporaries.

For mitigation m, report a vector of completed coverage, useful throughput, peak VRAM, retry outcomes, and diagnostic evidence. A normalized throughput comparison is valid only when the numerator represents equivalent useful work.

Design a hypothetical 10,000-request suite with a fixed maximum live set and three lifetime classes. Predict which scenarios challenge each mitigation: boundary sizes, rare large requests, persistent separators, or delayed completion. State why a lower fragmentation ratio caused by rejecting large requests is not a fair improvement.

Part 4 - Experimental Design and Instrumentation

1. Generate exact integer request sizes, allocation roles, release events, stream dependencies, and seed metadata.
2. Validate a reference state model and the trace's live-demand bound.
3. Run each mitigation in a fresh worker with matched environment and useful work.
4. Vary one stress dimension at a time, then run selected combinations.
5. Collect minimal performance evidence for all runs and detailed diagnostics for representative failures or disagreements.
6. Minimize a failing trace while preserving the mechanism, initial allocator setup, and relevant lifetime dependencies.

7. Evaluate policies on held-out seeds and workload families without retuning.

Use timeouts and explicit outcomes. Do not kill unrelated GPU processes or fill all available VRAM indefinitely to manufacture a dramatic failure.

Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import random
import torch

@dataclass
class StressScenario:
    scenario_id: str
    seed: int
    request_count: int
    live_limit_bytes: int
    lifetime_policy: str
    size_policy: str

def generate_mixed_trace(scenario):
    # Preserve exact sizes, roles, and completion dependencies.
    ...

def verify_trace_demand(trace, limits):
    # Validate logical live demand before allocating on CUDA.
    ...

def run_strategy_worker(trace, strategy, config):
    # Use isolated startup configuration and bounded execution.
    ...
```

```
def classify_stress_outcome(result, diagnostic_evidence):
    # Separate capacity, placement, ownership, and support failures.
    ...

def minimize_reproducer(trace, initial_state, predicate):
    # Preserve the causal pattern and replay configuration.
    ...

def E18(config):
    # Compare strategies and retain all failed or censored runs.
    ...
    # Export a fair benchmark matrix and replay artifacts.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact trace identity across strategy comparisons or a clearly documented semantics-preserving transformation. Record all rejected and unfinished requests. Successful-only latency statistics must not conceal reduced workload coverage.

Report seed, request count, live-demand bound, coverage, useful throughput, memory peaks, native split metrics where supported, retries, OOM, and correctness failures. Include run-to-run variation rather than only the best seed. A zero observed-failure count establishes the tested scope, not universal allocator correctness.

Every claimed fragmentation failure should have block or history evidence, or remain a candidate diagnosis. Preserve the smallest reproducer and its last valid accounting state.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

A good stress suite challenges both the mechanism and the story told about it. It should reveal when an apparent improvement comes from extra padding, lower coverage, or a changed synchronization pattern.

Use the results to rank mitigations by feasibility, correctness, and useful performance under the actual budget. State the remaining untested conditions and avoid extending a single-device native-backend conclusion to every CUDA environment.

19.28.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Fragmentation Management System That Detects, Explains, and Reduces CUDA Memory Waste Under Highly Dynamic Workloads

Part 1 - Exercise Contract and Why It Matters

Integrate observation, request-aware risk detection, causal diagnosis, and legal mitigation into a coherent fragmentation-management runtime. Deliver the student-completed implementation, a benchmark dossier, and a support contract that precisely states what the system can observe and control. The scaffold intentionally leaves all calculations, decisions, CUDA operations, and validation unfinished.

The system should detect concerning allocation patterns, explain them with evidence, and select a bounded intervention while preserving useful work. It must also recognize healthy cache retention, genuine capacity exhaustion, unsupported metrics, and inconclusive evidence. Correctness and diagnostic honesty are independent requirements from performance.

Part 2 - System and Memory Mental Model

Separate five responsibilities. The observer collects backend-aware statistics and bounded history. The request model describes logical and backing demand, dependencies, and known releases. The detector estimates risk from causal observations. The diagnoser tests explanations against snapshot and replay evidence. The controller chooses only supported actions.

The controller may delay work, reuse owned buffers, bucket supported shapes, or change future allocation lifetimes. It cannot choose an arbitrary cached block by address, compact live tensors without handling aliases, or switch allocator backend inside a running process. Configuration and backend selection belong to offline calibration and worker startup.

Cache release is an optional measured intervention, not a universal fix. It does not free live tensors or generally compact partially occupied ordinary segments. Repeated cache release can increase allocation cost. Similarly, lower inactive split bytes can merely reflect a larger active application pool.

Preserve the distinction between a logical resource budget, allocator reservation, and physical device availability. External processes and unmanaged library allocations can change available memory despite a correct internal policy. Failure handling must classify typed OOM separately from unrelated runtime errors and preserve training-state integrity when training is supported.

Part 3 - Quantitative Prediction Before Execution

Define the optimization goal with useful work W, complete elapsed time T, and declared memory and correctness constraints:

$$\max_{\pi} \frac{W_{\text{completed}}(\pi)}{T(\pi)} \quad \text{subject to valid semantics and declared budgets.}$$

Do not optimize a fragmentation ratio alone. Report a diagnostic vector containing active demand, reserved capacity, internal slack, supported split-block signals, request coverage, and observation uncertainty.

For action a, estimate benefit and cost on comparable boundaries:

$$\widehat{\Delta M}(a) = \widehat{M}_{\text{before}} - \widehat{M}_{\text{after}}, \qquad \widehat{\Delta T}(a) = \widehat{T}_{\text{action}} + \widehat{T}_{\text{later penalty}}.$$

The memory term must name its accounting layer. Reducing application capacity is different from reducing driver-visible usage.

Construct a hypothetical case with stable live demand, increasing native split bytes, a known large queued request, and limited growth headroom. Predict the evidence needed to choose waiting, owned-buffer reuse, or a legal shape policy. Then construct a capacity-only case and explain why the same diagnosis would be wrong.

Part 4 - Experimental Design and Instrumentation

1. Write a support matrix for backends, snapshot schemas, buffer roles, shapes, precision, and training or inference semantics.

2. Integrate scalar observations with typed request and lifetime metadata. Preserve unsupported and stale-data states.

3. Calibrate risk thresholds and action costs on separate traces. Freeze them before evaluation.

4. Validate ownership, dependency, budget, and progress invariants in a host simulator.

5. Run CUDA correctness checks, then compare default allocation, individual mitigations, and the integrated controller.

6. Evaluate stable, variable, mixed-lifetime, Transformer, and capacity-only traces. Include healthy-cache negative controls.

7. Trigger bounded diagnostic capture on warnings or incidents. Minimize representative failures and verify a counterfactual cause.

8. Run ablations for monitoring, candidate-fit information, hysteresis, reuse, and shape policies, changing one component at a time.

Measure startup-inclusive and warmed useful throughput, tail latency, memory peaks, workload coverage, and monitoring overhead. Preserve all failed and unsupported configurations.
Reproducibility record. Preserve GPU/device identity, PyTorch and CUDA versions, allocator backend, seed, model dimensions, optimizer, precision, shape, and initial-state identifier. Record cold-start behavior separately from warmed execution. Synchronize only at deliberate measurement boundaries, reset peaks for the declared region. Allocation-only experiments need an explicit allocation region; training experiments include forward, backward, and optimizer update. Export CPU-only scalars: never retain live autograd graphs in the evidence log. Use a fixed seed for the primary comparison and additional seeds to check repeatability. State whether timing includes transfer, collation, calibration, and recovery.

Part 5 - PyTorch/CUDA Implementation

Complete the following scaffold. Every ... marks work for the learner: calculations, control decisions, CUDA operations, validation, and evidence export remain intentionally unfinished. The scaffold is not a runnable implementation until those steps are completed. Keep the implementation explicit; do not hide the exercise inside a high-level trainer.

```
from dataclasses import dataclass
import torch

@dataclass
class RuntimeContract:
    backend: str
    supported_roles: tuple
    supported_actions: tuple
    memory_budget_bytes: int
    maximum_observation_age: float
```

```
@dataclass
class Diagnosis:
    incident_id: int
    classification: str
    evidence_ids: tuple
    confidence: str
    unresolved_causes: tuple

class FragmentationManager:
    def __init__(self, contract, observer, calibrated_policy):
        # Establish ledgers, support checks, and bounded history.
        ...

    def observe(self, request_context):
        # Preserve metric scope, support, age, and reset epoch.
        ...

    def predict_risk(self, observation, known_queue):
        # Use causal evidence and request-specific uncertainty.
        ...

    def diagnose(self, incident, snapshots):
        # Separate capacity, retention, pending work, and trapping.
        ...

    def enumerate_actions(self, request, diagnosis):
        # Admit only ownership-safe and semantic-preserving actions.
        ...

    def choose_action(self, actions, estimated_costs):
        # Balance useful performance, budget, and bounded progress.
        ...

    def execute_action(self, action):
        # Enforce dependencies and classify execution failures.
        ...

    def capture_incident(self, incident):
        # Save bounded evidence without retaining live graphs.
        ...

    def audit(self):
        # Reconcile owned capacity and completed useful work.
        ...
```

```
    def shutdown(self, deadline):
        # Stop admission, drain supported work, and report leftovers.
        ...

def benchmark_system(trace_suite, strategies, config):
    # Compare equivalent workloads and preserve failed outcomes.
    ...

def E19(config):
    # Validate contracts, causal features, and runtime invariants.
    ...
    # Run correctness, performance, ablation, and stress phases.
    ...
    # Export a diagnosis dossier and conditional recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires four independent gates. First, accepted work preserves the intended numerical and data semantics. Second, ownership and completion rules prevent unsafe reuse. Third, every diagnosis separates direct evidence from inference and unknowns. Fourth, performance comparisons account for complete useful work and all resource costs.

The dossier must include environment and configuration, support matrix, exact traces, predictions, observations, snapshot references, numerical errors, memory accounting by layer, warning precision and lead time, action counts, latency distributions, coverage, and useful throughput. Report internal slack and retained idle capacity separately from native split-block indicators.

Demonstrate safe behavior with missing metrics, stale snapshots, no feasible action, delayed completion, and an unrelated runtime error. A scheduler that rejects every difficult request does not demonstrate successful fragmentation management. If no benefit over default allocation is observed, state that clearly and identify the tested scope.

Evidence format. Keep prediction, observation, and interpretation in separate columns. Each request or experiment needs an ID, configuration, input shape, budget in bytes, peak allocated/reserved bytes, elapsed seconds, outcome, and failure phase when applicable. Use explicit not-measured and unsupported values. A fragmentation pattern or OOM that does not reproduce is an experimental outcome, not permission to invent hardware results. Include the smallest counterexample that invalidates a proposed rule, or state that no counterexample was observed in the tested range.

Part 7 - Engineering Interpretation and Philosophy

The completed system should make a modest but precise promise: it observes supported memory behavior, explains incidents with evidence, and applies legal workload changes when their expected benefit justifies their cost. It does not eliminate every form of memory waste or guarantee that external pressure cannot cause OOM.

Use the results to recommend the smallest effective set of mechanisms. Explain when default allocation is sufficient, when workload regularization helps, and when backend-specific tuning

deserves a separate evaluation. Finish with a supported deployment scope and one concrete experiment needed before expanding that scope.

19.29 DMM27

Chapter Title: Tensor Reuse and Buffer Reuse
Specialization: Dynamic Memory Management and CUDA Systems

19.29.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Tensor Storage Reuse, Temporary Buffers, Workspace Lifetimes, and Allocation Elimination

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model for tensor objects, logical values, backing storage, temporary outputs, and operator workspaces. Identify which allocations can be removed by retaining an owned destination and which values must remain distinct. The result must explain both storage savings and the conditions that make reuse legal.

Part 2 - System and Memory Mental Model

A tensor describes values through metadata and backing storage. Different views can share storage; assigning a fresh result to an old variable does not imply storage reuse. Application reuse retains ownership across iterations, whereas the caching allocator can recycle a released allocation underneath the program. A value remains protected until its final consumer, including aliases and asynchronous device readers, has finished or is correctly ordered before the next write. Start with single-stream inference, not saved training activations.

Part 3 - Quantitative Prediction Before Execution

For owned slot capacities c_j, calculate $B_{\text{pool}} = \sum_j c_j$. For distinct live values, calculate $B_{\text{live}}(t) = \sum_{i \in L(t)} b_i$, without charging aliases as independent physical storage. Consider three 4 MiB values: a remains live while b is consumed; c begins after b is no longer needed. Predict which values may share a slot. Repeat after a view of b escapes to a later consumer. These are hypothetical predictions, not GPU measurements.

Part 4 - Experimental Design and Instrumentation

Draw separate logical-value and physical-storage tables. Mark each producer, reader, alias, and release boundary. Compare fresh outputs, a persistent output, and a view of that output. Use deterministic values and inspect each generation before overwrite. State whether returned outputs are borrowed until the next call or independently retainable. Record setup capacity separately from warmed allocation requests and reserved memory.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class TensorLifetime:
    key: str
    payload_bytes: int
    birth: int
    final_consumer: int
    alias_group: str
    owner: str

def storage_record(tensor, owner, generation):
    # Record base, offset, capacity, shape, and ownership evidence.
    ...

def legal_reuse(previous, following, lifetime_table):
    # Check value lifetimes and all aliases before permitting a write.
    ...

def E00(config):
    # Construct the three cases and verify the predicted sharing.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check intermediate values, not only the final result. A repeated address after release does not establish continuous ownership, and a different view pointer does not establish different backing storage. Include an escaped-output case that makes an otherwise valid overwrite illegal. Workspace demand not observed by the instrument must remain unknown.

Part 7 - Engineering Interpretation and Philosophy

Reuse shortens physical storage ownership requirements without shortening the semantic lifetime of a required value. The optimization starts with an explicit consumer contract; it does not start with a pointer or a lower memory counter.

19.29.2 Exercise 01

Exercise Title: Measure the Number and Total Bytes of Temporary CUDA Tensors Created During a Repeated PyTorch Workload

Part 1 - Exercise Contract and Why It Matters

Measure temporary allocation activity during a repeated CUDA workload. Separate logical tensor-producing operations, requested payload bytes, allocator events, and driver allocation calls when observable. A final live-memory difference is not the cumulative amount of temporary storage requested.

Part 2 - System and Memory Mental Model

A materialized result can request storage even when the allocator satisfies it from its cache. A view creates tensor metadata without allocating another full payload. Profiler memory activity, operator call counts, and backend counters have different scopes. Nested operator aggregates can double count activity; net memory change can cancel allocations against frees. Choose one supported event layer and document its attribution rules.

Part 3 - Quantitative Prediction Before Execution

For N iterations that deliberately materialize two independent n-element outputs of element width s, predict logical request traffic $Q = 2Nns$. Exclude inputs, views, and unobserved workspaces from this formula. Estimate peak live bytes from the lifetime timeline rather than from Q. Add one view and predict the effect on object count and backing payload separately.

Part 4 - Experimental Design and Instrumentation

Use fixed shapes, deterministic inputs, eager execution, and an explicitly bounded repeated region. Warm up before the main census. Collect a short memory trace, preserve positive allocations and frees separately, and reconcile one tiny trace by hand. Compare supported allocator-counter deltas over the same region. Run a view-only control and repeat timing without profiling. Record GPU, PyTorch/CUDA versions, backend, seed, shape, dtype, and reset boundaries.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class AllocationCensus:
    logical_requests: object
    payload_bytes: object
    allocator_events: object
    driver_events: object
    unsupported_fields: tuple

def repeated_workload(inputs, repetitions):
    # Materialize the declared outputs; consume and release each safely.
    ...

def collect_census(workload, config):
    # Choose supported profiling/counter APIs and one accounting layer.
    ...

def reconcile_events(trace, logical_operations):
    # Deduplicate nested attribution and retain unknown allocations.
    ...
```

```
def E01(config):
    # Validate the short trace before measuring a longer replay.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not sum inclusive memory columns across nested operators as unique traffic. A zero final delta does not mean zero allocation. Unsupported profiler schemas or backend fields must not become zero counts. Compare profiler-on and profiler-off behavior and report observer overhead. Direct library allocations outside PyTorch's allocator may be invisible to its memory diagnostics.

Part 7 - Engineering Interpretation and Philosophy

An allocation count is meaningful only when the counted entity and interval are explicit. Preserve traffic, peak demand, and final residency as separate measurements so later reuse claims can be audited at the same layer.

19.29.3 Exercise 02

Exercise Title: Replace Repeated Tensor Creation with a Preallocated CUDA Output Buffer and Measure Allocation Reduction

Part 1 - Exercise Contract and Why It Matters

Replace repeated fixed-shape result creation with one preallocated CUDA output. Compare numerical values and output-allocation requests with a fresh-result baseline. Define the result as borrowed until the next write, or charge the extra storage needed for independently retained outputs.

Part 2 - System and Memory Mental Model

A destination allocated before the loop moves allocation cost into setup and retains capacity between calls. It does not remove setup or every internal workspace. Use a supported destination-writing operation with disjoint inputs and output. Start with matching shape, dtype, device, and contiguous layout in inference mode. Do not disable gradients in a training workload merely to admit an output-buffer API.

Part 3 - Quantitative Prediction Before Execution

For N calls producing b payload bytes, predict N baseline logical output requests versus one setup request when direct reuse is supported. Nominal removed request traffic is $(N-1)b$, not necessarily peak-VRAM savings. Predict why a promptly released baseline can already have a small peak. Then retain K outputs and calculate the additional ownership required.

Part 4 - Experimental Design and Instrumentation

Pre-generate inputs and establish an independent reference. Allocate the reuse destination once, validate every generation before overwrite, and inspect storage metadata. Measure setup-inclusive and warmed runs separately. Count requests at E01's layer; reset peaks at declared boundaries but retain absolute owned capacity. Include a test where the caller keeps an old output and require an explicit lease rejection, extra slot, or charged copy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class OutputLease:
    generation: int
    shape: tuple
    borrowed_until_next_write: bool

def fresh_step(inputs):
    # Produce the reference result using ordinary allocation.
    ...

def buffered_step(inputs, destination, lease):
    # Validate compatibility and write directly where supported.
    ...

def E02(config):
    # Allocate the persistent destination and account for setup.
    ...
    # Check outputs, lease behavior, and output request reduction.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check reference independence: it must not alias the destination being tested. Report absolute allocated/reserved peaks and end-state capacity; a peak reset after pool creation must not conceal the pool. Unexpected storage changes need shape, dtype, layout, and API investigation. A correct final result does not validate an old retained output that was silently overwritten.

Part 7 - Engineering Interpretation and Philosophy

Preallocation trades flexible result ownership for predictable persistent capacity. Recommend it only when the caller accepts the output lifetime and the measured request benefit justifies retained memory and compatibility checks.

19.29.4 Exercise 03

Exercise Title: Reuse a Persistent Tensor with copy_() Instead of Allocating a New Tensor Every Iteration and Compare Runtime Behavior

Part 1 - Exercise Contract and Why It Matters

Compare a fresh independent copy with copying successive already available source values into one persistent destination. Measure destination requests, copy traffic, values, and complete runtime. Separately examine compute-then-copy so source-expression allocations are not hidden.

Part 2 - System and Memory Mental Model

The destination can remain owned while its values change. Copying still moves bytes, and a newly computed source can still allocate every iteration. Begin with identical shape, dtype, and device; broadcasting, conversion, and transfers are separate cases. A view of the destination sees later writes. Keep the initial experiment outside gradient recording and define when consumers release each generation.

Part 3 - Quantitative Prediction Before Execution

For a b-byte payload copied N times, predict Nb logical copied bytes. A simple same-device bandwidth model reads and writes about $2Nb$ bytes, excluding cache and implementation effects. Compare $T_{\text{fresh}} \approx T_{\text{allocation}} + T_{\text{copy}}$ with $T_{\text{reuse}} \approx T_{\text{copy}} + T_{\text{checks}}$. Predict what remains unchanged when the source itself is freshly allocated.

Part 4 - Experimental Design and Instrumentation

Prepare deterministic sources with a declared lifetime. Compare a fresh clone and persistent-destination copy with identical consumption. Inspect each result before the next overwrite and correlate destination metadata with allocation evidence. Run a compute-then-copy control and charge its source creation. Time completion at comparable boundaries, excluding validation from both timing paths or including it in both. Test retained views separately.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
import torch

def fresh_copy(source):
    # Create an independent destination for the reference contract.
    ...

def copy_into_existing(source, destination, contract):
    # Check shape/dtype/device, lease, and gradient restrictions.
    ...
    # Perform the copy and establish any required dependencies.
    ...

def account_source_and_destination(events):
    # Separate source allocations, destination requests, and traffic.
    ...
```

```
def E03(config):
    # Compare existing-source and compute-then-copy cases explicitly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check each source generation against an independent reference. A persistent address does not prove source allocation elimination. A result requiring broadcasting or conversion is a changed test contract and must be labeled. Report total bytes copied and numerical error. Retaining historical outputs requires copies or additional slots whose costs belong in the comparison.

Part 7 - Engineering Interpretation and Philosophy

Persistent copying is useful when the destination must remain stable. Direct production into a destination solves a different problem: it can avoid the source-result materialization that compute-then-copy still pays for.

19.29.5 Exercise 04

Exercise Title: Use PyTorch out= Variants Where Supported and Verify That Existing Storage Is Reused Without Changing Numerical Results

Part 1 - Exercise Contract and Why It Matters

Use supported PyTorch output variants to write directly into existing storage. Build a support table covering a pointwise operation, matrix multiplication, and deliberately rejected configurations. Verify values and destination storage without claiming that all operator workspace allocation disappears.

Part 2 - System and Memory Mental Model

An output argument is operation-specific. Cases needing gradients are not supported by the documented out semantics. Use correctly shaped, compatible, disjoint destinations in the initial inference experiment. Do not depend on resizing a nonempty incorrectly shaped output. Layout, dtype promotion, and input/output overlap must satisfy the selected operator's contract.

Part 3 - Quantitative Prediction Before Execution

For output shape (m, n) and element width s, predict mns payload bytes. For matrix multiplication, separately account for both inputs and measured workspace. Predict acceptance for a matching inference destination, rejection or unsupported status for a gradient-required case, and the diagnostic outcome for a wrong-shape destination. Write expected and observed statuses separately.

Part 4 - Experimental Design and Instrumentation

Read the actual installed-version operator signatures. Create independent fresh references and preallocated outputs. Compare values with declared precision and tolerances, then record shape, strides, storage base, and observed requests. Change dtype, layout, shape, overlap, and gradient requirements one at a time. Preserve rejection reasons and warnings instead of silently casting, resizing, or disabling differentiation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class OutCase:
    operator: str
    shape: tuple
    dtype: object
    requires_grad: bool
    expected_status: str

def admit_out_case(case, inputs, destination):
    # Check the selected operator's actual destination contract.
    ...

def execute_out_case(case, inputs, destination):
    # Complete only supported direct-output operations.
    ...

def E04(config):
    # Build the support table; validate values and storage evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct results, the promised output-storage behavior, and an unchanged gradient contract. Input/output aliasing is not universally legal just because a destination argument exists. A supported noncontiguous output needs its own test. Internal allocation observed during a valid out call must be attributed rather than misreported as a fresh output allocation.

Part 7 - Engineering Interpretation and Philosophy

A measured allowlist is stronger than assuming every operation can write into arbitrary scratch. Keep unsupported behavior explicit so the eventual planner can reject it or use a charged fallback without changing program semantics.

19.29.6 Exercise 05

Exercise Title: Compare Fresh Allocation, out= Reuse, and copy_() Reuse by Allocation Count, Peak VRAM, Reserved Memory, and Latency

Part 1 - Exercise Contract and Why It Matters

Benchmark fresh result allocation, direct output reuse, and compute-then-copy reuse under equivalent useful work. Report allocation count, peak allocated VRAM, reserved memory, and latency separately. Preserve source-result costs in the copy variant and validate correctness before ranking performance.

Part 2 - System and Memory Mental Model

Warm caching can satisfy many requests without driver allocation. Persistent buffers retain capacity even when idle, and compute-then-copy can keep a fresh result and destination live together. These effects can move different metrics in opposite directions. Match output leases, arithmetic, input residency, and completion boundaries across all three strategies.

Part 3 - Quantitative Prediction Before Execution

At one named counting layer, define request reduction $\rho_A = 1 - A_r/A_b$ for $A_b > 0$ and speedup $S = T_b/T_r$ for $T_r > 0$. Keep undefined ratios undefined. For a b-byte temporary copied into a persistent destination, predict an additional b live bytes while both coexist. Construct a prediction where request count improves but latency or retained capacity does not.

Part 4 - Experimental Design and Instrumentation

Use small and larger fixed shapes with deterministic inputs. Measure cold setup and warmed execution separately. Capture short allocation traces in separate diagnostic replays, then run repeated unprofiled timing trials in randomized strategy order. Synchronize at complete trial boundaries, record absolute peaks and end-state capacity, and keep raw latency samples. If outputs must be retained, charge all strategies for the same retention guarantee.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class ReuseResult:
    strategy: str
    request_layer: str
    request_count: object
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    elapsed_seconds: object
    numerical_error: object

def run_strategy(strategy, inputs, contract, phase):
    # Implement equivalent fresh, direct-output, and copy variants.
    ...

def compare_strategies(results, raw_samples):
    # Check equivalence before comparing counts, bytes, and timings.
```

```
    ...

def E05(config):
    # Separate profiling from timing and retain adverse results.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A mismatched lease, omitted source allocation, or incomplete CUDA timing invalidates the ranking. Distinct pointer counts are not allocation counts. Report median and a declared tail statistic with trial counts, plus setup cost and owned capacity. Explain unchanged reserved memory without treating it as proof that allocation reduction failed.

Part 7 - Engineering Interpretation and Philosophy

The winning strategy depends on the measured objective and caller contract. Choose among latency, request reduction, and capacity predictability explicitly; a single favorable counter does not establish a universally better execution.

19.29.7 Exercise 06

Exercise Title: Build a Shape-Compatible Scratch Buffer and Reuse It Across Repeated Matrix Operations

Part 1 - Exercise Contract and Why It Matters

Build reusable scratch for a repeated matrix chain while preserving every matrix input until its final read. Deliver a dimension-checked slot layout, correct intermediate values, and a comparison with fresh intermediate results. Determine the required number of simultaneous destinations before allocating.

Part 2 - System and Memory Mental Model

For $Y = AB$ and $Z = YC$, producing Z reads Y. Do not overwrite Y with Z unless the selected operation explicitly permits that overlap. A dedicated scratch slot plus a separate final output is a safe initial design. Capacity alone does not establish compatibility: shape, dtype, device, layout, aliasing, and completion also matter. Begin with one-stream inference.

Part 3 - Quantitative Prediction Before Execution

For $A : (m, k)$, $B : (k, n)$, $C : (n, p)$ and element width s, calculate $b_Y = mns$ and $b_Z = mps$. Under a disjoint-output contract, account for both during the second multiplication. Extend the chain and compare exact-sized slots with two maximum-capacity alternating slots. Predict retained slack as well as slot count, keeping library workspace separate.

Part 4 - Experimental Design and Instrumentation

Draw read/write sets and dimensions for each operation. Allocate deterministic inputs, build a fresh reference, and complete a supported direct-destination chain. Validate each stage in a diagnostic replay, then benchmark without those extra captures. Test incompatible dimensions, a retained intermediate, and a noncontiguous case with explicit support or rejection. Record matrix precision settings and use justified numerical tolerances.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class MatrixScratch:
    slot_id: int
    shape: tuple
    capacity_bytes: int
    dtype: object
    device: object

def validate_matrix_destination(left, right, output, spec):
    # Check dimensions, capacity, layout, and unsupported overlap.
    ...

def matrix_chain(inputs, scratch_slots, final_output):
    # Assign destinations without overwriting still-readable inputs.
    ...

def E06(config):
    # Compare stage values, allocation requests, and complete runtime.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A small correct final output does not excuse an invalid overlap schedule. Verify intermediate values and reject the retained-input conflict. Report visible scratch requests separately from operator workspace. Do not hide validation copies in only one strategy's timing or present inference output reuse as a gradient-preserving training implementation.

Part 7 - Engineering Interpretation and Philosophy

Scratch compatibility combines geometry with time. The smallest useful pool preserves the actual matrix dependencies; a larger generic pool is justified only when its flexibility compensates for extra retained capacity.

19.29.8 Exercise 07

Exercise Title: Resize a Reusable Tensor Across Variable Input Shapes and Determine When PyTorch Can Preserve Existing Storage

Part 1 - Exercise Contract and Why It Matters

Investigate when a dedicated reusable tensor can change logical shape without growing its backing storage. Record shape, strides, capacity, and pointer observations across shrink, within-capacity growth, and beyond-capacity growth. Treat this as scratch management rather than semantic reshaping of old values.

Part 2 - System and Memory Mental Model

The low-level resize operation retains backing storage when fewer elements are required and grows storage when capacity is insufficient. It can reinterpret strides as contiguous. It is not a general replacement for view or reshape. Start with owned, offset-zero contiguous scratch, no escaped aliases, and no gradient recording. Initialize every region before reading it; newly exposed bytes are not valid old tensor contents.

Part 3 - Quantitative Prediction Before Execution

For shape h_t and element width s, calculate logical demand $b_t = s \prod_d h_{t,d}$ and compare it with observed storage bytes. Predict transitions for element counts $1024, 256, 768, 2048, 512$. Identify which requests fit current measured capacity without assuming allocator rounding. Add equal numel shapes with different dimensions and explain why storage persistence does not preserve an intended matrix arrangement.

Part 4 - Experimental Design and Instrumentation

Capture old shape, strides, storage base, tensor pointer, storage offset, and capacity before each transition. Admit resize only after old borrowers are released. Resize, initialize the active region, and validate a deterministic operation against a fresh reference. Record growth and initialization time separately. Include an outstanding-view case that the admission policy rejects before mutation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class ResizeRecord:
    before_shape: tuple
    after_shape: tuple
    before_capacity: int
    after_capacity: int
    before_base: int
    after_base: int

def resize_owned_scratch(buffer, shape, ownership):
    # Reject aliases/borrowers and unsupported resize conditions.
    ...
    # Resize, record evidence, and initialize the entire active view.
    ...
```

```
def E07(config):
    # Predict transitions, then compare measured capacity behavior.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Never validate newly exposed elements by reading uninitialized memory. Empty tensors need separate handling because pointer values are not useful allocation witnesses. A stable address alone does not establish continuous identity after a growth transition. Report stale-view rejection, capacity changes, and unsupported storage contracts explicitly.

Part 7 - Engineering Interpretation and Philosophy

Logical size and retained capacity are different controls. Use the experiment to define when shape changes are cheap and when a new storage generation is required, then make those distinctions visible in the buffer interface.

19.29.9 Exercise 08

Exercise Title: Build a Capacity-Based Reusable Buffer That Grows Only When Required and Never Shrinks During Stable Workloads

Part 1 - Exercise Contract and Why It Matters

Build a typed capacity buffer that serves contiguous shaped prefix views, grows only when required, and never shrinks during the stable phase. Implement bounded admission, generation-aware borrowing, and a clear policy for growth while old users remain active.

Part 2 - System and Memory Mental Model

The active view can be smaller than its owned base without returning unused capacity. Growing must not silently retarget escaped views to new storage. Either reject or defer growth until release, or retain old generations until their readers finish. Charge both generations when they coexist. Use one dtype and device per pool and exclude unsupported strides or raw byte reinterpretation.

Part 3 - Quantitative Prediction Before Execution

For request r_t elements, capacity C_t, and growth factor $g > 1$, consider

$$C_{t+1} = \begin{cases} C_t, & r_t \le C_t, \\ \max(r_t, \lceil gC_t \rceil), & r_t > C_t. \end{cases}$$

Compare exact growth and $g = 2$ on $3, 5, 4, 9, 8$ elements. Calculate growth count, retained slack, and old-plus-new transition bytes. Handle zero initial capacity, empty requests, oversized shapes, and budget limits explicitly.

Part 4 - Experimental Design and Instrumentation

Simulate the capacity policy before allocating CUDA storage. Complete acquire and release with generation checks, then compare against fresh allocation on a fixed shape trace. Validate every active view against independent values. Test an outlier request, an outstanding borrower,

and a controlled growth refusal. Ensure failure leaves the previous usable state coherent and retries bounded.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class CapacityLease:
    generation: int
    shape: tuple
    release_token: object

class CapacityBuffer:
    def __init__(self, dtype, device, budget_bytes, growth_factor):
        self.dtype = dtype
        self.device = device
        self.budget_bytes = budget_bytes
        self.growth_factor = growth_factor
        # Initialize capacity, owner, generation, and borrower state.
        ...

    def acquire(self, shape):
        # Admit shape, grow safely if needed, and return a leased view.
        ...

    def release(self, lease):
        # Validate generation and completion before allowing overwrite.
        ...

def E08(config):
    # Compare growth events, transition peaks, slack, and correctness.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert monotone stable-phase capacity and sufficient capacity for every accepted view. Reject stale releases and unsafe growth with live borrowers. Distinguish budget refusal from allocator OOM. A final pool that fits the budget can still require excessive transition memory; report that peak rather than only end-state slack.

Part 7 - Engineering Interpretation and Philosophy

Growth policy trades allocation frequency for retained capacity. Choose it from measured shape demand and available headroom, and require an explicit phase boundary before any later shrink or pool reset.

19.29.10 Exercise 09

Exercise Title: Track Tensor data_ptr() Values Across Iterations and Prove When Storage Is Actually Reused Versus Reallocated

Part 1 - Exercise Contract and Why It Matters

Track tensor addresses together with storage bases, offsets, capacities, owner generations, and allocation events. Distinguish persistent owned reuse, views, recycled addresses after release, and replacement after growth. State what the combined evidence can actually establish.

Part 2 - System and Memory Mental Model

A tensor pointer identifies its first element; an offset view can have another pointer while sharing the same base storage. Conversely, a later fresh tensor can receive an old numerical address after the previous owner is released. Pointer equality is not a proof of continuous ownership. Keep a live owner for the persistent case and use the planner's explicit generation ledger.

Part 3 - Quantitative Prediction Before Execution

For supported ordinary dense tensors, test $p_{\text{tensor}} = p_{\text{storage}} + o\,s$, where o is offset in elements and s is element width. Predict four cases: persistent owned storage, an offset view, a released allocation followed by a new one, and growth. Identify which claims need allocation history and which follow from a continuously retained owner. Unique address count is descriptive, not an exact allocation census.

Part 4 - Experimental Design and Instrumentation

Record scalar metadata without retaining tensors in the evidence log. Run each identity case separately and correlate observations with E01's supported event layer. Validate generations before overwriting. Include an address-only classifier and a counterexample to its inference. Mark missing event history, empty tensors, and unsupported storage abstractions as inconclusive.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class StorageObservation:
    owner: str
    generation: int
    tensor_pointer: int
    storage_pointer: int
    storage_offset: int
    element_bytes: int
    capacity_bytes: int
```

```
def observe_storage(tensor, owner, generation):
    # Capture public metadata without extending the tensor's lifetime.
    ...

def classify_reuse(before, after, ownership, allocation_events):
    # Separate sharing, persistence, address recycling, and unknowns.
    ...

def E09(config):
    # Test the pointer-only counterexamples and stronger evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct classification of nonzero-offset views and refusal to call a recycled address continuous ownership. Evidence timestamps must cover the claimed interval. Private object IDs are not portable allocation IDs. If an instrument cannot exclude an intervening release/reallocation, preserve that uncertainty instead of labeling the observation proven reuse.

Part 7 - Engineering Interpretation and Philosophy

A pointer is evidence about location, not a complete identity history. The planner can make stronger claims about its continuously owned slots than about arbitrary tensors observed only through intermittent snapshots.

19.29.11 Exercise 10

Exercise Title: Reuse Intermediate Buffers Across Multiple Layers Without Accidentally Overwriting Values Still Required by Later Operations

Part 1 - Exercise Contract and Why It Matters

Reuse intermediate buffers across a multilayer inference graph containing a skip connection. Build read/write sets and reject any assignment that overwrites a value still required by another operation or an external consumer.

Part 2 - System and Memory Mental Model

Layer order does not imply simple last use. A residual path can retain an early activation through several later layers. Views extend the lifetime of the same storage. Start with one stream, a fixed graph, and no gradient recording; backward adds consumers that an inference-only lifetime table does not describe. Unsupported in-place overlap is forbidden even if one test happens to work.

Part 3 - Quantitative Prediction Before Execution

For $h_1 = f(x)$, $h_2 = g(h_1)$, and $y = h_2 + h_1$, predict why writing h_2 over h_1 destroys the residual input. Under disjoint destinations, compute the live bytes during each operation. Add another branch retaining a view of h_1 and update its final-use boundary. Distinguish payload demand from retained slot capacity.

Part 4 - Experimental Design and Instrumentation

Create a fixed residual graph with deterministic inputs. Enumerate producers, all readers, aliases, and external outputs. Validate a legal slot plan and an intentionally invalid plan in host metadata; execute only the admitted CUDA plan. Compare final and selected intermediate values against independent fresh execution. Repeat with multiple sentinel patterns so zero inputs do not hide premature overwrites.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class LayerAccess:
    operation_id: int
    reads: tuple
    writes: tuple
    allowed_aliases: tuple

def validate_layer_plan(operations, assignment, alias_groups):
    # Reject future-reader overwrites and unsupported same-op overlap.
    ...

def execute_layers(inputs, operations, slots, plan):
    # Use only admitted destinations and preserve output leases.
    ...

def E10(config):
    # Compare the safe plan; reject the invalid residual assignment.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validation must reject the bad plan independently of its sampled numerical result. Check every required intermediate before its slot is reassigned. A retained alias must extend protection. Do not treat deleting a local variable as release proof or silently switch off autograd to accept a training graph.

Part 7 - Engineering Interpretation and Philosophy

The graph's consumers determine legal reuse. An extra buffer is justified when it preserves a required residual or output; fewer buffers are not an improvement if they change the computation's observable values.

19.29.12 Exercise 11

Exercise Title: Analyze Tensor Lifetimes and Reuse the Same Storage for Non-Overlapping Intermediate Activations

Part 1 - Exercise Contract and Why It Matters

Derive activation lifetimes from a fixed execution schedule and assign the same storage to compatible values whose lifetimes do not overlap. Deliver a producer, consumer, alias, and release table with an explicit operation-boundary convention.

Part 2 - System and Memory Mental Model

A lifetime begins when storage is required for a value and ends only after its last required read. Treat an operation's inputs and disjoint output as live together during that operation. Aliases protect their shared region until the last relevant use; escaped outputs remain live until caller release. A linear schedule initially models one stream, not arbitrary asynchronous execution.

Part 3 - Quantitative Prediction Before Execution

Use half-open intervals $[b_i, e_i)$ with e_i defined after the last consuming operation. Temporal overlap occurs when $\max(b_i, b_j) < \min(e_i, e_j)$. Calculate a legal slot assignment for intervals $[0, 3), [1, 2), [3, 5), [2, 4)$ with sizes $8, 4, 8, 4$ MiB. Extend the first interval to 5 for an escaped alias and recalculate. Equal endpoint numbers must not excuse unsupported input/output overlap within one indivisible operation.

Part 4 - Experimental Design and Instrumentation

Select a small DAG and freeze its topological execution order. Derive lifetimes from actual read/write sets, union alias protection, and construct a live-byte timeline. Simulate sharing before materializing slots. Compare admitted CUDA execution with a fresh reference. Include fork/join dependencies, a retained output, and one uncertain lifetime that is conservatively extended.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class ValueInterval:
    key: str
    birth: int
    release_after: int
    payload_bytes: int
    alias_group: str

def derive_intervals(graph, schedule, external_releases):
    # Account for all consumers, aliases, and operation boundaries.
```

```
    ...

def assign_nonoverlapping_values(intervals, compatibility):
    # Respect both lifetimes and slot capacities.
    ...

def E11(config):
    # Check intervals in a host model before executing shared storage.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit all pairs sharing a slot, not only adjacent entries. Compare predicted live bytes and owned slot capacity without assuming equality. Reject a plan made unsafe by alias lifetime extension. A last host-use index is not a multi-stream completion proof, and an inference lifetime table does not account for tensors saved for backward.

Part 7 - Engineering Interpretation and Philosophy

A lifetime table is a claim about when information stops being needed. Its usefulness depends on honest boundaries and complete consumers, not on how aggressively it permits storage sharing.

19.29.13 Exercise 12

Exercise Title: Build a Simple Lifetime-Based Buffer Planner That Assigns Multiple Temporary Tensors to Shared Storage Slots

Part 1 - Exercise Contract and Why It Matters

Build a small planner assigning temporary values to owned storage slots using the validated lifetime table. Support a fixed, single-stream inference graph and an explicit operation allowlist. Materialize the plan only after checking its capacity, alias, and output-ownership invariants.

Part 2 - System and Memory Mental Model

Plan whole typed slots: at most one live value occupies a slot, with contiguous views for compatible shapes. Separate dtype and device pools. The application selects its own slots; it cannot select arbitrary cached allocator blocks by address. Unsupported destination-writing operations require a measured fallback or rejection. Returned views need leases or independently owned copies.

Part 3 - Quantitative Prediction Before Execution

For assignment $s(i)$ and request bytes b_i, require $C_{s(i)} \geq b_i$. For an exact static whole-slot plan, compute $C_j = \max_{i:s(i)=j} b_i$ and $B_{\text{owned}} = \sum_j C_j$. Compare this capacity with no-sharing bytes and the maximum live-payload lower bound. Add a retained output and predict which assignment becomes illegal.

Part 4 - Experimental Design and Instrumentation

Implement a host-only request and slot model first. Validate complete coverage, non-overlap, compatibility, and capacities independently of the assignment routine. Allocate slot bases once and execute a small supported graph. Compare fresh and shared execution with matching output contracts. Test an unsupported operator, oversized request, and stale output lease. Charge setup, fallbacks, and retained capacity in the benchmark.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class TemporaryRequest:
    key: str
    shape: tuple
    dtype: object
    device: object
    birth: int
    release_after: int

class BufferPlanner:
    def __init__(self, budget_bytes, supported_operators):
        self.budget_bytes = budget_bytes
        self.supported_operators = tuple(supported_operators)
        # Initialize slot specifications and ownership records.
        ...

    def plan(self, requests, aliases):
        # Assign compatible values to non-interfering whole slots.
        ...

    def validate(self, plan):
        # Independently check coverage, capacity, and lifetime rules.
        ...

    def execute(self, graph, inputs, plan):
        # Materialize owned slots and preserve supported semantics.
        ...

def E12(config):
    # Compare the legal plan against equivalent fresh execution.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require every accepted request to have one valid assignment. Count shared views once in owned capacity and reject unsupported dtype reinterpretation or strides. Reconcile pool bytes with the ownership ledger, then report allocator peaks separately. Reduced pool capacity does not guarantee equal driver-visible savings, and a fallback allocation must not disappear from the census.

Part 7 - Engineering Interpretation and Philosophy

A constrained planner is useful when its support and accounting are precise. Its promise is safe sharing of application-owned storage, not control over every allocation performed by PyTorch or its libraries.

19.29.14 Exercise 13

Exercise Title: Construct an Interference Graph from Tensor Lifetimes and Prevent Buffers with Overlapping Lifetimes from Sharing Storage

Part 1 - Exercise Contract and Why It Matters

Construct an interference graph from alias-aware tensor lifetimes. Retain an explanation for every temporal conflict and prevent conflicting values from sharing a whole slot. Distinguish lifetime conflicts from dtype, device, or layout incompatibility.

Part 2 - System and Memory Mental Model

A temporal edge means two values require protected storage during overlapping intervals. Aliases need union protection or explicit shared-region modeling; they are not independent values that can be freely colored. A fixed one-stream schedule gives interval order. Concurrent execution later requires a happens-before relation, not merely host submission indices.

Part 3 - Quantitative Prediction Before Execution

Define $(i, j) \in E$ when $i \neq j$ and $I_i \cap I_j \neq \varnothing$ under E11's endpoint convention. Build the graph for $[0, 4), [1, 2), [2, 3), [4, 6)$ and identify touching endpoints. For interchangeable equal-capacity slots, maximum concurrent live count is a lower bound. Appropriate interval-coloring algorithms can attain it for interval graphs; arbitrary greedy orders and weighted capacity objectives need separate analysis.

Part 4 - Experimental Design and Instrumentation

Create hand-checkable disjoint, chain, clique, fork/join, and escaped-alias examples. Generate edges with overlap witnesses and record compatibility partitions separately. Compare graph construction with an independent pairwise host oracle. Validate proposed slot assignments against every edge and capacity constraint before CUDA execution. Verify actual read/write boundaries agree with the interval model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
```

```
class Interference:
    first: str
    second: str
    reason: str
    overlap_witness: tuple

def build_interference(intervals, alias_groups, compatibility):
    # Generate symmetric conflicts with explicit supporting facts.
    ...

def validate_assignment(nodes, conflicts, assignment, capacities):
    # Reject shared slots across edges and incompatible contracts.
    ...

def E13(config):
    # Check hand examples and the independent graph oracle first.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check symmetry, missing overlapping pairs, unintended self-edges, and endpoint treatment. A graph-valid assignment can still fail capacity or operator overlap rules. Extend an escaped alias and require rejection of the now-invalid plan. Do not call an inference graph a complete model of backward or stream completion.

Part 7 - Engineering Interpretation and Philosophy

An interference edge should explain the exact value or contract preventing sharing. Preserve that explanation independently of the heuristic so a rejected assignment remains understandable when allocation policy changes.

19.29.15 Exercise 14

Exercise Title: Implement a Greedy Buffer Assignment Algorithm That Minimizes the Number of CUDA Storage Blocks Required by a Fixed Computation Graph

Part 1 - Exercise Contract and Why It Matters

Implement a deterministic greedy assignment aiming to reduce application-owned storage slots for a fixed graph. Report retained bytes as a separate objective. Compare legal plans with a bounded exact oracle on small instances; the title states an optimization goal, not a universal optimality guarantee.

Part 2 - System and Memory Mental Model

A candidate slot must have compatible dtype, device, layout, capacity, and non-interfering lifetimes. Request order and tie-breaking affect a heuristic's result. Keep the execution schedule fixed during the primary comparison. Application slots do not necessarily correspond one-to-one with allocator blocks or CUDA driver allocation calls.

Part 3 - Quantitative Prediction Before Execution

Let K be slot count and $B = \sum_j C_j$ retained capacity. Compare a slots-first objective (K, B) with a bytes-first objective. Construct variable-size requests where these preferences differ. For tiny cases with exact optimum K^*, report $K_{\text{greedy}} - K^*$ and capacity gap under the same model. An oracle timeout is not an optimality certificate.

Part 4 - Experimental Design and Instrumentation

Implement first-fit and one alternative with explicit deterministic ordering. Validate both using a checker independent of their selection logic. Enumerate legal tiny assignments with a declared size/time limit. Test multiple orders, equal-size interval cases, and adversarial variable-size cases. Materialize only valid plans and measure setup cost, requests, retained capacity, and runtime. Keep hidden workspaces outside slot count but inside complete memory evidence.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class PlanQuality:
    heuristic: str
    ordering: str
    slot_count: int
    retained_bytes: int
    oracle_status: str

def greedy_assignment(requests, conflicts, ordering, tie_break):
    # Select only compatible slots with no protected live conflict.
    ...

def exact_tiny_assignment(requests, conflicts, limits):
    # Search bounded cases and distinguish optimum from timeout.
    ...

def E14(config):
    # Validate plans before comparing objective values and hardware cost.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require legality before quality comparisons. Preserve worst observed gaps and adverse orderings, not only favorable examples. Matching an oracle on tested instances is not proof for every graph. Equal-size interval-coloring guarantees apply only when their ordering, compatibility, and objective assumptions hold.

Part 7 - Engineering Interpretation and Philosophy

A heuristic is trustworthy when its choices are reproducible, its legality is independently checked, and its quality limits are stated. Use measured workload needs to decide whether fewer slots or fewer retained bytes matters more.

19.29.16 Exercise 15

Exercise Title: Reuse Pinned CPU Staging Buffers Across Repeated Host-to-Device and Device-to-Host Transfers

Part 1 - Exercise Contract and Why It Matters

Reuse a bounded pinned-CPU staging pool for repeated H2D and D2H transfers. Define which event releases each host and device buffer, verify every payload, and compare complete transfer cycles with fresh staging allocation.

Part 2 - System and Memory Mental Model

Pinned sources must not be overwritten during in-flight H2D transfers, and D2H destinations must not be read or recycled before completion. Persistent pinning avoids repeated setup but retains page-locked host capacity. Nonblocking submission is not completion, and useful overlap depends on hardware, streams, dependencies, and workload. Host and device buffers can have different release boundaries.

Part 3 - Quantitative Prediction Before Execution

For K slots with separate host input and output sizes b_{in} and b_{out}, predict $B_{\text{pinned}} = K(b_{\text{in}} + b_{\text{out}})$. Count device staging separately. Compare a serialized fill/H2D/compute/D2H/consume time with a pipelined model bounded by its slowest effective stage and shared resource contention. Predict a two-slot ring's capacity cost and the evidence needed to establish overlap.

Part 4 - Experimental Design and Instrumentation

Build a serialized reference first. Complete persistent staging acquisition, asynchronous transfers, event waits, and host consumption, then add a two-slot ring. Tag each batch with a generation-specific sentinel. Apply backpressure when no slot is safely free. Measure setup-inclusive and warmed throughput, pinned bytes, device peaks, and transfer waits. Drain all outstanding work at shutdown.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class StagingLease:
    slot_id: int
    generation: int
    state: str
    h2d_done: object
```

```
    d2h_done: object

class PinnedStagingPool:
    def __init__(self, slots, host_budget, device_budget):
        # Create bounded owned buffers and per-direction states.
        ...

    def acquire_for_fill(self, shape):
        # Return only a host source safe for CPU writes.
        ...

    def transfer_and_compute(self, lease, streams):
        # Establish H2D, compute, and D2H dependencies.
        ...

    def consume(self, lease):
        # Confirm completion before CPU reads or recycling.
        ...

def E15(config):
    # Validate batches and compare serialized/pipelined reuse.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Use a host state-machine test to reject premature reads/writes without relying on a hardware race. Validate payloads only after readiness. Distinguish pinned allocation failure from CUDA OOM. Report observed overlap rather than inferring it from nonblocking flags, and never release an in-flight generation after an unrelated batch failure.

Part 7 - Engineering Interpretation and Philosophy

Pinned staging is a scheduling resource with two budgets: locked host memory and device capacity. Use the smallest measured ring that sustains throughput and explain each resource's actual release condition.

19.29.17 Exercise 16

Exercise Title: Make Reusable Buffers Safe Across Multiple CUDA Streams Using Events, Stream Dependencies, and Explicit Lifetime Tracking

Part 1 - Exercise Contract and Why It Matters

Make reusable slots safe across producer and consumer CUDA streams. Record write readiness, all reader completions, and next-write dependencies. Compare a validated concurrent design with equivalent serialized execution.

Part 2 - System and Memory Mental Model

A producer finishing does not release storage still read by another stream. Execution dependencies and allocator lifetime protection are separate duties. Recording stream use helps

prevent allocator recycling after release; it does not order an application's overwrite of a still-live persistent buffer. Retain owners or use appropriate allocator lifetime recording, and independently establish every required read/write dependency.

Part 3 - Quantitative Prediction Before Execution

For generation g, require $W_g \prec R_{g,1}$ and $W_g \prec R_{g,2}$, then $R_{g,1}, R_{g,2} \prec W_{g+1}$. Here $\prec$ denotes enforced happens-before. Draw a fast and slow reader and predict the earliest legal next write. Compare one-slot serialization with two-slot overlap, including capacity and event cost. A stream wait can order future work without blocking the host; state whether slot release means physical completion or safely ordered future reuse.

Part 4 - Experimental Design and Instrumentation

Model dependencies on the host first and reject missing producer readiness, missing final-reader joins, and stale generation tokens. Complete a bounded persistent CUDA pool using generation-specific events. Validate deterministic payloads against a serialized reference with multiple seeds. Measure overlap without placing a global synchronization inside every iteration. Test delayed readers and safe shutdown without executing deliberately invalid CUDA plans.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class StreamLease:
    slot_id: int
    generation: int
    ready_event: object
    reader_events: tuple

class StreamSafeBuffers:
    def acquire_for_write(self, shape, writer_stream):
        # Order this writer after every previous reader of the slot.
        ...

    def publish(self, lease, producer_stream):
        # Record readiness for this exact generation.
        ...

    def begin_read(self, lease, reader_stream):
        # Wait for readiness and maintain storage lifetime protection.
        ...

    def end_read(self, lease, reader_stream):
        # Register completion so future writers cannot race.
        ...
```

```
def E16(config):
    # Check dependencies, then validate concurrent values and timing.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Numerical success alone does not establish race freedom: a missing dependency may not fail on the sampled run. Require a ledger for each readiness and read-next-write edge. Stale events must not authorize another generation. Report host/event overhead, serialization, and allocator requests independently.

Part 7 - Engineering Interpretation and Philosophy

With multiple streams, lifetime becomes a dependency relation. A sound design separates who owns storage, when values become readable, when they may be overwritten, and when the allocator may reclaim their allocation.

19.29.18 Exercise 17

Exercise Title: Compare Buffer Reuse Against Activation Checkpointing for a Temporary-Memory-Heavy Workload and Explain Which Problem Each Technique Solves

Part 1 - Exercise Contract and Why It Matters

Compare legal buffer reuse with activation checkpointing for identical training work. Identify temporary scratch and saved activations separately, validate outputs and gradients, and measure complete forward/backward/update iterations. Compare combined behavior only when both mechanisms preserve the same semantics.

Part 2 - System and Memory Mental Model

Reuse shares storage after a value is no longer required; checkpointing avoids retaining selected forward intermediates and reconstructs them during backward. A saved activation cannot simply be overwritten because forward has passed it. Do not use inference-only out variants on differentiable paths. For an initial legal comparison, pair an ordinary differentiable model with nondifferentiable auxiliary scratch executed equally in every variant; label that limited reuse scope. Keep checkpoint recomputation independent of mutable scratch state.

Part 3 - Quantitative Prediction Before Execution

Draw the complete training lifetime timeline including parameters, gradients, optimizer state, saved activations, scratch, and workspace. For strategy m, compare $\Delta P_m = P_{\text{base}} - P_m$ and $\Delta T_m = T_m - T_{\text{base}}$. Do not add category peaks from different times. Predict an activation-dominated case and a scratch-heavy case. Explain why combined peak savings need not equal the sum of separate savings.

Part 4 - Experimental Design and Instrumentation

Clone model and optimizer state and pre-generate matching inputs. Compare baseline, legal scratch reuse, checkpointing, and their supported combination. Specify checkpoint implementation explicitly and preserve RNG/recomputation semantics. Validate loss, outputs,

gradients, updates, and multiple iterations before timing. Include auxiliary work, recomputation, and optimizer update in all matching regions. Vary saved-activation and scratch demand separately.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch
from torch.utils.checkpoint import checkpoint

@dataclass
class TrainingMode:
    checkpoint_enabled: bool
    scratch_reuse_enabled: bool
    reuse_scope: str

def differentiable_block(inputs, parameters):
    # Implement a replay-consistent function without stale scratch.
    ...

def auxiliary_scratch_work(inputs, pool, reuse_enabled):
    # Keep identical nondifferentiable work in every strategy.
    ...

def complete_training_step(model, optimizer, batch, mode, pool):
    # Preserve gradients and charge forward, backward, and update.
    ...

def E17(config):
    # Restore equal state and compare validated supported strategies.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Fail changed gradient participation, omitted updates, or state-dependent recomputation. Record dtype, tolerances, precision, RNG policy, and optimizer initialization boundaries. Auxiliary reuse is not evidence of safe shared saved activations. If broader differentiable reuse is unsupported, state that rather than disabling gradients or dropping required work.

Part 7 - Engineering Interpretation and Philosophy

Checkpointing spends compute to recover retained information; reuse controls storage for compatible lifetimes. Choose by the measured bottleneck and preserve the training transition before crediting any memory or throughput benefit.

19.29.19 Exercise 18

Exercise Title: Stress-Test a Reuse Planner with Variable Shapes, Dynamic Execution Paths, Shared Buffers, and Asynchronous CUDA Operations

Part 1 - Exercise Contract and Why It Matters

Stress-test the reuse planner with variable shapes, branches, aliases, retained outputs, and asynchronous readers. Deliver replayable traces, complete outcomes, and minimized failures. Test useful progress as well as memory safety.

Part 2 - System and Memory Mental Model

A plan valid for one path is not automatically valid for another. Use validated path-specific plans, conservative lifetimes, or a charged fallback. Growth must respect old generations and transition budgets; release must respect every reader. Generate invalid transitions as host metadata and reject them before CUDA execution rather than deliberately racing storage.

Part 3 - Quantitative Prediction Before Execution

For admitted requests N_a and correct completions N_c, calculate $\eta = N_c/N_a$ when $N_a > 0$. Also report total attempted coverage and useful throughput $W_{\text{correct}}/T_{\text{complete}}$. Predict growth, wait, fallback, or rejection for alternating small/large shapes, a long-lived branch output, a delayed reader, and an over-budget request. Declare outstanding-lease limits and a shutdown deadline.

Part 4 - Experimental Design and Instrumentation

Use fixed replay traces plus seed-controlled randomized host traces. Check capacity, generations, aliases, and dependencies independently. Execute only admitted CUDA cases and compare each generation with a fresh reference. Test unseen shapes, empty tensors, branch switches, retained views, controlled allocation refusal, and safe drain. Minimize failures while preserving the same path and release sequence; record versions, device, backend, seed, and trace ID.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class StressRequest:
    request_id: int
    shape: tuple
    branch: str
    retain_output: bool
    readers: tuple

def generate_traces(seed, support, limits):
    # Include valid adversarial cases and host-only invalid cases.
```

```
    ...

def validate_and_execute(trace, planner, reference):
    # Admit safe transitions and classify every request outcome.
    ...

def minimize_failure(trace, replay_predicate, limits):
    # Reduce a reproducible failure without changing its cause.
    ...

def E18(config):
    # Export coverage, progress, resources, and replayable evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report correct completions, justified rejections, fallbacks, numerical failures, typed OOM, timeouts, and unrelated errors separately. A planner that rejects all hard requests has not demonstrated useful optimization. Passing stress tests supports the tested scope, not every possible schedule. Preserve an unreproduced failure honestly and never present simulated metadata results as GPU outcomes.

Part 7 - Engineering Interpretation and Philosophy

A production claim needs both accepted-work correctness and explainable refusals. Use measured coverage, bounded resource use, and small counterexamples to define the planner's supported envelope before expanding it.

19.29.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Tensor-Reuse Planner That Minimizes Temporary CUDA Allocations Through Lifetime-Aware Storage Sharing

Part 1 - Exercise Contract and Why It Matters

Integrate lifetime analysis, storage assignment, capacity control, safe buffer execution, and measurement into a PyTorch tensor-reuse planner. Reduce temporary allocation requests while preserving useful computation and output ownership. Deliver a supported-operation contract and benchmark evidence, not an unsupported claim of zero allocations or globally optimal memory.

Part 2 - System and Memory Mental Model

Separate logical values and aliases, lifetime analysis, slot assignment, execution dependencies, and observation. Start with typed contiguous whole slots in fixed single-stream inference. Add dynamic paths and multiple streams only through their validated contracts. Gradient-required graphs need saved-value lifetimes and derivative validation; otherwise reject or use an equivalent charged fallback. The planner controls its owned buffers, not arbitrary cached allocator blocks or every operator workspace.

Part 3 - Quantitative Prediction Before Execution

Minimize $A_{\text{temp}}(\pi)$ at a declared allocation layer subject to correctness, budget, coverage, and progress. Derive no-sharing and legal-plan request/capacity predictions. Report slot count, owned bytes, peak allocated and reserved bytes, end-state capacity, and latency separately. Compare tiny cases with an exact oracle where feasible. Predict when retained capacity or planning overhead makes reuse worse despite fewer requests.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and tune on separate calibration traces. Validate host plans independently before allocating slots. Compare fresh allocation, dedicated preallocation, simple scratch, and the integrated planner on equivalent matrix chains, residual graphs, variable shapes, dynamic paths, retained outputs, and multi-stream readers. Separate correctness, diagnostic profiling, and timing replays. Include setup, fallback, growth transitions, and shutdown obligations. Run ablations without changing useful work and preserve adverse outcomes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the code is deliberately incomplete and is not a finished implementation.

```
from dataclasses import dataclass
import torch

@dataclass
class ReuseContract:
    operators: tuple
    dtypes: tuple
    layouts: tuple
    execution_modes: tuple
    output_lease: str
    budget_bytes: int

class TensorReusePlanner:
    def __init__(self, contract):
        self.contract = contract
        # Initialize bounded slots, generations, and evidence state.
        ...

    def analyze(self, graph, shapes, aliases):
        # Derive complete lifetimes and operator restrictions.
        ...

    def plan(self, analysis):
        # Assign compatible slots using the declared objective.
        ...

    def validate(self, plan):
        # Check coverage, interference, capacity, and ownership.
        ...
```

```
    def execute(self, graph, inputs, plan):
        # Enforce leases/dependencies and account for fallbacks.
        ...

    def release(self, lease, completion_tokens):
        # Prevent reuse until every required consumer is protected.
        ...

    def shutdown(self, deadline):
        # Stop admission, drain work, and report unresolved leases.
        ...

def E19(config):
    # Validate small plans, benchmark equivalent work, and stress-test.
    ...
    # Export measurements and a supported engineering recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct values, legal storage sharing, honest allocation accounting, and complete useful-work timing. Record environment, seeds, graph and trace IDs, shapes, precision, leases, raw request counts, owned capacity, allocated/reserved peaks, numerical errors, latency samples, coverage, fallbacks, and failures. Export CPU-only records without retaining live graphs.

Test an unsupported operator, late reader, outlier shape, retained output, budget refusal, and safe drain. Do not invent hardware results. Greedy success is not universal optimality, and unchanged reserved memory does not refute a measured reduction in allocation requests.

Part 7 - Engineering Interpretation and Philosophy

The planner succeeds when it safely shares owned storage and explains the resulting costs at named accounting layers. Recommend the smallest effective mechanism for the measured workload, and state the evidence needed before expanding operator, shape, stream, or training support.

19.30 DMM28

Chapter Title: In-Place Operations and Storage Aliasing
Specialization: Dynamic Memory Management and CUDA Systems

19.30.1 Exercise 00

Exercise Title: Build a Precise Mental Model of In-Place Operations, Tensor Storage, Views, Aliasing, and Autograd Version Counters

Part 1 - Exercise Contract and Why It Matters

Build a precise lifecycle model connecting tensor metadata, logical values, backing storage, views, mutation, and backward consumers. Explain which value an in-place operation destroys and why retaining the same storage does not necessarily preserve the same computation. Deliver a storage/consumer diagram and predictions for ordinary inference and gradient-recorded execution.

Part 2 - System and Memory Mental Model

An in-place operation writes through an existing tensor's storage. Other aliases can observe that write even when their Python objects differ. A tensor needed by backward can remain semantically live after its last visible forward use. Native autograd mutation bookkeeping can detect a changed saved value, but it does not define the application's intended output contract or establish cross-stream ordering. Treat physical sharing, gradient relationships, and remaining value consumers as separate facts in the initial model.

Part 3 - Quantitative Prediction Before Execution

For a dense nonempty tensor with n elements of width s, predict payload $b = ns$. Compare a fresh materialized result with an admitted in-place write: identify the potential b-byte result request avoided without claiming that peak memory must fall by exactly b. Draw live intervals for the original input, a view, an independent clone, and a backward-saved value. Predict which observers change after mutation and which require the old value.

Part 4 - Experimental Design and Instrumentation

Create deterministic small tensors before large CUDA experiments. Record shape, strides, storage offset, base storage address, tensor address, gradient requirements, and ownership. Compare fresh arithmetic, mutation through a view, and mutation of an independent copy. Keep ordinary inference and training cases separate. Use an independent reference snapshot only in a diagnostic replay; charge any copy required by the optimized algorithm in performance runs. Record device, versions, seed, precision, and execution mode.

Label each returned object as borrowed, owned, or externally retained. The same allocation can contain several logical generations over time. Record generation changes even when its address remains stable, so an old observer cannot be accidentally compared against a newer value.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MutationContract:
    value_id: str
    alias_group: str
    forward_readers: tuple
    backward_requirement: str
    external_owners: tuple
```

```
def describe_tensor(tensor, owner, generation):
    # Capture metadata and supported storage evidence only.
    ...

def predict_mutation_effects(contract, operation):
    # Identify changed values, protected readers, and unknown facts.
    ...

def E00(config):
    # Compare predicted and observed inference/autograd cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires distinguishing storage sharing from graph connectivity. A detached alias is not an independent snapshot, and a clone can preserve a gradient path while owning different storage. Include a case whose forward output changes without any autograd error. Version diagnostics must not be used as permission to overwrite application-visible values. Mark unsupported storage abstractions or unobserved consumers as unknown rather than safe.

Part 7 - Engineering Interpretation and Philosophy

In-place optimization spends the right to destroy an old value in exchange for avoiding another result allocation. The right must come from complete consumer and ownership knowledge. A smaller allocation trace is valuable only after the intended computation and observable histories remain intact.

19.30.2 Exercise 01

Exercise Title: Compare Out-of-Place x + y Against In-Place x.add_(y) and Measure Temporary CUDA Allocation Differences

Part 1 - Exercise Contract and Why It Matters

Compare ordinary addition with an in-place addition on equivalent inputs. Measure the visible output request, numerical result, and input side effects. Specify whether the caller permits input destruction before claiming an optimization. The experiment should establish a scoped allocation difference, not imply that all CUDA allocation or memory traffic disappears.

Part 2 - System and Memory Mental Model

Ordinary addition produces a separate result; in-place addition overwrites the left operand. Begin with same-shape, same-dtype, disjoint contiguous tensors outside gradient recording. Broadcasting and type promotion can make the in-place contract differ, so introduce them only as separate compatibility cases. Restoring a mutated input between trials is real work whose inclusion must be explicit. Allocator cache reuse can hide driver calls while logical result requests still differ.

Part 3 - Quantitative Prediction Before Execution

For n elements of width s, predict a $b = ns$ result payload in the out-of-place case. Construct a live-set diagram with both operands and the result, then remove only the result allocation allowed by the destructive contract. Predict allocation traffic separately from allocated and reserved peaks. For a caller that needs the original left operand afterward, estimate the extra preservation copy and reconsider the expected saving.

Part 4 - Experimental Design and Instrumentation

Pre-generate deterministic inputs and establish one reference addition. Use independent starting state for each strategy. Complete a short allocation census at a named layer, then time unprofiled replays with matching CUDA completion boundaries. Inspect original inputs, result values, and storage metadata. Run both a destructive-ownership case and a preserve-input control. Capture setup separately and avoid clearing the allocator cache inside every iteration just to exaggerate fresh-allocation overhead.

Add a read-only caller test that checks its left input after the function returns. If the contract requires that value unchanged, mutation must be refused or preservation charged. This catches a semantic mismatch that ordinary result comparison alone would overlook.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def fresh_add(left, right):
    # Implement the ordinary result-producing reference.
    ...

def destructive_add(left, right, ownership):
    # Admit compatible mutation only when the old left value is dead.
    ...
    # Perform the in-place addition and preserve required evidence.
    ...

def E01(config):
    # Match initial values, account for resets, and measure requests.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate output equality and the explicitly expected input mutation. Reject comparisons where one strategy includes cloning or initialization while the other does not, unless that difference is required by the caller contract and charged openly. A repeated pointer is not an allocation census. Include a retained alias that makes destructive addition semantically invalid, even though the arithmetic operation itself may execute successfully.

Part 7 - Engineering Interpretation and Philosophy

Addition becomes a memory optimization only when destructive ownership is available. State separately what the operator supports, what the caller allows, and what the measurement shows. If preservation costs cancel the apparent benefit, that is the correct result for that contract.

19.30.3 Exercise 02

Exercise Title: Measure Peak VRAM and Runtime Across Repeated Out-of-Place and In-Place Elementwise Operations

Part 1 - Exercise Contract and Why It Matters

Measure repeated out-of-place and in-place elementwise execution under the same recurrence, initial state, precision, and useful work. Report latency, allocation traffic, and absolute allocated/reserved peaks. Distinguish reducing request frequency from reducing live capacity or improving end-to-end runtime.

Part 2 - System and Memory Mental Model

A recurrence that replaces its current state can often reuse the old state's storage when no observer needs prior generations. A history-producing workload cannot discard those generations without changing its outputs. A warm allocator may already recycle buffers efficiently, while kernel and memory-bandwidth costs remain. In-place execution does not inherently fuse multiple operations or remove their reads and writes. Keep inference benchmarking separate from gradient-recorded recurrent graphs.

Part 3 - Quantitative Prediction Before Execution

For N updates of a b-byte state, estimate cumulative result-request traffic for the materializing recurrence and the persistent-state alternative. Predict peak live bytes from actual evaluation order, not from Nb. Model total time as setup, kernel execution, allocation/dispatch, synchronization, and any required restoration. Construct small and large state predictions where allocation savings may have different significance relative to bandwidth.

Part 4 - Experimental Design and Instrumentation

Fix a numerically bounded recurrence and generate identical initial states. Warm both strategies, validate several intermediate generations in diagnostic runs, and measure repeated unprofiled trials in randomized order. Reset peak counters at stated boundaries without hiding preallocated state. Use CUDA events for the intended device region and completed wall time for total work. State whether setup, input restoration, and output retention are included. Preserve raw timing samples rather than a single fastest trial.

For a recurrence that retains only its final state, ensure neither benchmark appends every intermediate tensor to a Python list. Such logging silently changes the live set and would turn a constant-history workload into a history-retaining experiment.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class RepeatedTrial:
    strategy: str
    updates: int
    request_count: object
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    wall_seconds: object
    device_seconds: object

def repeated_update(state, operand, count, strategy, contract):
    # Implement the same recurrence and explicit history policy.
    ...

def measure_replay(strategy, initial_state, config):
    # Separate setup, profiling, validation, and completion timing.
    ...

def E02(config):
    # Compare distributions, memory peaks, and generation values.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that both variants execute the same update count and recurrence. Overflow, NaNs, or divergent initial state must not masquerade as equivalence. Report numerical tolerances and finite-value checks. Reserved memory may remain high after request reduction because cached capacity is retained. A loss in latency or no measurable improvement must remain in the evidence rather than being excluded from the workload selection.

Part 7 - Engineering Interpretation and Philosophy

Repeated execution exposes the difference between allocation overhead and useful arithmetic. Recommend mutation from complete workload evidence, including history requirements. Do not translate fewer temporary requests into an unmeasured throughput claim or assume every tensor size has the same bottleneck.

19.30.4 Exercise 03

Exercise Title: Track data_ptr() Before and After In-Place Operations to Prove That Existing Tensor Storage Is Reused

Part 1 - Exercise Contract and Why It Matters

Track storage evidence around admitted native in-place operations and compare it with fresh results, views, and allocator address recycling. The title's proof requires a continuous ownership model, not only pointer equality. Deliver an observation ledger that states precisely which identity claim each measurement supports.

Part 2 - System and Memory Mental Model

The tensor data pointer addresses its first element; the storage base can precede that address when the tensor has a nonzero offset. Keeping the same live owned allocation across a supported in-place arithmetic call provides stronger evidence than observing the same address after release. Views and fresh allocations can defeat address-only classifiers. Restrict the main experiment to ordinary nonempty dense tensors and exclude opaque or copy-on-write storage behavior from the initial support contract.

Part 3 - Quantitative Prediction Before Execution

For supported dense tensors, predict $p_{\text{tensor}} = p_{\text{storage}} + s\,o$, with element width s and storage offset o. Write expected before/after fields for an in-place update, a fresh update, an offset view, and a released-then-reallocated tensor. Explain which cases could have equal numerical addresses without the same ownership history. Predict capacity and shape stability separately from value changes.

Part 4 - Experimental Design and Instrumentation

Retain the owner during each persistence test and assign a generation on allocation or replacement. Capture shape, strides, offset, base address, tensor address, storage bytes, and matching trace IDs. Use deterministic inputs and verify values before and after the operation. Run fresh/released cases in separate replays and preserve event-history uncertainty. Never keep tensors in the logging structure merely to collect scalar metadata, because that would change their observed lifetimes.

Record whether pointer inspection itself is supported without materialization for the chosen tensor abstraction. The primary experiment excludes lazy or opaque storage. Do not turn an observer-induced copy into evidence about the original operation's allocation behavior.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PointerEvidence:
    owner_id: str
    generation: int
    tensor_pointer: int
    storage_base: int
    offset_elements: int
    storage_bytes: int

def pointer_evidence(tensor, owner_id, generation):
    # Capture public metadata without extending logged lifetimes.
    ...
```

```
def classify_storage_continuity(before, after, ledger, events):
    # Separate persistent ownership, shared views, and recycling.
    ...

def E03(config):
    # Reject pointer-only conclusions using controlled counterexamples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires recognizing storage sharing despite differing view pointers and refusing continuous-ownership claims after an unobserved release. A stable pointer establishes neither unchanged values nor gradient safety. Treat empty tensors separately and do not use a private storage identifier as a portable allocation identity. Reconcile the claimed interval with both the owner ledger and supported allocation observations.

Part 7 - Engineering Interpretation and Philosophy

Identity has a temporal component. Strong claims about an owned allocation can be justified within a controlled lifetime; intermittent pointer snapshots of arbitrary tensors require weaker language. Use that distinction in the later mutation analyzer rather than promoting a convenient address proxy to a universal storage proof.

19.30.5 Exercise 04

Exercise Title: Compare add, mul, relu, and Their In-Place Variants and Identify Which Temporary Allocations Disappear

Part 1 - Exercise Contract and Why It Matters

Compare addition, multiplication, and ReLU with their supported in-place variants. Identify which visible result requests disappear, which operands are overwritten, and which configurations are rejected. Deliver an operator-by-case support table rather than generalizing one successful mutation to every operation, dtype, layout, or training use.

Part 2 - System and Memory Mental Model

The underscore convention suggests mutation but does not erase operator-specific shape, casting, overlap, and autograd restrictions. Addition and multiplication read different value sets from ReLU, and backward may depend on inputs or outputs differently. A visible output request can disappear while internal workspaces, launch overhead, and memory traffic remain. Use non-overlapping same-shaped operands first and treat expanded or internally overlapping views as unsupported mutation destinations unless specifically justified.

Part 3 - Quantitative Prediction Before Execution

For each case, calculate output payload ns and predict request differences under an admitted destructive contract. Write separate predictions for same-dtype inference, dtype promotion, broadcasting that would change the left-hand shape, a leaf requiring gradients, and an appropriate nonleaf. Estimate the live-set peak from the schedule and list which facts remain unknown until operator and backward behavior are inspected.

Part 4 - Experimental Design and Instrumentation

Build independent references and starting inputs for every operator. Validate values and permitted side effects, then collect short traces at one accounting layer. Probe one restriction at a time and record actual acceptance, warning, or exception category. Run inference and training tests separately. For accepted training cases compare input gradients, not only outputs. Preserve installed version, backend, shape, dtype, strides, seed, and precision with each row.

Keep input restoration outside both timed paths for a destructive-state benchmark, or inside both when resets are part of useful work. Record that choice in the support table because repeated mutation otherwise changes the values each operator receives.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class OperatorMutationCase:
    operation: str
    shape: tuple
    dtype: object
    layout: str
    execution_mode: str
    expected_status: str

def admit_operator_case(case, inputs, alias_contract):
    # Check the actual operator, ownership, and autograd restrictions.
    ...

def execute_operator_case(case, inputs):
    # Implement the selected fresh or in-place operation explicitly.
    ...

def E04(config):
    # Export numerical, side-effect, request, and rejection evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not silently cast, broadcast to another shape, detach, or disable gradient recording to turn a rejected case into a different task. A successful forward does not establish safe backward or safe application-visible aliases. Include numerically awkward values and empty inputs where supported. Classify a lower request count without lower peak memory as a valid distinct outcome, not a measurement contradiction.

Part 7 - Engineering Interpretation and Philosophy

An operator allowlist should encode complete contracts, not just names ending with underscores. The useful artifact is a table that explains when mutation preserves the intended computation and what measured cost changes under those conditions.

19.30.6 Exercise 05

Exercise Title: Build a Chain of Elementwise Operations and Rewrite It Selectively In-Place to Minimize Peak CUDA Memory

Part 1 - Exercise Contract and Why It Matters

Rewrite an elementwise chain selectively in-place while preserving the declared input and intermediate-value contracts. Compare a fully materializing baseline with a validated partial rewrite. Identify the old values that can be destroyed and the branch or observer that forces a separate result.

Part 2 - System and Memory Mental Model

A chain of operations need not require every intermediate to have distinct storage, but the first input may still belong to the caller. A residual branch can require an earlier value long after the next arithmetic call. Starting with one owned copy and mutating that copy may be legal yet remove less traffic than mutating caller input. Native in-place operations still launch their kernels; this exercise does not claim automatic fusion or a new arithmetic association.

Part 3 - Quantitative Prediction Before Execution

Choose a chain such as multiply, add, ReLU, and a final scale with fixed operation order. Draw live intervals for each materialized result and calculate payload peaks for destructive-input and preserved-input contracts. Add a branch that reads a pre-ReLU value and recompute the legal overwrite points. Predict which request savings survive after charging a necessary initial copy or preserved branch value.

Part 4 - Experimental Design and Instrumentation

Create a host read/write schedule and freeze operator order, dtype, precision, and output retention. Mark every candidate mutation as admitted, rejected, or unknown with a reason. Complete the selected rewrite and compare intermediate values at declared observation points in separate diagnostic runs. Profile short matching traces, then time equivalent unprofiled replays. Introduce one retained alias and verify the policy changes before executing the revised plan.

Do not introduce algebraic reassociation while changing destination ownership. A multiply-add rewrite into another fused primitive is a different arithmetic experiment. Preserve the sequence of operations first, then study fusion separately if it becomes a later objective.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class ChainDecision:
    operation_id: int
    candidate_input: str
    remaining_readers: tuple
    decision: str
    reason: str

def plan_chain_mutations(operations, owners, aliases):
    # Include branches, outputs, and operation-specific restrictions.
    ...

def execute_chain(inputs, decisions, preserve_input):
    # Complete only admitted in-place rewrites in the original order.
    ...

def E05(config):
    # Compare peaks and requests after charging preservation copies.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Fail any rewrite that alters a promised input, residual, or historical output. An independent reference must not share mutable scratch with the candidate. Report required copies and absolute owned capacity, not just removed result requests. Keep training out of the initial inference comparison; an eventual training extension needs saved-value and gradient validation. Retain a case where copy cost or workload size removes the expected benefit.

Part 7 - Engineering Interpretation and Philosophy

Selective mutation is a value-lifetime decision rather than a mechanical replacement of every operator. The best rewrite preserves the original arithmetic schedule and destroys only information that no supported consumer still needs.

19.30.7 Exercise 06

Exercise Title: Reproduce an Autograd Failure by Modifying a Tensor In-Place After It Has Been Saved for Backward

Part 1 - Exercise Contract and Why It Matters

Reproduce a saved-for-backward version mismatch using a small controlled graph. Distinguish this deferred error from the immediate restriction on mutating a leaf requiring gradients. Explain which original value backward needed, why it became invalid, and which legal repair preserves the intended objective.

Part 2 - System and Memory Mental Model

A backward formula can retain a forward tensor together with mutation metadata. If native mutation changes that saved value before backward reads it, autograd can reject the inconsistent history. Use a nonleaf intermediate so the experiment reaches this check instead of stopping at a leaf mutation. Executing the mutation under no-grad changes recording behavior but does not make a previously saved value unnecessary. Detaching a sharing alias also does not create an independent preserved value.

Part 3 - Quantitative Prediction Before Execution

Construct a nonleaf $h = 2x$ and a scalar loss based on h^2. Before execution, derive the baseline gradient and identify the h value its backward needs. Predict outcomes for no mutation, mutation after loss construction, and mutation of a separate clone only. Compare storage and preservation cost for repairs. Do not redefine the baseline loss after mutation and claim equivalence to the original forward graph.

Part 4 - Experimental Design and Instrumentation

Use tiny deterministic tensors and build a fresh graph for every case. Capture forward success, mutation success, backward success or failure, and actual exception phase. Use anomaly detection only in a diagnostic replay to help locate the saved-value producer. Validate the unmodified reference and each legal repair with independent gradients. Record PyTorch version and execution mode; do not suppress errors through data aliases, manual counter manipulation, or a blanket backward exception handler.

When using anomaly diagnostics, include forward graph construction in the diagnostic scope so the report can identify the saved-value producer. Keep that diagnostic replay separate from timing and preserve the actual failing backward phase in the record.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def build_saved_value_case(input_value):
    # Construct a nonleaf and a loss whose backward needs its old value.
    ...

def run_mutation_case(initial_value, mutation_policy):
    # Build a fresh graph and preserve expected failure phases.
    ...
    # Perform backward or record the specific expected rejection.
    ...

def validate_repair(reference, repaired, tolerances):
    # Check the same forward objective and corresponding gradients.
    ...
```

```
def E06(config):
    # Separate leaf rejection from saved-for-backward invalidation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the intended saved-value failure rather than accepting any RuntimeError as success. Validate the baseline analytically on the tiny graph. A repair that merely detaches the loss or drops a gradient path is invalid. If the chosen operation does not save the value expected in the installed version, revise the case transparently and explain the actual dependency before drawing a conclusion.

Part 7 - Engineering Interpretation and Philosophy

The error protects consistency between a forward computation and its backward history. Repair the value lifecycle or eliminate an unnecessary mutation; do not treat an exception as an obstacle to bypass or confuse an error-free new objective with preserved training semantics.

19.30.8 Exercise 07

Exercise Title: Inspect Tensor Version Counters and Explain How PyTorch Detects Unsafe In-Place Mutations Required by Backward

Part 1 - Exercise Contract and Why It Matters

Observe mutation bookkeeping around ordinary tensors, native views, detached aliases, and independent clones. Explain how saved-value checks use version information and distinguish that mechanism from a general proof of mutation safety. Deliver a diagnostic timeline and explicitly label private or unsupported inspection paths.

Part 2 - System and Memory Mental Model

Ordinary native in-place operations update autograd's mutation bookkeeping. Saved-value validation compares the relevant state when backward accesses the saved tensor. Direct counter inspection through `_version` is a version-sensitive laboratory diagnostic, not a stable public analyzer contract. Inference tensors can lack such counters. A counter change can indicate a write but does not identify every external reader, prove numerical change, or supply CUDA stream dependencies.

Part 3 - Quantitative Prediction Before Execution

Predict a timeline for a no-op-valued native write, an arithmetic write, view creation without writing, clone creation, and backward after a protected value changes. Compare expected counter relationships for ordinary native aliases without generalizing to arbitrary externally constructed storage wrappers. Predict the inspection status for a tensor created in inference mode. Separate unknown counter state from a measured zero and from an unchanged observed counter.

Part 4 - Experimental Design and Instrumentation

Feature-check the diagnostic attribute and retain unsupported outcomes. Use small ordinary tensors for the main timeline, recording observations before saving, after saving, after mutation, and at backward. Keep a live owner and log scalar metadata only. Compare original, native view, detached alias, and clone cases with fresh graphs. Add an inference-created tensor as a

documented exception test. Do not manually increment counters to make a failing graph pass; incrementing cannot recover an overwritten value.

Compare a zero-valued write with a read-only metadata observation. Both may leave tensor values unchanged, but they need not have the same bookkeeping behavior. This distinguishes a numerical equality test from evidence about recorded mutation history.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class VersionObservation:
    tensor_label: str
    phase: str
    observed_version: object
    inspection_status: str
    execution_mode: str

def inspect_version_if_supported(tensor, label, phase, mode):
    # Treat private diagnostic access and unavailable counters explicitly.
    ...

def record_version_timeline(case, config):
    # Observe native writes and the actual backward outcome.
    ...

def E07(config):
    # Compare ordinary alias, clone, and inference-created cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not hard-code a universal exact increment count across composite operations or versions. A write adding zero may still invalidate a saved value despite unchanged numerical contents. Counter absence is not permission to mutate. Distinguish immediate leaf errors, backward mismatch, unsupported inspection, and successful supported cases. Production admission should rely on declared semantics and dependencies, not only a private diagnostic number.

Part 7 - Engineering Interpretation and Philosophy

Version bookkeeping is a consistency alarm with a defined scope. Its value is explaining why a saved history became invalid, while the analyzer must still reason about ownership, application consumers, operator contracts, and stream ordering independently.

19.30.9 Exercise 08

Exercise Title: Create Multiple Views of the Same Tensor and Prove That an In-Place Mutation Through One View Changes the Shared Underlying Storage

Part 1 - Exercise Contract and Why It Matters

Create several ordinary views of one owned tensor and demonstrate exactly which logical elements change when a permitted in-place write goes through a view. Distinguish sharing the same backing allocation from overlapping the same elements. Deliver a coordinate map, alias diagram, and observed value changes.

Part 2 - System and Memory Mental Model

A view can change shape, strides, or starting offset while referring to the same backing storage. Two disjoint slices can share an allocation without sharing elements; a transpose can describe the same elements in another coordinate order. Begin outside gradient recording and use ordinary dense positive-stride views. Internally overlapping expanded views are not ordinary writable destinations and should be rejected in the initial mutation contract.

Part 3 - Quantitative Prediction Before Execution

For a contiguous base with shape $(4, 6)$ and element width s, predict element addresses from offset and strides. Define two overlapping row slices, a disjoint slice, and a transpose. Mark which coordinates a selected view write will change in every observer. Calculate the base payload once rather than charging every view a full allocation, and predict the difference between shared-base and overlapping-region reports.

Part 4 - Experimental Design and Instrumentation

Fill the base with unique deterministic values and preserve an independent expected snapshot. Record shape, stride, offset, tensor pointer, storage base, and capacity for each view. Mutate one admitted view and compare every observer with the coordinate prediction. Repeat with another slice offset and a transposed view. Run a clone control and an expanded-view rejection case. Keep instrumentation copies outside the measured allocation region unless they are part of the declared workload.

Enumerate element offsets only for tiny cases with a strict size limit. Large coordinate sets can overwhelm host memory and are unnecessary for the CUDA benchmark. Retain the tiny oracle as independent validation of the conservative geometry calculation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ViewDescription:
    label: str
    shape: tuple
    strides: tuple
    offset_elements: int
```

```
    storage_owner: str

def map_view_elements(description, limits):
    # Enumerate tiny supported cases for an independent overlap oracle.
    ...

def mutate_selected_view(views, selected, mutation_contract):
    # Admit the write, then compare all mapped observers.
    ...

def E08(config):
    # Distinguish same-storage sharing from actual element overlap.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate untouched coordinates as carefully as changed ones. Matching base addresses alone cannot identify region overlap, and differing first-element pointers cannot exclude it. A bounding-range overlap can be conservative for strided views; exact tiny coordinate enumeration helps expose false positives. Reject unsupported internal overlap before launching the write rather than relying on one accidental runtime outcome.

Part 7 - Engineering Interpretation and Philosophy

Aliasing has geometry. Knowing that two tensors share storage is a starting point; deciding whether a mutation affects another value requires element regions and consumers. Preserve that distinction when building a conservative tracker later in the chapter.

19.30.10 Exercise 09

Exercise Title: Reproduce a Hidden Aliasing Bug Where Modifying One Tensor Unexpectedly Changes Another Tensor View

Part 1 - Exercise Contract and Why It Matters

Reproduce an application-level aliasing bug in which a helper mutates a view and unexpectedly changes values another component still needs. Demonstrate that this error can occur during inference without an autograd exception. Repair the ownership boundary and compare the costs of the legal alternatives.

Part 2 - System and Memory Mental Model

A Python variable, a slice result, or a container entry is not automatically an independent value snapshot. A helper receiving a view can modify a region of its caller's tensor. Detaching can remove gradient connectivity while preserving this sharing. The bug depends on the intended contract: mutation may be legal for an explicitly borrowed mutable argument but illegal for read-only input or historical data. Name those contracts before repairing anything.

Part 3 - Quantitative Prediction Before Execution

Use a base with unique values, create a slice representing a stored historical feature, and apply a normalization-like destructive update through another view. Predict every affected coordinate and a later aggregate that should have used the old values. Calculate the bytes required for cloning the slice versus cloning the entire base. Compare these costs with a read-only helper that returns a fresh result only when needed.

Part 4 - Experimental Design and Instrumentation

Construct a tiny deterministic reproduction with a clearly stated expected historical value. Capture evidence before helper entry, after mutation, and at the later consumer. Use separate fresh setups for the buggy helper, a read-only rewrite, and an ownership-copy repair. Validate complete observations rather than just the helper's returned result. Include a detached-alias non-repair case and a legitimate mutable-borrow case so the rule does not become an unconditional ban on all mutation.

Include a container-based historical record holding a view instead of a copy. Verify the record before and after helper execution. This makes the contract failure visible even when the mutating helper returns a numerically correct result for its immediate caller.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ArgumentContract:
    name: str
    access: str
    historical_readers: tuple
    alias_group: str

def destructive_helper(value, contract):
    # Enforce mutable ownership before completing the operation.
    ...

def reproduce_hidden_alias(config):
    # Build overlapping observers and identify the violated expectation.
    ...

def compare_ownership_repairs(reference, candidate_cases):
    # Check history preservation and charge required copying.
    ...

def E09(config):
    # Compare bug, legal repairs, and the detached-alias non-repair.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Require an explicit failed assertion for the later consumer, not merely a pointer match. Validate that the repair restores the original observable history. A full-base copy may be unnecessarily expensive, but a narrow slice copy must still cover all required values. Preserve allocation and latency costs of each repair. Absence of backward or a version error does not make the original helper correct.

Part 7 - Engineering Interpretation and Philosophy

The hidden bug is often an undocumented ownership transfer. Make read-only, borrowed-mutable, and independently retained values explicit. A repair should restore that contract with the smallest justified copy or change in helper behavior.

19.30.11 Exercise 10

Exercise Title: Distinguish Views, Copies, Clones, and Detached Tensors by Storage Pointer, Gradient History, and Mutation Behavior

Part 1 - Exercise Contract and Why It Matters

Distinguish views, actual copies, clones, detached aliases, and reshape results using storage observations, mutation behavior, and gradient relationships. Build a behavior matrix that avoids equating a new Python object with a new allocation or equating independent storage with a disconnected computation graph.

Part 2 - System and Memory Mental Model

Ordinary views share backing storage. Clone creates a separate value copy and can remain differentiable with respect to its source. Detach returns a tensor without that gradient relationship while sharing storage. Reshape and contiguous operations can return sharing results or new storage depending on layout and requirements. Classify observed behavior for the actual case rather than assuming every method name implies one permanent allocation rule. Start with ordinary dense tensors and record unsupported abstractions explicitly.

Part 3 - Quantitative Prediction Before Execution

Predict matrix columns for operation, object identity, backing-storage sharing, region overlap, gradient path, mutation effect, and payload request. Include a contiguous reshape, a noncontiguous case requiring materialization, a clone, a detached alias, and an independent detached clone. Calculate backing bytes once per live owner. Predict how a mutation propagates to existing observers and which scalar losses can legitimately produce source gradients.

Part 4 - Experimental Design and Instrumentation

Create deterministic source tensors with controlled layout and gradient state. Build one fresh graph per gradient test and separate mutation demonstrations from already-saved backward values. Record shape, strides, offset, storage base, requires-grad status, leaf status, and graph-function description where available. Validate values and gradients with independent references. Use tiny coordinate enumeration for region overlap and a short allocation trace for copy claims. Check same-device no-op conversions separately from forced copies.

Test ordinary slicing separately from advanced indexing. Do not assign sharing behavior to all indexing expressions by appearance. Record the exact indexing operation, actual storage evidence, and observed mutation propagation in each row of the behavior matrix.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TensorBehavior:
    operation: str
    shares_storage: object
    overlaps_source: object
    source_gradient_path: object
    source_changes_on_write: object
    payload_request: object

def construct_behavior_case(source, operation):
    # Apply the selected view/copy/detach transformation.
    ...

def verify_behavior(source, candidate, expected, config):
    # Test storage, values, and gradients in independent replays.
    ...

def E10(config):
    # Export the behavior matrix with unknown/unsupported states.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not use a differing tensor pointer as proof of different storage or a missing graph function as proof of independent memory. Nonleaf gradients are not populated by default; test source gradients through the intended loss rather than calling every absent gradient a failure. Preserve layout changes introduced by copying. If an operation can choose view or copy behavior, record the observed case and its conditions rather than making a universal method-name claim.

Part 7 - Engineering Interpretation and Philosophy

Storage independence and differentiation are separate axes. A reliable mental model names both explicitly, then asks what each observer can read after a write. That model is more useful than memorizing a list of methods as simply safe or unsafe.

19.30.12 Exercise 11

Exercise Title: Compare clone(), detach(), and detach().clone() by Memory Allocation, Storage Sharing, and Autograd Semantics

Part 1 - Exercise Contract and Why It Matters

Compare clone, detach, and detach-followed-by-clone for payload allocation, storage sharing, gradient connectivity, and mutation effects. Select each operation according to a concrete ownership and differentiation requirement, not merely because it suppresses a warning or changes a graph display.

Part 2 - System and Memory Mental Model

Clone gives independent storage while preserving a gradient relationship when the source is tracked. Detach disconnects the result from the source's gradient history without supplying an independent snapshot. Detach-followed-by-clone combines disconnection with independent storage. These descriptions concern the constructed result; later explicitly enabling gradients on an independent result creates a new local differentiation task rather than restoring the original connection. Copy cost remains real even when no backward graph is recorded for it.

Part 3 - Quantitative Prediction Before Execution

For an n-element dense source of width s, predict additional copied payload for the three choices and compare with allocator request measurements. Define a scalar function of each result and predict whether the original source has a gradient path. Include one result that cannot support the proposed backward call because it has no tracked inputs. Predict observer changes under a permitted write and explain why gradient detachment does not isolate storage.

Part 4 - Experimental Design and Instrumentation

Use separate source instances for numerical mutation tests and gradient-path tests. Keep source values deterministic and preserve independent expected snapshots outside the measured region. Collect storage and allocation evidence, then time repeated transformations without profiling overhead. Test a regular contiguous source and a supported noncontiguous view, recording resulting layout. Compare the practical requirements of a read-only logged snapshot, a differentiable branch, and an independent trainable copy.

The source may remain physically resident because another alias still owns its storage, even when a detached result has no gradient connection. Track residency and connectivity independently so a graph simplification is not misreported as released memory.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CopyChoice:
    name: str
    independent_storage_required: bool
    source_gradient_required: bool
```

```
    expected_payload_bytes: object

def construct_copy_choice(source, choice):
    # Implement the selected transformation without changing the contract.
    ...

def test_gradient_connection(source, result, expectation):
    # Distinguish no path, expected backward refusal, and a valid path.
    ...

def E11(config):
    # Compare storage isolation, traffic, layout, and gradient evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A detached alias is not a safe historical snapshot of a tensor that will be mutated. A clone is not automatically detached. Do not invoke backward on an untracked scalar and classify the resulting error as a corrupted autograd engine. Record expected path absence explicitly. Charge required snapshots and any retained source ownership, including capacity that remains live because an alias still refers to its backing allocation.

Part 7 - Engineering Interpretation and Philosophy

Choose the cheapest transformation that satisfies both ownership and gradient requirements. A smaller allocation count is irrelevant if an intended snapshot keeps changing, and removing a desired gradient path is a semantic change rather than a memory optimization.

19.30.13 Exercise 12

Exercise Title: Use copy_() to Refill Preallocated CUDA Buffers and Compare It Against Recreating Destination Tensors Every Iteration

Part 1 - Exercise Contract and Why It Matters

Refill preallocated CUDA destinations with successive source values and compare against independently recreating destination tensors each iteration. Measure request elimination, copy traffic, destination identity, and observable history. Do not conflate stable destination storage with eliminating source creation or making its contents safe for every consumer.

Part 2 - System and Memory Mental Model

Copy is an in-place write to the destination. A persistent destination can avoid repeated output allocation but still needs exclusive permission to overwrite its current generation. Broadcasting, conversion, and host/device movement expand the copy contract; exclude them from the initial same-device, same-shape test. A destination saved for backward is not ordinary free staging space, and previous returned views see subsequent refills unless they have an independent ownership guarantee.

Part 3 - Quantitative Prediction Before Execution

For N copies of b bytes, calculate Nb logical copied payload and estimate simple same-device read-plus-write traffic separately. Predict fresh destination request count versus one setup allocation. Draw a case where newly computed sources still allocate every iteration, and another where a retained prior output forces another slot or copy. Predict absolute live bytes during source and destination coexistence instead of treating cumulative traffic as peak memory.

Part 4 - Experimental Design and Instrumentation

Prepare deterministic source generations and declare the destination lease. Complete a fresh-copy baseline and persistent-refill path with identical consumption. Inspect every generation before overwrite, record storage metadata, and collect a short allocation trace. Time warmed unprofiled runs with completed CUDA boundaries and report setup separately. Add a retained-view rejection case and a destination-needed-by-backward case. Keep nonblocking cross-device transfer extensions separate and require their completion rules.

A supported training extension must consider destinations whose previous values were saved in an earlier graph. Reusing a destination across iterations requires completed backward obligations or an explicit alternative value lifecycle, not just an iteration counter advancing.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RefillLease:
    destination_id: str
    generation: int
    consumers: tuple
    completion_tokens: tuple

def admit_refill(destination, source, lease, contract):
    # Check ownership, compatibility, autograd use, and readiness.
    ...

def refill_destination(destination, source, lease):
    # Complete the copy only after legal admission.
    ...

def E12(config):
    # Compare fresh copies and persistent generations with equal work.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Check the reference does not alias the refilled buffer. A saved value must not be overwritten merely because its Python forward consumer has returned. Report source requests and destination requests separately. Do not hide required copies in setup for only one strategy. Preserve unsupported, rejected, and delayed-consumer outcomes; a stable address alone says nothing about whether an old generation remains valid to its observer.

Part 7 - Engineering Interpretation and Philosophy

Refill is controlled destruction of one generation and publication of another. Its usefulness depends on lease duration and copy cost, not only persistent addresses. A preallocated buffer is safe when the ownership protocol makes every read and overwrite boundary explicit.

19.30.14 Exercise 13

Exercise Title: Identify When In-Place ReLU Saves Memory and When Autograd Requirements Eliminate or Reduce the Expected Benefit

Part 1 - Exercise Contract and Why It Matters

Determine when in-place ReLU removes a useful temporary and when ownership or autograd needs reduce that benefit. Compare inference, an admitted nonleaf training chain, and a branched graph requiring the original preactivation. Validate complete outputs and gradients before measuring savings.

Part 2 - System and Memory Mental Model

ReLU replaces negative entries with zero, destroying information about the original negative magnitudes. A later branch may still need that original preactivation. A supported native in-place ReLU can work in some training graphs, but a leaf requiring gradients and later mutation of backward-needed results create different restrictions. The retained values needed by backward and other live regions determine whether removing one visible result actually changes the total training peak.

Part 3 - Quantitative Prediction Before Execution

For a b-byte preactivation, predict the visible result request potentially avoided. Compare a sequential graph with a residual branch using preactivation values before ReLU. Add a preservation copy and calculate whether its bytes cancel the local saving. Sketch forward and backward peaks separately, including parameters, gradients, and operator workspaces at their actual times. Do not subtract b from a global peak unless the removed allocation was live there.

Part 4 - Experimental Design and Instrumentation

Build independent models and inputs with identical state and precision. Use a nonleaf activation for the admitted training case and a distinct test for leaf rejection. Compare fresh and in-place ReLU under matching arithmetic order, then add the preactivation branch. Check outputs, input and parameter gradients, and multi-step updates before timing. Use tiny diagnostic saved-value observations separately from low-overhead peak measurements so the observer does not retain activations and move the peak.

Run a second mutation after the admitted ReLU in a separate diagnostic graph to test whether the result remains protected for backward. Classify that follow-up independently; acceptance of the ReLU does not grant unrestricted permission to overwrite its output.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ReluCase:
    mode: str
    preactivation_readers: tuple
    expected_acceptance: str
    preservation_required: bool

def execute_relu_case(model, inputs, case, inplace):
    # Preserve the full graph and admit only legal mutation sites.
    ...

def compare_relu_training(reference, candidate, tolerances):
    # Check outputs, all required gradients, and updates.
    ...

def E13(config):
    # Compare local requests and actual complete-step memory peaks.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not interpret a valid nonleaf example as permission to mutate every ReLU input. A branch can be wrong without triggering the intended autograd error. Include values on both sides of zero and state the framework convention at zero. If preservation is required, charge its allocation and lifetime. Report small or absent global savings honestly even when the local result request has disappeared.

Part 7 - Engineering Interpretation and Philosophy

An activation's local implementation cannot determine its global memory benefit alone. The useful question is whether the preactivation can be destroyed and whether its removed result overlaps the true peak without requiring an equally large preserved substitute.

19.30.15 Exercise 14

Exercise Title: Build an Alias Tracker That Detects Tensors Sharing the Same Underlying Storage Before Allowing an In-Place Mutation

Part 1 - Exercise Contract and Why It Matters

Build a conservative tracker for registered tensors sharing owned dense storage. Before admitting mutation, identify potential observers and the region affected. Deliver explicit same-storage, disjoint-region, overlapping-region, and unknown classifications with reasons. Do not claim universal discovery of every Python or external-library alias.

Part 2 - System and Memory Mental Model

Storage grouping and exact element overlap are different tasks. A base address, device, capacity, and continuous owner generation can identify ordinary owned backing storage within a restricted runtime. Address reuse after owner release requires another generation. Positive-stride region bounds can conservatively flag overlap but may overapproximate strided element sets. Escaped or externally constructed aliases and unsupported tensor layouts must force conservative handling or refusal, not an invented disjoint result.

Part 3 - Quantitative Prediction Before Execution

For a positive-stride dense view, calculate a conservative addressed span from offset, shape, strides, and element width. Explain why overlapping spans do not always mean overlapping elements, while disjoint valid spans can establish non-overlap in the supported case. Enumerate tiny stepped slices to compare exact element sets with bounds. Define how empty tensors and different devices are classified without grouping unrelated zero pointers.

Part 4 - Experimental Design and Instrumentation

Register a base, overlapping slices, disjoint slices, transpose, clone, and detached alias. Keep live-owner metadata explicit without allowing diagnostic logs to retain tensors indefinitely. Compare conservative reports against a tiny coordinate-enumeration oracle. Introduce release/reallocation and verify generation separation. Test an unregistered escape and unsupported internal overlap; admission should remain unknown or rejected. Check the tracker before mutation, then validate all registered observers afterward.

Use allocation generations in the registry key and invalidate stale records after owner replacement. A coincidentally repeated address must not transfer an old alias relationship to unrelated storage or erase an obligation belonging to an older still-live generation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AliasRecord:
    tensor_key: str
    owner_generation: tuple
    shape: tuple
    strides: tuple
    offset_elements: int
    element_bytes: int
    support_status: str

class AliasTracker:
```

```
    def register(self, tensor, ownership):
        # Record supported geometry and continuously owned storage.
        ...

    def potential_observers(self, tensor_key, write_region):
        # Separate proven disjointness from conservative conflicts.
        ...

    def admit_mutation(self, tensor_key, operation, consumers):
        # Refuse unknown escapes and protected overlapping readers.
        ...

def E14(config):
    # Compare tracker reports with independent tiny overlap cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no false-safe classifications in the supported test suite; report conservative false positives separately. Storage aliases must not be assumed to share every internal autograd bookkeeping detail under arbitrary external construction. A reference-count or container scan is not a proof that no alias escaped. Preserve the registration contract, owner generations, and unsupported geometry in each mutation decision.

Part 7 - Engineering Interpretation and Philosophy

A conservative tracker earns trust by distinguishing what it can establish from what it cannot observe. Its purpose is safe admission within an explicit ownership boundary, with explanations for rejected opportunities rather than an unsupported global claim about all tensors.

19.30.16 Exercise 15

Exercise Title: Create a Memory Planner That Marks Intermediate Tensors as Safe or Unsafe for In-Place Reuse from Their Remaining Consumers

Part 1 - Exercise Contract and Why It Matters

Create a planner that classifies candidate intermediate mutations as safe, unsafe, or unknown from remaining consumers and explicit operator contracts. Account for forward readers, backward-saved requirements, aliases, external outputs, and device completion. Deliver reasoned decisions and an independently validated schedule, not a rewrite based only on the next Python use.

Part 2 - System and Memory Mental Model

A value can be dead for one forward branch yet still needed by another branch or backward. The planner must model the specific value an operator overwrites, not merely the lifetime of its tensor object. Native autograd support also depends on leaf/view restrictions and the selected operation. Begin with a fixed graph and one stream; unknown operators or saved-value behavior require an unchanged out-of-place path. Remaining-consumer count alone is therefore necessary context, not a complete safety certificate.

Part 3 - Quantitative Prediction Before Execution

For value v at candidate site j, list remaining forward readers $F(v, j)$, backward requirements $B(v, j)$, and external observers $O(v, j)$. Construct a sufficient admission rule combining discharged obligations, compatible aliases, supported operator semantics, and ordered final readers. Compare a chain, a residual branch, and a backward-saved intermediate. Predict which decisions stay unknown when backward requirements cannot be established without relying on private graph internals.

Part 4 - Experimental Design and Instrumentation

Represent explicit read/write sets, alias groups, and ownership contracts in host metadata. Derive candidate decisions before executing the optimized graph. Validate them using an independent checker and small hand-labeled examples. Execute only admitted rewrites, keeping unknown sites out-of-place. Compare values and gradients with the original graph. Change a consumer or expose an output alias and require invalidation of the old plan. Log the exact reason and evidence for every acceptance and rejection.

Plan validity belongs to a graph and contract version. Adding a branch, changing an output lease, or altering an operator can invalidate previous last-use facts. Require reanalysis or a checked unchanged path instead of reusing stale decisions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MutationDecision:
    operation_id: int
    value_id: str
    forward_obligations: tuple
    backward_obligations: tuple
    alias_obligations: tuple
    status: str
    reason: str

def classify_candidate(site, graph_contract, alias_tracker):
    # Combine consumers with operator, ownership, and backward rules.
    ...

def validate_mutation_plan(plan, independent_model):
    # Reject stale graph assumptions and unsupported safety claims.
    ...

def E15(config):
```

```
    # Compare predicted decisions with preserved graph behavior.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Test at least one site with no remaining ordinary forward reader that is still unsafe because backward or an external alias requires the old value. Require unknown decisions to remain unmodified. A successful backward run supports the executed case but does not discover every possible caller contract. Preserve false-safe findings as correctness failures and conservative rejections as missed opportunities, with distinct metrics.

Part 7 - Engineering Interpretation and Philosophy

Planning mutation means discharging all obligations to the old value. A useful planner can explain why a site is refused and what extra information would change that decision. It should optimize within known semantics rather than guess those semantics from an empty forward-use list.

19.30.17 Exercise 16

Exercise Title: Rewrite a Memory-Heavy PyTorch Forward Pass with Selective In-Place Operations While Preserving Exact Outputs and Gradients

Part 1 - Exercise Contract and Why It Matters

Rewrite a memory-heavy forward graph using selected supported in-place operations while preserving the same outputs and gradients. Treat exact preservation as the target: keep arithmetic order and derivative participation unchanged, and distinguish bitwise evidence from tolerance-based numerical agreement. Never present an approximate rewrite as exact.

Part 2 - System and Memory Mental Model

A legal storage rewrite changes where values reside, not which function is computed. Protect saved activations, residual inputs, caller-owned tensors, and returned histories. Replacing operations can still interact with floating point behavior, layout, or kernel selection; do not assume identical bits without checking the actual environment. A clone used to establish ownership must be included in memory and time. Parameter updates under no-grad do not justify arbitrary mutation during forward.

Part 3 - Quantitative Prediction Before Execution

Build an operation-by-operation live-byte prediction for the original and candidate graphs. Calculate which result requests disappear and where required preservation copies reintroduce bytes. Predict the true peak by time, not by summing removed payloads. Define output and gradient acceptance thresholds before testing, including a separate bitwise comparison where supported. Choose finite deterministic inputs for the strict primary comparison and additional boundary-value cases for robustness.

Part 4 - Experimental Design and Instrumentation

Clone identical model and optimizer initial state and pre-generate matching batches. Freeze dtype, precision settings, RNG policy, layout, operation order, and training mode. Validate every named parameter gradient, input gradient, output, loss, and update across several steps. Diagnose mismatches before profiling performance. Use independent fresh graphs for each

strategy and exclude anomaly tracing from timed runs. Add a residual branch and an aliased input to verify the admission policy refuses invalid opportunities.

Check caller-visible input tensors and model buffers as well as trainable parameters. A rewrite that preserves loss and parameter gradients can still modify a promised input or running statistic, changing later behavior outside the immediate comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class EquivalenceReport:
    outputs_bitwise_equal: object
    gradients_bitwise_equal: object
    maximum_output_error: object
    maximum_gradient_error: object
    missing_gradients: tuple
    update_status: str

def original_forward(model, inputs):
    # Build the reference graph with unchanged intended arithmetic.
    ...

def selective_forward(model, inputs, validated_plan):
    # Apply only justified storage rewrites and charge required copies.
    ...

def verify_complete_equivalence(reference, candidate, contract):
    # Compare outputs, inputs, named gradients, losses, and updates.
    ...

def E16(config):
    # Restore identical state and validate multi-step semantics first.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A matching scalar loss can hide incorrect individual gradients. Missing or unexpected gradients require explicit comparison, and a detached branch is a failure even if output values match. If only tolerance agreement is achieved, state that limitation rather than calling the result bitwise exact. Keep nonfinite handling explicit and preserve the exact failing configuration. No performance recommendation is accepted before the declared equivalence gate passes.

Part 7 - Engineering Interpretation and Philosophy

Storage optimization is justified by a preserved computation, not by a smaller memory graph alone. Separate the intended exact semantics from the empirical numerical evidence available on a particular device, and keep all required preservation costs in the final engineering result.

19.30.18 Exercise 17

Exercise Title: Profile the Optimized and Original Forward Pass and Determine Whether Reduced Allocations Improve Real Performance or Only VRAM Usage

Part 1 - Exercise Contract and Why It Matters

Profile original and validated selective-in-place execution to determine whether fewer allocations improve latency, peak VRAM, both, or neither. Keep the successful equivalence contract from E16 fixed. Deliver diagnostic traces, unprofiled timing distributions, and a conclusion tied to the actual workload rather than the number of rewritten sites.

Part 2 - System and Memory Mental Model

Allocation overhead may be small relative to kernels, memory bandwidth, and host dispatch. In-place operations do not automatically fuse a chain or reduce its arithmetic count. A warm allocator can already recycle temporary storage, while preserved aliases or gradients can keep capacity live. Profiling can retain metadata or change overhead, so use separate diagnostic and timing replays. Treat eager and compiled execution as different explicit experiments if compilation is introduced at all.

Part 3 - Quantitative Prediction Before Execution

Define relative request reduction $1 - A_m/A_b$ for $A_b > 0$, memory reduction $P_b - P_m$ at a named peak layer, and speedup T_b/T_m for $T_m > 0$. Keep undefined ratios undefined. Predict outcomes for tiny tensors dominated by dispatch, large bandwidth-bound tensors, and a graph whose peak lies outside the optimized region. Estimate added checks and preservation-copy costs before measurement and explain why fewer requests need not lower reserved memory.

Part 4 - Experimental Design and Instrumentation

Use the same graph, model state, inputs, gradient mode, precision, output contract, and useful iteration count. Collect a bounded profiler trace with memory activity and an operation timeline. Reconcile visible request savings, then perform repeated unprofiled warmed trials in randomized order. Record complete wall time and an appropriately bounded device-time region. Include forward/backward/update for training comparisons and label a forward-only benchmark explicitly. Report cold setup separately and keep raw samples.

If checking whether results match forces a device synchronization, keep that check out of both timed paths or explicitly include it in both. Avoid accidentally giving one strategy a completed kernel region and the other only a host-submission interval.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class PerformanceEvidence:
    strategy: str
    allocation_layer: str
    request_count: object
    peak_allocated_bytes: object
    peak_reserved_bytes: object
    wall_samples: tuple
    device_samples: tuple

def diagnostic_profile(workload, config):
    # Collect bounded allocation and kernel evidence in its own replay.
    ...

def unprofiled_trials(workload, trial_order, config):
    # Match state, completion boundaries, and complete useful work.
    ...

def E17(config):
    # Preserve the equivalence gate and compare measured distributions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not compare a profiled original with an unprofiled optimized run. Attribute extra copies, synchronization, and plan-check overhead. Report median and a declared tail statistic with sample counts and variability. A memory-only benefit can be useful without a speedup, while a slower optimized graph is an adverse result that must remain visible. Never invent benchmark values when a CUDA environment or measurement field is unavailable.

Part 7 - Engineering Interpretation and Philosophy

Performance is the completed workload's behavior, not the aesthetic quality of an allocation trace. Recommend the rewrite only for the measured objective and operating range, explaining when saved capacity matters more than latency and when the original execution is already sufficient.

19.30.19 Exercise 18

Exercise Title: Stress-Test In-Place Optimization with Views, Residual Connections, Shared Storage, Autograd, and Multiple CUDA Streams

Part 1 - Exercise Contract and Why It Matters

Stress-test mutation decisions with views, residuals, shared storage, saved backward values, and multiple CUDA streams. Validate both accepted rewrites and explainable refusals. Preserve replayable traces and minimized counterexamples so a planner's claimed support can be audited beyond one successful graph.

Part 2 - System and Memory Mental Model

Mutation safety depends on which reader sees which generation. Stream order must place a write after all old-value readers and before all new-value readers. Allocator lifetime protection does not itself order application overwrites. Autograd can detect some invalid saved histories but is not a complete detector for stream races or wrong forward contracts. Apply host dependency validation before executing concurrent CUDA tests, and use supported runtime diagnostics only as additional evidence.

Part 3 - Quantitative Prediction Before Execution

Construct a schedule with two streams reading an old generation and a later writer publishing a new one. Predict the required happens-before edges, then remove one edge in host metadata and require rejection. Add an escaped view, a residual consumer, and a backward-saved value to the same ownership model. Report accepted workload coverage, correct completions, rejected opportunities, and bounded outstanding generations rather than an error rate alone.

Part 4 - Experimental Design and Instrumentation

Generate small deterministic cases plus seed-controlled randomized graph and alias metadata. Use an independent oracle for tiny overlap and dependency cases. Execute only validated plans with matching fresh references; compare outputs and gradients where supported. Test delayed readers, variable shapes, retained outputs, repeated backward requirements, unsupported layouts, and shutdown with outstanding work. Rebuild state for every replay. Minimize failures while preserving the same dependency and alias cause; never run a known-invalid concurrent write merely to seek visible corruption.

Protect host diagnostic state from unbounded growth during long stress runs. Use bounded scalar records and replay IDs; retain detailed traces only for selected incidents. Instrumentation must not keep every graph or tensor alive and thereby change the memory problem.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MutationStressCase:
    case_id: str
    alias_description: tuple
    residual_readers: tuple
    backward_requirements: tuple
    stream_dependencies: tuple
    expected_decision: str

def validate_stress_schedule(case, independent_model):
    # Reject missing old-reader/new-writer ordering before CUDA use.
    ...
```

```
def execute_accepted_case(case, analyzer, reference, config):
    # Compare values, gradients, and generation-specific observations.
    ...

def minimize_mutation_failure(case, replay_predicate, limits):
    # Preserve the causal conflict in a bounded small reproduction.
    ...

def E18(config):
    # Export coverage, admitted correctness, refusals, and replay data.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Passing numeric tests alone cannot prove a race-free dependency graph. Require explicit edge and ownership invariants. Classify expected leaf or saved-value errors separately from numerical bugs, timeouts, OOM, and unrelated failures. A planner rejecting all difficult work has low useful coverage even if it never corrupts memory. Preserve unreproduced hypotheses honestly and distinguish host simulation evidence from actual CUDA observations.

Part 7 - Engineering Interpretation and Philosophy

A trustworthy optimizer knows its boundary. Use adversarial traces to refine that boundary, with zero tolerated false-safe decisions in the tested scope and transparent conservative refusals. Expand support only when the missing alias, backward, or completion information can be validated.

19.30.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch In-Place Optimization Analyzer That Identifies Safe Mutation Opportunities and Quantifies Memory Savings

Part 1 - Exercise Contract and Why It Matters

Build an analyzer that identifies supported safe mutation opportunities, explains refused or unknown sites, and benchmarks selected rewrites. Integrate ownership, alias geometry, remaining consumers, backward requirements, and stream order. Quantify measured memory and request savings while preserving the exact intended computation and useful workload coverage.

Part 2 - System and Memory Mental Model

Separate observation, semantic analysis, admission, execution, and measurement. Start from an explicit fixed graph and a small operator allowlist rather than claiming automatic correctness for arbitrary Python programs. Registered owned storage defines the alias boundary. Unknown consumers, opaque operators, unsupported layouts, or unavailable backward requirements keep a site out-of-place. Diagnostic version observations can explain an incident but are not the sole production admission rule. Accepted sites still need numerical and dependency validation.

Part 3 - Quantitative Prediction Before Execution

For candidate plan π, define an objective such as reducing temporary request bytes under correctness, coverage, memory-budget, and progress constraints. Predict removed result requests, preservation-copy demand, peak live bytes, and analyzer overhead at each site. Aggregate peaks on a timeline rather than summing local savings. Compare an unchanged baseline, one-site rewrites, and the integrated plan. State that safety and measured improvement do not imply global minimal memory or a universally optimal selection.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and calibrate decisions on separate traces. Validate plans with an independent host checker, then execute equivalent inference and supported training graphs from identical states. Include elementwise chains, residuals, views, detached aliases, saved activations, and stream-dependent consumers. Compare output values, input and parameter gradients, updates, request traffic, absolute allocated/reserved peaks, and unprofiled timing. Run ablations for alias analysis and consumer information without weakening the safety gate. Keep rejected and unknown opportunities in the report.

Report opportunity coverage separately from execution coverage. An unchanged out-of-place fallback can preserve useful work while admitting no mutations in a difficult region. That is different from refusing the workload entirely and must have a different reported outcome.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AnalyzerContract:
    supported_operations: tuple
    supported_layouts: tuple
    execution_modes: tuple
    alias_boundary: str
    backward_policy: str
    stream_policy: str

class InPlaceOptimizationAnalyzer:
    def __init__(self, contract):
        self.contract = contract
        # Initialize bounded metadata, evidence IDs, and support checks.
        ...

    def analyze(self, graph, ownership, aliases, dependencies):
        # Derive old-value obligations and candidate mutation sites.
        ...

    def classify(self, site, analysis):
        # Return safe, unsafe, or unknown with explicit supporting facts.
```

```
        ...

    def select(self, decisions, memory_model):
        # Balance expected savings with preservation and checking cost.
        ...

    def validate(self, plan, independent_checker):
        # Verify operator, alias, backward, output, and stream contracts.
        ...

    def execute(self, graph, inputs, validated_plan):
        # Apply only admitted rewrites without changing arithmetic order.
        ...

    def explain(self, site_id):
        # Export reasons without retaining live computation graphs.
        ...

def E19(config):
    # Validate semantics, profile separately, and benchmark useful work.
    ...
    # Export a supported recommendation and unresolved limitations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires four gates: preserved outputs and gradient participation; valid ownership, alias, and completion obligations; honest layer-specific allocation accounting; and equivalent complete-workload timing. Record device, versions, backend, seeds, precision, graph/trace IDs, support status, decision reasons, preservation copies, request counts/bytes, absolute peaks, error metrics, timing samples, and workload coverage. Export CPU-only metadata.

Demonstrate a useful accepted site, protected residual, detached-alias hazard, saved-value rejection, unknown operator, and delayed reader. No site may be called safe merely because its sampled backward succeeds. Preserve missing hardware measurements as not measured and retain adverse performance results.

Part 7 - Engineering Interpretation and Philosophy

The analyzer is useful when it can justify a small safe rewrite and quantify its actual consequence. Its promise is conditional optimization within known contracts, not universal mutation safety. Recommend the smallest effective configuration and name the next specific experiment required before extending operator, alias, training, or stream support.

19.31 DMM29

Chapter Title: Meta Device and Zero-Allocation Model Construction
Specialization: Dynamic Memory Management and CUDA Systems

19.31.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Meta Tensors, Tensor Metadata, Deferred Storage Allocation, and Zero-Data Model Construction

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model separating a model's structural description, allocated parameter storage, valid initialized values, checkpoint-backed values, and execution readiness. Explain what meta construction postpones and which costs remain. Deliver a state diagram and an accounting table rather than equating a large logical parameter count with already resident physical weights.

Part 2 - System and Memory Mental Model

Meta tensors represent metadata without real element values. Shapes, strides, dtypes, and gradient requirements can describe future computation, but they cannot supply unknown weights. Python modules, tensor metadata, registries, and the interpreter still consume host memory. Zero-data construction therefore means avoiding parameter payload allocation, not zero process allocation. Materialization supplies storage; initialization or checkpoint loading supplies valid contents. Execution also needs supported operators, inputs, buffers, activation capacity, and any required device transfers.

Part 3 - Quantitative Prediction Before Execution

For logical tensors with element counts n_i and target element widths s_i, predict nominal payload $B = \sum_i n_i s_i$ under an explicitly untied dense model. Separate metadata overhead, buffers, gradients, optimizer state, and workspaces. Draw lifecycle peaks for ordinary construction, meta followed by initialization, and meta followed by checkpoint assignment. Mark which values and resources exist at each stage and identify the assumptions behind every predicted avoided allocation.

Part 4 - Experimental Design and Instrumentation

Use a small ordinary model as a numerical reference and a configurable meta skeleton for structural comparisons. Record architecture, versions, dtype, parameter/buffer counts, process baseline, and CUDA initialization state. Inspect metadata without reading nonexistent values. Create a readiness record that distinguishes meta-only, allocated-uninitialized, checkpoint-loaded, and verified states. Keep model construction, storage allocation, value production, and first execution as separate measured phases. Log only bounded scalar records so instrumentation does not become a second model registry.

Keep logical size, storage readiness, and value authority in separate fields. A later consumer must not infer readiness from the presence of a Parameter object or from a non-meta device label alone; both can precede valid contents.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn
```

```
@dataclass
class ModelLifecycle:
    architecture_id: str
    logical_parameter_elements: int
    nominal_payload_bytes: int
    storage_state: str
    value_state: str
    ready_for_execution: bool

def classify_model_state(model, value_ledger):
    # Distinguish metadata, allocated storage, valid values, and readiness.
    ...

def predict_construction_cost(architecture, target_policy):
    # Separate payload, metadata, buffers, and execution headroom.
    ...

def E00(config):
    # Validate lifecycle predictions with small supported cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not treat a reported logical byte size as physically resident data on meta. A successful metadata-only forward is not numerical validation of real weights. A model can contain a mixture of meta and real tensors, so inspect all relevant parameters and buffers rather than one representative weight. Preserve unknown or unsupported state explicitly. A materialized model whose contents have never been initialized or loaded must remain unavailable for numerical use.

Part 7 - Engineering Interpretation and Philosophy

Meta construction separates knowing what a model requires from paying for its values. That separation is useful for planning, but it does not create missing data or promise cheap execution. A trustworthy loader makes every transition from description to valid resident state explicit.

19.31.2 Exercise 01

Exercise Title: Create PyTorch Tensors on device="meta" and Inspect Shape, Stride, Dtype, and Gradient Metadata Without Allocating Real Storage

Part 1 - Exercise Contract and Why It Matters

Create ordinary dense meta tensors and inspect their metadata without materializing element data. Compare shape, strides, dtype, device, element count, and gradient flags across factory and view operations. State which observations describe logical structure and which would require actual values.

Part 2 - System and Memory Mental Model

A meta factory can describe a tensor with a very large logical shape without allocating its element payload. A stride change or view can remain metadata-only when a supported meta implementation exists. Data-dependent results such as a scalar value extraction cannot be inferred from shape alone. Gradient metadata and even a structural autograd graph are not numerical gradients. Keep these facts separate from process overhead and unsupported meta operators.

Part 3 - Quantitative Prediction Before Execution

For a contiguous shape (a, b, c), derive expected element count and strides before execution. Predict metadata after a transpose and a compatible reshape. Calculate nominal bytes for two dtypes but label that quantity future logical payload. List expected outcomes for metadata inspection, a supported shape-only operation, scalar extraction, and an operation whose result shape depends on values. Do not predict zero host RSS merely because the payload is absent.

Part 4 - Experimental Design and Instrumentation

Choose small hand-checkable shapes plus a bounded larger shape. Complete meta factories and collect public metadata in CPU-only records. Compare with tiny real tensors having the same structure and layout. Feature-test operator support rather than assuming every PyTorch operation has a meta kernel. Add intentional value-dependent probes in isolated cases and record their actual failure categories. Measure the process baseline separately from newly created tensor metadata, and do not inspect pointers as though meta addresses proved real backing allocations.

Compare metadata inspection with a tiny real tensor only after matching the layout contract. CPU and CUDA metadata behavior can differ for some operators. Preserve the intended target semantics and treat a structural disagreement as a case requiring investigation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class TensorMetadata:
    shape: tuple
    strides: tuple
    dtype: object
    device: object
    requires_grad: bool
    is_meta: bool
    logical_elements: int

def construct_meta_case(shape, dtype, requires_grad):
    # Create the requested metadata-only tensor explicitly.
    ...
```

```
def inspect_metadata(tensor):
    # Export structural fields without scalar value extraction.
    ...

def E01(config):
    # Compare structural predictions and supported/unsupported probes.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact agreement on the declared metadata in supported cases. Record unsupported kernels independently from value-dependent impossibility. Empty shapes and noncontiguous views need their own predictions. A storage object's logical capacity, if exposed, is not evidence of allocated real data. Do not silently replace a failed meta operation with a real CPU allocation and then report the result as a metadata-only experiment.

Part 7 - Engineering Interpretation and Philosophy

Metadata is useful information with precise limits. The exercise succeeds when the learner can state what a meta tensor establishes, what remains unknown until values exist, and what a missing operator implementation prevents within the tested software version.

19.31.3 Exercise 02

Exercise Title: Compare CPU, CUDA, and Meta Tensor Construction and Measure the RAM and VRAM Avoided by Meta Allocation

Part 1 - Exercise Contract and Why It Matters

Compare CPU, CUDA, and meta construction at matching shapes and dtypes. Measure host process changes, CUDA allocated/reserved peaks, and complete phase times. Separate uninitialized allocation from initialization so deferred physical page commitment or skipped value production does not distort the comparison.

Part 2 - System and Memory Mental Model

CPU allocation can reserve virtual space before every page is physically touched. CUDA context and allocator setup can dominate a first tensor. Meta avoids element payload but still creates host metadata. An empty real tensor and a filled real tensor therefore test different commitment boundaries. Reported tensor bytes, RSS, virtual size, allocator bytes, and driver-visible usage are different measurements and must not be merged into one memory number.

Part 3 - Quantitative Prediction Before Execution

Predict nominal payload $b = ns$ for each real tensor and zero real element payload for its meta counterpart. Add expected framework and metadata overhead as separate unknown or measured terms. Predict CPU RSS before and after touching all elements and CUDA peaks with a warmed context. Construct a timeline showing why a quick empty allocation cannot establish the full resident cost of an initialized model or a future execution.

Part 4 - Experimental Design and Instrumentation

Run independent bounded processes for each device and phase. Record a baseline, factory return, explicit real-data initialization, and release observations. Use supported process-memory instruments and named CUDA counters, with explicit synchronization for completed GPU phases. Choose sizes admitted by a safe preflight estimate; skip unsupported CUDA rather than inventing measurements. Repeat small and larger cases, preserving cold-context and warmed-context results separately. State whether page touching, validation, garbage collection, and allocator cache retention are included in every reported interval.

For CPU initialized trials, record whether data pages were actually touched. For CUDA trials, record when the context was first created. These controls prevent a virtual reservation or one-time framework startup from being confused with parameter-payload savings.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ConstructionMeasurement:
    device_kind: str
    phase: str
    rss_bytes: object
    virtual_bytes: object
    cuda_allocated_bytes: object
    cuda_reserved_bytes: object
    elapsed_seconds: object

def construct_and_measure(shape, dtype, device, phase, config):
    # Keep allocation and value initialization as distinct regions.
    ...

def compare_device_trials(trials, measurement_contract):
    # Compare matching commitment and completion boundaries only.
    ...

def E02(config):
    # Preflight sizes and retain unavailable/unsupported outcomes.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the same logical shape and dtype and distinguish factory latency from initialization latency. A sampled RSS value is not a guaranteed process high watermark. A meta timing need not beat a tiny CPU operation. Report process, allocator, and physical-memory uncertainty

honestly. Avoid a deliberately unsafe real allocation merely to demonstrate OOM; predicted oversized real cases can remain analytically classified and unexecuted.

Part 7 - Engineering Interpretation and Philosophy

Avoided payload is a structural benefit; measured resident savings depend on commitment, caching, and observation boundaries. The meaningful comparison names those boundaries and includes the future cost when data is eventually needed.

19.31.4 Exercise 03

Exercise Title: Instantiate an Entire nn.Module Inside with torch.device("meta") and Verify That Its Parameters Contain Metadata but No Real Values

Part 1 - Exercise Contract and Why It Matters

Construct an entire supported module under a meta device context and audit all registered parameters and buffers. Verify that its architecture and metadata match a tiny real reference while identifying any constructor work that escapes the metadata-only contract.

Part 2 - System and Memory Mental Model

A device context supplies a default to eligible factory calls; an explicit CPU or CUDA argument can override it. Constructors may also allocate ordinary Python data, load files, perform value-dependent decisions, or retain unregistered tensors. Meta support must therefore be checked for the concrete module rather than inferred from one context manager. Registered persistent and nonpersistent buffers both matter for later execution, even though their checkpoint participation differs.

Part 3 - Quantitative Prediction Before Execution

Predict parameter shapes and element counts for a short multilayer module including a registered buffer. Estimate future parameter and buffer payloads separately. Add a deliberately explicit CPU factory inside one test constructor and predict how a complete audit detects the escape. Compare module count, parameter-object count, and logical element count without treating tied names as independent physical values.

Part 4 - Experimental Design and Instrumentation

Define a transparent small module with known submodules and buffer registration. Complete construction in the requested device context and traverse all registered state with duplicate handling documented. Compare shapes, dtypes, requires-grad flags, and expected buffer persistence against a real reference. Audit declared constructor-owned nonregistered resources separately. Include one explicit-device escape and one value-dependent constructor as negative controls. Do not run a real numerical forward through a model that still contains unmaterialized required state.

Inspect buffers registered with persistence disabled even though they do not appear in an ordinary state dictionary. A checkpoint-key audit alone cannot verify all execution state; maintain an architecture inventory covering both checkpointed and separately initialized resources.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn

@dataclass
class StateAudit:
    name: str
    role: str
    shape: tuple
    dtype: object
    device: object
    is_meta: bool
    checkpoint_expected: bool

def build_module_on_meta(factory, architecture):
    # Apply the context and construct only the supported architecture.
    ...

def audit_module_state(model, declared_extra_resources):
    # Include parameters, all registered buffers, and explicit escapes.
    ...

def E03(config):
    # Compare the structural reference and constructor escape controls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires that every required payload is meta in the supported case, not merely that the first parameter is meta. Record legitimate exceptions or fail the zero-data construction contract. A missing persistent checkpoint entry and a nonpersistent buffer are different conditions. Exclude unsupported custom constructors from broad claims and keep structural agreement separate from numerical model equivalence.

Part 7 - Engineering Interpretation and Philosophy

A construction context is a useful default, not an enforcement sandbox. Reliable deferred construction starts with an audited architecture and a complete inventory of what its constructor creates, retains, and requires for later readiness.

19.31.5 Exercise 04

Exercise Title: Construct a Model Too Large to Fit in Available RAM Using the Meta Device Without Triggering an Allocation Failure

Part 1 - Exercise Contract and Why It Matters

Describe a dense model whose hypothetical real parameter payload exceeds available host RAM, then construct its metadata-only skeleton within a bounded host budget. Establish feasibility of the description without executing a known-oversized real allocation or promising that every constructor can avoid failure.

Part 2 - System and Memory Mental Model

Logical payload and metadata complexity scale differently. A few very large matrix shapes can represent enormous parameter counts with relatively few objects. Millions of separate tensors can instead exhaust host metadata despite using meta. Shape integer limits, unsupported operations, explicit device allocations, and value-dependent initialization can also fail. The title's allocation-avoidance goal concerns element payload, not immunity from every host or framework resource limit.

Part 3 - Quantitative Prediction Before Execution

For L independent dense square weights of width d and target element width s, calculate Ld^2s nominal bytes plus declared biases and buffers. Choose bounded (L, d) cases whose logical payload crosses a documented RAM reference. Predict host metadata growth for fixed L with increasing d, then for increasing L. Explain why neither experiment establishes that real weights, activations, or training state will fit.

Part 4 - Experimental Design and Instrumentation

Use a dedicated child process with a deadline and a host-memory ceiling for controlled construction tests. Preflight shape arithmetic and prohibit real materialization in the oversized path. Start with a tiny real structural reference, then scale the meta architecture in steps. Record object counts, logical bytes, process high-water evidence, elapsed time, and outcomes. Keep explicit CPU factory escapes out of the supported model and test their detection only at safe sizes. Preserve unsupported or interrupted cases without turning them into successful constructions.

Do not generate a real checkpoint of the oversized artificial model as part of this exercise. A tiny representative checkpoint is sufficient for format validation elsewhere; oversized meta construction needs no real payload file and must not silently create one.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn

@dataclass
class OversizedModelCase:
    layer_count: int
    width: int
    target_dtype: object
    logical_payload_bytes: int
    host_metadata_limit: int
```

```
def preflight_oversized_case(case, limits):
    # Check logical arithmetic and bounded metadata complexity.
    ...

def construct_bounded_meta_model(case):
    # Never create real parameter payload in the oversized path.
    ...

def E04(config):
    # Scale meta cases and report measured overhead without real OOM tests.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require an audit that all required oversized parameter payloads remain meta. A constructor interrupted by its resource limit is a failure or incomplete case, not proof of small memory. Report host overhead relative to logical bytes without calling it literally zero. Avoid checksums, cloning to real devices, or value-dependent probes that accidentally materialize or invalidate the experiment.

Part 7 - Engineering Interpretation and Philosophy

A large model can be describable before it is affordable to instantiate with values. Use that capability to reject impossible placement plans early, not to imply that a logical billion-parameter object is already an executable or trainable resident model.

19.31.6 Exercise 05

Exercise Title: Calculate the Future Parameter Memory Footprint of a Meta Model Before Materializing Any Parameter Storage

Part 1 - Exercise Contract and Why It Matters

Calculate future parameter payload from a meta model before creating real parameter storage. Deliver named logical totals, canonical unique-parameter totals, buffer totals, and declared layout assumptions. Distinguish an estimate for dense weights from a complete training-memory budget.

Part 2 - System and Memory Mental Model

Shape and target dtype determine nominal dense payload, but names can refer to one tied parameter. Distinct parameter objects can also share regions under an explicitly declared architecture. Meta addresses cannot serve as real storage identity evidence. Use architectural ties and canonical ownership records rather than grouping every meta tensor by a nonexistent data address. Target conversion, padding, quantization metadata, sparse layouts, and future optimizer state require separate models.

Part 3 - Quantitative Prediction Before Execution

For canonical dense parameters p with shape dimensions $h_{p,k}$, compute $B_{\text{parameters}} = \sum_p s_p \prod_k h_{p,k}$. Calculate a named sum as a separate diagnostic and explain the gap from tied names. Add

registered buffers without merging them into parameter count. Compare target float32 and bfloat16 plans, then identify exclusions such as allocator rounding, activations, gradients, master weights, and optimizer state.

Part 4 - Experimental Design and Instrumentation

Create a small architecture containing an ordinary parameter, a tied parameter with two names, and a buffer. Enumerate with duplicate handling explicit and build a canonical alias manifest. Check the formulas against a tiny real model with the same declared ties. Test integer, floating, and frozen parameter metadata without assuming all buffers use the default parameter dtype. Export bytes and MiB/GiB with conversion units stated. Reject unsupported sparse or quantized accounting rather than silently applying dense element-width formulas.

For one Parameter object registered under several names, preserve every name while counting its canonical payload once. For distinct shared views, require an explicit storage/region manifest rather than assuming object-identity deduplication completely captures physical sharing.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ParameterEstimate:
    canonical_key: str
    names: tuple
    shape: tuple
    source_dtype: object
    target_dtype: object
    nominal_bytes: int

def canonicalize_parameter_names(model, architecture_aliases):
    # Preserve true ties without treating meta pointers as identities.
    ...

def estimate_dense_payload(records, target_policy):
    # Compute target bytes and retain excluded/unsupported categories.
    ...

def E05(config):
    # Validate tied and untied estimates against a tiny real model.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact arithmetic for the supported dense case and a traceable mapping from each name to canonical ownership. A nominal total is not a physical peak or driver allocation prediction. Detect incompatible target-device or dtype requests for a single tied group. Report whether frozen weights still occupy storage and why the absence of gradients changes training additions rather than removing the weight payload itself.

Part 7 - Engineering Interpretation and Philosophy

Planning improves when totals preserve ownership and scope. The useful number is not the largest impressive parameter count, but an auditable payload estimate that states what is counted once, what remains separate, and which execution costs have not yet been budgeted.

19.31.7 Exercise 06

Exercise Title: Traverse a Meta Model and Build a Layer-by-Layer Memory Plan from Parameter Shapes, Dtypes, and Target Devices

Part 1 - Exercise Contract and Why It Matters

Traverse a meta model and produce a layer-level placement and memory plan before materialization. Map every required parameter and buffer to a target device, dtype policy, canonical owner, and loading group. Include transfer boundaries and headroom rather than optimizing weight bytes in isolation.

Part 2 - System and Memory Mental Model

Module hierarchy is not always a unique ownership tree: modules and parameters can be shared across paths. Layer-level device choices must therefore agree with canonical tied groups. Buffers and inputs must be compatible with the operations that use them. A mixed CPU/CUDA assignment does not automatically insert activation transfers or provide a dynamic execution engine. Keep the placement description separate from the mechanism that will execute it.

Part 3 - Quantitative Prediction Before Execution

For each target device d, calculate canonical planned payload $B_d = \sum_{g:\text{place}(g)=d} B_g$. Add known buffers and named margins for staging, activations, and libraries. Draw a sequential model split between CPU and CUDA and count activation transfer boundaries. Introduce a tied group spanning two layers and predict why conflicting placements require rejection or an explicitly changed replication contract.

Part 4 - Experimental Design and Instrumentation

Freeze a small architecture and build a complete name-to-owner manifest. Traverse parameters and buffers without dropping shared paths, then assign canonical groups. Validate device/dtype compatibility, budgets, and expected execution transfers in a host simulator. Compare predicted payloads with a tiny materialized plan and verify output parity using explicit transfers. Include missing-map entries, double-counted shared weights, and unsupported custom modules as negative controls. Record plan and architecture version IDs so later loading cannot silently use stale shapes or ownership.

Record whether placement groups are execution layers or larger canonical tie groups. They need not coincide. A cross-layer shared weight can force several layer names to follow one ownership decision even when their other parameters are placed independently.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PlacementGroup:
    group_id: str
    state_names: tuple
    canonical_owners: tuple
    target_device: object
    target_dtype: object
    predicted_payload_bytes: int

def build_layer_inventory(model, alias_manifest):
    # Include buffers, shared paths, and execution boundary requirements.
    ...

def validate_placement(groups, budgets, execution_contract):
    # Check coverage, ties, dtypes, and target headroom before allocation.
    ...

def E06(config):
    # Compare host predictions with a bounded materialized reference.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Every required state entry needs a target or an explicit deferred status. Reject conflicting tied-owner placements and distinguish unsupported execution from a valid storage map. A lower GPU weight total is not proof the next forward fits. Preserve modeled and unmodeled headroom separately; do not interpret a software weight budget as a guarantee about external device memory pressure.

Part 7 - Engineering Interpretation and Philosophy

A placement map is a resource contract for a concrete execution plan. It becomes useful when ownership, required values, transfer boundaries, and headroom are all visible before the loader commits real storage.

19.31.8 Exercise 07

Exercise Title: Reproduce the Failure of Trying to Copy Data Directly Out of a Meta Tensor and Explain Why Meta Tensors Have No Underlying Values

Part 1 - Exercise Contract and Why It Matters

Reproduce failure when attempting to copy values directly from a meta tensor to CPU or CUDA. Explain the difference between moving known contents and creating new storage with newly supplied contents. Provide legal alternatives without pretending that meta had retained original random or checkpoint data.

Part 2 - System and Memory Mental Model

A meta tensor describes possible data but contains no element values to copy. A factory can allocate a compatible real tensor, and module materialization can create uninitialized real state, but neither operation reconstructs missing weights. Loading a checkpoint with meta mapping can inspect structure while also discarding access to real loaded values in that object. Keep the original checkpoint source available when later materialization needs authoritative contents.

Part 3 - Quantitative Prediction Before Execution

Predict the outcomes of metadata inspection, direct conversion to CPU, conversion to CUDA, a compatible real factory, and initialization from a separately defined rule. For each, state whether it preserves existing values, creates unspecified values, or supplies valid new values. Calculate target payload from shape and dtype without labeling it transferred data. Define the expected failure phase and distinguish it from CUDA unavailability or OOM.

Part 4 - Experimental Design and Instrumentation

Use tiny ordinary meta tensors and one small real reference. Isolate each conversion probe with a specific expected outcome and preserve the actual exception category/message. Complete a legal real-allocation path and then initialize or load it from an explicit authority before numerical comparison. Test scalar extraction separately from device conversion. Avoid catching every exception as the intended no-data failure. If CUDA is unavailable, retain the CPU reproduction and mark that CUDA case untested rather than fabricating it.

If the source was itself loaded with a meta map location, retain the checkpoint path as the authority for a later real load. The meta object is a structural representation, not a lazy real-valued source that ordinary copying can recover.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ConversionOutcome:
    operation: str
    expected_status: str
    observed_status: str
    value_authority: str
    failure_phase: object
```

```
def probe_meta_conversion(meta_tensor, target, support):
    # Capture the specific no-data outcome separately from other errors.
    ...

def allocate_and_supply_values(metadata, target, authority):
    # Distinguish storage creation from initialization/checkpoint data.
    ...

def E07(config):
    # Compare forbidden copies and valid authority-backed alternatives.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires the intended no-values failure in the supported direct-copy case and correct values only after a declared authority supplies them. A real empty tensor is not equivalent to a previously initialized model. Do not replace the source with arbitrary zeros and claim successful copying. Preserve shape and dtype agreement as structural evidence, not proof that unknown weights were recovered.

Part 7 - Engineering Interpretation and Philosophy

A failed copy reveals a missing information source rather than merely a missing memory block. The repair must answer where valid contents come from, then allocate storage and publish those contents under an explicit readiness contract.

19.31.9 Exercise 08

Exercise Title: Materialize a Meta Module with Module.to_empty() and Initialize Its Real Parameters Safely on CPU or CUDA

Part 1 - Exercise Contract and Why It Matters

Materialize a small supported meta module with the module empty-materialization API, then supply valid parameters and buffers before execution. Demonstrate that allocated storage and initialized values are different states. Preserve shared parameter relationships and construct optimizers only after final parameter identity and placement are established.

Part 2 - System and Memory Mental Model

Empty materialization creates device storage without copying nonexistent meta values. The resulting contents must be initialized or loaded, including required buffers that are not trainable parameters. A generic recursive initialization pass can initialize shared objects repeatedly or miss module-specific state. Use a declared per-module initialization policy and canonical ownership ledger. Avoid applying whole-model empty materialization after some weights have already been loaded, because it can replace valid state with uninitialized storage.

Part 3 - Quantitative Prediction Before Execution

Predict target parameter and buffer bytes, initial host metadata, and allocation peaks. Define readiness transitions from meta to allocated-uninitialized to initialized-verified. For a

tied parameter, calculate capacity once and predict what verification is needed after conversion. Specify a deterministic initialization rule for a tiny model so expected values and outputs can be computed without relying on an assumed unchanged random-number consumption order.

Part 4 - Experimental Design and Instrumentation

Audit the meta skeleton, materialize once on a chosen CPU or CUDA target, and mark every required entry unready. Complete an initialization pass covering parameters, persistent buffers, and nonpersistent execution buffers. Verify values, dtypes, devices, and ties before a tiny forward. Compare with an independent model initialized by the same declared rule. Test a deliberately omitted buffer and require readiness rejection before execution. Measure allocation and initialization as separate phases.

Define initialization callbacks for the supported architecture explicitly. Not every container implements a reset method, and blindly applying callbacks at both parent and child levels can repeat initialization. Verify canonical values and required buffer contents after the pass.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn

@dataclass
class StateReadiness:
    canonical_key: str
    storage_allocated: bool
    values_supplied: bool
    source: str
    verified: bool

def materialize_empty(model, target, ownership_manifest):
    # Allocate supported state once and invalidate value readiness.
    ...

def initialize_required_state(model, policy, readiness):
    # Initialize each canonical parameter and every required buffer.
    ...

def E08(config):
    # Verify contents/ties before forwarding or creating an optimizer.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Never validate uninitialized memory by checking whether it happens to look finite. Require positive evidence that every entry received its intended values. Re-audit tied identity and shared storage after conversion rather than assuming preservation. An initialization routine unsupported by the architecture must fail explicitly. A successful allocation is not a successful numerical model construction until readiness and reference checks pass.

Part 7 - Engineering Interpretation and Philosophy

Materialization is a controlled resource transition, not value recovery. An explicit readiness ledger prevents accidental execution on garbage contents and makes it clear whether weights came from initialization, a checkpoint, or another declared authority.

19.31.10 Exercise 09

Exercise Title: Compare Ordinary Model Initialization Against Meta Construction Followed by to_empty() by Peak RAM, Peak VRAM, and Initialization Time

Part 1 - Exercise Contract and Why It Matters

Compare ordinary real model construction and initialization with meta construction followed by empty materialization and the same valid initialization. Measure complete readiness time, peak host memory, peak VRAM, and final state. Do not confuse skipping useful initialization with making initialization cheaper.

Part 2 - System and Memory Mental Model

Meta can avoid a real default initialization that would otherwise be replaced, but a newly initialized model still needs valid values eventually. Constructors may perform architecture work independent of payload. Allocation, page touching, CUDA setup, and initialization each influence measured peaks and latency. Equal random seeds alone do not guarantee equal initialized values if the two paths consume random streams differently; define the equivalence policy explicitly.

Part 3 - Quantitative Prediction Before Execution

Draw phase timelines for direct construction and deferred construction. Calculate final dense payload and identify any avoidable temporary or duplicate initialization. Predict a case with little improvement because both routes must initialize the same final weights, and a case where an ordinary temporary CPU model precedes CUDA placement. Mark the latter as a separate baseline rather than silently comparing it with direct CUDA construction.

Part 4 - Experimental Design and Instrumentation

Use a supported transparent architecture and a deterministic initialization rule for the primary comparison. Run isolated trials from matching process and CUDA context states. Record construction return, allocation completion, initialization completion, verification, and first-ready-forward boundaries. Touch real data through legitimate initialization, not arbitrary benchmark-only reads. Compare final values, buffers, and ties before reporting performance. Repeat cold and warmed trials, stating whether checkpoints, page cache, constructor defaults, and validation are part of the experiment.

Use a separate numerical equivalence run when verifying every tensor would change the timing region. If verification is part of readiness, include that cost consistently in both strategies. The benchmark must state which boundary it actually measures.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class InitializationTrial:
    strategy: str
    architecture_id: str
    initialization_policy: str
    peak_rss_bytes: object
    peak_cuda_allocated: object
    complete_ready_seconds: object
    equivalent: bool

def run_initialization_strategy(factory, strategy, policy, config):
    # Measure all phases through verified real values and readiness.
    ...

def compare_ready_models(reference, candidate, contract):
    # Check values, buffers, ownership, and supported outputs.
    ...

def E09(config):
    # Compare equivalent complete initialization, including adverse cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A timer ending before value initialization is not comparable with a fully initialized baseline. Report default initialization skipped and final initialization performed separately. Preserve CPU high-water uncertainty and CUDA context overhead. If numerical initialization differs, classify the comparison accordingly instead of presenting a memory benefit as evidence of exact model equivalence. Retain neutral or slower deferred-construction results.

Part 7 - Engineering Interpretation and Philosophy

Deferred construction is most valuable when it removes work that the final state does not need. The honest benchmark follows both paths to the same verified readiness boundary and explains whether it saved payload overlap, initialization work, or neither.

19.31.11 Exercise 10

Exercise Title: Load a Checkpoint with torch.load(..., mmap=True, weights_only=True) While Avoiding an Eager Full-RAM Copy of Tensor Storage

Part 1 - Exercise Contract and Why It Matters

Load a locally generated, supported checkpoint using memory mapping and the restricted weights-only path. Compare mapping, first value access, complete value access, and ordinary eager loading. Demonstrate avoidance of an eager full payload copy without equating mapping with zero RAM use or zero disk I/O.

Part 2 - System and Memory Mental Model

Mapping makes supported serialized storage accessible through virtual memory; physical pages become resident as touched and managed by the operating system. Tensor dictionaries and metadata still deserialize. Use an explicit CPU map location so saved CUDA tags do not trigger unintended GPU placement. The weights-only flag restricts deserialization; it does not mean only trainable parameters are returned or that all metadata and buffers disappear. A standard path-based compatible checkpoint format is part of the initial contract.

Part 3 - Quantitative Prediction Before Execution

Let B be checkpoint storage payload and B_t the subset accessed so far. Predict mapped virtual space, metadata cost, file-backed residency, anonymous copy demand, and page-cache effects separately. Compare mapping return with a full-read checksum phase. Predict how dtype conversion or a GPU transfer can create new allocations and force source pages to be read. Do not call reduced return latency a completed full-model I/O speedup.

Part 4 - Experimental Design and Instrumentation

Generate a small trusted plain tensor state dictionary outside the measured region and save it with a supported current serialization format. Feature-check path-based mapping support and record platform/filesystem details. Complete ordinary and mapped loads with explicit CPU placement. Measure baseline, load return, bounded subset access, complete data access, and release phases. Keep file-cache state described as observed or uncontrolled rather than claiming a cold run without evidence. Test unsupported file-object or format cases through documented rejection, not guessed compatibility.

Keep the backing checkpoint immutable for the initial mapping experiment. A separate controlled mutation test should record mapping policy and any private page growth; it must not overwrite the evidence source or assume changes are written back automatically.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MappingPhase:
    phase: str
    virtual_bytes: object
    rss_bytes: object
    anonymous_bytes: object
    file_backed_bytes: object
    elapsed_seconds: object
```

```
def load_checkpoint_mapping(path, support_contract):
    # Use explicit mmap, weights_only, and CPU map-location choices.
    ...

def measure_checkpoint_access(state, access_schedule, config):
    # Separate mapping return from actual payload touch and conversion.
    ...

def E10(config):
    # Compare phase-matched eager and mapped runs with valid files.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate tensor keys, shapes, dtypes, and actual values on the bounded case. An unsupported mapping option must not silently fall back to eager loading inside the mapped benchmark. Deleting a local variable does not guarantee mapping release while tensor aliases survive. Record private-copy behavior if mutation is tested under the supported platform's default mapping policy; do not assume mapped training updates are free or persisted to the file.

Part 7 - Engineering Interpretation and Philosophy

Memory mapping changes when storage is read and copied, not whether useful values eventually require physical resources. A good result distinguishes lazy access, reduced anonymous duplication, page residency, and complete readiness cost.

19.31.12 Exercise 11

Exercise Title: Load Memory-Mapped Checkpoint Tensors into a Meta-Initialized Model with load_state_dict(assign=True)

Part 1 - Exercise Contract and Why It Matters

Load a mapped real checkpoint into a meta skeleton using assignment semantics. Verify values, device/dtype properties, remaining meta state, parameter identity, and tied relationships. Establish when the model becomes ready and create the optimizer only after its final parameter set and placement are settled.

Part 2 - System and Memory Mental Model

Ordinary state loading generally copies into existing destinations; copying into meta does not supply real resident values. Assignment can install the state dictionary's real tensor properties instead, while parameter gradient requirements follow the module contract. CPU-mapped weights do not become CUDA weights merely because the skeleton's intended execution target was CUDA. Shared references can keep the mapped storage alive after the source dictionary is removed. Architecture ties need explicit verification.

Part 3 - Quantitative Prediction Before Execution

Predict the state of a CPU-mapped parameter before and after assignment into meta. Compare it with copying into a preallocated real destination and with ordinary loading into meta. Calculate payload overlap under each ownership model, avoiding double counting a model and dictionary sharing the same backing storage. Predict which registered nonpersistent buffers remain meta and why checkpoint assignment alone cannot make those buffers ready.

Part 4 - Experimental Design and Instrumentation

Create matching tiny source and meta architectures with persistent and nonpersistent state plus a declared tie. Load the supported checkpoint on CPU with mapping, audit keys and shapes, and complete assignment. Inspect missing and unexpected keys rather than using non-strict loading as blanket acceptance. Supply any required noncheckpoint state, verify ties and real values, finalize placement, and only then construct an optimizer if training is tested. Remove source references and verify model values remain valid without claiming their storage was freed.

Record model-state properties after assignment rather than only before it. The skeleton's requested dtype is not a conversion instruction for assigned checkpoint tensors. Any required target cast or transfer needs its own explicit operation, memory estimate, and validation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AssignmentAudit:
    missing_keys: tuple
    unexpected_keys: tuple
    remaining_meta_names: tuple
    incorrect_devices: tuple
    broken_ties: tuple
    values_verified: bool

def assign_mapped_state(model, mapped_state, contract):
    # Validate schema, apply assign semantics, and audit final state.
    ...

def finish_noncheckpoint_state(model, initialization_policy):
    # Supply required nonpersistent buffers and other declared values.
    ...

def E11(config):
    # Verify readiness/ownership before optional optimizer creation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A successful key-match message is not sufficient readiness evidence. Check all execution-required state, final device/dtype, and parameter references. Do not call empty materialization after assignment as a way to move valid checkpoint weights; it does not preserve their contents. If tying must be reestablished, use a declared canonical binding and validate values and gradient behavior before constructing the optimizer.

Part 7 - Engineering Interpretation and Philosophy

Assignment is an ownership transition, not a promise of a new independent copy or automatic target-device placement. Its benefit comes from avoiding unnecessary duplicate destinations while making the final model's actual values and references explicit.

19.31.13 Exercise 12

Exercise Title: Compare Conventional Checkpoint Loading Against mmap=True + meta + assign=True and Quantify Peak Host-Memory Reduction

Part 1 - Exercise Contract and Why It Matters

Compare conventional checkpoint loading with the combined mapped-checkpoint, meta-skeleton, and assignment path. Quantify host memory, VRAM, and complete ready-to-use latency at matching workload boundaries. Report reduced duplication separately from differences in page residency or lazy return time.

Part 2 - System and Memory Mental Model

A conventional path can hold initialized model payload and checkpoint payload at once before copying. The combined path can avoid that duplicate destination when it adopts compatible real checkpoint storage. File-backed pages still consume resources as accessed, and GPU placement creates device storage and reads source pages. Model, state dictionary, and mapped file may share owners; count unique backing rather than adding every named tensor's bytes.

Part 3 - Quantitative Prediction Before Execution

Draw phase peaks for construct/load/copy and map/meta/assign. Estimate a nominal two-payload overlap only under explicitly independent dense model and checkpoint storage assumptions. Add target conversion, buffers, and GPU transfer staging where used. Predict CPU-resident and GPU-ready final variants separately. Calculate memory reduction at a specified boundary and explain why mapping-only RSS and first-complete-forward RSS can differ substantially.

Part 4 - Experimental Design and Instrumentation

Use identical architecture, checkpoint, final dtype/device, execution mode, and required buffers. Run isolated process trials with recorded baseline and cache context. Verify keys, values, ties, and a real forward before accepting readiness. Measure mapping return, assignment/copy completion, target placement, and first useful execution separately. Capture supported host high-water metrics and CUDA peaks, with absolute values rather than hidden postallocation deltas. Repeat trial order and retain neutral or adverse results.

Compare peak measurements in isolated processes when earlier allocations or mappings would otherwise contaminate the next strategy. Resetting a CUDA peak counter does not reset process RSS history or the operating system file cache, so preserve those distinctions.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LoadingTrial:
    strategy: str
    final_device_policy: str
    checkpoint_id: str
    peak_host_bytes: object
    peak_cuda_bytes: object
    ready_seconds: object
    first_forward_seconds: object
    equivalent: bool

def conventional_load(factory, checkpoint_path, target, config):
    # Include the declared real constructor and loading overlap.
    ...

def mapped_meta_assign_load(factory, checkpoint_path, target, config):
    # Include all phases through the same verified readiness boundary.
    ...

def E12(config):
    # Compare equivalent resident models, not only load-return times.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Fail comparisons where one model remains meta, uninitialized, on another device, or missing buffers. A lower RSS can reflect untouched file pages rather than permanently removed resource demand; explain the access schedule. If host instrumentation lacks a true high-water metric, label sampled estimates. Do not claim complete-model reduction from a tiny inspected subset or omit final conversion cost for only one strategy.

Part 7 - Engineering Interpretation and Philosophy

The strongest comparison follows equivalent data to equivalent readiness. Savings should be attributable to removed duplicate storage or work, with laziness and cache effects described separately so the conclusion survives real model use.

19.31.14 Exercise 13

Exercise Title: Reproduce an Optimizer Reference Bug Caused by Creating the Optimizer Before load_state_dict(assign=True) and Repair the Initialization Order

Part 1 - Exercise Contract and Why It Matters

Reproduce a stale optimizer-reference bug by creating the optimizer before assignment-based loading under a configuration that replaces parameter objects. Repair the order and verify that the optimizer updates the model's current parameters. Distinguish version/configuration-dependent reference preservation from a failed reproduction.

Part 2 - System and Memory Mental Model

An optimizer holds parameter references and may also hold state indexed by those parameters. Assignment or later conversion can invalidate an optimizer created too early. Supported swap-based behavior can preserve references in some configurations, so record the actual future-flag and software version. The robust initial protocol is load, finalize dtype/device and ties, verify state, then construct the optimizer. Identity mismatch and absent model updates provide stronger evidence than a step call returning normally.

Part 3 - Quantitative Prediction Before Execution

List parameter identities held by the model and optimizer before loading, after assignment, and after final placement. Predict gradients and updates for a stale optimizer versus a correctly constructed one. Define an equality check on the current parameter set and a tiny loss whose nonzero gradients should produce a detectable update. Include optimizer state bytes separately from weight payload and distinguish state initialization from model loading.

Part 4 - Experimental Design and Instrumentation

Use a tiny controlled checkpoint and fresh model per trial. Explicitly select and record a supported replacement configuration for the main reproduction, restoring global configuration afterward. Construct the early optimizer, assign the state, run forward/backward, and inspect which objects receive gradients and which objects the optimizer owns. Repeat with final-order construction and compare updates. Add a reference-preserving configuration as a distinct control when available; if the bug does not reproduce, retain that observed outcome rather than inventing stale references.

For the repaired case, inspect optimizer-owned references after final placement and retie operations, not just immediately after loading. A later parameter replacement can recreate the same class of bug even when the initial loading order was correct.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class OptimizerReferenceAudit:
    model_parameter_ids: tuple
    optimizer_parameter_ids: tuple
    missing_current_parameters: tuple
    stale_parameters: tuple
    current_update_verified: bool
```

```
def audit_optimizer_references(model, optimizer):
    # Compare live parameter identity sets and declared tied ownership.
    ...

def run_optimizer_order_case(factory, state, order, swap_policy):
    # Build fresh state, load/place, and verify actual gradients/updates.
    ...

def E13(config):
    # Compare early creation, repaired order, and supported controls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not treat a silent optimizer step as proof that model weights changed. Check named current parameters and expected updates. Rebinding optimizer parameter groups alone may leave old momentum or other state inconsistent; use fresh construction for the primary repair. Record whether a later device conversion changes identity. The reference audit must occur after all loading, retie, and placement operations that can alter parameter ownership.

Part 7 - Engineering Interpretation and Philosophy

Initialization order is part of correctness whenever components retain object references. The repair is to publish a stable final parameter set before building dependent optimizer state, with explicit tests for the actual runtime configuration.

19.31.15 Exercise 14

Exercise Title: Materialize Different Meta Model Layers Directly onto CPU and CUDA According to a Precomputed Memory Placement Map

Part 1 - Exercise Contract and Why It Matters

Materialize distinct meta model groups directly on planned CPU or CUDA targets without first creating the complete real model on one device. Preserve valid contents, buffers, canonical ties, and a complete name-to-location audit. Keep storage placement separate from the transfers needed for execution.

Part 2 - System and Memory Mental Model

A whole-model recursive materialization can overwrite or relocate already loaded state, so selective work must respect owning modules and recurse policy. For supported independent layer groups, allocate only that group's required state, then initialize or copy authoritative values. Cross-group ties need one canonical storage contract and compatible placement. Assigning a CPU checkpoint tensor to a meta parameter installs CPU state unless a target conversion was explicitly performed; a placement map alone changes no tensor. Choose target dtypes while state is still meta when the supported architecture permits it, so a later real-to-real cast does not introduce an avoidable full group copy.

Part 3 - Quantitative Prediction Before Execution

Calculate target payload per canonical group and device. Include the largest overlap of live source values, conversion workspace, and target destinations. Draw a three-layer CPU/CUDA split with explicit activation transfers. Compare direct group placement with an unnecessary full CPU model followed by transfer. Add a tie spanning proposed devices and predict refusal unless the model's semantics explicitly permit replication and its consistency obligations are separately implemented.

Part 4 - Experimental Design and Instrumentation

Validate the complete map before allocating. Complete one supported group's allocation and value supply at a time, avoiding recursive actions on already ready descendants. Audit parameters, persistent buffers, and nonpersistent execution state after each group. Verify final ties and values against a tiny ordinary reference. Execute with explicit activation transfer boundaries and record their cost. Test missing entries, conflicting ties, and a midload failure that must not publish a partially ready model.

Before materializing a group, check that its ownership boundary does not recurse into an already loaded child. Use the actual module API's supported recurse behavior and an explicit group manifest rather than relying on incidental attribute traversal order.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MaterializationGroup:
    group_id: str
    owner_names: tuple
    target_device: object
    target_dtype: object
    source_keys: tuple
    expected_bytes: int

def materialize_group(model, group, authority, ownership):
    # Allocate only intended owners and supply valid target values.
    ...

def verify_group_placement(model, group, readiness):
    # Check buffers, ties, dtype/device, and authoritative contents.
    ...

def E14(config):
    # Validate the map, load groups, and execute a tiny mixed-device case.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require every ready group to remain valid after later groups are processed. Detect accidentally recursive materialization and changed tied bindings. A mixed-device forward failure is not necessarily a loading error; inspect input and activation placement. Record unavailable CUDA as unsupported or untested, not successful placement. A final CPU weight sharing mapped source storage remains an owner even after loader-local references are dropped.

Part 7 - Engineering Interpretation and Philosophy

Direct placement removes unnecessary intermediate ownership only when the loader follows the canonical map precisely. Its result should be a verified resident state with explicit execution boundaries, not merely a collection of tensors distributed across devices.

19.31.16 Exercise 15

Exercise Title: Load and Materialize Model Parameters One Layer at a Time Instead of Creating the Entire Real Model in Memory Simultaneously

Part 1 - Exercise Contract and Why It Matters

Load real state into a meta skeleton one supported layer or ownership group at a time. Bound temporary source/conversion demand and preserve final model values. Distinguish construction-time incremental loading from execution-time offloading: final resident weights still accumulate when every layer remains loaded.

Part 2 - System and Memory Mental Model

Incremental materialization can avoid a duplicate full real destination model, but it does not make retained final payload disappear. A standard mapped checkpoint exposes a full metadata dictionary while allowing selected data access; it is not automatically a per-key file-stream API. Sharded checkpoints provide another explicit access model. Tied groups may cross layer boundaries and require canonical treatment larger than one syntactic layer. Source references can be released only when no retained destination or pending copy still depends on them.

Part 3 - Quantitative Prediction Before Execution

Let F_i be final payload retained after group i and T_i active temporary source/conversion capacity. Predict peak as a timeline involving $F_i + T_i$, not merely the largest layer size. Add staging and library margins separately. Compare a mapped source adopted by a CPU destination with a new converted GPU destination. Explain why deleting a source dictionary entry can remove a reference without reducing final owned CPU payload.

Part 4 - Experimental Design and Instrumentation

Create a small checkpoint with several groups and a declared tie. Freeze the source format, ordering, target map, and readiness protocol. Validate names, shapes, dtypes, and aliases before publishing values. Complete each group's materialization, verification, dependency completion, and source-reference release. Compare final values with an ordinary loader and track phase peaks. Inject a missing key and a controlled budget refusal, requiring incomplete state to remain unpublished. Record group order and failure phase for replay.

Include a source dictionary reference audit in the small case. Removing one entry can leave another tied name or local alias owning the same storage. Reference release is not equivalent to immediate physical page eviction or reduction of final model bytes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class GroupLoadState:
    group_id: str
    canonical_keys: tuple
    target_device: object
    source_status: str
    destination_status: str
    ready: bool

def load_one_group(model, source, group, placement, ledger):
    # Bound active conversion and preserve canonical ownership.
    ...

def release_group_sources(group_state, completion, retained_owners):
    # Release references only after all actual obligations finish.
    ...

def E15(config):
    # Compare final state and accumulated payload/temporary peaks.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not claim a whole resident model fits within the largest single layer's bytes. Verify all loaded parameters and required buffers, including cross-group ties. A mapped tensor assigned to the model keeps source storage alive; report that ownership instead of declaring it freed. Partial non-strict loads must reconcile intentional deferred names with accidental missing names before final readiness is granted.

Part 7 - Engineering Interpretation and Philosophy

Layerwise loading controls transient overlap, while final residency follows the placement policy. The distinction prevents a useful construction technique from being misrepresented as a complete out-of-core execution system.

19.31.17 Exercise 16

Exercise Title: Combine Meta Construction with Dynamic Parameter Placement to Build a Model Whose Initial Residency Is Determined by a Fixed VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Combine a meta skeleton with budget-aware initial parameter placement. Determine which canonical groups become GPU-resident, CPU-resident, or explicitly deferred, then load only admitted storage. Define readiness for the supported execution mode and distinguish an initial VRAM plan from a future runtime migration policy.

Part 2 - System and Memory Mental Model

GPU weight capacity is only part of useful execution demand. Inputs, activations, operator workspace, buffers, transfer staging, and external pressure also need headroom. CPU fallback consumes real host resources; deferred meta weights are not executable values. A runtime that later promotes groups needs an explicit authority, completion protocol, and execution schedule. This exercise establishes initial residency and those interfaces without pretending the placement map alone implements dynamic inference or training.

Part 3 - Quantitative Prediction Before Execution

For GPU budget V, choose group placement satisfying $B_{\text{GPU weights}} + B_{\text{GPU buffers}} + H \leq V$, with named headroom H. Compute CPU and deferred totals separately. Predict transient demand when one group is converted while earlier groups remain resident. Compare static group order and a workload-informed priority under the same budget. Reject a target below mandatory state rather than reporting a feasible plan that omits required work.

Part 4 - Experimental Design and Instrumentation

Preflight architecture, canonical ties, source availability, and both host/GPU budgets. Simulate admission before allocating and retain a decision ledger. Load accepted groups directly to their target locations, verifying actual payload and readiness after each step. Test budgets above and below a group boundary, unavailable CUDA, a tied-placement conflict, and a controlled allocation failure. Run a small supported execution schedule only after its needed groups are ready and explicit transfers are established. Record predicted and observed peaks without calling external memory availability guaranteed.

Attach an authority and readiness status to every deferred group. A group that remains meta cannot participate in an ordinary forward. The initial plan must either provide a supported promotion schedule or report that execution mode as unavailable.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class InitialResidency:
    group_id: str
    state: str
    device: object
    payload_bytes: int
    authority: str
    ready: bool
```

```
def plan_initial_residency(groups, budgets, execution_headroom):
    # Admit canonical groups without hiding CPU or deferred demand.
    ...

def execute_residency_plan(model, source, plan, ledger):
    # Materialize validated placements and preserve failure consistency.
    ...

def E16(config):
    # Test budget boundaries and verify the supported readiness contract.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A plan meeting the weight budget can still fail the first forward; preserve that distinction. CPU-resident groups must have valid data, and deferred meta groups must remain blocked from ordinary execution. Account for partial-load cleanup after failure without damaging previously authoritative sources. Report admission refusal separately from CUDA OOM and unrelated runtime errors. Training state requires a further budget beyond the initial weight placement.

Part 7 - Engineering Interpretation and Philosophy

A fixed budget is useful when it governs real commitments and states what remains outside them. Initial placement should leave a coherent authority and readiness model so later dynamic movement can be added without inventing missing values or capacity.

19.31.18 Exercise 17

Exercise Title: Build a Streaming Checkpoint Loader That Reads, Materializes, Places, and Releases Parameter Groups Without Holding Duplicate Full-Model Copies

Part 1 - Exercise Contract and Why It Matters

Build a bounded checkpoint loader that processes validated parameter groups, converts or copies them to planned targets, and releases transient references when safe. Avoid duplicate full-model payload while preserving canonical ties, complete value verification, and explainable failure outcomes.

Part 2 - System and Memory Mental Model

Streaming can mean lazy access through one mapped checkpoint or bounded access to explicit shard files. State which source interface is implemented; repeatedly calling ordinary full-file loading for each layer is not a bounded per-group reader. Final CPU tensors may intentionally retain mapped source storage. Converted destinations and asynchronous transfers need separate lifetime rules. A bounded queue must charge active source owners, pinned staging, conversion buffers, and destination reservations rather than only counting group objects.

Part 3 - Quantitative Prediction Before Execution

For final retained payload $F(t)$, in-flight group set $Q(t)$, and transient demand $T_g(t)$, predict a host/device timeline from $F(t)$ and the relevant $\sum_{g \in Q(t)} T_g(t)$. Avoid double counting a mapped source shared with its CPU destination. Compare queue depths one and two and calculate transition headroom. Include file metadata, storage aliases, and whole-shard granularity when one group access keeps more source storage alive than its logical slice.

Part 4 - Experimental Design and Instrumentation

Generate trusted small checkpoints in the declared format and a complete key-to-group manifest. Validate schemas and aliases before target publication. Implement bounded source access, admission, conversion/transfer, completion, verification, and release. Compare with a normal loader on final values and first useful execution. Test missing keys, shape mismatch, controlled read failure, duplicate group requests, and cancellation. Capture exact source IDs, group ordering, in-flight capacity, final ownership, and failure phase for replay. Do not remove backing files while live consumers still rely on their mapped storage.

Keep group publication atomic at the logical readiness boundary: readers see either a verified completed group or an unavailable one. For asynchronous copies, release source references only after the relevant completion obligation is satisfied, even if host submission returned.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class GroupTicket:
    group_id: str
    source_owner_ids: tuple
    reserved_host_bytes: int
    reserved_device_bytes: int
    completion_token: object
    status: str

class StreamingCheckpointLoader:
    def open_source(self, path, format_contract):
        # Establish mapped or sharded access with bounded metadata rules.
        ...

    def admit(self, group, budgets):
        # Reserve source, staging, conversion, and destination capacity.
        ...

    def materialize_and_verify(self, ticket, model, placement):
        # Supply values and publish only verified completed groups.
        ...

    def release_transients(self, ticket, retained_owners):
        # Keep references required by final CPU state or pending copies.
```

```
        ...

    def shutdown(self, deadline):
        # Stop admission, finish supported work, and report leftovers.
        ...

def E17(config):
    # Compare queue bounds, correctness, failures, and complete loading cost.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires complete key coverage, correct final contents, valid ties, and no false release of storage still used by a destination. A small queue does not prove a small peak if each shard or conversion is large. Report mapped and anonymous residency separately where instruments support it. Preserve partial/cancelled loads as unavailable rather than publishing a model with mixed valid and uninitialized state.

Part 7 - Engineering Interpretation and Philosophy

Streaming is a lifetime and admission discipline over a concrete source format. Its success is removing unnecessary overlap while retaining the final state the application needs, with bounded in-flight commitments and honest ownership after each release.

19.31.19 Exercise 18

Exercise Title: Stress-Test Zero-Allocation Construction with an Artificial Model Containing Billions of Logical Parameters and Verify That Construction Memory Remains Small

Part 1 - Exercise Contract and Why It Matters

Stress-test meta construction with billions of logical parameters while bounding actual host metadata and prohibiting real payload materialization. Measure scaling with shape and with object count separately. Demonstrate that construction can remain small relative to hypothetical weight bytes without claiming constant or zero process memory.

Part 2 - System and Memory Mental Model

A huge dimension on a few dense weights can represent billions of elements with modest object overhead. Increasing module count or tensor count grows Python and framework metadata. Constructor escapes, unsupported meta kernels, integer limits, and host-resource exhaustion still matter. The stress test checks describability and metadata cost, not checkpoint availability, numerical correctness, training feasibility, or the ability to execute a full forward on the target hardware.

Part 3 - Quantitative Prediction Before Execution

Define two sweeps: fixed layer count with growing width, and fixed width with growing layer count. Calculate logical parameter bytes for each case and predict different metadata scaling. Estimate baseline-adjusted host overhead per module from measured supported cases, not a universal constant. Choose cases beyond the declared real-memory reference while retaining

explicit object-count, time, and host-memory ceilings. Predict refusal or interruption states rather than demanding every arbitrary scale succeed.

Part 4 - Experimental Design and Instrumentation

Use isolated bounded child processes and progressive sizes. Audit every required state entry for meta status and forbid conversion, value extraction, real initialization, or checkpoint generation at oversized scales. Validate shape/count formulas against tiny real models first. Record logical elements, module/tensor counts, supported host high-water evidence, elapsed time, software version, architecture ID, and completion status. Include a safe-size explicit CPU allocation escape as a detection control. Preserve resource-limit stops and unsupported constructors separately from completed meta-only cases.

Bound the observer by module and tensor count rather than creating one record per logical element. A billion-element tensor requires a small metadata record; an accidentally expanded diagnostic list would test the observer instead of meta construction.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MetaStressResult:
    case_id: str
    logical_parameter_elements: int
    nominal_real_payload_bytes: int
    module_count: int
    tensor_count: int
    peak_host_bytes: object
    completed: bool
    payload_audit_status: str

def generate_meta_scale_cases(shape_limits, object_limits):
    # Separate dimension growth from metadata-object growth.
    ...

def run_bounded_construction(case, process_limits):
    # Audit meta-only state without creating real oversized payload.
    ...

def E18(config):
    # Export scaling evidence, safe controls, and interrupted outcomes.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require all audited payload to remain meta and every successful case to finish within its declared limits. A small current RSS after a process exits is not its construction peak. Report logical billions precisely and avoid expanding arrays of parameter names or per-element records in the observer. A shape-only forward may itself be unsupported or costly; it is optional and must not be substituted for the construction-memory measurement.

Part 7 - Engineering Interpretation and Philosophy

Large logical scale is useful when it enables reliable planning before real commitment. The test should expose where metadata complexity or architecture behavior becomes the limiting resource rather than celebrate an unexecuted parameter count as a working model.

19.31.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Memory-Aware Model Loader That Constructs on Meta, Memory-Maps the Checkpoint, and Materializes Parameters Directly into Their Planned CPU or GPU Locations

Part 1 - Exercise Contract and Why It Matters

Integrate meta construction, mapped checkpoint access, canonical placement, bounded materialization, readiness validation, and measurement into a model loader. Produce verified CPU/GPU state without unnecessary duplicate full-model payload. Preserve complete useful-work timing and explicit limits on source format, architecture, aliasing, and execution support.

Part 2 - System and Memory Mental Model

Separate architecture metadata, authoritative checkpoint storage, planned locations, active loading resources, and published ready values. The loader must not confuse assignment with conversion or empty allocation with initialized contents. Canonical tied groups constrain placement and parameter identity. Mapped source owners can survive as final CPU model storage. Optimizers depend on final references; deferred meta state remains blocked from unsupported execution. Unknown custom modules and tensor layouts require explicit refusal or a measured alternative path.

Part 3 - Quantitative Prediction Before Execution

For each plan, predict final CPU/GPU payload, buffer demand, maximum active source/conversion overlap, staging capacity, and readiness time components. Compare conventional loading, mapped/meta/assignment, and budgeted group placement under the same final model contract. Define the objective as reducing unnecessary overlap subject to correct contents, complete coverage, budgets, and progress. Report nominal bytes, resident memory evidence, allocator peaks, and latency independently; a valid plan is not a proof of globally minimal memory or future execution feasibility.

Part 4 - Experimental Design and Instrumentation

Freeze an architecture/source support matrix and validate keys, shapes, dtypes, ties, and noncheckpoint buffers. Build and independently check the placement plan before real allocation. Complete group admission, value supply, completion, verification, source release, and final publication. Compare tiny reference outputs and supported training gradients/updates before timing. Evaluate CPU, mixed-device, tight-budget, shared-weight, missing-key, conversion, and controlled-failure cases. Separate mapping return, ready-model completion, first useful

execution, and later warmed execution. Preserve cache context, version/configuration, and raw phase samples.

Separate source-read completion from final-resident ownership in the dossier. A loader can finish reading and still retain mapped storage as valid CPU weights. Report that useful retained state rather than forcing unnecessary clones solely to make a source-release counter look better.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LoaderContract:
    architecture_id: str
    checkpoint_format: str
    supported_layouts: tuple
    target_policy: tuple
    host_budget_bytes: int
    device_budget_bytes: int
    readiness_policy: str

class MemoryAwareModelLoader:
    def __init__(self, contract):
        self.contract = contract
        # Initialize canonical ownership, bounded ledgers, and support checks.
        ...

    def construct_meta(self, factory):
        # Audit required state and constructor escapes.
        ...

    def open_checkpoint(self, path):
        # Establish explicit mapped CPU source and restricted loading policy.
        ...

    def plan(self, model_metadata, checkpoint_metadata):
        # Validate schemas, aliases, dtypes, placement, and headroom.
        ...

    def materialize(self, plan):
        # Process admitted groups without hidden full-model duplication.
        ...

    def verify_readiness(self, model, reference_contract):
        # Check authoritative values, buffers, ties, and final locations.
        ...
```

```
    def finalize_dependents(self, model, training_contract):
        # Create optimizers only after final parameter identities settle.
        ...

    def shutdown(self, deadline):
        # Resolve active copies and preserve retained source ownership.
        ...

def E19(config):
    # Compare equivalent loaders and retain all unsupported/failure outcomes.
    ...
    # Export complete memory, readiness, numerical, and timing evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct authoritative contents, complete required state, valid alias/identity contracts, coherent failure handling, and comparable useful work. Record architecture/checkpoint IDs, device and software versions, source format, target dtype/device, ties, buffer policies, phase peaks, mapping/resident metrics, allocation counters, readiness latency, output/gradient errors, and request outcomes. Export scalar metadata without retaining duplicate graphs.

Demonstrate one mapped CPU owner retained by the model, one GPU conversion, a tied-placement conflict, a missing buffer, a stale-optimizer prevention check, and an interrupted group. Missing hardware measurements remain not measured. Do not publish partial or uninitialized state as a loaded model.

Part 7 - Engineering Interpretation and Philosophy

The loader succeeds when a model moves from description to verified resident values with unnecessary overlap removed and necessary ownership preserved. Recommend the smallest supported loading path that meets measured budgets, and identify the next concrete experiment required before expanding architecture, checkpoint, alias, training, or multi-device support.

19.32 DMM30

Chapter Title: Lazy Parameter Materialization
Specialization: Dynamic Memory Management and CUDA Systems

19.32.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Lazy Parameter Materialization, Deferred Storage Allocation, and On-Demand Weight Creation

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model for weights whose shape, storage, or values become available at different times. Distinguish first-input shape inference from on-demand checkpoint residency. Deliver a state diagram covering request, admission, creation, valid-value publication, consumption, release, and later recreation, with an explicit authority for every required weight value.

Part 2 - System and Memory Mental Model

An unknown-shape uninitialized parameter differs from a known-shape meta parameter. Allocating storage is also different from supplying correct values. Built-in lazy layers primarily defer shape-dependent initialization; they do not automatically provide repeated eviction, checkpoint paging, or budget scheduling. The later runtime is an explicitly designed inference system with canonical ownership and completion rules. Host metadata remains allocated, and a model whose weights are described but not ready is not yet an executable real-valued model.

Part 3 - Quantitative Prediction Before Execution

For group g, predict target payload $B_g = \sum_i n_i s_i$ under a dense canonical ownership model. Draw eager and deferred timelines for a two-branch model where one branch is unused. Estimate startup payload avoided, first-use allocation, and final residency separately. Add a second access to the same group and predict reuse versus recreation. List which costs return when the weight is actually needed and which can be permanently avoided for an unused branch.

Part 4 - Experimental Design and Instrumentation

Use a tiny eager reference and a transparent lazy architecture. Record shape status, storage state, value source/version, target device, initialization state, and readiness generation. Exercise unknown shape, known-shape meta, allocated-uninitialized, and valid-resident cases separately. Begin with single-process eager inference and no optimizer. Capture constructor time, first useful execution, and warmed execution as distinct phases. Record versions, seed, architecture, dtype, device, and the exact path used; do not compare an unexecuted lazy skeleton with a completed eager workload.

For newly initialized rather than checkpoint-backed values, define how a canonical value becomes reproducible across later demand. Reusing a global random stream at another time can produce different weights; recreation must not silently change the function being executed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn

@dataclass
class WeightLifecycle:
    canonical_key: str
    shape_status: str
    storage_status: str
    value_authority: str
    value_version: int
    resident_generation: int
    readiness: str

def classify_lazy_state(parameter, specification, value_ledger):
    # Separate unknown shape, meta metadata, storage, and valid values.
```

```
    ...

def predict_first_use(request, lifecycle, execution_contract):
    # Include admission, creation, value supply, and completion.
    ...

def E00(config):
    # Compare lifecycle predictions with tiny supported examples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require explicit readiness before computation and a retained authority before any later dematerialization. An empty allocation or finite-looking garbage cannot establish initialized contents. Shape-only execution does not establish numerical correctness. Shared names must refer to canonical values rather than independent accidental allocations. Keep unsupported training, custom storage, and dynamic compiler behavior outside the initial runtime contract instead of silently assuming they follow the same lifecycle.

Part 7 - Engineering Interpretation and Philosophy

Laziness changes when an obligation is paid; it does not remove the obligation to provide correct values. The useful design makes shape knowledge, resource commitment, and value authority independently visible so on-demand work can be admitted, delayed, or refused honestly.

19.32.2 Exercise 01

Exercise Title: Create an nn.Module Whose Parameters Exist as Metadata Before Real Tensor Storage Is Allocated

Part 1 - Exercise Contract and Why It Matters

Create a module whose weights are represented before real payload allocation. Support a known-shape metadata case and an unknown-input-shape case, while making their different inspection capabilities explicit. Preserve proper module registration so later enumeration, loading, and readiness checks can find the weights.

Part 2 - System and Memory Mental Model

A known-shape meta parameter can carry dimensions and dtype without values. An uninitialized parameter can defer the shape itself, so querying its shape or element count may fail. Neither is equivalent to an arbitrary Python tensor attribute that the module registry ignores. Device and dtype preferences can be declared before real materialization. Constructor-owned buffers and explicit CPU allocations remain part of the audit even when the main weight is lazy.

Part 3 - Quantitative Prediction Before Execution

Choose an output width o and distinguish a known input width d from an unknown width discovered later. For the known case predict weight and bias metadata and future payload $(od + o)s$ when bias is enabled. For the unknown case leave payload unresolved rather than

inventing zero. Predict which inspection fields are available in each state and which require runtime input or an external architecture specification.

Part 4 - Experimental Design and Instrumentation

Define a small registered module and a separate serializable specification record. Complete both lazy representations without real weight initialization. Audit parameters, buffers, and declared extra resources. Inspect the known metadata safely and feature-test uninitialized-state detection before requesting shape fields. Compare a tiny materialized reference after valid values exist. Add an unregistered tensor attribute and an explicit CPU factory as safe-sized negative controls. Report their detection rather than claiming a device context prohibits every constructor escape.

Check serialization behavior without assuming all deferred parameters already have ordinary tensor metadata. A state dictionary may contain uninitialized entries. Preserve the separate specification needed to distinguish an unknown shape from a known shape whose values are deferred.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch import nn
from torch.nn.parameter import UninitializedParameter

@dataclass
class DeferredWeightSpec:
    output_features: int
    input_features: object
    dtype: object
    preferred_device: object
    value_source: str

class DeferredModule(nn.Module):
    def __init__(self, specification):
        super().__init__()
        self.specification = specification
        # Register the appropriate known- or unknown-shape state.
        ...

    def forward(self, value):
        # Require admitted, value-ready state before computation.
        ...

def E01(config):
    # Audit registration and distinguish available metadata fields.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not call element-count or shape inspection on an unknown-shape parameter without first classifying it. A zero placeholder is not an estimated payload. Require all execution-relevant registered and declared extra state to appear in the audit. A successful constructor alone does not prove future loading or numerical execution is supported. Preserve unsupported constructors and buffer initialization obligations explicitly.

Part 7 - Engineering Interpretation and Philosophy

A lazy module needs a discoverable contract before it needs real weights. The specification provides that contract without pretending unknown dimensions are already known or confusing registered deferred parameters with ordinary untracked Python attributes.

19.32.3 Exercise 02

Exercise Title: Compare Eager Parameter Initialization Against Lazy Materialization by Peak RAM, Peak VRAM, and Startup Time

Part 1 - Exercise Contract and Why It Matters

Compare eager construction and initialization with lazy first-use materialization under the same architecture, value policy, and useful workload. Measure startup, first complete result, warmed latency, host peaks, and VRAM peaks separately. Include both exercised and unexercised branches in the interpretation.

Part 2 - System and Memory Mental Model

Eager construction pays for weights before use; lazy construction can defer that work and avoid unused branch payload. A workload that eventually uses every group may simply move cost into first execution. Random initialization order can differ between eager and lazy modules even with the same global seed. CUDA context setup, CPU page commitment, allocator caching, and checkpoint page access also affect the observed boundary. Define equivalent values through a controlled initializer or common checkpoint.

Part 3 - Quantitative Prediction Before Execution

For branch groups with payloads B_1 and B_2, predict resident weight demand when only branch one executes and when both eventually execute. Model first result as construction plus admitted materialization plus completed computation. Calculate potential startup deferral without claiming it is an end-to-end speedup. Predict a tiny workload where hook or policy overhead exceeds the allocation saving and a larger unused branch where retained capacity differs substantially.

Part 4 - Experimental Design and Instrumentation

Run independent bounded trials with matching initial state, input path, dtype, execution mode, and output contract. Capture process baseline, constructor return, first ready result, and repeated warmed execution. Use supported host high-water instruments and absolute CUDA allocator peaks, synchronizing only at declared completion boundaries. Verify actual weights and outputs with a small eager reference. Randomize strategy order, describe file-cache/context conditions, and retain raw timing samples. Charge initialization, checkpoint reads, placement, and required validation consistently across strategies.

For a conditional workload, report which branch outputs were requested and completed. Avoid timing an eager model on both branches while the lazy model executes one, unless the comparison explicitly measures unused eager initialization rather than different inference work.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LazyStartupTrial:
    strategy: str
    executed_path: tuple
    construction_seconds: object
    first_result_seconds: object
    warm_samples: tuple
    peak_host_bytes: object
    peak_cuda_bytes: object
    verified: bool

def measure_startup_strategy(factory, strategy, authority, inputs, config):
    # Follow equivalent weights through first complete useful execution.
    ...

def E02(config):
    # Compare startup deferral, final residency, and warmed cost separately.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A timer stopping before real values are ready is not comparable with an eager first-forward result. Do not infer peak physical memory from nominal payload or a single RSS sample. Report branch coverage so skipped work does not look like a faster equivalent computation. Preserve cases with no memory benefit, slower first-use latency, or unavailable CUDA instead of selecting only favorable trials.

Part 7 - Engineering Interpretation and Philosophy

The benefit of laziness depends on what the workload actually needs and when. A fair result states whether it avoided unused work, reduced overlap, shifted cost into first use, or merely changed the measurement boundary.

19.32.4 Exercise 03

Exercise Title: Build a Lazy Linear Layer That Allocates Its Weight Storage Only When the First Real Input Arrives

Part 1 - Exercise Contract and Why It Matters

Build a linear layer whose real weight allocation and initialization occur only after a valid first input supplies the missing input width. Compare it with a built-in lazy linear reference and verify that later compatible calls reuse the initialized parameter set rather than resetting it.

Part 2 - System and Memory Mental Model

For a linear transformation, the last input dimension determines input features; leading dimensions describe batches or other independent positions. A built-in lazy linear layer performs one-time shape initialization, not automatic reshaping for every later feature width. Device and dtype preferences must already agree with the supported input contract. A custom implementation needs an explicit state transition so invalid input, partial initialization, or a second call cannot silently replace correct existing weights.

Part 3 - Quantitative Prediction Before Execution

For input shape (b, t, d) and output width o, predict weight shape (o, d), optional bias shape (o), output shape (b, t, o), and dense payload. Compare first-call creation with a later call that changes only b or t. Predict rejection for a changed feature width after initialization. Define deterministic values for a tiny case so numerical expectations do not depend on different random-number consumption order.

Part 4 - Experimental Design and Instrumentation

Create a transparent custom module and a built-in reference at the intended dtype/device before their initialization runs. Test registration before use, first valid input, repeated compatible input, disabled bias, and invalid rank or feature width. Complete value initialization and verify parameters and outputs against a conventional linear reference with matching weights. Count materialization generations and real requests in a diagnostic replay. Create an optimizer only after the selected custom implementation's final parameter identity is stable if training is separately tested.

Publish weight and bias readiness as one supported layer transition. A failure after allocating only one component must not expose a half-ready linear layer. Keep the previous deferred state or a specific failed ticket that later callers can diagnose.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch import nn
from torch.nn.parameter import UninitializedParameter

class StudentLazyLinear(nn.Module):
    def __init__(self, output_features, bias=True, device=None, dtype=None):
        super().__init__()
        self.output_features = output_features
        self.use_bias = bias
        # Register uninitialized weight/bias and explicit lifecycle state.
        ...
```

```
    def initialize_from_input(self, value):
        # Validate shape/device/dtype, allocate once, and supply values.
        ...

    def forward(self, value):
        # Initialize only when needed; otherwise check compatibility.
        ...

def E03(config):
    # Compare first use and repeated calls with matching reference weights.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require one valid materialization for repeated compatible calls. An incompatible later input must not silently destroy learned or checkpoint-loaded weights. Check both bias policies and empty leading batch dimensions where supported. A first-input error must leave a coherent deferred or failed state, not a half-published parameter set. Distinguish built-in lazy-layer behavior from additional features implemented by the student runtime.

Part 7 - Engineering Interpretation and Philosophy

The first real input can complete a structural contract, but later inputs must obey the contract it established. One-time shape discovery is useful because it removes guesswork, not because it permits arbitrary parameter replacement during ordinary execution.

19.32.5 Exercise 04

Exercise Title: Initialize Parameter Shape from Runtime Input Dimensions and Verify Correct Materialization on the Target Device

Part 1 - Exercise Contract and Why It Matters

Infer parameter shape from runtime input under an explicit rank, feature, dtype, and device contract. Verify direct placement and initialized values. Separate shape inference from resource admission so an unexpectedly large input cannot force an uncontrolled weight allocation.

Part 2 - System and Memory Mental Model

Input metadata can reveal dimensions without revealing valid parameter values. A target device preference is not a guarantee that every input tensor and operator is compatible with it. Leading dimensions can change while the learned feature contract remains fixed. Dtype promotion or CPU/GPU movement must be intentional, not an incidental attempt to make a mismatched first call succeed. Shape arithmetic also needs bounds before requesting physical storage.

Part 3 - Quantitative Prediction Before Execution

For a weight derived from runtime feature width d and output width o, calculate ods bytes and optional bias demand. Predict output shapes for a vector, a matrix, and a higher-rank supported input. Declare how zero feature width, empty batches, oversized dimensions, and a

changed later feature width are handled. Estimate allocation and execution headroom before deciding that the target can admit the request.

Part 4 - Experimental Design and Instrumentation

Use a table of deterministic input metadata and expected decisions before running real allocations. Complete shape normalization, dtype/device checks, budget preflight, and value initialization as separate steps. Test CPU and CUDA only where available and supported, with independent reference weights and outputs. Record actual parameter device/dtype after materialization rather than inferring it from the input alone. Include a controlled oversized request that is rejected before allocation and a compatible later batch-shape change.

If a checkpoint authority already fixes the weight shape, validate the runtime feature width against that shape before allocation. Input-driven inference must not override an authoritative checkpoint dimension merely to admit an incompatible request.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class InferredParameterRequest:
    weight_shape: tuple
    bias_shape: object
    target_device: object
    target_dtype: object
    payload_bytes: int
    admitted: bool

def infer_request(input_metadata, layer_specification):
    # Bound dimensions and preserve the established feature contract.
    ...

def materialize_inferred_request(request, initializer, budget):
    # Admit before allocation and verify actual device/dtype/values.
    ...

def E04(config):
    # Test supported ranks, batch changes, and preflight rejections.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact inferred shapes and explicit refusal of unsupported cases. Do not query nonexistent parameter shape as a substitute for input-driven inference. A successful empty-batch

forward does not establish initialized weights were consumed meaningfully; verify readiness independently. Preserve shape errors, policy refusals, unavailable devices, and genuine allocation failures as distinct outcomes. No silent cast or migration may change the comparison contract.

Part 7 - Engineering Interpretation and Philosophy

Runtime shape information is a planning input, not an allocation command. A good layer converts that information into a bounded request, then creates and publishes valid state only after compatibility and admission are established.

19.32.6 Exercise 05

Exercise Title: Detect Uninitialized Parameters Before Forward Execution and Produce a Clear Failure Instead of Silent Incorrect Behavior

Part 1 - Exercise Contract and Why It Matters

Detect deferred or invalid parameter state before numerical module execution. Produce a clear supported transition or a specific failure instead of using missing, meta, partially initialized, or stale values. Include required buffers and checkpoint readiness rather than testing only one parameter class.

Part 2 - System and Memory Mental Model

Unknown-shape parameters, known-shape meta tensors, allocated-but-uninitialized storage, in-progress copies, and valid resident weights are different states. Some can be classified through public tensor/module information; semantic value readiness needs an explicit runtime ledger. Shape inspection itself can fail on unknown-shape state. A preflight guard can legitimately allow first-use initialization when a valid input and policy are available, but must prevent execution until that transition completes.

Part 3 - Quantitative Prediction Before Execution

Design a state/decision table for unresolved shape, meta-only, allocating, loading, ready, failed, and stale-authority cases. Predict which can initialize, which must wait, and which must fail. Include one nonpersistent buffer absent from the checkpoint. Define error evidence containing module path, canonical key, lifecycle state, requested device, missing obligation, and retry policy without pretending a zero payload means a resolved unknown shape.

Part 4 - Experimental Design and Instrumentation

Build tiny modules representing each state and complete a guard that classifies before reading unsupported properties. Exercise explicit initialization, automatic first-use admission, direct guarded execution, and a failed initializer. Verify errors occur before arithmetic and preserve their phase. Test a partly loaded module with one required buffer missing. Compare ready cases with an eager reference, and ensure logs contain scalar metadata rather than live weights. Keep exceptions narrow so unrelated computation errors are not misclassified as deferred-parameter failures.

Feature-check built-in lazy inspection methods because a layer may change its class after initialization. The guard must still recognize the resulting ready ordinary module instead of assuming the same lazy-only method exists throughout its lifecycle.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ReadinessFailure:
    module_path: str
    canonical_key: str
    state: str
    missing_obligation: str
    target_device: object
    retry_allowed: bool

def inspect_deferred_state(module, lifecycle_ledger):
    # Classify unknown shapes safely before accessing their properties.
    ...

def require_ready_or_materialize(module, request, policy):
    # Resolve valid transitions or raise a precise pre-compute failure.
    ...

def E05(config):
    # Test every lifecycle state, including missing buffers and load errors.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A non-meta device label or finite-looking storage is insufficient evidence of initialized values. A guard that allows a pending CUDA copy to execute without the necessary dependency is incorrect. Preserve failed and unknown states distinctly and do not publish readiness after a swallowed exception. Repeated checks on an already ready generation must not reinitialize or replace its weights.

Part 7 - Engineering Interpretation and Philosophy

Clear readiness checks turn laziness into an explicit protocol rather than a source of accidental late errors. The guard should explain what remains unresolved and whether it can be supplied, while protecting already valid state from unnecessary replacement.

19.32.7 Exercise 06

Exercise Title: Materialize Lazy Parameters Directly on CUDA Without Creating an Intermediate Full CPU Copy

Part 1 - Exercise Contract and Why It Matters

Materialize supported lazy weights directly on CUDA after input-shape and budget validation, avoiding an unnecessary full CPU weight allocation. Separate direct random initialization from checkpoint loading, whose source bytes still need an authority and transfer path.

Part 2 - System and Memory Mental Model

A built-in unknown-shape lazy layer can receive its intended device and dtype before its first initialization run. A custom known-shape runtime can allocate real target storage directly. Neither path guarantees zero host memory: metadata, source mappings, and optional staging remain. A CPU checkpoint cannot magically become GPU values without reading and transferring its data. Define which full CPU destination copy is actually eliminated and which source resources are still present.

Part 3 - Quantitative Prediction Before Execution

For weight and bias payload B, predict direct target allocation and compare with a baseline creating a full independent CPU model before CUDA placement. Add input/output and operator headroom separately. For checkpoint-backed initialization, predict source residency, transfer traffic, and transient staging. Distinguish the avoided redundant CPU model from the authoritative checkpoint pages that still provide values.

Part 4 - Experimental Design and Instrumentation

Use small same-dtype layers with a deterministic initializer or common checkpoint. Preflight target capacity, configure the lazy module before first use, and complete direct CUDA materialization. Verify all parameters, buffers, and outputs on the intended device. Measure construction, allocation, value supply, and first result separately. Compare with an explicitly labeled CPU-first baseline in isolated trials. Inspect allocation evidence rather than merely checking the final device. Preserve unavailable CUDA and policy refusal as nonexecuted outcomes.

A meta-only shape pass is not a real CUDA materialization. If such a pass resolves dimensions, keep storage and value readiness unresolved until actual target allocation and initialization or loading complete. Report those phases separately.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch import nn

def prepare_cuda_lazy_module(layer_specification, dtype, device):
    # Set target preferences before any supported shape-initializing run.
    ...

def create_cuda_values(request, authority, budget_ledger):
    # Allocate directly, supply values, and enforce completion/readiness.
    ...

def compare_cpu_first_and_direct(trials, measurement_contract):
    # Isolate redundant CPU payload from required source/staging demand.
    ...
```

```
def E06(config):
    # Verify values/device placement and phase-matched memory evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not count checkpoint source pages as an unexpected full model destination, or claim they do not exist. A constructor that silently allocates real CPU weights violates the direct-creation contract. Target initialization must produce valid contents, not only allocate empty storage. Record allocator peaks and host peaks independently; lower nominal payload does not guarantee that external GPU pressure cannot cause allocation failure.

Part 7 - Engineering Interpretation and Philosophy

Direct creation is useful when it removes a redundant ownership stage. The precise claim names that stage and retains the unavoidable costs of metadata, authoritative values, transfer, and the final device allocation.

19.32.8 Exercise 07

Exercise Title: Materialize Lazy Parameters Directly on CPU When the Current VRAM Budget Cannot Admit Them

Part 1 - Exercise Contract and Why It Matters

Materialize weights on CPU when a declared GPU admission budget cannot accept them. Verify valid CPU values and a supported execution route rather than allowing a GPU input to meet CPU weights accidentally. Account for host capacity and any transfer cost introduced by fallback.

Part 2 - System and Memory Mental Model

CPU fallback is placement, not allocation cancellation. It consumes host RAM and can require moving inputs or intermediate activations. Some dtype/operator combinations differ in support or performance across devices. Keep the initial case to an explicitly supported CPU linear computation. A policy may choose CPU before attempting CUDA rather than repeatedly provoking OOM. If neither device can admit the required resources, it must return a bounded refusal instead of looping indefinitely.

Part 3 - Quantitative Prediction Before Execution

Calculate weight/bias payload and execution headroom on both devices. Given a hypothetical GPU allowance below the request and a sufficient CPU allowance, predict the selected location and transfer boundaries. Add input and output bytes to a fallback latency model. Compare CPU-resident computation with a future promotion policy without assuming the latter exists already. Construct a second case where both budgets reject the request.

Part 4 - Experimental Design and Instrumentation

Use a software admission limit to force a safe fallback at small sizes. Complete CPU allocation and initialization or loading without an unnecessary failed CUDA attempt. Validate device/dtype, inputs, buffers, outputs, and the caller-visible output-device contract. Compare

numerical results with matching weights in a supported eager reference. Record fallback reason, capacity reservations, transfer bytes, and completed latency. Test CPU budget denial and unsupported CPU dtype/operator cases as explicit refusals.

The fallback contract should specify whether results remain on CPU or return to the caller's original device. Either is possible under an explicit API, but silently changing it can break later layers even when the fallback calculation itself is correct.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class FallbackDecision:
    selected_device: object
    reason: str
    weight_bytes: int
    execution_headroom_bytes: int
    input_transfer_required: bool
    output_contract: str

def choose_cpu_fallback(request, budgets, support_contract):
    # Reject unsupported execution or insufficient host capacity.
    ...

def execute_cpu_materialized(module, inputs, decision, authority):
    # Supply valid CPU weights and perform explicit input/output routing.
    ...

def E07(config):
    # Force safe small fallback and verify both placement and useful work.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not report success after moving only the weights while computation still fails on a device mismatch. Preserve output placement semantics or charge explicit restoration. Host RSS, mapped source ownership, and any pinned staging remain separate costs. Distinguish planned GPU refusal from genuine OOM and unrelated exceptions. A supported fallback must complete the same intended operation, not skip the difficult layer.

Part 7 - Engineering Interpretation and Philosophy

Fallback is successful when it preserves useful work under an honest resource and transfer contract. A placement decision should explain the new bottleneck and its cost rather than presenting CPU residency as free memory relief.

19.32.9 Exercise 08

Exercise Title: Build a Device-Aware Materialization Policy That Chooses CPU or GPU from Parameter Size and Live Memory Headroom

Part 1 - Exercise Contract and Why It Matters

Build a materialization policy choosing CPU, CUDA, waiting, or refusal from canonical payload, reserved commitments, execution headroom, and supported operations. Separate the runtime's logical budgets from sampled physical availability and retain uncertainty in every decision.

Part 2 - System and Memory Mental Model

A device can appear to have free memory while several admitted requests have not allocated yet. Reservations must therefore include in-flight commitments without double counting already realized storage. Allocator reserved capacity, active tensor bytes, and driver availability describe different layers. External processes and unmanaged library allocations can change conditions after sampling. CPU placement also needs host budget and execution support; an optimistic device choice is not a guarantee against OOM.

Part 3 - Quantitative Prediction Before Execution

Define projected owned commitment as resident canonical bytes plus admitted unrealized reservations plus request transition demand and named headroom. Predict decisions for a resident cache hit, a new GPU group, a group larger than remaining GPU allowance but acceptable on CPU, and no feasible target. Record observation age and units. Explain why subtracting allocator reserved bytes from driver free bytes can double count memory already reflected in the physical observation.

Part 4 - Experimental Design and Instrumentation

Implement the policy first in a host simulator with fixed observations and auditable reservation transitions. Feed simultaneous hypothetical requests to verify admission does not overcommit. Test stale or unsupported metrics, changing external headroom, resident hits, and CPU support denial. Execute small admitted CUDA/CPU cases and compare predicted with observed payload, headroom, and outcomes. Preserve actual allocation failure without claiming the software budget guaranteed physical success. Release reservations only through explicit completion, failure, or cancellation transitions.

Use one coherent observation snapshot per admission decision and preserve its timestamp. Mixing an old driver observation with a new reservation ledger can hide overcommitment; the report should expose that uncertainty rather than manufacturing an exact free-capacity result.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CapacityObservation:
    device: object
```

```
    driver_free_bytes: object
    owned_resident_bytes: int
    unrealized_reservations: int
    sampled_at: float
    unsupported_fields: tuple

def decide_materialization(request, observations, budgets, support):
    # Separate accounting layers and include all admitted commitments.
    ...

def reconcile_reservation(ticket, outcome, ledger):
    # Convert or release reservations exactly once after valid transitions.
    ...

def E08(config):
    # Validate host admission invariants before bounded device trials.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative ledgers and exactly-once reservation settlement. Unknown or stale observations must not become fictitious zero demand or unlimited capacity. A resident alias hit must not reserve duplicate canonical storage. Report action, reason, uncertainty, and subsequent outcome. Include a case where the decision was reasonable but external pressure still caused OOM; classify it rather than rewriting the original observation.

Part 7 - Engineering Interpretation and Philosophy

A placement policy is a disciplined estimate under uncertainty. Its credibility comes from coherent commitments, bounded fallback, and honest outcomes, not from pretending a sampled memory number predicts every future allocation.

19.32.10 Exercise 09

Exercise Title: Load Parameter Values from a Memory-Mapped Checkpoint Only When the Owning Module Is First Needed

Part 1 - Exercise Contract and Why It Matters

Use a memory-mapped checkpoint as the value authority and materialize a module's weights only when it is first demanded. Compare logical source access, physical page activity where observable, target creation, and cache hits without claiming that opening the checkpoint costs no metadata or I/O.

Part 2 - System and Memory Mental Model

Mapping can expose tensor metadata before all data pages are touched, but standard loading is not a per-key disk-stream API. Keep CPU map location explicit to avoid saved GPU tags causing eager placement. CPU assignment can adopt mapped storage and retain its owner;

GPU placement reads and transfers values into new device storage. First demand must verify keys, shapes, dtype, canonical ties, and required buffers before publishing readiness.

Part 3 - Quantitative Prediction Before Execution

For a checkpoint with groups A and B, predict source metadata at open, touched payload when only A is demanded, target bytes for A, and no materialization of unused B. Then request A again and predict cache-hit behavior. Add a dtype conversion and account for its temporary overlap. Separate demand trace bytes from actual page-cache/read-ahead behavior, which may exceed the logical requested group.

Part 4 - Experimental Design and Instrumentation

Generate a trusted small compatible checkpoint and a complete name-to-group manifest. Open it under the declared mapping policy, then execute a branch that demands only one module. Complete value supply, readiness verification, and publication at that demand. Record source-access IDs, allocation events, phase timings, and actual touched-page evidence only where supported. Add repeat access, a missing key, and a changed checkpoint-version test. Compare with eager loading through the same first useful output boundary.

Associate the checkpoint with a stable value-version contract, not only a filename. A changed file or schema invalidates an old materialization assumption. Keep the initial backing source immutable while resident mapped aliases or pending transfers depend on it.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CheckpointDemand:
    group_id: str
    source_version: str
    target_device: object
    target_dtype: object
    expected_keys: tuple

def open_lazy_checkpoint(path, format_contract):
    # Use explicit mapped CPU loading and preserve authoritative ownership.
    ...

def satisfy_checkpoint_demand(model, demand, source, registry):
    # Validate, create or adopt values, and publish one ready generation.
    ...

def E09(config):
    # Compare first demand, cache hit, unused groups, and schema failures.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

A low mapping-return RSS is not proof that subsequent computation needs little RAM. Deleting a dictionary entry does not free source storage retained by a CPU parameter. Do not replace checkpoint values with random initialization on a load error. Preserve incomplete readiness and specific failure phase. If physical page-access instrumentation is unavailable, report logical demand without inventing exact disk traffic.

Part 7 - Engineering Interpretation and Philosophy

Demand loading is useful when it avoids unnecessary value access or target ownership. The correct evidence distinguishes those benefits from mapping laziness, operating-system cache effects, and storage that remains intentionally owned by the loaded module.

19.32.11 Exercise 10

Exercise Title: Materialize One Transformer Block at a Time from Checkpoint Storage and Release Initialization Buffers Immediately After Loading

Part 1 - Exercise Contract and Why It Matters

Materialize transformer-style blocks from checkpoint storage one ownership group at a time and release only their transient initialization resources. Verify attention, feed-forward, normalization, and buffer contents against a tiny eager reference. Distinguish bounded loading overlap from a complete weight-eviction runtime.

Part 2 - System and Memory Mental Model

A block's required state can include several projections, biases, normalization weights, buffers, and cross-block ties. Loading one block does not imply that previously loaded blocks have been released. Initialization scratch, mapped source owners, pinned staging, final weights, activations, and optional key/value caches have separate lifetimes. A source used by an asynchronous transfer must remain protected until completion; host copy submission is not an immediate release boundary.

Part 3 - Quantitative Prediction Before Execution

Calculate canonical block payload and predict a timeline of accumulated final weights plus the active group's source, conversion, and staging demand. Compare one-group loading with full duplicate model construction. If previous blocks remain resident, show why total final weights still accumulate. Add an optional cache and a tied projection group and calculate their distinct residency obligations. Do not count persistent execution caches as discarded initialization buffers.

Part 4 - Experimental Design and Instrumentation

Use a small deterministic transformer-style architecture and compatible checkpoint, with dropout disabled or controlled for numerical comparison. Build group manifests and validate cross-block ties before allocation. Complete one group's materialization, verification, completion, and scratch release before admitting the next under a one-group policy. Compare block

outputs with the eager reference using matching attention backend and masks. Track temporary reference ownership and actual allocator peaks. Introduce a controlled load failure and ensure partial block state is not published as ready.

If one tied projection spans blocks, treat it as a canonical ownership group rather than releasing it with the first block's temporary buffers. The loading schedule can be block-oriented without pretending every resource is owned exclusively by one block.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BlockMaterialization:
    block_id: str
    canonical_groups: tuple
    final_weight_bytes: int
    temporary_bytes: int
    completion_event: object
    ready: bool

def materialize_transformer_block(block, source, plan, ledger):
    # Include every projection, normalization state, buffer, and tie.
    ...

def release_block_initialization_resources(ticket, retained_owners):
    # Wait or order completion; never release live final weights/caches.
    ...

def E10(config):
    # Verify outputs and separate accumulated residency from scratch overlap.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require all expected state and masks to match the reference. A checksum or comparison that touches every mapped tensor can warm the whole checkpoint; keep verification scope and timing explicit. Report source storage adopted by CPU weights as retained ownership. Unchanged reserved memory after scratch release does not prove a leak, while dropping a Python variable does not prove allocator or driver capacity was returned.

Part 7 - Engineering Interpretation and Philosophy

Blockwise creation controls the temporary working set. Its claim becomes stronger when every retained final weight, cache, and transient source is named, so an apparent release cannot accidentally discard useful state or conceal accumulating residency.

19.32.12 Exercise 11

Exercise Title: Build Forward Pre-Hooks That Trigger Parameter Materialization Automatically Before Module Execution

Part 1 - Exercise Contract and Why It Matters

Build forward pre-hooks that invoke the validated materialization protocol before a supported module computes. Preserve positional and keyword argument contracts, avoid reentrant initialization, and ensure an already ready generation is not recreated on every call.

Part 2 - System and Memory Mental Model

A pre-hook runs through the module call mechanism, not as a universal interceptor for every direct invocation of a forward method. Hooks can observe arguments and, under the configured signature, return modified arguments. Materializing weights on another device does not itself move inputs. Hook order, keyword handling, handles, exceptions, and nested module calls must be explicit. One-time built-in lazy initialization and a persistent demand-runtime hook serve different lifecycles.

Part 3 - Quantitative Prediction Before Execution

Predict hook counts and materialization counts for first use, repeated ready use, a nested module call, and a direct forward-method bypass test. Design transitions for cold, in-progress, ready, and failed states. State when the hook returns no argument modification and when an explicit placement policy requires transformed inputs. Include the cost of waiting for readiness rather than counting only hook dispatch.

Part 4 - Experimental Design and Instrumentation

Implement a small custom module with a clear call path and register the hook using the appropriate keyword-argument policy. Route demand to a registry rather than recursively calling the same module to initialize it. Verify first-use values, repeated-call stability, failure propagation, and hook removal at shutdown. Test an input passed by keyword and a CPU fallback needing explicit argument routing. Record global/local hook ordering if other hooks are present. Keep the main benchmark in eager mode and mark tracing or compilation support as a separate unvalidated extension.

Keep lease release and device completion explicit outside the pre-hook. Hook entry ensures readiness before a call; it does not by itself establish when all readers finish or automatically provide exception-safe lifecycle cleanup for every later operation.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

def materialization_pre_hook(module, args, kwargs):
    # Resolve readiness without recursively invoking the same module.
    ...
    # Return the documented input form only if routing changes arguments.
    ...
```

```
def install_materialization_hooks(model, registry, support_contract):
    # Configure signatures/order and retain removable handles.
    ...

def remove_materialization_hooks(handles, runtime_state):
    # Stop new demand and remove hooks only through supported lifecycle.
    ...

def E11(config):
    # Test first call, ready hit, keyword input, bypass, and failure paths.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require numerical equivalence and exactly the expected materialization count. Do not claim a pre-hook protects direct forward bypasses; enforce the supported entrypoint or provide an explicit guard. A post-hook returning on the host would not prove CUDA consumers finished. Failed initialization must not leave a ready marker or leaked admission ticket. Preserve unexpected exceptions rather than treating them as an ordinary cache miss.

Part 7 - Engineering Interpretation and Philosophy

A hook is an integration point, not the ownership protocol itself. Keeping materialization in a validated registry makes automatic first use understandable, testable, and removable without hiding resource or execution obligations.

19.32.13 Exercise 12

Exercise Title: Prevent Duplicate Materialization When Shared or Tied Parameters Are Referenced by Multiple Modules

Part 1 - Exercise Contract and Why It Matters

Prevent multiple module paths from independently materializing one shared or tied weight. Build a canonical registry that preserves the intended parameter identity or declared shared-region relationship and charges resident capacity once per actual owner.

Part 2 - System and Memory Mental Model

A shared parameter can have several module names but one value authority. Meta addresses do not provide useful real storage identity, and two different parameter objects with equal values are not necessarily tied. Start with explicit architecture-declared ties of ordinary dense parameters. Cross-device requests for one tied value can conflict with the single-resident contract; replication requires a separately specified consistency policy rather than silently breaking the tie.

Part 3 - Quantitative Prediction Before Execution

Compare a named payload sum with a canonical sum for two modules sharing one weight and owning independent biases. Predict one first materialization, multiple bindings, and repeated cache hits. Add incompatible shape, dtype, source version, and target-device requests for the same canonical key. Specify which are compatible, which need a new validated generation, and which must be refused while current readers remain active.

Part 4 - Experimental Design and Instrumentation

Construct a tiny tied model with a matching eager reference and explicit name-to-owner manifest. Complete canonical demand resolution and binding after one value-ready materialization. Verify identity or the declared storage-region tie, outputs through both module paths, and canonical byte accounting. Test reversed access order and an unused alias. Add a conflicting target request and require a coherent decision. Keep training out of dynamic replacement unless optimizer references and saved values have been explicitly handled.

Equal checkpoint values under two names do not prove the architecture ties those parameters. Preserve declared ties and independent owners separately so accidental value equality does not merge parameters that should be able to evolve independently.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CanonicalWeight:
    key: str
    bound_names: tuple
    shape_contract: tuple
    authority_version: str
    resident_generation: int
    readiness: str

class SharedMaterializationRegistry:
    def resolve(self, module_path, parameter_name):
        # Use explicit architecture ownership, never meta pointer equality.
        ...

    def acquire(self, canonical_key, request):
        # Reuse one compatible resident/in-progress generation.
        ...

    def bind_aliases(self, canonical_key, model):
        # Preserve all declared names and parameter identity semantics.
        ...

def E12(config):
    # Verify one canonical creation and correct behavior through both paths.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Require no duplicate charged storage for an ordinary tied owner and no silent split into independent weights. An identity test alone is insufficient for more general shared views; those require a supported region manifest or explicit refusal. Preserve authority version and shape contract in cache keys. A stale module binding must not keep an older generation available after the registry claims it was replaced or dematerialized.

Part 7 - Engineering Interpretation and Philosophy

Canonical ownership converts many logical names into one coherent materialization obligation. It is essential for both memory accounting and model semantics: saving allocation bytes is invalid if the resulting model no longer shares the values its architecture requires.

19.32.14 Exercise 13

Exercise Title: Reproduce a Race Condition Where Two Execution Paths Attempt to Materialize the Same Parameter Concurrently and Fix It Safely

Part 1 - Exercise Contract and Why It Matters

Reproduce a duplicate-materialization race in a small controlled host-side registry, then implement a protocol that lets competing requesters share one result or one failure. Protect publication and reservation settlement without relying on timing luck or unsafe concurrent GPU writes.

Part 2 - System and Memory Mental Model

A check-then-create sequence can let two paths observe a cold key before either publishes its allocation. The Python interpreter lock is not a complete application protocol across waits or operations that release it. Canonical states need an atomic owner transition and a generation-specific completion object. Host publication and CUDA value readiness are different events. A lock protecting state does not automatically make a pending device copy complete or permit arbitrary concurrent mutation of module bindings.

Part 3 - Quantitative Prediction Before Execution

Draw two request timelines passing a cold-state check, reserving bytes, and attempting publication. Predict duplicate allocation and possible last-writer replacement under the broken host model. Design a single-creator transition with waiting requesters and bounded failure propagation. Calculate reservation settlement for success, load failure, and requester cancellation. Explain why cancelling one waiter must not free storage still required by another.

Part 4 - Experimental Design and Instrumentation

Use barriers or an explicit deterministic host interleaving to expose the broken check-then-create logic on tiny safe mock or CPU resources. Record creator count, ticket count, published generation, waiter outcomes, and cleanup. Complete the repaired protocol with supported host synchronization and a separate device-ready token where needed. Test two simultaneous demands, creator failure, cancellation, timeout, and a stale late completion. Serialize actual module binding under the supported contract; do not deliberately launch a known-invalid CUDA data race to demonstrate the bug.

Bound every barrier and waiter in the deterministic race test. A deadlocked test is an outcome to diagnose, not a successful repaired protocol. Record which requester became creator and whether every remaining waiter received the same published generation or failure.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CreationTicket:
    canonical_key: str
    generation: int
    creator_id: str
    waiter_ids: tuple
    completion: object
    outcome: str

class SingleCreatorRegistry:
    def request(self, key, demand):
        # Atomically become creator or join a compatible existing ticket.
        ...

    def publish(self, ticket, values, readiness_token):
        # Verify generation and publish exactly once after valid creation.
        ...

    def fail(self, ticket, error):
        # Notify all waiters and settle reservations exactly once.
        ...

def E13(config):
    # Reproduce the host race, then test repaired controlled interleavings.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require one published compatible generation, bounded waiters, and no leaked or double-released reservations. A passing unsynchronized run does not prove safety; the deterministic broken interleaving must actually expose the intended logical conflict. Preserve creator errors for every waiter. Ignore or safely reject stale completion tokens rather than allowing an old generation to overwrite newer authoritative state.

Part 7 - Engineering Interpretation and Philosophy

Concurrent laziness needs a publication protocol, not merely a cache dictionary. The useful repair establishes who creates, who waits, when values are readable, and who settles each resource commitment under every supported outcome.

19.32.15 Exercise 14

Exercise Title: Add Reference Counting to Track Which Materialized Parameters Are Still Required by Active or Future Computation

Part 1 - Exercise Contract and Why It Matters

Add explicit lease and reference accounting for resident weights used by active or declared future computation. Separate ordinary Python references, logical consumers, device completion, and speculative future hints. Use the accounting to decide when release is safe without confusing a scheduling prediction with a guaranteed future use.

Part 2 - System and Memory Mental Model

An active request can finish its Python call while GPU kernels still read the weights. A resident group can also be retained by aliases, external outputs, backward, or optimizer state under broader execution contracts. A simple module reference count does not capture those obligations. Future conditional branches may be unknown; they need a bounded prefetch reservation or recreation authority, not an indefinitely increasing fictional consumer count. Start with explicit inference leases and declared completion tokens.

Part 3 - Quantitative Prediction Before Execution

For canonical generation g, track active leases, completed-but-not-yet-reconciled readers, and bounded prefetch reservations separately. Define release eligibility from discharged hard obligations plus retained valid authority. Compare a known sequential next use, an untaken speculative branch, and an external consumer holding a lease. Predict why zero host leases alone cannot establish safe overwrite or free while a device reader remains outstanding.

Part 4 - Experimental Design and Instrumentation

Build a host lifecycle simulator before connecting real CUDA completion. Complete generation-aware acquire, attach-reader, release, cancellation, and reconciliation transitions. Test shared-module consumers, delayed GPU completion, repeated release, stale leases, and speculative branch cancellation. Validate bounded resident ownership against an independent event trace. Use explicit runtime tokens rather than interpreter reference-count functions as the primary oracle. If training is unsupported, reject it clearly; do not release weights needed by saved activations or dependent optimizer references.

Check count reconciliation against a separate event list on tiny traces. Looking only at the final zero can hide an earlier premature decrement. Audit each transition, including the interval where the host lease is gone but a CUDA read remains protected.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class WeightLease:
    canonical_key: str
    generation: int
```

```
    consumer_id: str
    completion_token: object
    purpose: str

class WeightLeaseLedger:
    def acquire(self, key, generation, consumer, purpose):
        # Register a hard reader or separately bounded speculative claim.
        ...

    def release(self, lease):
        # Validate generation and completion; prevent duplicate settlement.
        ...

    def eligible_for_release(self, key, authority_state):
        # Include all readers, aliases, and retained-value obligations.
        ...

def E14(config):
    # Test host/device lifetime differences and conditional cancellation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative counts and exactly-once release for every supported lease. A stale generation must never decrement the current generation's active count. Report undeclared or escaped consumers as unknown and retain storage or refuse eviction. Preserve delayed completion without pretending it is a leak. A future hint may be cancelled, but a hard reader cannot be dropped merely because keeping it resident exceeds the preferred cache target.

Part 7 - Engineering Interpretation and Philosophy

Reference accounting is useful when it counts real obligations rather than convenient objects. Safety comes from complete active lifetimes; efficiency comes from deciding which future hints are worth retaining or recreating within that safe boundary.

19.32.16 Exercise 15

Exercise Title: Dematerialize Cold Parameters Back to Metadata Plus External Storage and Measure the Cost of Recreating Them Later

Part 1 - Exercise Contract and Why It Matters

Dematerialize cold resident weights into metadata plus a retained external value authority, then recreate exactly the required version on later demand. Measure release effects and recreation latency. Begin with immutable checkpoint-backed inference weights and refuse unsupported dirty or training-dependent state.

Part 2 - System and Memory Mental Model

Discarding storage is legal only after readers finish and another authority can reproduce the same values. Moving a tensor description to meta loses its resident contents; it is not a

persistence mechanism. A changed trained weight cannot be recovered from an older checkpoint unless validated writeback updates the authority. Tied module bindings, external aliases, registry references, and asynchronous readers can all keep storage live or make replacement unsafe. Allocator reserved capacity can remain after real tensor ownership ends.

Part 3 - Quantitative Prediction Before Execution

For group payload B, predict released logical residency, remaining authority storage, and recreation demand. Model reload cost as source access, conversion, transfer, validation, and synchronization. Compare retaining a hot group with recreating a cold one after an idle interval, without inventing a universal break-even time. Add a dirty version newer than its checkpoint and predict refusal or required durable writeback before dematerialization.

Part 4 - Experimental Design and Instrumentation

Create a small checkpoint-backed inference group with known values and explicit leases. Verify authority version and completed readers, capture required metadata, and complete a supported unbinding/rebinding path for every tied name. Remove actual resident owners without private data hacks. Record allocated/reserved memory and retained references separately. Demand the group again, validate exact values and outputs, and charge complete recreation. Test outstanding readers, escaped aliases, dirty versions, missing source files, and stale module bindings as rejection cases.

A failed recreation must leave the external authority intact and the group unavailable, not publish partially loaded bytes. Retain metadata and the failure reason so another supported attempt can proceed without losing the only correct copy of the model values.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DematerializationPlan:
    canonical_key: str
    resident_generation: int
    authority_version: str
    metadata_specification: object
    bound_names: tuple
    eligible: bool
    reason: str

def plan_dematerialization(key, registry, leases, authority):
    # Require completed obligations and reproducible current values.
    ...

def dematerialize_and_rebind(plan, model, registry):
    # Replace supported bindings with metadata and remove true owners.
```

```
    ...

def recreate_and_verify(key, authority, target, registry):
    # Restore the same value version before publishing a new generation.
    ...

def E15(config):
    # Compare retention, release, recreation, and refused dirty-state cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require unchanged authoritative values after recreation and coherent ties. A low count in the registry is not proof old tensors were released elsewhere. An unchanged reserved-memory reading is not by itself failure. Do not discard weights still referenced by autograd or an optimizer under an unsupported training contract. If writeback is not implemented, dirty groups remain ineligible; random reinitialization is never a repair for missing authoritative contents.

Part 7 - Engineering Interpretation and Philosophy

Cold storage eviction is a reversible residency decision only when the value history survives elsewhere. The useful runtime trades measured recreation cost against retained capacity while preserving authority, readers, and the exact model version.

19.32.17 Exercise 16

Exercise Title: Combine Lazy Materialization with Prefetching So the Next Layer Is Created Before the Current Layer Finishes Computing

Part 1 - Exercise Contract and Why It Matters

Prefetch the next supported weight group while the current group computes. Preserve bounded source/staging ownership and order consumer execution after value readiness. Compare demand-only loading with the same workload under prefetch rather than assuming asynchronous submission guarantees overlap.

Part 2 - System and Memory Mental Model

Source-page access, CPU conversion, pinned staging, host-to-device transfer, and GPU compute can overlap only when their resources and dependencies permit. A mapped pageable source does not automatically provide a pinned asynchronous pipeline. Prefetched groups consume capacity before use and may never be used on a conditional path. The canonical registry must deduplicate prefetch and demand for the same generation. Cancellation cannot release a source or destination still used by in-flight work.

Part 3 - Quantitative Prediction Before Execution

For current compute time T_c and next-group ready time T_l, predict an idealized exposed stall $\max(0, T_l - T_c)$ when independent resources permit full overlap. Add contention, host preparation, and synchronization as explicit limitations. Calculate peak weights for current

plus prefetched groups and staging. Compare lookahead zero and one, then predict wasted bytes/time for a mispredicted branch. These are models to test, not promised timings.

Part 4 - Experimental Design and Instrumentation

Use a fixed two- or three-group inference trace with known checkpoint values. Implement separate supported preparation/transfer work and generation-specific ready events. Make the compute consumer wait on the correct token, and protect source/staging buffers until copies complete. Compare outputs with demand-only execution. Record a timeline or equivalent supported overlap evidence, completed wall time, exposed waits, peak capacity, and unused prefetches. Test a demand racing with its prefetch and a cancelled speculative branch. Keep profiling separate from low-overhead timing.

Record the ready event after all required conversion and transfer work, not merely after source access begins. If preparation runs on the host, connect its completion to the device work explicitly before claiming the consumer can safely proceed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PrefetchTicket:
    canonical_key: str
    generation: int
    source_owners: tuple
    reserved_bytes: int
    ready_event: object
    status: str

def schedule_prefetch(next_request, registry, budgets, streams):
    # Join existing creation or admit one bounded speculative ticket.
    ...

def wait_for_prefetched_group(ticket, consumer_stream):
    # Order actual use after generation-specific value readiness.
    ...

def cancel_prefetch(ticket, completion, ledger):
    # Release only after in-flight obligations allow safe cleanup.
    ...

def E16(config):
    # Compare demand-only and lookahead execution with equal useful work.
```

. . .

Part 6 - Measurement, Validation, and Failure Analysis

Require correct values and no duplicate creation on a demand/prefetch collision. Record pinned capacity and conversion buffers rather than only GPU weights. A host timer ending at submission cannot establish overlap or readiness. Preserve slow or unused prefetch outcomes; useful throughput must not count speculatively loaded but unexecuted work as completed computation. Supported cancellation must not erase a hard demand already waiting for the same group.

Part 7 - Engineering Interpretation and Philosophy

Prefetch spends capacity now to reduce a later critical-path wait. It is justified when measured overlap and path predictability compensate for earlier ownership, staging demand, and wasted speculation within the same safety protocol as ordinary demand.

19.32.18 Exercise 17

Exercise Title: Build a Materialization Scheduler That Limits Concurrent Weight Creation According to RAM, VRAM, and Transfer Budgets

Part 1 - Exercise Contract and Why It Matters

Build a scheduler that bounds simultaneous weight creation using host bytes, device bytes, staging demand, and transfer concurrency. Preserve progress for hard demands while limiting speculative work. Deliver admission decisions, resource ledgers, queue behavior, and failure/cancellation accounting.

Part 2 - System and Memory Mental Model

A count of active groups is not a capacity budget when groups differ in size. Resources also have different units: queued transfer bytes, concurrency slots, measured bandwidth, and time deadlines cannot be added as one number. Reserve complete transition requirements before creation, converting reservations to resident ownership when realized. Avoid deadlock from partially holding one resource while waiting indefinitely for another. A hard request larger than the supported execution floor needs an explicit alternative or refusal.

Part 3 - Quantitative Prediction Before Execution

Represent admission demand as a vector of host bytes, device bytes, pinned bytes, and transfer slots. For each resource r, require existing commitment plus the new request's increment not to exceed its declared allowance. Compute a timeline for two unequal groups and a next-layer prefetch. Predict when queueing, cancellation of speculative work, CPU fallback, or refusal is legal. Separate a per-transfer concurrency cap from a workload-level throughput estimate and define a bounded progress rule.

Part 4 - Experimental Design and Instrumentation

Implement the scheduler in a deterministic host simulator with atomic or ordered multiresource admission. Test mixed group sizes, already-resident hits, shared in-progress tickets, deadline expiry, creator failure, and waiter cancellation. Validate nonnegative ledgers and

exactly-once settlement independently. Then run bounded small CPU/CUDA traces with explicit events and reference outputs. Measure queue wait, transfer wait, recreation count, speculative waste, peak owned resources, and useful throughput. Freeze policy parameters before evaluating held-out traces so tuning does not hide adverse cases.

Do not hold a registry lock while waiting indefinitely for a creator whose publication needs the same lock. The host simulator should include this lock/dependency pattern and verify bounded progress or clear timeout handling under the declared protocol.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ResourceDemand:
    host_bytes: int
    device_bytes: int
    pinned_bytes: int
    transfer_slots: int
    speculative: bool

class MaterializationScheduler:
    def admit(self, request, resource_demand, observations):
        # Reserve compatible resources without partial-hold deadlock.
        ...

    def dispatch(self, ticket, runtime):
        # Launch only supported creation work and retain ownership.
        ...

    def settle(self, ticket, outcome):
        # Reconcile realized residency, failures, and cancellations once.
        ...

    def shutdown(self, deadline):
        # Stop admission, drain supported work, and report unresolved state.
        ...

def E17(config):
    # Verify host invariants before measuring bounded real execution.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require bounded outstanding commitments and explain any refusal that reduces workload coverage. A scheduler that rejects all large requests does not prove successful memory-aware

execution. External pressure can still cause a real allocation failure; preserve it separately from admission denial. Do not release reservations merely because the host function returned or a speculative waiter disappeared while other consumers still depend on the ticket.

Part 7 - Engineering Interpretation and Philosophy

Scheduling is a joint capacity and progress contract. The best policy is the smallest one that keeps hard work moving within declared resource bounds, with enough evidence to explain waits, fallbacks, refused work, and the cost of speculation.

19.32.19 Exercise 18

Exercise Title: Stress-Test Lazy Materialization on a Deep Model with Conditional Execution Paths, Shared Weights, and a VRAM Budget Far Below Total Model Size

Part 1 - Exercise Contract and Why It Matters

Stress-test lazy residency on a deep conditional inference model whose total weight payload exceeds its declared GPU allowance. Exercise shared weights, recreation, prefetch, and branch changes while preserving outputs and bounded resource commitments. Distinguish software-budget testing from deliberately exhausting physical VRAM.

Part 2 - System and Memory Mental Model

A budget far below total model size can be feasible only if the active supported working set, transition storage, and execution headroom fit somewhere. At least one required group or operation can still exceed the feasible floor. Conditional paths alter future demand and can invalidate speculative priorities. Shared weights require canonical ownership even when different branches access them. A full authoritative checkpoint and host resources remain necessary; a small GPU pool does not imply the entire system has negligible memory demand.

Part 3 - Quantitative Prediction Before Execution

Calculate total canonical payload and the largest mandatory active set for selected traces. Include current weights, next-group prefetch, activations, residuals, staging, and library margins where applicable. Predict feasible and infeasible budget levels before execution. For branch traces, estimate cache hits, recreations, unused prefetches, and useful path coverage. Explain why a claim of arbitrarily tiny GPU execution would be false without additional operator splitting or an explicit CPU route.

Part 4 - Experimental Design and Instrumentation

Use trusted small checkpoints and a configurable deep model with an eager reference that fits the validation environment. Force low residency through software admission caps. Generate deterministic path traces plus seeded conditional cases, including shared-group revisits and delayed completion. Validate every accepted output, generation version, lease transition, and budget ledger. Test missing authority, conflicting ties, no feasible target, midcreation failure, and shutdown. Minimize reproducible failures and retain the source IDs, path, seed, policy, and completion ordering needed to replay them.

Keep the eager validation reference small enough for the test environment. The low-budget claim can be exercised through a smaller software cap without constructing an uncontrolled oversized real model or fabricating a physical OOM to make the demonstration convincing.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LazyStressTrace:
    trace_id: str
    path: tuple
    shared_groups: tuple
    software_vram_limit: int
    prefetch_policy: str
    completion_schedule: tuple

def predict_active_floor(trace, architecture, execution_contract):
    # Include all mandatory live and transition resources.
    ...

def execute_stress_trace(trace, runtime, eager_reference):
    # Compare accepted outputs and audit generation/resource invariants.
    ...

def minimize_lazy_failure(trace, replay_predicate, limits):
    # Preserve the causal branch, ownership, and completion conflict.
    ...

def E18(config):
    # Report coverage, correctness, recreation cost, and infeasible cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require useful completed work at the claimed budget and no false release or stale-generation use in admitted traces. Distinguish expected infeasibility, policy refusal, numerical error, OOM, timeout, and unrelated exceptions. A nonreproducing failure remains unresolved evidence. Do not claim a successful path skipped necessary layers or replace a missing checkpoint group with random values to keep a benchmark running.

Part 7 - Engineering Interpretation and Philosophy

The stress test defines a deployment envelope rather than a universal memory miracle. A strong result identifies the smallest feasible working set and shows correct progress across changing paths, with every remaining authority, host cost, and unsupported case accounted for.

19.32.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Lazy Weight Runtime That Materializes, Places, Prefetches, and Dematerializes Parameters On Demand Under Dynamic Memory Budgets

Part 1 - Exercise Contract and Why It Matters

Integrate shape readiness, canonical ownership, demand creation, placement, prefetch, leases, dematerialization, and budget scheduling into a lazy weight runtime. Begin with immutable checkpoint-backed eager inference and publish explicit support limits. Benchmark equivalent useful work rather than counting only fast constructor returns or successful cache lookups.

Part 2 - System and Memory Mental Model

Separate architecture specifications, authoritative value versions, resident generations, pending creation tickets, consumers, and scheduler commitments. Built-in one-time lazy initialization is an optional front-end mechanism, not the complete runtime. A canonical registry deduplicates shared and concurrent demand. Ready values require correct contents and ordered completion; eviction requires discharged readers and reproducible authority. Dynamic parameter replacement during training needs additional optimizer, gradient, and saved-value protocols and is unsupported unless those mechanisms are explicitly implemented and validated.

Part 3 - Quantitative Prediction Before Execution

Define the objective as completed correct useful work per complete elapsed time under host, device, staging, and progress constraints. Predict demand payload, cache-hit opportunities, recreation cost, prefetch overlap, authority residency, and transition peaks for each trace. Compare eager full residency, demand-only lazy loading, lazy eviction, and the integrated prefetched policy. Report startup, first output, warmed throughput, tail latency, and absolute memory peaks separately. Safety and good measured behavior do not establish globally optimal placement or zero allocation.

Part 4 - Experimental Design and Instrumentation

Freeze an architecture/checkpoint/operator support matrix and calibrate on separate traces. Validate host admission, lease, generation, and publication invariants before CUDA execution. Complete demand through creation, value verification, binding, consumption, and safe release. Compare small outputs with an eager reference under matching weights, masks, precision, and path. Evaluate sequential, conditional, shared-weight, concurrent-request, tight-budget, and delayed-completion traces. Run ablations without weakening correctness. Separate diagnostic profiling from unprofiled timing and retain CPU fallback, unsupported, failed, and cancelled outcomes in coverage reports.

Document the final runtime as inference-only unless training has its own validated value-update and identity protocol. Supporting first-use allocation in a small training layer does not establish that arbitrary dynamic eviction and parameter replacement preserve optimizer or backward semantics.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LazyRuntimeContract:
    architecture_id: str
    checkpoint_format: str
    execution_mode: str
    supported_layouts: tuple
    host_budget_bytes: int
    device_budget_bytes: int
    pinned_budget_bytes: int
    maximum_creation_tickets: int

class LazyWeightRuntime:
    def __init__(self, contract):
        self.contract = contract
        # Initialize canonical authority, generations, leases, and ledgers.
        ...

    def request(self, canonical_key, input_contract, consumer):
        # Resolve shape, join existing creation, or admit one new ticket.
        ...

    def materialize(self, ticket):
        # Supply authoritative values at the selected target safely.
        ...

    def publish(self, ticket, readiness):
        # Bind one valid generation and notify compatible waiters.
        ...

    def prefetch(self, future_request):
        # Admit bounded speculation without duplicating hard demand.
        ...

    def release(self, lease, completion):
        # Reconcile all actual readers before release eligibility.
        ...

    def dematerialize(self, canonical_key):
        # Preserve current authority and invalidate every stale binding.
        ...

    def audit(self):
        # Reconcile committed resources, values, generations, and outcomes.
        ...
```

```
    def shutdown(self, deadline):
        # Stop admission, resolve work, and report unresolved obligations.
        ...

def E19(config):
    # Validate tiny references and adversarial lifecycle cases first.
    ...
    # Benchmark equivalent work and export a supported recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct authoritative values and outputs, valid ownership and completion rules, coherent resource admission, and honest useful-work timing. Record versions, device identity, backend, source/version IDs, architecture, path/seed, dtype, masks, initial state, requests, creation counts, hit/recreation rates, authority residency, host/VRAM/pinned peaks, queue waits, latency samples, coverage, and all failure phases. Export bounded scalar records rather than retaining graphs or full weights in telemetry.

Demonstrate deduplicated tied demand, CPU fallback, a failed creator with waiters, a cancelled prefetch, a protected late reader, cold recreation, and an infeasible budget. Missing hardware results remain not measured; no benchmark values may be invented.

Part 7 - Engineering Interpretation and Philosophy

A useful lazy runtime preserves the model's values while deciding when their physical residency is worth paying for. Recommend the smallest measured policy that meets the workload contract, and name the evidence required before expanding shape, alias, concurrency, source-format, training, or compiler support.

19.33 DMM31

Chapter Title: Memory-Mapped Data and Large Dataset Access
Specialization: Dynamic Memory Management and CUDA Systems

19.33.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Memory Mapping, Virtual Address Space, Page Faults, Lazy Loading, and File-Backed Tensor Storage

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle model connecting file bytes, virtual mappings, page access, resident file-backed pages, ordinary tensor copies, pinned staging, and CUDA storage. Explain precisely what memory mapping defers and which resources still exist. Deliver an accounting diagram and predictions that distinguish mapping a large file from reading or copying all its contents.

Part 2 - System and Memory Mental Model

A mapping exposes a virtual address range backed by a file; it does not promise that every page is already resident or that every future read is free. Page faults can establish resident

mappings without disk I/O or require storage access, depending on cache and operating-system state. Readahead can touch more data than the requested logical slice. File-backed tensor views, private modifications, collation, transforms, pinned copies, and CUDA transfers introduce different ownership and allocation boundaries. Zero eager payload copy does not mean zero host memory.

Part 3 - Quantitative Prediction Before Execution

For file size F, page size P, touched page set S, and independent batch copies totaling B, distinguish mapped virtual size, observed resident file pages, and anonymous/pinned payload. Estimate a page-cover lower bound for a small requested byte range, but do not claim it is exact physical I/O. Draw mapping-only, sparse access, full scan, and batch-to-GPU timelines. Explain why summing RSS over processes can count shared pages repeatedly.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic raw file and a larger safely bounded fixture. Record file format, logical and allocated size, dtype, byte order, platform, filesystem, process baseline, mapping policy, and access schedule. Collect supported RSS, PSS, anonymous/file-backed, page-fault, and I/O observations separately. Label unavailable instruments rather than substituting zeros. Verify values on selected regions before any performance claims. Keep mapping creation, first useful access, complete scan, collation, and device transfer as distinct phases, with controlled or explicitly uncontrolled cache conditions.

Add a tiny page-address worksheet using the platform's observed granularity. For each phase, mark which layer owns the bytes and which event first needs their values. Include a batch transform that returns independent storage and a view that retains the mapping. Explain how those choices change release eligibility even when their numerical contents match. Keep the worksheet separate from empirical counters so its predictions can be disproved by the actual access path.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class MappingObservation:
    phase: str
    mapped_virtual_bytes: object
    resident_bytes: object
    proportional_resident_bytes: object
    minor_faults: object
    major_faults: object
    logical_bytes_requested: int
    observed_io_bytes: object

def classify_pipeline_storage(file_spec, views, staging, device_state):
    # Distinguish file-backed pages from independent batch allocations.
```

```
    ...

def E00(config):
    # Compare predicted and observed phases without inventing OS metrics.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A minor fault is not a disk read, and a major-fault count is not an exact byte counter. A full scan can grow residency even when no full anonymous dataset tensor is created. Do not identify unused logical regions with pages proven never touched by the OS. Shared source pages and batch copies require separate accounting. A numerically correct slice does not establish that a benchmark avoided accidental full-file validation or copying elsewhere.

Attach an accounting-layer label to every reported byte field. A process resident total, a system cache observation, and a logical tensor payload must not be added as disjoint quantities without checking overlap. When the instrument cannot resolve sharing, preserve a bounded estimate or unknown rather than inventing an exact physical total.

Part 7 - Engineering Interpretation and Philosophy

Memory mapping offers controlled access to file-backed values while the OS manages page residency. The strongest mental model preserves the difference between requested data, cached data, copied data, and completed useful work instead of treating the mapping itself as an infinite-memory abstraction.

19.33.2 Exercise 01

Exercise Title: Create a Large Binary Tensor File and Compare Ordinary File Loading Against Memory-Mapped Access Without Loading the Entire Dataset into RAM

Part 1 - Exercise Contract and Why It Matters

Create a deterministic raw binary tensor file in bounded chunks and compare eager loading with mapped selective access. Specify the binary format and measure equivalent requested values. Keep file generation separate from the read benchmark, including its effect on storage cache and file allocation.

Part 2 - System and Memory Mental Model

A headerless raw file needs an external schema: dtype, byte order, element count, shape, and data offset. It is not interchangeable with a serialized PyTorch checkpoint. Generating a full source tensor before writing would already defeat the bounded-construction goal. Truncating a file can create sparse regions whose zero pages do not represent ordinary disk-backed data throughput. Eager reading and mapping return also have different readiness boundaries until the requested values are actually consumed.

Part 3 - Quantitative Prediction Before Execution

For N elements of width s, predict $F = Ns$ raw payload and a bounded generation workspace C independent of F. Compare eager independent payload ownership with a mapping plus selected-region copies. Calculate bytes requested by the same sample trace for both

readers and distinguish them from bytes read by the device. Predict why a freshly generated file may already be warm and why mapping-return timing alone would give a misleading result.

Part 4 - Experimental Design and Instrumentation

Preflight free disk space, chosen fixture size, and generation workspace. Write deterministic chunks with sample identifiers and an integrity manifest; close publication before readers start. Validate the complete tiny fixture, then use bounded spot checks for large timing runs with validation scope recorded. Complete eager and mapped readers and consume the same selected regions to a scalar result. Record generation time separately, cache context, logical/allocated file size, mapping time, access time, memory observations, and actual I/O only where supported.

Embed sample identifiers and a bounded verification pattern in each generated chunk so selective reads can be checked without scanning all bytes. Publish the manifest only after the writer has completed the declared file protocol. Record whether the filesystem uses compression, sparse allocation, or another feature affecting physical storage demand. A large filename size alone is insufficient to establish that the benchmark contains an equally large ordinary payload on the underlying device.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RawTensorFileSpec:
    path: str
    dtype_name: str
    byte_order: str
    element_count: int
    shape: tuple
    payload_bytes: int

def create_chunked_fixture(specification, chunk_bytes, limits):
    # Write real deterministic payload without building the entire tensor.
    ...

def compare_eager_and_mapped(specification, region_trace, config):
    # Consume equivalent requested values after explicit readiness points.
    ...

def E01(config):
    # Verify format, bounded generation, and phase-matched reading evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject truncated files, schema mismatch, unsupported endianness, and unsafe sizes before mapping. A sparse all-zero fixture must be labeled and must not stand in for realistic storage throughput. Do not compare a full eager scan with a tiny mapped subset as the same workload; identify that as a selective-access comparison. Preserve file-generation cache effects and avoid claiming cold storage without an independent justified procedure.

Run an intentionally wrong dtype interpretation on a tiny disposable fixture and require schema validation to reject it. Equal file length does not make two dtype/byte-order contracts equivalent. Keep accidental reinterpretation errors separate from numerical transform differences, and retain the exact manifest used by each reader for reproducibility.

Part 7 - Engineering Interpretation and Philosophy

The binary file is a data contract, not just a convenient extension. Bounded generation and fair access traces make it possible to attribute savings to avoided eager copying rather than to missing data, sparse allocation, or unequal useful work.

19.33.3 Exercise 02

Exercise Title: Create a File-Backed CPU Tensor with torch.from_file() and Verify That Its Storage Is Backed Directly by a Memory-Mapped File

Part 1 - Exercise Contract and Why It Matters

Create an ordinary dense CPU tensor from a compatible raw file and verify file-backed behavior using independent value and mapping-policy tests. Separate private copy-on-write access from shared write-through behavior without modifying the benchmark's authoritative dataset.

Part 2 - System and Memory Mental Model

The raw file tensor API takes an element count, not a byte count, and uses an explicit dtype contract. Its ordinary mapped storage is CPU storage and cannot be created directly as pinned storage under the documented restriction. Private mapping prevents writes from changing the file but is not a read-only tensor guarantee; writes can create private pages. Shared mapping allows file changes and interprocess visibility but does not supply synchronization or durable-publication guarantees by itself.

Part 3 - Quantitative Prediction Before Execution

Compute required bytes as Ns and predict failure when an existing private-map file is too short. For a tiny disposable file, predict observed values after one private mutation and after one shared mutation using separate mappings. Calculate the single element's byte location from dtype width. Distinguish file-backed residency from private dirty-page growth and explain why a stable pointer alone would not establish the backing relationship.

Part 4 - Experimental Design and Instrumentation

Prepare an immutable benchmark file and separate tiny scratch copies for mutation tests. Complete explicit CPU/dtype/size mapping and compare selected values with an independent byte reader. On scratch files, test private and shared changes, coordination, reopening, and the supported persistence boundary. Record policy, file identity, mapping lifetime, and verification scope. Keep all training-dataset access logically read-only. Test empty requests, length mismatch, and unsupported pinned/device choices with precise status instead of silently allocating another kind of tensor.

Use one scratch-file element and one untouched neighbor to verify the exact mutation extent. Reopen independently after the declared observation boundary and compare both locations. If a persistence experiment is included, specify its actual file/mapping synchronization mechanism rather than assuming a PyTorch tensor offers a generic flush method. The main dataset benchmark must continue to use an unchanged source and a nonmutating transform contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class FileMappingContract:
    path: str
    element_count: int
    dtype: object
    shared: bool
    application_writable: bool

def open_file_tensor(contract):
    # Validate file bounds and explicit CPU mapping properties.
    ...

def verify_backing_behavior(contract, disposable_copy, probes):
    # Compare private/shared behavior using independent file observations.
    ...

def E02(config):
    # Keep mutation controls separate from immutable dataset evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require independent file observations, not only tensor aliases reflecting the same memory. Shared visibility is not proof of completed durable writeback; state the supported flush/close contract if durability is measured. Never mutate an OS read-only mapping through a tensor wrapper to test protection. File truncation or replacement during access is outside the immutable-source contract and must not be used as a routine benchmark case.

Check that the mapping remains alive while a returned view is consumed and that shutdown does not close or replace its backing prematurely. A tensor's logical byte count can exceed its currently resident pages; report these separately. The read/write policy test should never depend on deliberately causing an invalid access to a truncated mapping.

Part 7 - Engineering Interpretation and Philosophy

File-backed storage has an explicit policy and lifetime. Correct use depends on knowing whether a write changes private memory or authoritative file data, and on preserving that distinction when the tensor enters the larger input pipeline.

19.33.4 Exercise 03

Exercise Title: Read Selected Tensor Regions from a Memory-Mapped File and Prove That Unused Dataset Regions Do Not Need to Be Materialized Up Front

Part 1 - Exercise Contract and Why It Matters

Read selected regions from a much larger logical mapping and establish that an independent full dataset payload need not be created before useful access. State the observation model behind the title's proof and distinguish application materialization from operating-system residency and readahead.

Part 2 - System and Memory Mental Model

Creating a slice can create only a view; it may not read element data until a computation consumes the values. Converting, cloning, stacking, or computing an aggregate can touch pages and allocate outputs. The OS can prefetch neighboring pages even when the application requests a smaller region. A file can therefore be partly resident without a full anonymous tensor copy, but exact untouched-page claims need page-level evidence and cannot follow from source code or RSS alone.

Part 3 - Quantitative Prediction Before Execution

For a requested byte interval $[a, a + b)$ and observed page size P, calculate its intersecting page set and logical payload. Compare two distant intervals, adjacent intervals, and repeated access to one interval. Predict mapping-only, view-only, consumed-view, and copied-view outcomes. Explain how a checksum over the entire mapping would invalidate a claim that the experiment accessed only a few selected regions, even if the checksum is called validation.

Part 4 - Experimental Design and Instrumentation

Generate deterministic tiny truth data and a safely sized larger file. Define an exact region trace before opening. Complete selective views and consume only those regions through bounded operations. Capture process/file-backed observations and supported page/I/O evidence at each phase. Run a deliberately full-scan control in another replay, not before the selective test. Compare values against the manifest or an independent bounded reader. Preserve cache state, sample trace, dtype, offset units, mapping owner, and any observer activity that itself touches data.

Include a view-only phase that records metadata without calculating a sum, then a consumed-view phase that actually needs the selected values. This control reveals whether the measurement labels an unexecuted slice as a completed read. Add a bounded copied-view phase and account for both its source access and independent destination. Compare those phases with a separate full traversal using identical lightweight consumption per requested byte.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RegionRequest:
    request_id: str
    byte_offset: int
    byte_length: int
    consumer: str
    copy_required: bool

def validate_region(request, file_specification):
    # Check bounds, dtype alignment, and declared address units.
    ...

def read_selected_regions(mapping, requests, ownership_contract):
    # Distinguish view creation from actual value consumption and copying.
    ...

def E03(config):
    # Compare selective access with an independent full-scan control.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct selected values and no unintended full materialization by transforms, logging, or validation. Low RSS cannot prove every unrequested page remained untouched; label that claim unsupported unless directly observed. A repeated region can be cached and must not be counted as new disk traffic by assumption. Keep logical bytes, fault counts, resident pages, and independent copy bytes in distinct fields.

A profiler or logging helper can itself inspect the entire tensor. Audit such observers before trusting sparse-access evidence. If the OS reads neighboring pages, preserve that observation without calling the application eager. The claim is absence of a required upfront independent full payload, not control over every page the kernel may cache.

Part 7 - Engineering Interpretation and Philosophy

Selective mapping is valuable because useful work can begin from a bounded requested subset. A precise claim describes which application copies were avoided and which access was observed, while leaving OS speculation and unmeasured page residency as explicit uncertainty.

19.33.5 Exercise 04

Exercise Title: Benchmark Sequential and Random Access Patterns on the Same Memory-Mapped Tensor and Explain the Difference in Effective Throughput

Part 1 - Exercise Contract and Why It Matters

Benchmark sequential and random region access on the same mapped tensor. Explain effective throughput using locality, caching, page faults, access size, and storage behavior rather than assuming one pattern always wins. Keep requested work, coverage, and consumption identical or explicitly label the differences.

Part 2 - System and Memory Mental Model

Sequential access can benefit from locality and readahead; random access can increase per-request overhead and reduce cache reuse. A fully cached file may primarily measure CPU and memory behavior rather than disk. A random permutation without replacement differs from independent random indices with repeats. Fault counters and storage-byte counters answer different questions. The chosen reduction or transform can also dominate timing, hiding the data-access cost the experiment aims to study.

Part 3 - Quantitative Prediction Before Execution

For K requests of b bytes, calculate logical throughput Kb/T only when all requests complete and the numerator matches consumed data. Predict unique page demand for tiny hand-checkable traces and contrast it with repeated requests. Model a coarse request cost as access latency plus bytes divided by effective bandwidth, stating its limits. Predict cold-like and warm-cache rankings separately without inventing cache control.

Part 4 - Experimental Design and Instrumentation

Pre-generate sequential and seeded permutation traces outside the timed region. Use matching blocks, total coverage, scalar consumption, and trial boundaries. Record file/system context and run several randomized trial orders. Measure mapping setup separately, then capture complete access time, faults, supported I/O counters, and memory. Include a repeated-small-working-set control and a larger traversal that stresses locality. Preserve all samples and classify cache state as measured or uncontrolled. Compare storage characteristics without assuming HDD and NVMe must exhibit the same magnitude of effect.

For the random policy, record whether accesses are a permutation or sampled with replacement, and keep both when studying reuse. Compute a tiny trace's exact unique-byte and unique-page sets as an independent reference. Generate index order once before timing so permutation generation does not inflate only the random path. Include a consumer-only control operating on already resident bounded data to estimate the transform/dispatch floor.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AccessTrial:
    pattern: str
    request_count: int
    logical_bytes: int
    unique_pages_estimate: object
    elapsed_seconds: object
    io_bytes: object
```

```
    fault_counts: object
    checksum: object

def generate_access_trace(pattern, bounds, seed):
    # Make coverage/replacement policy explicit before timing.
    ...

def run_access_trace(mapping, trace, config):
    # Consume equivalent values and measure completed access.
    ...

def E04(config):
    # Compare sequential, permutation, and cached-working-set controls.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate the scalar result or sample IDs so skipped reads cannot appear fast. Report repeated logical bytes separately from unique payload and observed I/O. A warmed second trial is not independent evidence of storage speed. Do not convert major faults directly into bytes or label every slowdown random-I/O thrashing. Preserve neutral outcomes, timing variability, and instrument limitations alongside any locality advantage.

Check whether the consumer forces completion and whether results remain finite and meaningful. A reduction over unread or uninitialized output is not evidence of successful file access. Report useful requested throughput, unique-payload coverage, and physical I/O only at their actual observed scopes, with no assumed conversion between them.

Part 7 - Engineering Interpretation and Philosophy

Access order is part of the resource demand. The useful conclusion identifies when locality helps this workload and whether the bottleneck was storage, resident-memory access, or CPU consumption, with enough trace detail to test the explanation.

19.33.6 Exercise 05

Exercise Title: Sweep Access Block Size and Determine How Small Reads, Large Reads, and OS Page Behavior Affect Dataset Throughput

Part 1 - Exercise Contract and Why It Matters

Sweep logical access block size while holding the total requested payload and consumption work comparable. Identify when request overhead, page coverage, readahead, CPU processing, and storage bandwidth explain the result. Separate application block size from operating-system page size and mapping granularity.

Part 2 - System and Memory Mental Model

A request smaller than a page can still require a whole page to become accessible, while adjacent requests may reuse that page. Larger blocks can amortize Python and dispatch overhead but increase working set or read unneeded data. Mapping offset alignment rules and page

sizes differ by platform; use observed supported values instead of assuming one universal size. A vectorized transform over a large block may change the compute implementation, so access and processing costs need separate controls.

Part 3 - Quantitative Prediction Before Execution

For each block size b, compute request count for a fixed logical payload and predict page-cover counts on a tiny trace. Include aligned and deliberately misaligned requests that remain valid for the selected API. Estimate useful bytes divided by completed time and separate physical read amplification where measurable. Predict a plateau or reversal when larger blocks no longer remove per-request overhead and instead raise memory or cache pressure.

Part 4 - Experimental Design and Instrumentation

Choose a bounded size sweep spanning below-page, near-page, and larger requests. Precompute traces and control coverage, replacement, and boundary handling. Measure a lightweight consumer and a fixed representative transform separately. Capture request time, completed throughput, faults, supported I/O bytes, resident memory, and variability across trials. Record cache context and actual page granularity. Include the last partial block consistently rather than dropping it from only one configuration. Keep fixture generation, trace generation, and full-data verification outside timed regions unless explicitly included.

Add two alignment cases with the same useful payload but different starting offsets inside a page. For a tiny fixture, calculate page intersections by hand and compare with the index arithmetic. Keep mapping creation alignment rules distinct from logical slice alignment: a supported full-file mapping can expose slices that do not themselves begin at a page boundary. Record which layer of alignment the test changes.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BlockSweepCase:
    block_bytes: int
    request_count: int
    alignment_policy: str
    logical_payload_bytes: int
    consumer_kind: str

def build_block_sweep(file_specification, sizes, coverage_contract):
    # Preserve useful payload and define partial-boundary handling.
    ...

def measure_block_case(mapping, case, trace, instruments):
    # Separate access cost, consumer cost, page evidence, and I/O.
    ...
```

```
def E05(config):
    # Explain the observed curve using controls rather than one counter.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not report speedup from reading fewer useful bytes or changing transform semantics. A page-cover estimate is not a measured disk-byte count. Preserve cached and uncontrolled runs as such. If the smallest block is dominated by Python-loop overhead, demonstrate that with a compute/access control rather than calling the device slow. Report peak staging or copied block capacity when it changes with block size.

If a larger block reads extra padding, exclude that padding from useful-byte throughput and report it as additional access. Preserve the last-block handling and total sample coverage for every size. A benchmark that drops awkward boundaries is not measuring the same dataset and cannot establish a fair block-size optimum.

Part 7 - Engineering Interpretation and Philosophy

Block size is a tradeoff between overhead amortization and working-set demand. Select a range justified by the measured data path, not a single page-sized rule assumed to apply to every dataset, storage device, transform, or platform.

19.33.7 Exercise 06

Exercise Title: Compare Resident RAM Growth for Eager Dataset Loading and Memory-Mapped Access While Processing an Identical Dataset

Part 1 - Exercise Contract and Why It Matters

Compare resident-memory evolution for eager dataset ownership and mapped access while processing identical samples. Measure the complete timeline, including batches and transforms, and distinguish removed anonymous duplication from file-backed residency that grows as data is touched.

Part 2 - System and Memory Mental Model

Eager reading can create an independent anonymous dataset copy while file pages also remain cached. Mapping can avoid that full copy yet still accumulate resident file-backed pages during a scan. RSS, PSS, anonymous memory, shared file pages, and system page cache are related but noninterchangeable. Summing process RSS can overstate physical use when pages are shared. Queues, collated batches, pinned buffers, and retained outputs can dominate memory even with a perfectly lazy source.

Part 3 - Quantitative Prediction Before Execution

For dataset payload F, active batch copies B, index metadata I, and mapped resident pages $R_f(t)$, sketch a scoped model separating independent payload from file-backed residency. Predict mapping-only, first batch, full epoch, and idle-after-epoch states. Compare selected-subset and complete-scan workloads separately. Define the measured peak and explain why a final RSS delta can miss a transient eager-copy peak or retained queue.

Part 4 - Experimental Design and Instrumentation

Run eager and mapped strategies in isolated processes with the same access order, transform, batching, and reduction. Capture baseline and phase memory using supported high-water and sampled instruments, labeling their scopes. On Linux, distinguish process file/anonymous and proportional observations when available; other platforms must report unavailable fields honestly. Record worker count as zero initially and add workers only in a separate extension. Verify all requested sample IDs and values. Avoid storing batch tensors in the evidence log, and measure release without assuming the OS immediately evicts cached pages.

Track the owner count of batches held by the application in addition to source mappings. Include one controlled diagnostic run retaining several batches, then remove that retention in the equivalent production comparison. This demonstrates why a mapped source alone does not bound total pipeline memory. Keep the retained-batch control small and label its changed contract rather than treating it as the eager strategy's default behavior.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ResidentMemoryPoint:
    phase: str
    rss_bytes: object
    pss_bytes: object
    anonymous_bytes: object
    file_backed_bytes: object
    independent_batch_bytes: int
    measurement_scope: str

def process_identical_trace(reader, trace, consumer, config):
    # Keep sample coverage and bounded batch ownership equivalent.
    ...

def compare_memory_timelines(eager, mapped, metric_contract):
    # Separate high-water evidence from sampled and final observations.
    ...

def E06(config):
    # Audit complete work and retain all memory-accounting limitations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A mapped full scan reaching a large RSS is not proof the source was eagerly copied into anonymous memory. Conversely, low source residency does not excuse unbounded output retention. Compare each reported layer with an independent owner inventory. Do not add process and system cache bytes without explaining shared accounting. Preserve failed or unsupported measurements rather than turning them into a perfect reduction percentage.

Record when each memory observation was sampled relative to consumer completion and reference release. Sampling after cleanup can miss the only overlap that matters. A claimed peak based on periodic samples needs its interval and limitations stated; a platform high-water value needs its process lifetime scope rather than being treated as a resettable phase counter.

Part 7 - Engineering Interpretation and Philosophy

Resident-memory savings should be attributed to specific ownership removed, not to a convenient final counter. The useful result follows the same data through the same work and explains which pages were mapped, copied, retained, and merely eligible for reclamation.

19.33.8 Exercise 07

Exercise Title: Build a Memory-Mapped Dataset Class That Converts File Offsets into PyTorch Tensor Samples Without Loading the Whole File

Part 1 - Exercise Contract and Why It Matters

Build a map-style dataset translating validated sample IDs into bounded tensor regions of a raw mapped file. Preserve schema, source ownership, and explicit copy semantics. Demonstrate correct sample access without creating a full independent dataset payload at construction.

Part 2 - System and Memory Mental Model

A file path and a dtype are insufficient without sample layout, shape, byte order, offsets, and bounds. For a fixed-size dense format, a process-local mapping can expose sample views, but transforms must not mutate authoritative source bytes or accidentally private-copy the dataset. Batching may intentionally stack samples into new bounded storage. Keep mapping owners alive while views are used and avoid relying on unspecified serialization of a live huge mapped view across processes.

Part 3 - Quantitative Prediction Before Execution

For fixed sample shape h, element width s, and sample index i, calculate sample bytes $b = s \prod_k h_k$ and byte offset ib under a headerless contiguous format. Convert byte offsets to element indices only after checking divisibility. Predict constructor payload, one view, a transformed sample copy, and a collated batch separately. Include index bounds and a truncated-file case before any real read.

Part 4 - Experimental Design and Instrumentation

Create a tiny deterministic sample file and manifest. Complete lazy opening in the consuming process, sample range validation, view construction, and read-only source usage. Compare every tiny sample with an independent in-memory reference, then test sparse selected access on a larger bounded file. Audit constructor behavior and returned view ownership. Add an in-place transform that must receive an independent bounded copy. Document the collation contract so future worker processes transmit bounded batches rather than an unintended full mapped backing storage.

Give each sample an explicit ownership policy: borrowed immutable view or independent bounded tensor. The collator must know which form it receives and create any necessary writable batch storage before transforms that mutate. Test a sample retained across several later fetches to ensure the implementation does not reuse a temporary destination behind its caller's back. Keep labels and sample IDs bound to their exact data region.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.utils.data import Dataset

@dataclass
class FixedSampleSchema:
    path: str
    sample_count: int
    sample_shape: tuple
    dtype: object
    byte_order: str
    payload_bytes: int

class MappedTensorDataset(Dataset):
    def __init__(self, schema):
        self.schema = schema
        # Store lightweight metadata and unopened process-local state.
        ...

    def __len__(self):
        # Return the validated logical sample count.
        ...

    def __getitem__(self, index):
        # Open locally, validate range, and return the declared sample form.
        ...

def E07(config):
    # Compare samples and audit bounded source/copy ownership.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact sample IDs, shapes, dtypes, and values for the supported format. Negative indexing, empty datasets, and out-of-range IDs need an explicit policy. Do not interpret a raw byte offset as an element offset. A returned view is not an independently writable sample. Detect unexpected constructor scanning, full-source cloning, or hidden materialization by a transform. Keep unsupported endianness or layouts outside the initial format contract.

Verify file size and source version at opening, then rely on the immutable source contract during normal access. Reopening a replaced path is not necessarily the same data authority. A production extension needing live updates would require versioned publication and reader lifetimes; it must not be assumed by this fixed-file dataset.

Part 7 - Engineering Interpretation and Philosophy

A mapped dataset is an address translation interface with an ownership contract. Its value comes from making a requested sample cheap and auditable, while keeping later transforms, collation, and process transfer explicit rather than claiming the entire pipeline is copy-free.

19.33.9 Exercise 08

Exercise Title: Store Variable-Length Samples in a Shared Memory-Mapped Data File with a Separate Offset and Length Index

Part 1 - Exercise Contract and Why It Matters

Store variable-length samples in one immutable raw data file with a separate validated offset/length index. Recover each sample lazily and define batching, padding, or packed output semantics. Account for index memory as well as data payload.

Part 2 - System and Memory Mental Model

Variable-length records need unambiguous units, dtype, byte order, shape interpretation, and source version. An offset can refer to bytes while a length can refer to elements; mixing them creates silent addressing errors. Overlapping ranges may represent intentional sharing or corrupt metadata and must follow the declared format. A large index can itself exceed memory, so mapping or compact fixed-width index representation belongs to the design. Padding and collation materialize bounded output even when source access is view-based.

Part 3 - Quantitative Prediction Before Execution

For records (o_i, ℓ_i), validate each byte range using element width and file payload bounds. Calculate index bytes for two fixed-width fields plus any shape/label metadata, without assuming Python object tuples have that compact representation. For one batch, compare packed payload with padded payload using the longest record and include masks. Predict a long outlier's effect on batch capacity and define an admission rule.

Part 4 - Experimental Design and Instrumentation

Write deterministic short, empty, and longer records in bounded chunks and publish the data/index pair under one versioned manifest. Complete validated index access, bounded sample views, and the selected collator. Compare every tiny reconstructed sample with a reference. Test misaligned offsets, overflow arithmetic, negative lengths, truncated data, stale index versions, and an explicitly allowed overlap. Keep malformed-case validation in host metadata rather than intentionally dereferencing invalid mapped pages. Measure index, source residency, and padded batch bytes separately.

Compare an index stored as compact fixed-width records with a deliberately small Python-object index. Measure metadata overhead separately from data pages, and do not extrapolate a Python tuple's cost from its serialized field width. For batching, retain original lengths so a padding mask can be checked against every reconstructed record. Include one record spanning a locality window and verify it is not split or duplicated accidentally.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class VariableRecord:
    sample_id: int
    byte_offset: int
    element_count: int
    shape_metadata: tuple
    data_version: str

def validate_index_record(record, file_specification, limits):
    # Check units, alignment, overflow, version, and complete byte bounds.
    ...

def fetch_variable_record(mapping, record, ownership_contract):
    # Construct only the supported bounded sample representation.
    ...

def collate_variable_samples(samples, batch_policy):
    # Bound packing/padding and preserve lengths, masks, and labels.
    ...

def E08(config):
    # Validate data/index agreement and outlier-batch admission.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require matching sample content, lengths, masks, and labels, not only total file size. Empty records must not create invalid reads or misleading pointer identity. A compact on-disk index does not prove compact resident Python metadata. Reject stale or corrupt manifests before source access. Preserve outlier refusal and unsupported shapes explicitly instead of truncating records silently to make a batch fit.

Bounds checks must cover the full addressed record, not only its first element. Validate arithmetic before converting to a narrower integer field. If overlapping ranges are supported, record whether the overlap is intentional shared content or unrelated logical samples; the consumer's mutability contract must preserve the authoritative bytes for both.

Part 7 - Engineering Interpretation and Philosophy

Variable-length access makes metadata part of the data path. The store is reliable when every record can be translated and bounded independently and when batching costs remain visible rather than being hidden behind a lazy source interface.

19.33.10 Exercise 09

Exercise Title: Build a DataLoader Around a Memory-Mapped Dataset and Verify Safe Access Across Multiple Worker Processes

Part 1 - Exercise Contract and Why It Matters

Use a mapped dataset with multiple DataLoader worker processes and verify correct sample coverage, process-local source opening, reproducible transforms, and bounded batch transfer. Explicitly select and test supported process-start behavior instead of assuming one platform default.

Part 2 - System and Memory Mental Model

Workers are separate processes with their own dataset state and runtime resources. Start methods can inherit or serialize objects differently and can vary with platform and Python version. Keep datasets and initialization/collation functions picklable where needed and use a guarded main entrypoint. Open or reopen mappings in the consuming process using lightweight source metadata. Return CPU samples and collated batches; CUDA transfer belongs in the main training process under the initial contract.

Part 3 - Quantitative Prediction Before Execution

For W workers and configured prefetch depth p, estimate queued batch payload from Wpb as a starting component, then add active workers, main-process batches, IPC, metadata, and optional pinning separately. Predict shared-source page accounting versus duplicated Python state. Specify expected IDs for a map-style epoch and distinguish it from worker-sharded iterable behavior. Predict which failures arise when live mapping objects are blindly serialized.

Part 4 - Experimental Design and Instrumentation

Begin with one process and validate all tiny samples. Complete a top-level worker-safe dataset, process-local mapping cache, pickling state, collator, and explicit start-method configuration. Test zero, one, and several workers, with bounded batches materialized before IPC. Verify sample IDs, labels, values, and transform seeds across epochs. Record worker PIDs, open/reopen events, resource observations, persistent-worker policy, and shutdown. Test worker failure on a controlled bad manifest and preserve its useful diagnostic without launching unsafe reads or CUDA work in workers.

Exercise at least one explicitly configured spawn-compatible run where the platform supports it, using top-level definitions and a guarded entrypoint. Audit whether opening occurs in the parent, worker, or both, with PIDs recorded. A lightweight path/schema object should reconstruct local access without serializing an entire live mapping. Include a second epoch with persistent workers to verify source identity and per-epoch randomness do not silently become stale.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.data import Dataset, DataLoader

class WorkerMappedDataset(Dataset):
    def __init__(self, schema):
        self.schema = schema
        # Keep only serializable metadata and process-local lazy state.
        ...

    def __getstate__(self):
        # Exclude live process-owned mappings from serialized state.
        ...

    def __len__(self):
        ...

    def __getitem__(self, index):
        # Reopen locally when required and validate bounded access.
        ...

def worker_initialize(worker_id):
    # Set required independent RNG state and process-local resources.
    ...

def E09(config):
    # Use a guarded script entrypoint and verify coverage/cleanup.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not assume multiple workers multiply unique physical source pages by W, or that all Python metadata is shared. Default collation can create a batch copy; account for it. With disabled batching or a passthrough collator, returning views of huge source storage needs an explicit IPC/lifetime design. Preserve dropped-last and duplicate-ID policies so apparent throughput cannot hide missing or repeated data.

Compare complete epoch ID multisets with the sampler's declared expectation. Process scheduling can change completion order without justifying lost or duplicated samples. Keep worker-local file resources alive through batch construction and resolve them at shutdown; do not rely on a destructor's unobserved timing as the only correctness argument.

Part 7 - Engineering Interpretation and Philosophy

Safe multiprocessing starts from explicit process ownership and sample semantics. A mapped source can be shared physically while each process still needs correct metadata, lifecycle, randomness, and bounded independent outputs.

19.33.11 Exercise 10

Exercise Title: Compare num_workers Values on a Memory-Mapped Dataset and Identify When Storage Bandwidth, Page Faults, or CPU Processing Become the Bottleneck

Part 1 - Exercise Contract and Why It Matters

Sweep DataLoader worker count and identify the measured limiting stage for a mapped dataset. Compare storage demand, page activity, transforms, collation, IPC, and consumer waits. Preserve complete sample coverage and queue capacity so a larger worker count does not silently change the workload.

Part 2 - System and Memory Mental Model

Workers can overlap useful preparation but can also compete for storage, CPU cores, memory bandwidth, and cache. More workers increase queue and metadata resources and can worsen random access. A low observed GPU utilization is not by itself proof of storage starvation; compute size, transfer dependencies, and host synchronization can produce similar symptoms. Worker count and prefetch depth are separate policy dimensions, and total in-flight payload must remain part of the comparison.

Part 3 - Quantitative Prediction Before Execution

Construct a stage model for source access, transform, collation/IPC, transfer, and GPU compute. Predict throughput bounded by the slowest effective stage, including contention rather than summing nominal capacities. For each worker count estimate queued/active batch bytes and useful samples per second. Predict a storage-heavy trace and a CPU-transform-heavy trace, then state the observations that would distinguish bandwidth saturation from CPU saturation or excess page churn.

Part 4 - Experimental Design and Instrumentation

Freeze sample order, batch size, transforms, useful consumer work, and seeds. Sweep a safe small set of worker counts with explicit valid zero-worker configuration. Run source-only and transform-heavy controls, then the full pipeline. Record worker CPU time, batch-ready latency, supported storage/page metrics, main-process waits, pinned capacity, and completed useful throughput. Measure worker startup separately from steady epochs and document persistent workers. Use equal useful data and preserve queue changes as measured policy costs. Repeat trial order and cache context without selectively discarding slow runs.

Add one trial holding approximate in-flight bytes constant while changing worker count, and another preserving the normal prefetch policy so total queue cost can vary. These are different policy questions and should have separate tables. Observe main-thread batch waits and worker preparation times together; an aggregate samples-per-second number cannot reveal whether extra workers hide I/O or merely move contention into another queue.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
```

```
class WorkerSweepResult:
    workers: int
    prefetch_depth: object
    completed_samples: int
    batch_wait_samples: tuple
    host_peak_bytes: object
    storage_evidence: object
    cpu_evidence: object
    complete_seconds: object

def configure_worker_trial(dataset, case, support_contract):
    # Handle zero-worker options and bounded in-flight resources explicitly.
    ...

def diagnose_pipeline_limit(stage_evidence, controlled_replays):
    # Separate directly measured facts from bottleneck hypotheses.
    ...

def E10(config):
    # Compare worker counts on equivalent source/transform/full workloads.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A higher sample rate is invalid if IDs are duplicated, dropped unexpectedly, or transformed differently. Compare trial duration through completed device work, not only loader iteration submission. Fault counts alone do not establish disk contention, and CPU occupancy alone does not establish useful transforms. Preserve the smallest worker count attaining stable measured performance and report the uncertainty when instruments cannot separate competing explanations.

Report CPU transform threads as well as worker processes where relevant. Nested thread pools can oversubscribe cores even at a modest worker count. Do not infer a storage bottleneck from low throughput without a controlled source-only or resident-data comparison. Keep the alternative explanation visible until supporting evidence resolves it.

Part 7 - Engineering Interpretation and Philosophy

Concurrency is beneficial only while it hides a real bottleneck without creating a worse one. Choose worker count from complete stage evidence and resource cost, not from available core count or the assumption that more parallel readers always feed the GPU faster.

19.33.12 Exercise 11

Exercise Title: Combine Memory-Mapped Dataset Access with Pinned Host Buffers and Non-Blocking CUDA Transfers

Part 1 - Exercise Contract and Why It Matters

Stage mapped samples into bounded pinned host buffers and transfer them to CUDA with explicit completion ordering. Demonstrate correct values, safe buffer reuse, and complete latency. Identify every copy instead of labeling the path zero-copy because the original source is mapped.

Part 2 - System and Memory Mental Model

File-backed tensor storage is not directly pinned by the documented raw-file mapping API. Collation and pinning can create independent batches before host-to-device transfer. A pinned source must not be overwritten while its transfer is in flight, and a CUDA destination must not be reused while readers remain. Nonblocking submission does not prove completed transfer or actual overlap. Automatic DataLoader pinning and a custom reusable pinned pool are different strategies whose costs should not be silently combined or omitted.

Part 3 - Quantitative Prediction Before Execution

For batch payload b and K staging slots, predict pinned capacity Kb plus any collated source batch and device slots. Count source-to-batch, batch-to-pinned, and pinned-to-device traffic under the selected route. Draw the timeline for one serialized slot and a two-slot ring. Estimate copy/setup overhead and potential overlap limits, keeping the source mapping's resident pages separate from locked host storage and VRAM.

Part 4 - Experimental Design and Instrumentation

Start with deterministic small CPU batches and a serialized reference. Complete one explicit staging strategy with generation tags and readiness/completion events, then compare it with a supported automatic-pinning baseline. Verify checksums only after completion and before overwrite. Measure setup, fill, transfer, GPU consumption, waits, and complete time consistently. Apply bounded backpressure when slots are unavailable and test delayed transfer completion. Keep CUDA work in the main process, and record whether custom batch types support the selected DataLoader pinning behavior.

Use a host-side lease simulator to validate one-slot and two-slot transfer schedules before CUDA execution. A new batch generation cannot inherit a stale completion token from an older use of the same slot. Check a delayed consumer and early-stop sequence, including all retained source owners. If a custom pool replaces automatic pinning, ensure automatic pinning is not still adding an unintended independent pinned copy.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BatchTransferLease:
    batch_id: int
    slot_id: int
    generation: int
    source_owner: object
    copy_done: object
    consumer_done: object
```

```
def fill_pinned_slot(mapped_batch, lease, pool_contract):
    # Admit a safe host destination and account for the staging copy.
    ...

def transfer_and_consume(lease, streams, device_slots):
    # Order H2D and compute; protect source and destination lifetimes.
    ...

def E11(config):
    # Verify values and compare serialized versus bounded staged execution.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no host overwrite before H2D completion and no device overwrite before consumer release. Host state-machine tests should reject illegal transitions without intentionally racing memory. Report pinned bytes and any double staging introduced by configuration. If CUDA or pinning support is unavailable, keep the case untested or unsupported. A faster submission timer must not be presented as higher completed transfer bandwidth.

Measure copied payload and retained capacity independently. The same pinned buffer can carry many generations, so cumulative transfer bytes can be much larger than pool size. Conversely, allocating a new pinned tensor for every queued batch can grow retained capacity even when each transfer is correct; report that ownership cost explicitly.

Part 7 - Engineering Interpretation and Philosophy

Pinning creates a controlled transfer resource with its own cost and lease. The useful pipeline makes ownership visible from file view through batch copies to the final device consumer, then measures whether that extra staging actually reduces critical-path waits.

19.33.13 Exercise 12

Exercise Title: Build a Dataset Prefetcher That Reads Future Memory-Mapped Regions While the GPU Computes the Current Batch

Part 1 - Exercise Contract and Why It Matters

Prefetch future mapped regions or prepared batches while the GPU consumes the current batch. Implement bounded lookahead, explicit readiness, and cancellation. Separate application prefetch from OS readahead and DataLoader's own worker prefetch to avoid unbounded overlapping queues.

Part 2 - System and Memory Mental Model

A prefetch request can prepare source pages, decode/transform samples, create collated storage, fill pinned buffers, or submit a transfer. These stages have different readiness and memory costs. The OS need not keep prefetched pages resident until use, and asynchronous hints do not guarantee useful overlap. A CUDA consumer must wait for actual batch readiness.

Abandoned future work still needs safe source/staging cleanup, especially if transfer or compute has already begun.

Part 3 - Quantitative Prediction Before Execution

For current compute time T_c and next-batch preparation time T_p, model an ideal exposed wait as $\max(0, T_p - T_c)$ under independent resources. Add queue contention and transfer dependencies explicitly. Calculate payload for current, prefetched, collated, pinned, and device batches at the chosen lookahead. Predict behavior for a slow storage burst and an early epoch stop. Compare logical prefetched bytes with bytes ultimately used by the workload.

Part 4 - Experimental Design and Instrumentation

Use a fixed sample trace and demand-only reference first. Complete one bounded prefetch layer while recording existing worker and OS policies. Publish a batch only after all required preparation and transfer dependencies are valid. Compare one- and two-batch lookahead where budgets allow, using supported timeline evidence and completed throughput. Test early termination, a failed source read, delayed GPU consumption, and shutdown. Preserve sample order, labels, and no-duplication guarantees. Measure unused preparation and queue residency rather than counting speculative bytes as useful data.

Label readiness by stage: source accessed, transformed, collated, pinned, H2D submitted, or device-ready. A single generic ready flag can authorize a later consumer too early. Record the stage that the prefetcher actually owns and define how it hands off to existing loader and transfer components. Use a fixed queue capacity in both successful and cancelled cases rather than allowing exception paths to retain unlimited prepared batches.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DatasetPrefetchTicket:
    batch_id: int
    sample_ids: tuple
    stage: str
    reserved_host_bytes: int
    ready_token: object
    cancelled: bool

class BoundedDatasetPrefetcher:
    def request(self, sample_ids):
        # Join existing demand or admit bounded future preparation.
        ...

    def publish(self, ticket, batch, readiness):
        # Preserve order and make completed stage semantics explicit.
        ...
```

```
    def consume(self, ticket, consumer_stream):
        # Wait on the actual generation/stage dependencies.
        ...

    def shutdown(self, deadline):
        # Drain or cancel without freeing in-flight resources early.
        ...

def E12(config):
    # Compare useful work, exposed waits, residency, and unused prefetch.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equivalent completed sample IDs and correct values. An application prefetch queue must not secretly multiply the loader's already queued batches beyond budget. A page hint alone cannot authorize CUDA use. Preserve failures and cancellation as explicit outcomes, settling each resource exactly once. If no measurable overlap occurs, report the tested stages and explain the evidence rather than assuming the tool failed to observe a promised speedup.

A completed batch may still wait for its ordered turn; retain that state separately from a failed preparation. If a later batch finishes first, preserve the declared ordering or explicitly label a changed ordering contract. Useful prefetch analysis must include head-of-line waits and unused work, not only the latency of the fastest future request.

Part 7 - Engineering Interpretation and Philosophy

Prefetch spends resources early to reduce a later wait. It is useful when measured locality and preparation overlap compensate for extra residency and unused work under a bounded lifecycle, not simply when more data is queued.

19.33.14 Exercise 13

Exercise Title: Compare Sequential Sampling, Fully Random Sampling, and Locality-Aware Shuffling and Measure Their Effects on Storage Throughput and GPU Idle Time

Part 1 - Exercise Contract and Why It Matters

Compare sequential order, full random permutations, and locality-aware shuffling for storage behavior, batch readiness, and GPU idle intervals. Preserve epoch coverage and distinguish systems efficiency from the statistical consequences of changing training order.

Part 2 - System and Memory Mental Model

Sequential order can exploit physical locality but may follow labels or time if the file was sorted. Fully random order can disrupt storage locality while improving some mixing properties. Locality-aware order trades between those objectives and is not automatically equivalent to a uniform permutation. Different SGD orders can produce different updates even with identical sample coverage. GPU inactivity needs stage evidence before being attributed to data starvation.

Part 3 - Quantitative Prediction Before Execution

For tiny indexed samples, compute page/locality groups and the number of region transitions under each order. Predict useful bytes, repeated page coverage, batch-wait intervals, and transfer/compute overlap. Define equal coverage and drop-last policy, then specify training-quality measurements separately from exact per-sample correctness. Predict a label-sorted dataset where excellent sequential throughput could hide a harmful ordering effect.

Part 4 - Experimental Design and Instrumentation

Generate all sample orders before timing with recorded seeds. Use identical batches sizes, transforms, worker settings, and useful compute. First compare source and full-pipeline stage evidence, then run a bounded training-quality comparison under stated epochs or examples and validation protocol. Record class/length composition, lagged order correlations, sample coverage, storage observations, batch-ready latency, and supported GPU idle evidence. Preserve cache context and raw trial variability. Do not infer model-quality equivalence from a histogram alone or call unmatched training trajectories numerical loading failures.

Include a tiny dataset sorted by class or time as a diagnostic ordering control, then a representative realistic ordering for the actual recommendation. Inspect per-batch composition and local adjacency without assuming either metric establishes statistical independence. Report comparisons under both fixed examples processed and, if useful, fixed elapsed budget as separate experiments. They answer different questions about efficiency and attainable training progress.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class SamplingComparison:
    policy: str
    seed: int
    sample_order: tuple
    locality_evidence: object
    batch_waits: tuple
    gpu_idle_evidence: object
    quality_metrics: object

def build_sampling_orders(index, policies, epoch_contract):
    # Preserve coverage while making each distribution explicit.
    ...

def compare_sampling_pipelines(orders, workload, config):
    # Separate system throughput from statistical/optimization outcomes.
    ...

def E13(config):
```

```
    # Compare sequential, random, and locality-aware policies honestly.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject missing/duplicate IDs unless the sampler contract explicitly permits them. GPU utilization percentages alone cannot quantify data-wait time. Preserve length-dependent padding and class imbalance as possible confounders. A locality policy that changes sample coverage or useful training work cannot claim pure I/O acceleration. Retain adverse validation outcomes even if throughput improves, and report uncertainty where the tested training budget cannot distinguish quality effects.

Preserve the exact seed schedule and order trace for reproducibility, while acknowledging that changing order intentionally changes the training trajectory. The numerical data-reader check should compare the same sample values; the learning comparison should evaluate the resulting model under a separate validation protocol rather than demand identical SGD gradients.

Part 7 - Engineering Interpretation and Philosophy

Sampling order is both a systems policy and a learning choice. Recommend a tradeoff only after measuring locality, useful pipeline progress, and the relevant training behavior instead of assuming one convenient shuffle offers all benefits without consequences.

19.33.15 Exercise 14

Exercise Title: Build a Page-Locality-Aware Batch Sampler That Reduces Random File Access While Preserving Useful Training Randomness

Part 1 - Exercise Contract and Why It Matters

Build a page-locality-aware batch sampler with explicit randomization and exact epoch coverage. Group nearby sample regions while varying window order and sample order reproducibly. Measure locality and useful training behavior rather than claiming page grouping preserves every property of full random sampling.

Part 2 - System and Memory Mental Model

A sample can span several pages, and variable-length records can overlap multiple locality windows. Page grouping therefore needs a deterministic primary assignment or another explicit policy to avoid duplicates. A page-size estimate is a locality heuristic, not an exclusive OS-residency contract. Randomizing windows and within-window order can leave correlations related to file layout, labels, lengths, or time. The sampler must make those limitations inspectable and keep batch formation compatible with the loader.

Part 3 - Quantitative Prediction Before Execution

Using observed page size P, derive each sample's start page and page span from byte metadata. Build a tiny hand-checkable assignment with samples crossing boundaries and calculate exact sample coverage. Predict batch payload, padding, page-span spread, and window transitions. Define the random variables used each epoch and their seed schedule. Compare these properties with a full permutation without asserting equal distributions or guaranteed convergence.

Part 4 - Experimental Design and Instrumentation

Implement the sampler independently of data reads first. Validate a bijection between expected IDs and emitted IDs under the declared last-batch policy. Test overlapping records, long outliers, empty windows, partial batches, epoch restart, and fixed-seed reproducibility. Integrate through a supported batch sampler configuration rather than simultaneously supplying conflicting shuffle options. Compare page-locality evidence and full pipeline throughput. On a small representative training task, inspect class/length mixing and validation quality under equal useful work. Store compact metadata instead of a per-byte or per-page Python object for every source element.

Test epoch restart and checkpoint-resume semantics on the sampler itself. Record enough seed, epoch, and position metadata to reproduce the intended remaining batch order without silently repeating already consumed examples. If resume is unsupported, state that limit. Compare compact window metadata with a full explicit permutation, charging both construction time and host bytes rather than assuming locality bookkeeping is free at very large scale.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.utils.data import Sampler

@dataclass
class LocalityWindow:
    window_id: int
    sample_ids: tuple
    first_page: int
    last_page: int

class PageLocalBatchSampler(Sampler):
    def __init__(self, index, batch_policy, window_policy, seed):
        # Build compact deterministic ownership and epoch configuration.
        ...

    def set_epoch(self, epoch):
        # Select reproducible epoch-specific randomization.
        ...

    def __iter__(self):
        # Emit batches with exact declared coverage and bounded payload.
        ...

    def __len__(self):
        # Match the actual batch/drop policy rather than a rough guess.
        ...
```

```
def E14(config):
    # Validate sampler invariants before evaluating system/quality tradeoffs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no false coverage from assigning a spanning sample to several windows. A reproducible seed alone does not prove adequate training mixing. Report window, batch, and length policies with every result. Reject oversized batches or define an explicit outlier route; silent truncation changes the dataset. If locality gains vanish on a cached workload, retain that result rather than forcing an artificial general conclusion.

Check class and length correlations within windows and across their boundaries. A window permutation with within-window shuffle is not a full uniform permutation, even when each ID appears once. Report its actual distributional contract and require task-appropriate evidence before calling the available mixing useful for training.

Part 7 - Engineering Interpretation and Philosophy

A locality sampler should offer a controlled and measurable ordering tradeoff. Its credibility rests on exact sample semantics and transparent randomization, with learning-quality evidence appropriate to the actual task rather than an unsupported promise of unchanged randomness.

19.33.16 Exercise 15

Exercise Title: Load a Large PyTorch Checkpoint with torch.load(..., mmap=True) and Process Individual Tensors Without Eagerly Loading Every Storage into RAM

Part 1 - Exercise Contract and Why It Matters

Load a supported PyTorch checkpoint with mapped storage and process selected tensors without eagerly creating an independent copy of every storage. Distinguish this archive-aware loading path from a raw dataset mapping and measure mapping, access, conversion, and retained ownership separately.

Part 2 - System and Memory Mental Model

A PyTorch checkpoint contains metadata and serialized storages under a defined format; it is not a headerless raw tensor file. Mapping can defer storage page access while metadata still loads. Explicit CPU map location avoids unintended restoration to saved CUDA devices. Shared storage and views can make several state names refer to one payload. Processing a tensor by cloning, converting dtype, or moving it to CUDA creates additional resources and reads source values, so lazy loading is not free materialization.

Part 3 - Quantitative Prediction Before Execution

For named tensors sharing canonical storage, calculate logical named bytes and unique payload separately. Predict resources at mapping return, selected tensor processing, full scan, and release. Include conversion output, source pages, and transfer staging where used. Explain why deleting one state-dictionary entry may not release storage held by another alias or final model parameter. A lower immediate load time is not a completed full-checkpoint processing speedup.

Part 4 - Experimental Design and Instrumentation

Generate a trusted tiny plain tensor checkpoint with a view and tied storage, plus a larger bounded fixture in the supported format. Complete mapped CPU loading with an explicit deserialization policy, validate schema, and process one selected group at a time. Compare outputs with ordinary eager loading on equivalent selected work. Track source owners, aliases, memory phases, and observed page/I/O activity where available. Test unsupported mapping inputs without silent eager fallback. Preserve immutable source files until all live mapped owners and pending copies finish.

Use a checkpoint containing two views with distinct element offsets into one storage. Process them independently and inspect whether source references still share a canonical owner. A conversion can break that sharing and create additional payload; record whether preserving the original alias relationship is required. Keep the checkpoint immutable during the primary comparison so private dirty pages or shared writes do not alter the access experiment.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CheckpointTensorRequest:
    name: str
    expected_shape: tuple
    expected_dtype: object
    target_device: object
    copy_policy: str

def open_mapped_checkpoint(path, format_contract):
    # Use explicit CPU placement and restricted supported loading options.
    ...

def process_checkpoint_group(state, requests, ownership_ledger):
    # Account for aliases, conversions, targets, and source lifetimes.
    ...

def E15(config):
    # Compare selected and full processing at matching completion boundaries.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require correct selected values and preserve state aliases where the contract needs them. A private mapped update can cause copy-on-write memory and must not be assumed persistent or free. Do not apply a raw file offset formula to the checkpoint archive without validated

format support. If every tensor is scanned during validation, record that full access instead of claiming only a small group was touched.

A state dictionary is not necessarily composed only of independent floating weights. Validate buffers, scalar tensors, and the supported layout/dtype set. Weights-only loading describes a restricted deserialization policy, not removal of buffers or a guarantee that every arbitrary checkpoint schema can be served by the same bounded reader.

Part 7 - Engineering Interpretation and Philosophy

Archive-aware mapping lets useful tensor processing begin before an eager full independent payload is needed. Its value depends on the access schedule and final ownership, with metadata, file pages, conversions, and aliases all remaining part of the account.

19.33.17 Exercise 16

Exercise Title: Inspect a Large Checkpoint with FakeTensorMode and Extract Tensor Shapes, Dtypes, Strides, and Storage Offsets Without Allocating the Real Tensor Data

Part 1 - Exercise Contract and Why It Matters

Inspect a compatible checkpoint under FakeTensorMode and extract structural tensor metadata without allocating its real payload. Separate element offsets within storage from optional byte offsets within the checkpoint archive. Treat private inspection fields as feature-gated diagnostics, not universal portable reconstruction APIs.

Part 2 - System and Memory Mental Model

Fake tensors describe metadata and logical device behavior without supplying real element values. They are not ordinary resident CPU weights, and their visible device need not be a simple meta label. The documented inspection recipe uses an underscore-prefixed import path, while checkpoint byte-offset annotations are also version-sensitive. A tensor storage offset is measured in elements relative to its storage; a checkpoint storage offset addresses archive bytes. Shared views require both layers to interpret locations.

Part 3 - Quantitative Prediction Before Execution

For a tiny dense tensor view, calculate shape, strides, element width, and its logical storage displacement. If a supported archive storage-byte offset is available, derive the first addressed payload location under the declared uncompressed dense-format assumptions. State why that does not alone validate arbitrary strided span, sparse layout, compression, endianness, or file integrity. Predict metadata memory scaling with tensor count rather than logical element count and distinguish no payload allocation from zero process overhead.

Part 4 - Experimental Design and Instrumentation

Create a trusted small checkpoint with contiguous tensors, an offset view, and shared storage. Feature-check FakeTensorMode and optional offset annotations. Complete inspection and export only CPU scalar metadata, marking unavailable fields explicitly. Compare with ordinary loading on the tiny reference for shapes, strides, dtypes, and storage relationships. Do not extract numerical values from fake tensors. For large inspection, measure metadata cost without performing an accidental real load. Preserve format/version and source identity, and test unsupported cases through safe classification rather than blind byte reads.

Build a metadata unit test with a base storage, an offset slice, and a transpose. Check the element-displacement formula independently on the tiny real reference before considering any

archive location. Export the presence or absence of optional annotations explicitly, preserving the software and format version that produced them. For a large report, stream metadata rows or cap retained details instead of constructing unbounded Python diagnostic objects.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CheckpointMetadata:
    name: str
    shape: tuple
    strides: tuple
    dtype: object
    storage_offset_elements: int
    checkpoint_storage_offset_bytes: object
    inspection_support: str

def inspect_fake_checkpoint(path, feature_contract):
    # Feature-check the documented diagnostic mode before opening.
    ...

def extract_fake_metadata(state, source_manifest):
    # Keep element offsets and optional archive byte offsets distinct.
    ...

def E16(config):
    # Compare tiny real metadata without using fake tensors as values.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Unknown checkpoint offsets must not become zero. Do not infer real payload residency or validity from a fake tensor pointer or device string. An offset annotation is not permission to mutate arbitrary archive bytes. If a private field changes across versions, retain a partial metadata report rather than inventing compatibility. Numerical equality requires a separate legitimate real load; metadata inspection alone cannot verify checkpoint contents.

The documented fake inspection path may change because it uses internal names. Feature checks should distinguish missing import, unsupported archive, and absent optional storage annotation. Do not catch all three and emit a fabricated valid offset. A partial shape/dtype report can remain useful without claiming complete raw payload reconstruction support.

Part 7 - Engineering Interpretation and Philosophy

Structural inspection is valuable before committing real storage, provided its limits remain visible. The strongest output is a versioned metadata report with exact units and honest unsupported fields, not a claim that fake values or private offsets replace a validated data reader.

19.33.18 Exercise 17

Exercise Title: Build a Unified File-Backed Tensor Store That Serves Dataset Samples and Model Tensors Through Byte Offsets, Metadata, and Lazy Materialization

Part 1 - Exercise Contract and Why It Matters

Build a unified metadata and ownership interface for dataset records and checkpoint tensors, while preserving separate format-specific readers. Serve bounded views or lazy materialized results using validated byte metadata, source versions, and explicit leases. Do not flatten every file format into one unchecked raw-address operation.

Part 2 - System and Memory Mental Model

Raw dense sample files, variable-length indexes, and serialized checkpoints have different layout contracts. A common record can describe source identity, format, dtype, shape, strides, logical offset, and ownership, but an archive adapter must still respect its supported schema. Endianness conversion, noncontiguous views, aliases, pinning, and device placement can require copies. Mapped owners and outstanding transfers must survive while returned values still depend on them. Read-only source usage is an application contract.

Part 3 - Quantitative Prediction Before Execution

Define a resource model for mapped source residency, compact metadata, independent output bytes, pinned staging, and target device bytes. Calculate span bounds for a supported dense record and reject malformed ranges before access. For two aliased checkpoint names, distinguish logical record count from unique source owner count. Predict a request that returns a view, one requiring conversion, and one requiring CUDA placement, including each copy and completion obligation.

Part 4 - Experimental Design and Instrumentation

Implement raw-dataset and checkpoint adapters behind one validated request schema. Use tiny authoritative fixtures for exact values and alias checks. Validate source/version, format support, range arithmetic, dtype, shape, and layout before creating outputs. Complete lease acquisition, lazy access, conversion, transfer, and release with bounded caches. Test stale manifests, unsupported endianness/layout, shared owners, cancellation, and shutdown. Benchmark equivalent consumer requests while reporting adapter-specific costs. Keep source files immutable and preserve mapped owners until their final leases and device dependencies are discharged.

Give each adapter a clear decision between borrowed view and independently owned output. The unified store must preserve that decision in its lease so a consumer cannot assume all results are writable. Track source-version and canonical-owner keys independently of record names, and test two requests sharing storage alongside two equal-valued but independent records. Equality of contents is not an ownership identity test.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class FileBackedRecord:
    record_id: str
    source_id: str
    format_id: str
    dtype: object
    shape: tuple
    strides: tuple
    offset_contract: object
    canonical_owner: str

class FileBackedTensorStore:
    def register_source(self, manifest, adapter):
        # Validate immutable source identity and format support.
        ...

    def acquire(self, record_id, target_contract):
        # Return a bounded leased view or charged materialized result.
        ...

    def release(self, lease, completion):
        # Protect source owners, staging, and target readers correctly.
        ...

    def shutdown(self, deadline):
        # Stop admission and resolve live mappings and transfers safely.
        ...

def E17(config):
    # Verify both adapters and reconcile all ownership/copy boundaries.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the same values as each format's legitimate independent reader. A common interface cannot bypass bounds or archive compatibility checks. Do not identify raw byte offsets, tensor storage offsets, and checkpoint archive offsets as interchangeable fields. Report unknown ownership or unsupported geometry as refusal. A source cache hit must not double-count mapped payload, while a real conversion must not disappear from allocation and latency totals.

Avoid interpreting a supported diagnostic archive offset as blanket support for direct raw mapping of every checkpoint. Ordinary archive-aware loading can remain the adapter's correct

path. Report any copying or decoding that path requires instead of discarding format checks to meet an artificial zero-copy target.

Part 7 - Engineering Interpretation and Philosophy

Unification belongs in the request, metadata, and ownership contracts, not in pretending all files have one layout. A reliable store keeps format knowledge local while exposing every materialization and lifetime cost to the consumer.

19.33.19 Exercise 18

Exercise Title: Stress-Test Memory-Mapped Training on a Dataset Larger Than Available RAM and Diagnose Page Thrashing, Random-I/O Bottlenecks, Worker Contention, and GPU Starvation

Part 1 - Exercise Contract and Why It Matters

Stress-test training access when dataset payload exceeds an explicitly stated available-memory reference. Diagnose page churn, storage limits, worker contention, and GPU waits using controlled replays. Preserve learning work and process stability instead of deliberately exhausting the machine to obtain a dramatic failure.

Part 2 - System and Memory Mental Model

A file larger than RAM can be processed with bounded batches, but access locality and active working set determine repeated I/O. Random revisits can cause refaults, while worker queues and pinned buffers consume additional nonreclaimable or anonymous resources. Major faults, swap activity, and device utilization each have limited diagnostic scope. A GPU can be idle for reasons other than storage. Sparse files or highly compressible fixtures can also misrepresent the actual storage path.

Part 3 - Quantitative Prediction Before Execution

Calculate logical dataset size and compare it with a documented physical or isolated-workload allowance, specifying which is used. Estimate batch/index/queue/ pinned/device demand separately from source pages. Predict sequential one-pass, random-revisit, oversubscribed-worker, and CPU-heavy-transform traces. State which measurements would support thrashing rather than simply a slow first scan. Define a minimum supported active set and classify budgets below it as infeasible rather than claiming arbitrary low-memory training.

Part 4 - Experimental Design and Instrumentation

Preflight real disk capacity and choose an isolated bounded test environment. Generate or use an actual payload with allocation/compression properties recorded. Start with a smaller exact reference, then increase dataset or access working set safely. Freeze useful sample count, transform, model, batch, and training state for causal comparisons. Capture stage timelines, faults, supported I/O/reclaim observations, host and pinned peaks, worker resources, GPU waits, and completed updates. Vary one suspected cause at a time and minimize reproducing failures. Preserve abort limits, unavailable metrics, and unexecuted oversized cases honestly.

If an isolated memory limit is used, record its scope and whether file cache, anonymous batches, and pinned pages are charged by the environment. Do not assume it is equivalent to reducing physical installed RAM. Keep a minimum active-set estimate and stop before an unsupported configuration endangers the test host. Source generation and full verification may warm the file, so describe their relation to each stress replay explicitly.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class OutOfRamStressCase:
    trace_id: str
    dataset_payload_bytes: int
    memory_reference_bytes: int
    access_pattern: str
    workers: int
    queue_policy: tuple
    stop_limits: tuple

def preflight_stress_case(case, storage_manifest, limits):
    # Bound disk, metadata, batch, staging, and runtime commitments.
    ...

def run_stress_training(case, pipeline, model, instruments):
    # Preserve useful updates and record causal stage evidence.
    ...

def diagnose_memory_io_incident(evidence, controlled_replays):
    # Separate cache misses, thrashing, CPU limits, and transfer waits.
    ...

def E18(config):
    # Report completed scope, aborts, failures, and minimized explanations.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not call a software queue cap proof that the dataset exceeded physical RAM. State the actual memory reference and test environment. Preserve samples, labels, losses, and update counts so skipped work cannot explain a speedup. If no thrashing occurs, report that instead of inventing counters. An unavailable GPU leaves GPU-starvation claims unmeasured, while CPU-only source behavior can still be analyzed within its scope.

Evidence for thrashing should involve repeated page/refault or reclaim pressure consistent with the trace and useful throughput loss, where supported counters exist. A slow initial scan alone is insufficient. If the experiment cannot observe refault behavior, present a qualified hypothesis and the controlled comparison that would test it.

Part 7 - Engineering Interpretation and Philosophy

Out-of-RAM feasibility comes from a bounded active pipeline and a tolerable access pattern. The stress test should establish where that design works, where repeated data movement dominates, and which measured intervention changes the cause without changing the intended training work.

19.33.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Out-of-RAM Data Pipeline That Streams a Dataset Larger Than System Memory Through Memory Mapping, Prefetching, Pinned Buffers, and CUDA Transfers

Part 1 - Exercise Contract and Why It Matters

Integrate validated mapped sources, indexes, workers, locality sampling, prefetch, pinned staging, CUDA transfer, and measurement into a bounded out-of-RAM training pipeline. Preserve samples and useful updates while quantifying memory, I/O, waits, and throughput. State the tested dataset, platform, and resource envelope rather than promising universal streaming performance.

Part 2 - System and Memory Mental Model

Separate immutable source/version authority, process-local mappings, sample addressing, batch ownership, queue commitments, pinned leases, and device consumers. Mapping removes an eager full independent dataset copy, not every batch allocation or page-cache cost. Source reads, transforms, collation, IPC, pinning, transfer, and compute each have readiness boundaries. Sampling policy can alter optimization behavior; worker and prefetch policy can multiply resident copies. Every accepted request needs a safe release path, including early termination and failed workers.

Part 3 - Quantitative Prediction Before Execution

Define useful throughput as completed correct examples or updates divided by complete elapsed time. Predict source/metadata demand, independent queued batches, pinned capacity, device slots, page-locality behavior, and stage waits under the same workload contract. Compare eager feasible controls, mapped demand loading, worker tuning, and integrated prefetch/staging. Report startup, first batch, steady throughput, tail waits, and absolute resource peaks separately. If eager full loading is infeasible at the target size, retain an honest analytical or smaller control rather than pretending it ran.

Part 4 - Experimental Design and Instrumentation

Freeze format, transforms, seeds, order policy, batch/drop rules, model, precision, optimizer, and update count. Validate tiny fixtures and every component's ownership invariants before scaling. Run equivalent-data comparisons with independent output checks, then evaluate genuine larger-than-reference payload access under bounded limits. Use diagnostic traces separately from unprofiled timing. Include sequential/random/locality policies, variable lengths, multiple workers, delayed GPU consumers, early stop, malformed metadata, and controlled worker failure. Perform ablations without weakening sample correctness or hiding added copies. Publish all unsupported, refused, aborted, and failed cases alongside successful coverage.

Keep an explicit accounting inventory through source, sample, collated batch, IPC, pinned staging, device input, and output consumption. A resource can have several logical names but

one owner, or one logical batch can have several simultaneous physical copies. Audit those cases on a tiny trace before scaling. Check that shutdown stops new work and discharges existing leases without invalidating mapped views or outstanding DMA sources.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class OutOfRamPipelineContract:
    source_manifest_id: str
    format_id: str
    sampling_policy: str
    host_budget_bytes: int
    pinned_budget_bytes: int
    device_budget_bytes: int
    maximum_inflight_batches: int
    worker_policy: tuple

class OutOfRamDataPipeline:
    def __init__(self, contract):
        self.contract = contract
        # Initialize validated metadata, bounded queues, and ownership ledgers.
        ...

    def open_sources(self):
        # Establish process-local immutable mappings and format adapters.
        ...

    def plan_epoch(self, epoch):
        # Preserve declared coverage, seeds, locality, and batch semantics.
        ...

    def prepare(self, batch_request):
        # Bound source access, transforms, collation, IPC, and staging.
        ...

    def transfer(self, prepared_batch, consumer_stream):
        # Publish only correctly ordered generation-specific device values.
        ...

    def release(self, batch_lease, completion):
        # Reconcile source, host, pinned, and device obligations once.
        ...

    def audit(self):
```

```
        # Distinguish requested bytes, copied bytes, residency, and useful work.
        ...

    def shutdown(self, deadline):
        # Stop workers/admission and resolve live mappings and transfers.
        ...

def E19(config):
    # Validate correctness and bounded lifecycle before performance trials.
    ...
    # Export complete evidence and a scope-limited recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires correct samples/labels, complete useful updates, valid batch lifetimes, bounded commitments, and layer-specific memory/I/O accounting. Record source identity/size/allocation, schema, OS/filesystem, Python/PyTorch/CUDA versions, workers/start method, seeds, transforms, sampler, batch policy, queue depth, pinning, source/cache context, faults, supported physical I/O, RSS/PSS scope, pinned/device peaks, timing distributions, validation errors, coverage, and failure phases. Export bounded scalar evidence, not retained batch tensors or graphs.

Demonstrate a private-copy hazard prevented, a worker-safe reopen, a long-record outlier, a cancelled prefetch, a delayed transfer, and infeasible resource admission. Missing OS/GPU measurements remain unmeasured. No fabricated throughput, OOM, or thrashing result is acceptable.

Performance tables must identify whether their denominator includes worker startup, cache preparation, validation, transfer waits, and final GPU drain. Preserve raw phase samples so an apparent speedup can be traced to completed work. If the larger-than-memory target was not executed, distinguish the validated small-scale pipeline from the unmeasured target-scale claim.

Part 7 - Engineering Interpretation and Philosophy

A useful out-of-RAM pipeline makes large data accessible through a small controlled active set while preserving the computation that consumes it. Recommend the smallest measured configuration meeting the workload's memory and progress goals, and identify the next experiment needed before expanding format, worker, sampling, device, or scale support.

19.34 DMM32

Chapter Title: DataLoader Memory Optimization
Specialization: Dynamic Memory Management and CUDA Systems

19.34.1 Exercise 00

Exercise Title: Build a Precise Mental Model of DataLoader Memory Flow Across Dataset Storage, Worker Processes, Shared Memory, Pinned RAM, and GPU VRAM

Part 1 - Exercise Contract and Why It Matters

Build a lifecycle diagram for data moving from dataset authority through worker-local objects, batch collation, interprocess transport, optional pinning, CUDA transfer, and GPU consumption. Identify owners, possible copies, retention, and completion boundaries. Deliver a scoped memory ledger rather than one formula that treats every batch name as independent physical storage.

Part 2 - System and Memory Mental Model

DataLoader coordinates sampling and preparation but is not a universal memory budget enforcer. Workers can own independent metadata and caches while source pages or tensor transport storage are shared. Collated, pinned, and CUDA batches can coexist. Prefetch bounds outstanding work in batches under the configured policy, not a strict universal byte ceiling. Persistent workers extend process and dataset lifetimes. Host function return does not establish transfer or GPU consumer completion, and allocator caching differs from live tensor ownership.

Part 3 - Quantitative Prediction Before Execution

For workers W, prefetch factor p, and payload b, use Wpb only as an initial queued-work estimate when multiprocessing batching is active. Add worker working sets, active consumer batches, transport, pinning, and device slots with overlap checked. Draw one batch generation across the pipeline and predict which resources remain live when another batch is prefetched. Keep RSS, PSS, shared-memory occupancy, pinned payload, and VRAM as distinct measures.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic dataset carrying IDs and labels, plus a bounded representative workload. Record process start method, framework versions, worker policy, batch schema, source authority, transforms, and device support. Capture constructor, iterator startup, first batch, warmed steps, epoch end, and final drain phases. Build an owner table and a completed-use timeline before collecting performance numbers. Export scalar evidence without retaining batch tensors or autograd graphs. Classify unsupported instruments explicitly, and distinguish predicted commitments from actual observed memory at each layer.

Draw the lifecycle for one identified batch twice: once with a single process and once with two workers and pinning enabled. Annotate the moment that each owner may release its reference and the event that permits reuse. Include a sample view that retains a larger backing storage, because logical payload size alone can hide retained capacity. Keep file cache observations outside process-owned allocation totals.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class BatchMemoryFlow:
    batch_id: int
    source_owner: str
```

```
    worker_id: object
    transport_state: str
    pinned_generation: object
    device_generation: object
    consumer_completion: object

def describe_batch_owners(batch_schema, loader_policy, execution_contract):
    # Identify shared ownership, independent copies, and pending readers.
    ...

def E00(config):
    # Reconcile the predicted lifecycle with bounded observed evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not sum process RSS as an exact unique physical total or count pinned payload as an additional disjoint layer without checking where it is already included. A lower live counter after an epoch does not reveal its transient peak. Validate sample IDs and required updates so skipped work cannot explain apparent memory savings. Public queue configuration is not an exact observation of internal queue occupancy.

Reconcile the ledger at iterator creation, first delivery, steady consumption, and epoch completion. Explain why a worker's mapped pages, an IPC tensor, and a main-process view may describe overlapping physical resources. If unique ownership cannot be established, present separate scoped observations and an explicit uncertainty rather than subtracting an assumed shared fraction.

Part 7 - Engineering Interpretation and Philosophy

Memory optimization starts by naming what owns each useful value and when that ownership ends. A reliable pipeline model separates admission, preparation, transport, and completed consumption instead of assuming DataLoader settings translate directly into one predictable memory total.

19.34.2 Exercise 01

Exercise Title: Build a Single-Process DataLoader Baseline and Measure CPU RAM, Batch Preparation Time, GPU Idle Time, and End-to-End Throughput

Part 1 - Exercise Contract and Why It Matters

Build a zero-worker baseline that measures complete batch preparation, source/transform/collation costs where observable, host memory, transfer, and useful GPU work. Establish correctness and measurement boundaries before adding multiprocessing, pinning, or automatic tuning.

Part 2 - System and Memory Mental Model

With zero workers, sample fetching and collation run in the main process. The configuration must omit or disable options that require multiprocessing. A call waiting for the next batch can include source work, transforms, and collation; it is not automatically pure queue delay.

CUDA launches are asynchronous, so a short host call can coexist with unfinished device work. GPU idle time needs timeline or dependency evidence rather than inference from one utilization percentage.

Part 3 - Quantitative Prediction Before Execution

For batch payload b and N completed batches, calculate useful examples per complete elapsed time. Sketch preparation, H2D, forward/backward/update, and drain boundaries. Predict the initial serialized schedule and distinguish constructor time from first result and warmed throughput. Estimate host source, active batch, and device input capacity without treating cumulative bytes processed as peak memory. Declare whether validation and model/optimizer initialization belong to setup or useful work.

Part 4 - Experimental Design and Instrumentation

Use a supported deterministic dataset and fixed model state, dtype, batch policy, and seed. Complete a valid zero-worker loader with no multiprocessing prefetch or persistent workers. Validate sample/label order and a small reference update. Run diagnostic phase timing separately from low-overhead completed throughput trials. Synchronize only at declared measurement boundaries and preserve raw timings. Record CPU-only outcomes when CUDA is unavailable rather than inventing idle metrics. Sample or measure high-water host memory with its scope explicit and keep outputs bounded.

Use a deterministic sample generator with bounded dimensions before adding real storage. Save expected sample IDs and a checksum derived from consumed values so a faster loop cannot win by skipping preparation or GPU work. Decide whether first-use library initialization belongs to startup or warm execution, and apply that decision consistently to every later comparison.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
from torch.utils.data import DataLoader

@dataclass
class SingleProcessBaseline:
    completed_samples: int
    preparation_samples: tuple
    transfer_samples: tuple
    compute_samples: tuple
    complete_seconds: object
    peak_host_bytes: object
    idle_evidence: object

def build_single_process_loader(dataset, batch_contract):
    # Configure only supported zero-worker options.
    ...
```

```
def measure_baseline(loader, model, optimizer, config):
    # Separate diagnostic phase timing from complete useful-work trials.
    ...

def E01(config):
    # Verify data/update semantics and export the baseline evidence.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the same useful step count and include final device completion in the wall interval. A profiler-enabled baseline must not be directly compared with an unprofiled candidate. Per-step synchronization changes overlap and must be labeled as diagnostic. A sampled host peak is an estimate, not a resettable process high-water counter. Preserve unavailable stage attribution and instrument overhead as limitations.

Measure an empty timing harness and a compute-only replay with already resident inputs. These controls describe instrumentation overhead and an input supply ceiling; neither is a replacement for complete pipeline time. Explain whether the baseline is constrained by preparation, transfer, or computation, and retain unsupported GPU idle estimates as unavailable observations.

Part 7 - Engineering Interpretation and Philosophy

The baseline is the reference contract for every later optimization. Its purpose is to make useful work and costs reproducible, so worker or transfer changes can be assessed against a complete computation rather than a faster but unfinished host loop.

19.34.3 Exercise 02

Exercise Title: Sweep num_workers from Zero to High Concurrency and Find the Point Where Additional Workers Stop Improving Throughput

Part 1 - Exercise Contract and Why It Matters

Sweep worker count from zero through a safely bounded high-concurrency range. Find the tested throughput plateau and the least costly configuration near it. Preserve sample coverage, transformations, batching, and complete model work while measuring concurrency overhead.

Part 2 - System and Memory Mental Model

Additional workers can hide source or CPU preparation latency but can also increase storage contention, process overhead, shared-memory demand, and queue capacity. Worker processes may themselves use multithreaded libraries, causing CPU oversubscription. Zero workers is a distinct valid configuration, not an ordinary point with every multiprocessing option unchanged. Persistent-worker, prefetch, and pinning policies must be controlled or reported because they change the resource question being answered.

Part 3 - Quantitative Prediction Before Execution

For each W, predict preparation parallelism, approximate outstanding batch payload, worker metadata, and useful throughput limits from the stage model. Compare a slow-source workload

with an expensive-transform workload. Define a plateau rule using repeated completed trials and variability, not the single fastest observation. Predict a case where more workers reduce GPU waits but increase host memory, and another where contention lowers throughput.

Part 4 - Experimental Design and Instrumentation

Preflight a bounded worker range and host/shared-memory headroom. Freeze sample trace, batch size, useful updates, transform semantics, and per-sample random choices for the primary comparison. Use valid options per worker count and record the process context. Capture startup and warmed epochs separately, with randomized trial order and raw samples. Collect main batch waits, worker CPU evidence, memory, transport pressure, and complete useful throughput. Preserve refused and failed high-concurrency configurations without repeatedly exhausting the host or changing the data to make them appear feasible.

Record worker process IDs and the number of runnable CPU threads observed within the trial. Include dataset transforms that invoke threaded native libraries, because process concurrency can multiply internal parallelism. Keep CPU affinity and thread settings documented and stable during the main sweep. Change them only in a separately labeled intervention with matching workload and sample coverage.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class WorkerCountCase:
    workers: int
    prefetch_factor: object
    persistent_workers: bool
    cpu_thread_policy: tuple
    expected_host_bytes: object

def configure_worker_count(dataset, case, support_contract):
    # Handle zero-worker restrictions and explicit process context.
    ...

def choose_plateau_configuration(results, tolerance_policy):
    # Use repeated completed trials and report uncertainty/cost.
    ...

def E02(config):
    # Compare causal workload controls and preserve all trial outcomes.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject a faster configuration that duplicates, drops, or differently transforms samples. Keep worker startup outside steady-state timing only when it is excluded for every candidate. GPU utilization alone does not locate the plateau's cause. Report nested thread counts and queue policy. The best tested worker count is conditional on this workload, platform, source, batch shape, and measured range; it is not a universal setting.

A noisy winner at the largest worker count does not establish a plateau. Repeat adjacent candidates and show the spread of complete-run throughput, startup latency, and memory peaks. Choose an operational point with explicit uncertainty and budget margin. Report early termination or a resource limit as a failed candidate rather than assigning an invented throughput value.

Part 7 - Engineering Interpretation and Philosophy

Concurrency should be increased until measured hidden latency no longer justifies its memory and scheduling cost. A useful recommendation names the smallest stable near-plateau worker count and the evidence explaining why further workers stop helping.

19.34.4 Exercise 03

Exercise Title: Measure Host RAM Growth as num_workers Increases and Identify Dataset Objects Replicated or Retained Across Worker Processes

Part 1 - Exercise Contract and Why It Matters

Measure host-memory growth across worker counts and identify which dataset objects, caches, mappings, and batch resources are replicated or retained. Use controlled representations to distinguish metadata costs from source payload and transport queues.

Part 2 - System and Memory Mental Model

Process-start behavior affects inheritance and serialization, while later Python access or mutation can change physical sharing. Large Python object graphs can cost much more than compact numeric metadata. File-backed pages can be shared even when each worker has its own mapping object. Parent and worker RSS are therefore not disjoint physical totals. Worker-local caches, transforms, prefetched batches, IPC buffers, and pinning must not be blamed on dataset replication without separate evidence.

Part 3 - Quantitative Prediction Before Execution

For W workers, compare a dataset backed by a Python list of records with a compact index and process-local file access. Predict object-count growth, possible sharing, and independent batch demand. Define measured fields for RSS, proportional/private memory where available, source residency, and queued payload. Distinguish constructor duplication from growth during first access and from retained state after several epochs.

Part 4 - Experimental Design and Instrumentation

Use identical tiny sample semantics and two explicit metadata representations. Test the chosen start methods where supported, recording Python version and PIDs. Measure parent-only construction, worker startup, partial access, complete epoch, and idle retained workers. Keep prefetch and transform policies fixed or subtract only directly measured components. Audit cache entry counts and source-opening behavior with bounded scalar logs. Compare tiny exact owner inventories against supported OS memory evidence. Avoid retaining full batches in telemetry or relying on raw interpreter reference counts as a physical memory oracle.

Construct two equivalent dataset indexes: a collection of individual Python objects and a compact representation with the same identifiers. Verify that both produce identical samples. Observe memory before workers start and after they touch most index entries, since process creation alone can miss later copying or retention. State whether the platform starts workers through fork, spawn, or another supported context.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ProcessMemoryAudit:
    process_role: str
    process_id: int
    phase: str
    rss_bytes: object
    pss_bytes: object
    private_bytes: object
    dataset_cache_entries: object

def inspect_dataset_representation(dataset, representation_contract):
    # Inventory metadata, mappings, caches, and declared live objects.
    ...

def compare_worker_memory(cases, phase_samples, owner_inventory):
    # Separate replication from sharing and active pipeline resources.
    ...

def E03(config):
    # Attribute growth through controlled representation/process replays.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A shared page appearing in multiple RSS values must not be counted repeatedly as proven duplication. Conversely, a compact on-disk index does not guarantee compact worker Python state. Preserve unsupported private-memory metrics and uncertain attribution. A parent-only dataset change may not propagate to persistent worker replicas. Any claimed representation improvement must preserve sample content, labels, indexing, and transform behavior.

Do not interpret a larger sum of resident sets as an equal increase in unique physical memory. Where proportional accounting is available, report it beside private memory and shared mappings. Elsewhere preserve the measurement limit. Check that the compact representation did not merely move the same metadata into another unmeasured process or external cache.

Part 7 - Engineering Interpretation and Philosophy

Memory attribution requires both process evidence and knowledge of the objects being retained. Replace expensive representations only after demonstrating which ownership is duplicated or extended, rather than assuming every worker inherits the dataset cheaply or copies it completely.

19.34.5 Exercise 04

Exercise Title: Sweep prefetch_factor and Quantify the Trade-Off Between Ready Batches, Host Memory Consumption, and GPU Starvation

Part 1 - Exercise Contract and Why It Matters

Sweep multiprocessing prefetch depth and quantify readiness, queueing, host/shared-memory pressure, and useful GPU progress. Find when additional prepared work reduces waits and when it merely increases retention or speculation. Treat zero-worker loading as a separate unsupported-prefetch case.

Part 2 - System and Memory Mental Model

The prefetch factor controls the configured number of batches scheduled in advance per worker under multiprocessing. It is not an exact count of fully ready resident batches or a universal byte bound. Active workers, out-of-order completion, the main consumer, transport, and optional pinned copies can add other live resources. Variable-size batches make the same factor correspond to very different capacity. More prefetch cannot overcome a persistently slower source stage in steady state.

Part 3 - Quantitative Prediction Before Execution

For fixed payload b, use Wpb as a first estimate of scheduled batch payload, then list additional overlap terms. Predict exposed waits for bursty preparation and for a sustained producer bottleneck. For variable shapes, compare a mean payload estimate with a conservative supported upper bound. Define useful completed examples per second and unused prefetched work at early termination without assuming all scheduled batches were consumed.

Part 4 - Experimental Design and Instrumentation

Fix worker count, sample trace, batch semantics, model work, pinning, and process context. Sweep valid positive prefetch values by constructing separate loaders at controlled boundaries. Measure first batch, warmed throughput, batch-wait distributions, host/shared-memory evidence, and retained capacity. Use a slow-burst source control and a sustained-slow-source control to test the explanation. Include early stop and oversized variable batches. Preserve exact coverage and cleanup obligations and report uncertain internal queue occupancy rather than reading private fields as a stable public instrument.

Include a workload with a deliberately bounded occasional slow sample and another with stable service time. Match their total sample work across each prefetch setting. Collect delivery intervals and outstanding task estimates without claiming access to an exact public ready-queue length. Use variable batch sizes to show why an identical task count can retain different byte volumes across trials.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PrefetchDepthCase:
    workers: int
    prefetch_factor: int
    batch_payload_bound: object
    expected_scheduled_bytes: object
    host_limit_bytes: int

def plan_prefetch_depth(case, overlap_model):
    # Include active, transport, main, and pinned generations separately.
    ...

def measure_prefetch_depth(loader, workload, instruments):
    # Compare readiness and complete useful work, including early stop.
    ...

def E04(config):
    # Use fresh valid loaders and retain memory/latency tradeoffs.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not present scheduled tasks as measured ready batches. A configuration that exceeds budget or loses samples is not a faster successful trial. Preserve startup versus steady-state differences and source-cache conditions. Increasing prefetch while silently shrinking useful sample content changes the experiment. If GPU waits do not improve, retain the result and identify whether preparation, transfer, or compute limits remain unresolved.

Inspect the tail of each run as well as steady state: prefetched batches may remain when a short benchmark stops. Drain the declared finite workload or record cancelled tasks explicitly. Compare both typical and largest observed host payloads. Explain whether extra prefetch absorbed variance, enlarged unused retention, or exposed a different downstream bottleneck.

Part 7 - Engineering Interpretation and Philosophy

Prefetch is an early ownership decision intended to absorb variation. The best depth balances measured readiness against capacity and wasted work, with no expectation that an arbitrarily deep queue can repair every upstream bottleneck.

19.34.6 Exercise 05

Exercise Title: Combine num_workers and prefetch_factor in a Grid Search and Find the Highest Throughput Configuration Under a Fixed RAM Budget

Part 1 - Exercise Contract and Why It Matters

Search a bounded grid of worker count and prefetch depth for the highest measured useful throughput meeting an explicit host-memory contract. Separate calibration from evaluation and report infeasible, failed, and statistically indistinguishable configurations rather than publishing only a winning row.

Part 2 - System and Memory Mental Model

DataLoader has no generic automatic RAM admission cap for arbitrary dataset code and variable batches. A grid search therefore needs a declared resource model, preflight limits, bounded trials, and observed budget checks. Worker and prefetch choices interact with transport, pinning, caches, and active batch ownership. Changing configuration means constructing a valid loader; assigning new values to attributes is not a supported universal way to resize a live worker pool.

Part 3 - Quantitative Prediction Before Execution

Define feasible cases using named measured host scope and declared safety margin, keeping shared-memory and pinned constraints separate when relevant. Predict scheduled payload, worker overhead, and maximum supported batch overlap for each grid point. Define an objective from completed useful examples per second and a tie-break favoring lower resource cost within measured uncertainty. Explain why the optimum over a tested grid is not a global optimum for every workload or later epoch.

Part 4 - Experimental Design and Instrumentation

Choose safe candidate ranges from baseline evidence. Include zero-worker loading with valid options as its own case. Run isolated or cleanly scoped trials with identical data/order, transformations, model work, and initial state. Verify data correctness before performance ranking. Measure repeated complete runs, host peaks, shared-memory pressure, batch waits, and startup separately. Freeze the selection rule before evaluating held-out paths or shapes. Abort boundedly on a predicted or observed limit rather than repeatedly crashing workers. Preserve queue teardown and memory settling between candidates.

Separate candidate evaluation from final selection. Use the same finite calibration trace for the grid, then validate promising configurations on an unseen trace that includes a large batch and a slow sample. Preserve the exact RAM budget definition, sampling interval, and margin. Distinguish a measured process-group limit from a system-wide available-memory heuristic.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LoaderGridCandidate:
    workers: int
    prefetch_factor: object
    predicted_host_bytes: object
    feasibility: str
    reason: str
```

```
def preflight_loader_grid(candidates, workload_bounds, budgets):
    # Reject invalid combinations and unbounded batch assumptions early.
    ...

def evaluate_loader_candidate(candidate, trial_contract):
    # Build a fresh loader, verify useful work, and enforce stop limits.
    ...

def select_budgeted_candidate(results, decision_rule):
    # Rank only comparable correct feasible trials and retain uncertainty.
    ...

def E05(config):
    # Calibrate, freeze selection, and evaluate on held-out workload cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A row missing peak evidence cannot automatically be called budget-compliant. Keep sampled-peak uncertainty and process scope explicit. A faster trial with fewer completed updates is invalid. Report failures and censored trials as such, not slow finite observations. If several candidates overlap in timing variation, justify a conservative choice rather than claiming a precisely identified throughput maximum.

Keep a rejected-candidate table containing the configuration, failure phase, resource observation, and reason for exclusion. A candidate that produces incorrect sample coverage cannot be feasible even if it is fast and small. Show whether the selected point remains feasible during worker startup and iterator replacement, when transient coexistence can exceed steady memory.

Part 7 - Engineering Interpretation and Philosophy

Configuration search is a constrained measurement problem, not a parameter lottery. Its useful result is a reproducible near-best choice that stays within a stated resource envelope and explains where the evidence may stop applying.

19.34.7 Exercise 06

Exercise Title: Enable pin_memory=True and Measure Pinned Host Memory, H2D Transfer Latency, and GPU Utilization Against an Unpinned Baseline

Part 1 - Exercise Contract and Why It Matters

Compare pinned and unpinned loader output for known live host payload, H2D completion latency, GPU progress, and end-to-end throughput. Verify actual pinning support instead of treating a configuration flag as proof all batch tensors are page-locked.

Part 2 - System and Memory Mental Model

Automatic pinning can create additional host storage after preparation and transport. Allocation and host-copy work can offset transfer benefits, especially for small batches. Pinned tensor payload is not necessarily the allocator's total retained pinned capacity, and generic process locked-memory counters need not measure every accelerator-managed pinned allocation. CPU-only or unsupported configurations may not perform pinning as expected. Use actual leaf inspection and supported allocator observations where available, while retaining unavailable totals as unknown.

Part 3 - Quantitative Prediction Before Execution

For unique batch tensor payload b and K simultaneously retained pinned batches, predict known live pinned payload and source-copy overlap. Estimate H2D time as a latency-plus-bandwidth model with explicit scope. Compare a first pinned allocation with reuse/cache-warmed behavior. Predict cases where transfer time improves but complete workload time does not, and distinguish that outcome from absent actual pinning.

Part 4 - Experimental Design and Instrumentation

Use identical sample/order, worker/prefetch policy, model work, and initial state. Complete a batch tensor-leaf inventory with alias-aware accounting and verify pin status at main-process delivery. Measure unpinned and pinned paths separately through H2D completion and useful GPU consumption. Include pinning work in full-pipeline wall time. Run repeated trials without diagnostic synchronization in the throughput path, and preserve raw samples. Record supported host allocation metrics, known payload bounds, retained generations, and the limitation of every inferred total.

Compare pageable and pinned input paths using the same source values, tensor layout, batch dimensions, and destination operations. Record whether the loader actually returns pinned CPU leaves and whether custom or unsupported members remain unchanged. Avoid repeatedly pinning already pinned data inside the timed consumer unless that redundant operation is part of the declared workload.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PinningEvidence:
    batch_id: int
    tensor_leaf_count: int
    supported_pinned_leaf_count: int
    known_live_pinned_payload: int
    allocator_pinned_total: object
    h2d_seconds: object
    complete_seconds: object

def inspect_batch_pinning(batch, schema):
    # Check supported CPU leaves and deduplicate declared shared storage.
```

```
    ...

def compare_pinned_loading(strategies, workload, instruments):
    # Include preparation/pinning cost and completed transfer/use.
    ...

def E06(config):
    # Separate actual pinning, known payload, and measured performance.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not equate the sum of leaf sizes with exact OS-locked or allocator-reserved memory. Report empty or unsupported leaves explicitly. A CUDA event duration alone excludes host pinning cost; preserve completed wall time too. Pinning must not change sample values, metadata, labels, or the declared batch order. Keep unavailable accelerator experiments unmeasured rather than claiming a universal speedup.

Separate pin preparation cost, host transfer submission time, and completed transfer duration. A short submission interval cannot establish high transfer bandwidth. Also report end-to-end time and bounded host residency after several batches. If the operating system or build lacks a trustworthy total pinned-byte counter, report known live pinned tensor payload and state that narrower scope.

Part 7 - Engineering Interpretation and Philosophy

Pinned output is a transfer resource with preparation and retention costs. It is justified by measured complete progress under the chosen pipeline, with actual pin status and accounting scope established independently of the flag that requested it.

19.34.8 Exercise 07

Exercise Title: Move Pinned DataLoader Batches to CUDA with non_blocking=True and Verify Whether Host-to-Device Transfer Is Hidden Behind GPU Computation

Part 1 - Exercise Contract and Why It Matters

Transfer pinned loader batches with nonblocking submission and test whether H2D work overlaps useful computation. Preserve source/destination lifetimes, stream dependencies, and completed output correctness. Separate host asynchrony from device overlap and from end-to-end performance.

Part 2 - System and Memory Mental Model

A nonblocking copy can return before transfer completion. Operations on one stream remain ordered, so copy followed by compute on that same stream does not automatically overlap those two operations. A separate transfer stream and additional batch/device capacity can enable a pipeline when hardware and workload allow it. The consumer must wait on the correct ready event, while pinned source and device input storage remain protected through their final readers. Allocator lifetime protection is not a replacement for execution ordering.

Part 3 - Quantitative Prediction Before Execution

Draw serialized and pipelined timelines for two batches. Predict an ideal steady bottleneck from transfer and compute stage times, plus startup/drain cost. Calculate active pinned and device slots for the chosen overlap schedule. State evidence required to claim hidden transfer: actual overlap and reduced exposed wait at comparable completed work. Predict a compute-short or bandwidth-contended case where nonblocking submission does not hide transfer.

Part 4 - Experimental Design and Instrumentation

Build a serialized pinned baseline and a generation-tagged transfer/compute pipeline using supported CUDA streams/events. Verify batch IDs, values, and outputs after appropriate completion. Keep diagnostic timeline capture separate from unprofiled throughput. Measure submission, transfer completion, consumer wait, complete elapsed time, and memory peaks distinctly. Test delayed compute, a reused host source, and early termination in a host lifecycle model before running admitted CUDA schedules. Preserve fallback behavior if overlap support or memory headroom is insufficient.

Use two reusable batch slots only after defining their individual ownership states. A source slot becomes refillable after its transfer completes; a CUDA destination becomes overwriteable after all consuming kernels complete. Associate events with slot generations so an old completion cannot authorize reuse of a newer batch. Keep correctness checks outside the critical timing path but validate every slot during a small diagnostic replay.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AsyncBatchLease:
    batch_id: int
    generation: int
    pinned_source: object
    ready_event: object
    compute_done: object

def enqueue_batch_transfer(batch, lease, transfer_stream, device_slot):
    # Protect source ownership and record correct generation readiness.
    ...

def consume_transferred_batch(lease, compute_stream, workload):
    # Establish readiness before reads and final-reader completion.
    ...

def E07(config):
```

```
    # Compare serialized and validated overlapped schedules with equal work.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A host timer ending at enqueue cannot establish bandwidth or overlap. Require a dependency ledger and independent value checks; a race-free-looking sampled run is insufficient by itself. Do not release pinned storage before H2D completion or reuse device storage before compute finishes. Report extra slot capacity and synchronization overhead. Retain no-overlap or slower outcomes without silently changing the batch or compute workload.

Compare timeline evidence from a short trace with an unprofiled throughput run. Profiling overhead can change the overlap being investigated. Require visible copy and compute concurrency before claiming overlap, and quantify whether this concurrency reduces completed-work time. Include a negative same-stream control whose correct ordering serializes the dependent operations.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony is an opportunity to schedule work, not a performance guarantee. The useful design demonstrates that correct generation lifetimes and real resource overlap reduce exposed waits enough to justify the extra capacity and coordination.

19.34.9 Exercise 08

Exercise Title: Build a Custom Batch Type with a pin_memory() Method and Verify That Nested Tensors Are Correctly Page-Locked by the DataLoader

Part 1 - Exercise Contract and Why It Matters

Implement a custom batch type whose pinning method handles every declared nested tensor leaf and preserves non-tensor metadata. Verify DataLoader invokes the supported custom protocol and returns a structurally correct batch whose eligible CPU tensors are actually pinned.

Part 2 - System and Memory Mental Model

A custom container is not guaranteed to receive the same automatic recursive handling as built-in structures. Its pinning method must return the supported batch object form and define whether it mutates the container or creates a new one. Pinning a tensor can create a new storage owner, so external aliases and repeated references need an explicit policy. Non-tensor IDs, masks encoded as metadata, and nested ordering must remain associated with the correct samples. Unsupported tensor devices/layouts require clear handling.

Part 3 - Quantitative Prediction Before Execution

Specify a batch containing features, targets, nested auxiliary tensors, sample IDs, and an optional field. Predict eligible leaf count, unique payload, and any new pinned storage. Include repeated tensor references and explain whether the implementation preserves alias identity or deliberately supplies independent pinned copies. Define expected container shape and values before and after pinning without treating every Python object as tensor data.

Part 4 - Experimental Design and Instrumentation

Create a tiny deterministic dataset and top-level collator returning the custom batch. Complete recursive schema-aware pinning and a separate verifier. Compare direct method testing

with actual loader delivery under supported accelerator configuration. Check nested values, labels, optional fields, metadata, and leaf pin status. Exercise repeated references, empty supported tensors, already pinned leaves, and an unsupported device case. Track known payload and copy count separately from unknown allocator totals, and keep the implementation usable by the later main-process CUDA transfer path.

Define a batch schema containing inputs, labels, optional masks, nested containers, and a non-tensor sample identifier. Decide which leaves must be CPU tensors and which metadata should remain ordinary Python objects. Preserve the public return convention of the custom pinning method and verify that DataLoader dispatch reaches it in the installed version and accelerator setup.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class StudentBatch:
    features: object
    targets: object
    auxiliary: object
    sample_ids: tuple

    def pin_memory(self):
        # Handle declared nested CPU tensor leaves and return the batch form.
        ...

def collate_student_batch(samples):
    # Preserve schema, labels, and IDs while constructing bounded output.
    ...

def verify_custom_pinning(before, after, schema_contract):
    # Check structure, values, alias policy, and supported leaf pin status.
    ...

def E08(config):
    # Verify the actual DataLoader custom-batch protocol, not only a flag.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject a custom method that pins only the top-level feature tensor and leaves required nested targets unhandled. Do not silently replace metadata or change sample order. A leaf's pin status does not establish the whole batch's transfer readiness. If alias semantics change,

document and charge that change under the contract. Preserve unsupported pinning cases instead of forcing CUDA tensors through a CPU pin operation.

Check both tensor content and structural identity constraints after pinning. If two fields intentionally refer to the same object or view, state whether that relationship must survive the transformation. A recursive implementation that pins each leaf independently can alter sharing and allocation volume. Test absent optional fields and an empty batch according to the declared schema.

Part 7 - Engineering Interpretation and Philosophy

A custom batch protocol is an explicit schema transformation. It should make eligible storage ready for transfer while preserving the meaning, relationships, and ownership rules of the data the model will consume.

19.34.10 Exercise 09

Exercise Title: Compare persistent_workers=False and persistent_workers=True Across Multiple Epochs and Measure Worker Startup Cost and Retained RAM

Part 1 - Exercise Contract and Why It Matters

Compare persistent and nonpersistent workers across multiple epochs, measuring startup, epoch transition latency, warmed throughput, and retained host state. Preserve per-epoch sample/transform semantics instead of treating surviving workers as a purely mechanical speed setting.

Part 2 - System and Memory Mental Model

Persistence keeps worker processes and their dataset instances alive after an epoch. This can avoid repeated startup but retain caches, mappings, file handles, RNG state, and dataset-specific objects. Worker initialization is not an automatic per-epoch reset under persistence. Mutating the main process's dataset attributes does not generally mutate worker replicas. Sampler epoch control and worker-local epoch/augmentation state are separate channels with explicit propagation requirements.

Part 3 - Quantitative Prediction Before Execution

For E epochs, estimate repeated startup cost without persistence versus one startup plus retained-state overhead with it. Predict memory at startup, after each epoch, and between epochs. Define expected IDs and epoch-dependent random choices for both strategies. Include a dataset whose worker-local cache reaches a bounded plateau and another controlled case whose cache grows, without assuming persistence itself always causes a leak.

Part 4 - Experimental Design and Instrumentation

Use a replayable dataset with explicit epoch and randomness contracts. Complete both valid loader configurations and run the same epoch count, sample coverage, and useful model work. Record worker PIDs, initialization counts, epoch transition time, caches/resources, and supported private/proportional memory. Test the supported mechanism for worker epoch updates or reconstruct the loader when necessary. Verify that an old worker dataset version is not silently reused after source changes. Keep startup-inclusive and steady-state results separately and observe final lifecycle cleanup.

Compare several complete epochs rather than repeatedly timing only the first batch. Record iterator construction, first delivery, final delivery, and the between-epoch idle interval. Establish

how workers learn the epoch number before using it for randomized transforms. A main-process dataset assignment is not sufficient evidence that a persistent worker replica received a change.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class EpochWorkerObservation:
    epoch: int
    persistent: bool
    worker_ids: tuple
    initialization_count: int
    transition_seconds: object
    retained_host_bytes: object
    dataset_epoch_version: object

def run_epoch_worker_policy(dataset_factory, policy, epoch_contract):
    # Propagate required epoch state and preserve sample semantics.
    ...

def compare_worker_persistence(results, resource_inventory):
    # Separate avoided startup from retained caches and live resources.
    ...

def E09(config):
    # Verify multiple epochs and final cleanup with both strategies.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A first-epoch speed difference does not establish a long-job benefit. Retained memory can be intentional caching or unbounded growth; distinguish them by ownership and progression. Do not claim main-dataset reset methods ran inside workers without evidence. Persistent workers require multiprocessing, so a zero-worker case must be configured separately. Preserve exact restart and seed behavior rather than ignoring changed transformations in the comparison.

Show per-worker cache size, open-resource observations, and memory after each epoch when supported. Persistent state may be useful retained capacity rather than a leak, so distinguish bounded reuse from unbounded growth. Validate that both persistence policies produce the required epoch coverage and augmentation policy before comparing startup savings and retained memory.

Part 7 - Engineering Interpretation and Philosophy

Persistence trades recurring process creation for a longer-lived resource state. It is useful when that state remains bounded and correct across epochs, with the saved startup time measured together with its retention and lifecycle costs.

19.34.11 Exercise 10

Exercise Title: Reproduce Excessive Host Memory Growth from Persistent Workers and Design a Cleanup Strategy for Long-Running Training Jobs

Part 1 - Exercise Contract and Why It Matters

Reproduce excessive retained host state in a bounded persistent-worker example, identify its actual owner, and design cleanup that remains correct across epochs and long runs. Separate a genuine growing cache from allocator retention, file-page residency, or intentionally live batches.

Part 2 - System and Memory Mental Model

Persistence allows worker-local objects to survive, but it does not automatically make every dataset leak. Common causes include unbounded decoded-sample caches, append-only history, unreleased handles, and external references. Main-process cleanup does not directly clear worker-local containers. Garbage collection cannot reclaim objects that remain owned, and released objects do not guarantee immediate RSS reduction. Cleanup must also preserve mappings, leases, and samples still in use by queued or device work.

Part 3 - Quantitative Prediction Before Execution

Create a tiny worker-local cache with a known per-entry payload and an explicit capacity. Predict linear growth for a deliberately unbounded control and a plateau for bounded eviction. Include Python metadata and allocator uncertainty separately from cached tensor bytes. Define thresholds for unacceptable growth and a safe intervention boundary. Predict which counters should change after logical cleanup even if process RSS remains above its initial value.

Part 4 - Experimental Design and Instrumentation

Run isolated short jobs with strict sample/epoch and memory stop limits. Complete the controlled retained-state example and record cache entries, owned payload, worker PIDs, and supported memory metrics. Compare bounded cache, epoch reset through a verified worker communication mechanism, and orderly loader/process recreation. Validate all samples and any required epoch-dependent state after cleanup. Test early exit and a failed reset without pretending the worker became clean. Keep returned batches and logs bounded so the observer does not create the growth being diagnosed.

Use a deliberately bounded worker-local cache with a visible entry counter and a small controlled resource limit. Keep the experiment independent of the production dataset and stop before system pressure threatens unrelated work. Compare no cache, bounded eviction, and orderly worker replacement. Each policy must use equivalent sample computation and report any repeated initialization or reopened storage cost.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch
```

```
@dataclass
class WorkerRetentionReport:
    worker_id: int
    epoch: int
    cache_entries: int
    known_cache_payload_bytes: int
    open_resources: object
    observed_host_bytes: object
    cleanup_status: str

def inspect_worker_retention(worker_state, schema):
    # Attribute declared live owners rather than guessing from RSS alone.
    ...

def apply_cleanup_policy(worker_state, policy, lifecycle_boundary):
    # Bound caches or reset/recreate only after current obligations finish.
    ...

def E10(config):
    # Compare controlled growth, bounded cleanup, and preserved correctness.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the known retained owner to be reduced or bounded before crediting cleanup. A temporary RSS decline does not prove leak removal, and unchanged RSS does not prove live objects remain. Do not invoke undocumented worker internals as a portable cleanup API. Verify worker exit or reset completion through supported application lifecycle controls. Preserve failures and resource leftovers instead of claiming a clean long-running state.

A fall in Python object count without a fall in resident memory can reflect allocator retention rather than a failed logical cleanup. Report both outcomes without forcing equality. Conversely, stable resident memory does not prove that file handles or cache entries are bounded. Require acknowledgement or process exit evidence before declaring worker-local cleanup complete.

Part 7 - Engineering Interpretation and Philosophy

Long-running reliability comes from bounded ownership and verified lifecycle boundaries. A useful cleanup policy identifies what it releases, who executes that release, and which useful state remains valid afterward.

19.34.12 Exercise 11

Exercise Title: Replace Per-Sample ___getitem___() Work with Batched ___getitems___() Fetching and Measure the Reduction in Python and Worker Overhead

Part 1 - Exercise Contract and Why It Matters

Implement batched sample fetching through the supported map-style dataset protocol and compare it with per-sample access. Preserve one result per requested index, ordering, duplicates, labels, and transform semantics while reducing avoidable Python or source-operation overhead.

Part 2 - System and Memory Mental Model

Batched fetching can amortize source queries, vectorize parsing, or exploit locality. It does not automatically eliminate collation or return a ready-made batch under every loader contract. The standard supported protocol returns the requested sequence of samples for subsequent collation. Returning one already stacked tensor without matching the collator can double-batch or change shape. Batch-aware transformations can also consume randomness differently, so correctness needs a defined per-sample policy.

Part 3 - Quantitative Prediction Before Execution

For a batch of n requested IDs, compare n individual source/dispatch costs with one bounded grouped operation plus per-sample work. Predict output order for indices containing duplicates and a nonmonotonic sequence. Calculate intermediate memory for a vectorized read and the later collated result. Identify cases where the source already batches internally or the grouped implementation merely loops over individual access, giving little expected benefit.

Part 4 - Experimental Design and Instrumentation

Create a deterministic dataset supporting both paths and record which method the actual installed DataLoader invokes under batching. Complete a true bounded grouped fetch with a single-index fallback and compatible collator. Validate IDs, values, labels, lengths, duplicates, and augmentations against independent per-sample references. Compare source-call counts, host object/copy evidence, worker CPU time, batch-ready time, and completed workload throughput. Test partial last batches, empty requested groups where relevant, invalid IDs, and supported wrapper/subset behavior without bypassing overridden dataset logic.

Include repeated and nonconsecutive indices in one requested batch so a backend fetch optimization cannot silently sort away sampler order or remove duplicates. Compare the ordinary sample path with batched fetching under the same collation contract. Count dispatch calls and underlying storage requests separately; reducing Python calls does not necessarily reduce physical I/O or tensor copying.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.data import Dataset

class BatchedFetchDataset(Dataset):
    def __init__(self, source, schema, transform_policy):
        self.source = source
        self.schema = schema
        self.transform_policy = transform_policy
        ...

    def __len__(self):
```

```
        ...

    def __getitem__(self, index):
        # Preserve the authoritative single-sample semantics.
        ...

    def __getitems__(self, indices):
        # Return requested samples in matching order for the collator.
        ...

def E11(config):
    # Verify real dispatch, sample equivalence, and grouped-operation cost.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not claim batched-fetch acceleration when the new method silently changes sample count or pre-stacks into an incompatible collation contract. Preserve duplicate indices and source side effects where required. A vectorized transform with different random choices is a separate semantic experiment unless controlled by the contract. Feature-check the protocol and wrapper behavior rather than assuming every dataset adapter forwards it identically.

Verify the values, order, labels, and randomized transform policy for every requested position. If bulk decoding changes numerical results or augmentation randomness, classify it as a separate algorithmic variant. Test wrappers and subsets explicitly because the effective dataset object controls dispatch. Retain a fallback path when the installed framework cannot support the intended batched interface.

Part 7 - Engineering Interpretation and Philosophy

Batch-aware access is useful when it removes repeated overhead while retaining the meaning of each requested sample. Its proof is the dispatch and source work actually reduced under the same sample contract, not simply the presence of a plural method name.

19.34.13 Exercise 12

Exercise Title: Optimize collate_fn to Minimize Temporary Tensor Copies, Intermediate Python Objects, and Unnecessary Host Allocations

Part 1 - Exercise Contract and Why It Matters

Optimize collation to reduce unnecessary host copies, intermediate Python objects, and dtype/layout conversions while preserving the exact batch schema. Measure bounded output ownership and complete pipeline effects rather than assuming the fewest visible tensor calls guarantee the least memory.

Part 2 - System and Memory Mental Model

Collation turns per-sample values into a model-facing batch. Stacking commonly requires independent output storage; padding variable lengths adds meaningful capacity and masks. Avoiding that output is possible only if the consumer accepts another representation. Default collation may already use an efficient multiprocessing transport path, so a custom routine can

accidentally add copies. Reusing one output buffer can corrupt previously returned batches while they are queued, pinned, or consumed asynchronously.

Part 3 - Quantitative Prediction Before Execution

For fixed sample shape and n samples, calculate final tensor payload and list unavoidable versus optional copies for the declared schema. Compare list-to-tensor conversion, repeated concatenation, and one bounded final allocation as candidate designs without assuming their observed costs. For variable lengths, calculate padded data and mask bytes and preserve true lengths. Predict overlap between sample owners, collated output, transport, and pinned generations.

Part 4 - Experimental Design and Instrumentation

Start with a tiny default-collation reference and a fixed schema. Complete a custom routine with explicit dtype, layout, labels, IDs, optional fields, and ownership. Validate fixed and variable-size cases, partial batches, noncontiguous inputs, and retained prior batches. Collect allocation/copy and object-count evidence in separate diagnostics, then time equal useful work without that overhead. Compare in both single-process and multiprocessing contexts where supported. Charge conversion and transport work introduced by the custom path rather than reporting only its local function timer.

Build a copy ledger for decoding output, padding, stacking, dtype conversion, and contiguous layout conversion. Mark which steps are semantically required and which are accidental intermediates. A custom collator that returns views must preserve source lifetime until consumers finish. Test a short final batch and variable-length samples so a fixed-size optimization cannot hide invalid padding or stale values.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class CollationContract:
    schema_id: str
    output_dtype: object
    output_layout: str
    length_policy: str
    ownership_policy: str
    maximum_batch_bytes: int

def optimized_collate(samples, contract):
    # Construct the required output once where legal; preserve metadata.
    ...

def verify_collation(reference, candidate, input_owners, contract):
    # Check values, masks, labels, layout, and retained-batch independence.
```

```
    ...

def E12(config):
    # Compare default and custom collation through the complete data path.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A local zero-copy view may retain a huge source storage or violate the model's contiguous-batch contract. Preserve or explicitly change representation rather than silently omitting required padding. Any reusable output needs a supported lease/pool lifecycle across worker transport and device use; a single global scratch tensor is not automatically safe. A custom routine that loses the default transport optimization can be slower despite fewer local calls.

Measure collation in isolation only as a diagnostic, then repeat the complete worker and transfer pipeline. IPC handling can make a locally faster collator slower overall. Compare actual output payload, temporary peaks, object counts when available, and complete throughput. Do not reuse one global writable output for multiple queued batches without a proven ownership and completion protocol.

Part 7 - Engineering Interpretation and Philosophy

Good collation allocates the batch the model actually needs with no unnecessary intermediate forms. Optimize the complete ownership path and preserve schema semantics rather than treating every required output copy as a mistake.

19.34.14 Exercise 13

Exercise Title: Reproduce /dev/shm Exhaustion with Aggressive Multiprocessing and Diagnose Shared-Memory Pressure from Batch Size, Workers, and Prefetch Depth

Part 1 - Exercise Contract and Why It Matters

Reproduce shared-memory pressure in a disposable isolated multiprocessing test with a deliberately small explicit allowance. Diagnose the contribution of batch payload, worker count, prefetch, transport owners, and consumer retention. Keep the host's general shared-memory resources and unrelated jobs outside the experiment.

Part 2 - System and Memory Mental Model

Linux shared-memory transport can consume tmpfs-backed resources such as those exposed through the conventional shared-memory filesystem. Exhaustion can cause worker or IPC failures, but similar messages can arise from RAM, file-descriptor, address-space, or other process failures. Mount size, available capacity, sharing strategy, and open/unlinked objects need observation. A formula based only on scheduled batches is an estimate, not a universal exact usage law. Other platforms may expose different facilities.

Part 3 - Quantitative Prediction Before Execution

Predict transport pressure from variable/fixed batch payload and concurrent owners, distinguishing active consumer references from prefetched work. Compare small controlled worker/prefetch settings against an isolated allowance. Define a failure threshold and stop plan before the test.

List evidence needed to classify shared-memory exhaustion separately from CUDA OOM, host allocation failure, file-descriptor exhaustion, or an unrelated worker exception.

Part 4 - Experimental Design and Instrumentation

Use a disposable child/container test with bounded time, tiny known data, and a controlled shared-memory quota when supported. If isolation is unavailable, run only a host model or pressure preflight and mark actual exhaustion untested. Complete increasing-pressure trials and record mount/resource observations, batch owner counts, worker exits, and the original error phase. Compare lower prefetch, fewer workers, and released consumer references as controlled replays. Preserve useful IDs and failure evidence. Remove only resources owned by the test through its lifecycle; never delete arbitrary shared-memory entries as a cleanup shortcut.

Specify the disposable environment's shared-memory quota before launching workers. Select small synthetic batches and a bounded concurrency ramp that can reach that quota without exhausting host RAM. Capture mount capacity, process logs, worker exit status, and open-file limits when accessible. A simulated resource model is acceptable when isolation is unavailable, but must remain clearly separate from an observed operating-system failure.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class SharedMemoryPressureCase:
    workers: int
    prefetch_factor: int
    maximum_batch_bytes: int
    isolated_shm_limit_bytes: object
    retained_consumer_batches: int
    stop_deadline_seconds: float

def preflight_shm_case(case, platform_observations):
    # Require supported isolation and distinguish estimates from quotas.
    ...

def run_isolated_pressure_case(case, workload, evidence_contract):
    # Preserve bounded failures without exhausting the general host.
    ...

def E13(config):
    # Compare pressure controls and retain the original failure classification.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A worker bus error alone is not a complete diagnosis. Correlate resource pressure with the failing phase and counterfactual replay. Retain platform limitations and unknown usage rather than fabricating a quota measurement. Unlinked shared objects can remain live while referenced, and changing a sharing strategy is not a general memory-capacity solution. Any completed reproduction must show the controlled environment and its actual limits.

Correlate the first failed phase with capacity observations and an isolated lower-pressure replay. Shared-memory usage may outlive an individual tensor reference because other processes still own it. Let the test environment perform its own cleanup after workers terminate. Never delete unidentified shared objects to make a retry succeed or infer a diagnosis from one generic worker exception alone.

Part 7 - Engineering Interpretation and Philosophy

A useful failure experiment makes the cause small, isolated, and explainable. The engineering result is evidence linking ownership pressure to a bounded resource limit, with interventions that reduce the same cause rather than mask an unrelated error.

19.34.15 Exercise 14

Exercise Title: Recover from Shared-Memory Exhaustion by Dynamically Reducing Worker Count, Prefetch Depth, or Batch Memory Footprint

Part 1 - Exercise Contract and Why It Matters

Recover from a classified shared-memory failure by selecting a smaller valid loader configuration and resuming from an explicit committed-work boundary. Preserve sample/update semantics, teardown old ownership, and include failure, rebuild, and replay costs in the result.

Part 2 - System and Memory Mental Model

A live loader does not provide a universal supported hot-resize API for worker count and prefetch settings. Recovery therefore chooses new settings and recreates the loader or isolated input job at a defined boundary. Dispatched or prefetched IDs are not the same as successfully consumed IDs or committed optimizer updates. Stochastic transforms and nonseekable streams complicate exact replay. Reducing batch size can also change model behavior and must not be presented as an equivalent memory-only setting change.

Part 3 - Quantitative Prediction Before Execution

Define state recording committed update ID, consumed sample IDs, sampler position/replay authority, transform seed contract, and pending work. Predict which batches must be replayed or discarded after failure without losing or doubling committed updates. Compare first reducing prefetch or workers while keeping batch semantics fixed. If microbatching is considered, state its limitations for batch-dependent modules, randomness, and optimizer equivalence instead of assuming accumulation is always identical.

Part 4 - Experimental Design and Instrumentation

Use a tiny deterministic replayable dataset and isolated controlled failure from E13. Save training state at declared safe commits and record the input trace. Stop or drain old work through supported application/process lifetime controls, verify owned resources are released, then construct the reduced loader. Resume according to an explicit rollback/replay policy and compare with uninterrupted reference work. Bound retries and retain failure diagnostics.

Test one unrecoverable nonreplayable source case as refusal, not silent sample loss. Measure downtime, repeated work, final coverage, and complete training outcome.

Prepare a finite replayable source and an explicit committed-update record before injecting the controlled failure. Save sampler progress and random state at a supported boundary, then distinguish consumed batches from completed optimizer updates. The replacement loader must begin from a declared recovery point. Account for replayed preparation and computation as recovery cost, not as additional successfully trained examples.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class RecoveryBoundary:
    committed_update_id: int
    model_state_id: str
    optimizer_state_id: str
    sampler_state: object
    transform_seed_contract: object
    consumed_sample_ids: tuple

def choose_recovery_configuration(failure, current, workload, budgets):
    # Prefer valid smaller queues/workers without changing batch semantics.
    ...

def rebuild_and_resume(boundary, configuration, source_contract):
    # Stop old ownership and replay only under a verified recovery policy.
    ...

def E14(config):
    # Compare recovered useful updates with an uninterrupted reference.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not mutate loader attributes and claim existing processes reconfigured. A counter saying the next batch index advanced does not prove an update committed. Preserve IDs, weights, optimizer state, and required randomness. If exact state restoration is not implemented, label the recovery weaker or unsupported. Do not delete shared-memory objects belonging to other jobs; resource cleanup must follow the failed job's actual ownership.

Validate the recovered sample and update history against a fault-free control. If exact replay cannot be guaranteed for the source or stochastic operations, report the weaker recovery contract explicitly. Confirm that old workers have exited before measuring the replacement's

stable footprint. Stop after the bounded retry policy instead of progressively changing semantics until some configuration happens to finish.

Part 7 - Engineering Interpretation and Philosophy

Recovery is a transactional training/data lifecycle problem, not merely a smaller worker number. A good implementation restores a coherent computation with bounded retries and complete cost accounting, or explains precisely why its source cannot support that guarantee.

19.34.16 Exercise 15

Exercise Title: Build an IterableDataset with Multiple Workers and Eliminate Duplicate Samples Through Explicit Worker-Aware Data Sharding

Part 1 - Exercise Contract and Why It Matters

Build a multiworker iterable dataset with explicit source partitioning and verify no unintended duplicate or missing samples. Define epoch, restart, ordering, and last-batch behavior for the actual source. Keep worker sharding separate from map-style sampler dispatch.

Part 2 - System and Memory Mental Model

Each iterable worker receives a dataset replica and can otherwise traverse the same source. A worker-aware partition must assign authoritative records once under the chosen finite-epoch contract. Filtering a complete source in every worker can remove duplicate output while still duplicating expensive I/O, so compare physical source partitions when available. Last incomplete batches and loader length estimates require care because iterable worker replicas can finish unevenly. Persistent workers need explicit epoch-state handling rather than assumed reinitialization.

Part 3 - Quantitative Prediction Before Execution

For N known records and W workers, derive a deterministic partition and its expected ID union/intersection before execution. Calculate per-worker counts, partial final batches, and the declared drop policy. Compare contiguous shards and strided IDs for source locality without giving either an automatic quality guarantee. Predict behavior for fewer records than workers, an empty source, and a checkpoint-resume request requiring source-position authority.

Part 4 - Experimental Design and Instrumentation

Create a tiny finite authoritative source with IDs and labels. Complete worker-aware iteration using supported worker information and a zero-worker path. Verify exact ID coverage, labels, values, and duplicate policy for several worker counts. Compare cheap output filtering with real independent shard access if the source supports it. Test uneven shards, persistent epochs, controlled source failure, and an explicitly unsupported nonseekable resume. Record actual source reads as well as emitted samples. Keep distributed-rank sharding outside the initial scope or implement its separate composition explicitly rather than counting local worker uniqueness as global uniqueness.

Give every source record a stable identifier and define worker shards before applying worker-local transforms. Test source lengths that are not divisible by the worker count or batch size. Include one fewer sample than workers and a normal longer stream. Explain whether sharding avoids duplicate decoding and storage reads or only filters duplicates after expensive work has already been performed.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
from torch.utils.data import IterableDataset, get_worker_info

class ShardedIterableDataset(IterableDataset):
    def __init__(self, source_manifest, epoch_contract):
        self.source_manifest = source_manifest
        self.epoch_contract = epoch_contract
        ...

    def __iter__(self):
        # Derive process-local partition, open it, and emit each assigned ID.
        ...

def verify_iterable_coverage(observed_ids, partition_contract):
    # Check duplicates, omissions, partial batches, and source-read work.
    ...

def E15(config):
    # Compare zero-worker, multiple shards, and epoch/restart cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not use the loader's length heuristic as proof of exact iterable coverage. Record which samples a per-worker last-batch policy drops. Output deduplication alone does not establish nonduplicated source I/O or exactly-once training updates after failure. Preserve source authority and the declared replay model. An epoch-dependent transform must follow explicit worker-state propagation, with retained replica state audited under persistence.

Audit the multiset of delivered identifiers rather than relying on the loader's length estimate. With per-worker partial batches, dropping incomplete batches may discard more records than a global batching intuition predicts. Record exact omissions and duplicates by worker and epoch. For a non-replayable stream, restrict the recovery claim rather than inventing a deterministic restart position.

Part 7 - Engineering Interpretation and Philosophy

Iterable correctness starts with an ownership rule for records, not merely parallel iteration. A useful dataset makes its finite coverage, read work, epoch boundary, and restart limitations testable before concurrency is credited with improved throughput.

19.34.17 Exercise 16

Exercise Title: Compare Ordered and Out-of-Order Multi-Worker Batch Delivery and Measure the Throughput and Buffering Effects of in_order

Part 1 - Exercise Contract and Why It Matters

Compare ordered and supported out-of-order multiworker batch delivery under controlled service-time variation. Measure useful throughput, head-of-line waits, buffering, and delivered-data order. Treat training-distribution and reproducibility changes as part of the policy contract.

Part 2 - System and Memory Mental Model

Ordered delivery can wait for an earlier slow task even when later batches are prepared. Out-of-order delivery can reduce that wait but changes the sequence seen by the consumer. It need not eliminate every buffer or guarantee faster training. Fast and slow samples can correlate with labels or lengths, causing time-limited prefixes to become skewed. Feature-check the installed loader option and keep zero-worker behavior separate; lack of support must not silently substitute the ordered strategy under the same label.

Part 3 - Quantitative Prediction Before Execution

Construct a tiny dispatch trace containing one delayed batch and several quick batches. Predict ordered and out-of-order delivery IDs and waits under a clear model. Calculate expected full-epoch ID multisets and compare with time-limited prefixes. Predict buffering and capacity conservatively rather than assigning an exact internal queue count from the flag. Define learning-quality and reproducibility checks distinct from numerical per-sample data correctness.

Part 4 - Experimental Design and Instrumentation

Use deterministic sample values and controlled bounded preparation delays in an isolated diagnostic workload. Complete both supported configurations with the same dispatched work and worker/prefetch/pinning settings. Record batch IDs, task durations, arrival/delivery evidence where available, main waits, resource peaks, and completed throughput. Compare full epochs and fixed-time prefixes separately. Evaluate a label/length-correlated delay case to expose bias. Preserve training order as part of the result, and do not promise identical gradients across intentionally different SGD sequences.

Create a controlled service-time imbalance correlated with a visible sample class, then compare ordered and out-of-order delivery using identical worker assignments where practical. Inspect both a fixed-duration prefix and complete finite coverage. The prefix can reveal class skew even when every sample is eventually delivered exactly once. Preserve sample identities in the measurement trace without retaining full tensors.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class DeliveryObservation:
    task_id: int
    sample_ids: tuple
    preparation_interval: object
    delivered_position: int
```

```
    main_wait_seconds: object
    prefix_metadata: object

def configure_delivery_policy(dataset, in_order, support_contract):
    # Feature-check multiworker delivery semantics explicitly.
    ...

def compare_delivery_traces(ordered, unordered, workload_contract):
    # Separate coverage, prefix skew, head-of-line evidence, and throughput.
    ...

def E16(config):
    # Test controlled stragglers and realistic supported workload variation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A faster prefix containing easier or shorter data is not necessarily more useful training progress. Require exact final coverage under the declared epoch policy and report prefix composition. Do not infer exact buffer occupancy from delivery order alone. Preserve unsupported options, timing variability, and cases where out-of-order delivery does not improve complete work. Keep semantic permission for reordered training explicit.

Treat order changes as a semantic permission for the workload, not simply a speed switch. Training updates can change when batch arrival order changes, including effects on optimization and reproducibility. Report delivery gaps, completed throughput, and memory observations independently. If the installed DataLoader lacks the option, mark the experiment unsupported and retain the ordered baseline rather than monkey-patching internal queues.

Part 7 - Engineering Interpretation and Philosophy

Delivery order is a tradeoff among waiting, buffering, reproducibility, and learning behavior. Choose it only with measured service-time evidence and a consumer contract that permits the resulting sequence, rather than treating out-of-order execution as a free scheduling improvement.

19.34.18 Exercise 17

Exercise Title: Build a Runtime Monitor That Separates Storage Read Time, Worker Processing Time, Queue Wait Time, Pinning Time, H2D Transfer Time, and GPU Compute Time

Part 1 - Exercise Contract and Why It Matters

Build a bounded monitor for source access, worker preparation, collation, transport/queueing, pinning, H2D, and GPU compute. Define exact observable intervals, estimated bounds, and unavailable stages. Correlate task IDs across processes without pretending every internal loader transition is publicly instrumented.

Part 2 - System and Memory Mental Model

Main-process time waiting for the next batch can include unfinished worker work, transport, reordering, pinning, and scheduler delay. It is not pure queue residence. Wrapping dataset and collator functions reveals only their own intervals. Exact internal queue timing needs a version-pinned audited adapter or an explicitly owned transport stage; otherwise report combined delay or bounds. CPU clocks and CUDA event intervals have distinct semantics, and overlapping worker durations cannot be summed as serial wall time.

Part 3 - Quantitative Prediction Before Execution

Draw a correlated task timeline and define start/end events for each observable stage. Predict which intervals overlap, which include waiting, and which can only be bounded. Calculate useful complete time and a critical-path hypothesis without subtracting unrelated clock domains. Define instrumentation overhead and a maximum retained event count. A missing stage must remain unavailable, not zero milliseconds in a misleading stacked total.

Part 4 - Experimental Design and Instrumentation

Implement wrappers for owned source, transform, collation, and custom pinning boundaries where available. Attach bounded scalar timing metadata and stable task/batch IDs without retaining tensor graphs. Validate CPU timestamp domains before aligning processes and use CUDA events with deliberate completion boundaries. Test the monitor on a controlled synthetic pipeline with known stage placement, then compare instrumented and uninstrumented runs. Record transport intervals as exact only when the chosen supported instrumentation actually observes their boundaries. Preserve uncertainty and sampling mode in exported records.

Define a timestamp schema with process identity, batch identity, clock domain, and measurement boundary. Wrap only stages whose entry and exit are actually observable. A worker's completion timestamp and the consumer's return timestamp bound several transport and scheduling stages together unless additional instrumentation separates them. Keep instrumentation queues bounded so the monitor cannot become the dominant retained-memory source.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class StageInterval:
    task_id: str
    process_id: int
    stage: str
    clock_domain: str
    start: object
    end: object
    observation_kind: str
    limitations: tuple

class InputPipelineMonitor:
```

```
    def begin_stage(self, task_id, stage, clock_domain):
        # Record only owned/observed boundaries with bounded storage.
        ...

    def end_stage(self, token):
        # Preserve local interval meaning and incomplete/failure status.
        ...

    def correlate(self, event_records, support_contract):
        # Distinguish exact, estimated, combined, and unavailable stages.
        ...

    def export(self):
        # Emit CPU scalar metadata and observer-overhead evidence.
        ...

def E17(config):
    # Validate attribution limits before diagnosing real workloads.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not label elapsed next-batch wait as isolated queue time without evidence. Do not report worker clock values as CUDA timing or force concurrent intervals into an additive total. A private queue-size query is not a portable exact latency instrument. Preserve dropped-event counts and incomplete spans. A monitor changing overlap through frequent synchronization must be labeled diagnostic and compared with an unprofiled useful-work run.

Verify clock assumptions before subtracting timestamps from different processes or devices. CUDA events measure appropriate device intervals but do not directly share a timestamp origin with a Python wall clock. Show an overhead control and explain missing spans. Stage durations can overlap, so their sum is neither an automatic critical-path estimate nor a valid replacement for measured wall time.

Part 7 - Engineering Interpretation and Philosophy

A useful monitor says what it observed and what remains inferred. Honest stage boundaries reveal a causal bottleneck more reliably than a complete-looking chart filled with unsupported zeros or serial sums of concurrent activity.

19.34.19 Exercise 18

Exercise Title: Stress-Test the Input Pipeline with Slow Storage, Expensive CPU Transforms, Variable-Size Samples, Limited RAM, and a Fast GPU to Identify the True Bottleneck

Part 1 - Exercise Contract and Why It Matters

Stress-test an input pipeline against slow sources, expensive transforms, variable batch sizes, constrained host resources, and fast consumption. Identify the true limiting stage using counterfactual replays, while preserving useful training work and resource bounds.

Part 2 - System and Memory Mental Model

Several bottlenecks can coexist or move as settings change. Faster workers can saturate storage; deeper queues can increase RAM and shared-memory pressure; pinning can improve transfer while adding host copies. Variable lengths can inflate padding and alter compute cost. A fast GPU exposes preparation latency only if measured execution and dependencies justify that interpretation. Synthetic delays are controlled models, not measurements of actual disk or production transform performance.

Part 3 - Quantitative Prediction Before Execution

Build separate source-limited, transform-limited, transfer-limited, memory-limited, and compute-limited hypotheses. Predict stage intervals, queue behavior, resource peaks, and useful throughput under each. Calculate a conservative maximum active batch footprint for variable shapes. Define stop limits and infeasible cases before execution. Include an intervention expected to change one cause, such as resident-data replay or bounded transform substitution, without claiming that altered workload is the production performance result.

Part 4 - Experimental Design and Instrumentation

Use tiny exact references and safely bounded larger traces. Freeze sample IDs, labels, transformation semantics, model state, useful step count, and randomness where equivalence is required. Vary one stressor first, then test selected interactions. Capture monitor evidence with its attribution limits, worker/host/shared/pinned/device resources, and completed updates. Verify data and masks for every supported variable-length case. Include controlled worker failure, early stop, persistent-state growth, and unavailable accelerator outcomes. Minimize reproducing incidents with their source, trace, seed, configuration, and lifecycle boundary recorded.

Change one injected bottleneck at a time before combining stressors. Use a bounded transform cost, a documented storage-delay model, and a variable-shape sequence with a reproducible maximum payload. Keep sample content and required updates fixed. Compare the pipeline against compute-only and preparation-only controls so a fast GPU's apparent starvation has a measurable reference rather than a visual utilization guess.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PipelineStressCase:
    case_id: str
    source_policy: str
    transform_policy: str
    sample_shape_trace: tuple
    host_budget_bytes: int
    shared_memory_limit: object
    consumer_policy: str
    stop_limits: tuple
```

```
def predict_stress_case(case, resource_model, support_contract):
    # State causal expectations and infeasible floors before execution.
    ...

def run_stress_case(case, pipeline, model, monitor):
    # Preserve useful work and classify every failure/abort.
    ...

def diagnose_stressor(evidence, controlled_replays):
    # Separate directly observed stages from unresolved hypotheses.
    ...

def E18(config):
    # Report validated scope, resource limits, and causal counterexamples.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

A high GPU idle fraction is insufficient to identify storage as the cause. A speedup obtained by dropping long samples or changing transforms is not an equivalent pipeline optimization. Preserve padding and sample coverage costs. Report enforced versus sampled memory limits and keep actual failures distinct from preflight refusal. If a suspected bottleneck does not reproduce, retain that result and the next discriminating experiment rather than inventing supporting metrics.

Record the resource and phase at the first sustained degradation, including whether a queue is empty, downstream work is blocked, or workers are throttled. An artificial sleep models service delay but does not reproduce real storage cache and I/O behavior. Label that distinction and test at least one real source when available. Preserve all untested hardware conditions as explicit gaps.

Part 7 - Engineering Interpretation and Philosophy

Stress testing should expose the pipeline's operating envelope and the reason it fails or slows. Its strongest outcome is a small causal explanation linked to preserved useful work, with interventions and limits that remain visible when conditions change.

19.34.20 Exercise 19

Exercise Title: Build and Benchmark a Self-Tuning PyTorch DataLoader That Dynamically Chooses Worker Count, Prefetch Depth, Pinning, and Batch Delivery Strategy Under RAM and Throughput Constraints

Part 1 - Exercise Contract and Why It Matters

Build a controller that selects worker, prefetch, pinning, persistence, and supported delivery policies under explicit host/shared-memory and useful-throughput constraints. Reconfigure

at validated lifecycle boundaries, preserve training semantics, and include tuning, teardown, startup, replay, and failure costs.

Part 2 - System and Memory Mental Model

Self-tuning requires observation, candidate admission, evaluation, semantic validation, and controlled replacement. It is not arbitrary live mutation of loader attributes. Replayable source/sampler state, stable sample IDs, transform randomness, and committed model/optimizer boundaries determine which transitions are supportable. Out-of-order delivery and changed batch footprints require separate semantic permission. Unsupported streaming recovery or uncertain resource evidence should restrict candidates rather than produce silent data loss or invented budget compliance.

Part 3 - Quantitative Prediction Before Execution

Define an objective from completed correct useful work over full elapsed time, subject to named resource scopes, coverage, and progress. Estimate worker state, scheduled/active batches, transport, pinning, device overlap, and transition cost for each candidate. Add hysteresis and a minimum evidence window to avoid noisy oscillation. Predict when a small throughput gain cannot repay rebuild overhead. Compare fixed baseline, offline best-tested settings, and the controller under identical permitted workload semantics.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and calibrate on separate traces. Implement valid candidate generation, bounded trials, independent correctness/resource gates, and a decision ledger. Apply replacements at an epoch boundary or another explicit committed replay boundary, verifying old ownership ends before new queues increase pressure. Evaluate stable and changing source/transform/shape traces with controlled failure. Run ablations for monitoring, decision cost, hysteresis, and allowed policy dimensions without weakening sample correctness. Report held-out useful throughput, resource evidence, rebuild count, downtime, replayed work, coverage, and failures.

Use a small candidate set with a conservative known-valid fallback. Require minimum observation windows and a benefit threshold before replacement so noise cannot trigger continual worker churn. Reserve enough memory for a safe transition, or terminate the previous loader before constructing its successor. Treat ordering permission, batch semantics, and source replayability as hard constraints that the throughput objective cannot override.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LoaderTuningContract:
    source_replay_policy: str
    sample_semantics_id: str
    allowed_delivery_policies: tuple
    host_budget_bytes: int
    shared_memory_budget_bytes: object
```

```
    pinned_budget_bytes: object
    reconfiguration_boundary: str
    maximum_retries: int

class SelfTuningDataLoaderController:
    def __init__(self, contract):
        self.contract = contract
        # Initialize bounded observations, candidates, and decision state.
        ...

    def observe(self, stage_evidence, resource_evidence):
        # Preserve support, age, scope, and uncertainty of every metric.
        ...

    def candidates(self, workload_bounds):
        # Generate valid settings without unsupported live mutation.
        ...

    def evaluate(self, candidate, trial_boundary):
        # Check useful-work semantics, resources, and complete cost.
        ...

    def choose(self, results, current_configuration):
        # Account for uncertainty, hysteresis, and replacement overhead.
        ...

    def reconfigure(self, selected, committed_state):
        # Stop old ownership and rebuild at the supported replay boundary.
        ...

    def recover(self, failure, committed_state):
        # Classify cause, bound retries, and preserve exact supported replay.
        ...

    def shutdown(self, deadline):
        # Drain or stop owned processes/resources and report leftovers.
        ...

def E19(config):
    # Validate lifecycle/correctness, then compare held-out useful work.
    ...
    # Export decisions, resource evidence, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires preserved samples/labels, allowed ordering, coherent training commits, valid resource accounting, bounded lifecycle, and honest time denominators. Record

versions, process context, source/trace IDs, seeds, transforms, schema, batch policy, worker count, prefetch depth, persistence, pinning, and delivery settings, RSS/PSS scope, shared-memory evidence, known pinned payload, device peaks, stage intervals with support labels, update counts, latency samples, reconfiguration cost, coverage, and failure phases.

Demonstrate a rejected invalid zero-worker setting, a retained-worker cleanup, a batched-fetch equivalence check, custom pinning, a controlled shared-memory recovery, and a forbidden semantic reordering. Missing CPU/OS/GPU metrics remain unmeasured; no fabricated speedup or failure is acceptable.

Evaluate the controller on a held-out phase change and a stable workload. Compare total completed work against the best fixed feasible candidate, including calibration, replacement, and recovery costs. Report oscillations, rejected actions, and fallback use. The controller succeeds only when its resource contract and sample correctness hold throughout the run, not merely when its final selected configuration looks reasonable.

Part 7 - Engineering Interpretation and Philosophy

A self-tuning loader is useful when it makes a few justified configuration changes while preserving the computation it serves. Recommend the smallest controller that improves measured complete work within its tested envelope, and state the next evidence required before expanding source, ordering, recovery, device, or scale support.

19.35 DMM33

Chapter Title: Paged Memory and Virtualized Tensor Storage
Specialization: Dynamic Memory Management and CUDA Systems

19.35.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Virtual Addresses, Physical Memory, Pages, Frames, Page Tables, and Memory Translation

Part 1 - Exercise Contract and Why It Matters

Define the vocabulary and supported abstraction for the entire exercise sequence. Deliver a diagram separating a logical tensor address, a software page identifier, a CUDA tensor storage address, and hardware address translation. Use ordinary PyTorch tensors as application-managed page payloads. The resulting pager is a restricted software object with explicit access methods, not an ordinary tensor whose arbitrary operators transparently fault or translate.

Part 2 - System and Memory Mental Model

A virtual address names a location within an address space; a physical frame supplies backing storage at a lower layer. A software page table in this project maps logical page numbers to owned pool slots and generations. It does not inspect hardware page tables, choose GPU physical frames, or change CUDA MMU mappings. CUDA driver VMM is a separate lower-level interface with device support and granularity requirements. Ordinary tensor pointers are addresses, not evidence of physical adjacency. Keep these meanings distinct whenever using the phrase physical page in later exercises.

At the hardware layer, translation conceptually combines a virtual page number with an unchanged within-page byte offset. Page-table entries describe backing and access permissions; an invalid translation or forbidden access is not the same as a software pool miss. Translation

caches can retain recent mappings, so hardware access cost is not one literal full table walk for every element. Page sizes and translation mechanisms depend on the platform. A CPU model is useful for vocabulary, but must not be presented as a specification of every GPU's translation hierarchy, fault service, or migration behavior.

Part 3 - Quantitative Prediction Before Execution

For a flat logical element index i, positive page capacity P in elements, and element width s in bytes, predict page number and within-page offset:

$$p(i) = \lfloor i/P \rfloor, \qquad o(i) = i \bmod P.$$

A length n needs $\lceil n/P \rceil$ payload slots when every page is resident. Separate logical payload, slot capacity, table metadata, temporary results, and allocator-reserved memory. Compute a small boundary example before any CUDA operation, including an empty tensor and the final partially used page.

Part 4 - Experimental Design and Instrumentation

Start with a single device, one dtype, contiguous flattened values, explicit read and write methods, and no autograd support. Define half-open valid index ranges and integer bounds. Classify CPU backing, GPU residency, asynchronous ownership, and shared mappings as later extensions. Record the PyTorch build, CUDA runtime, device, allocator backend, page units, random seed, and supported operations. Build a CPU reference model whose values and ownership can be checked after every state transition.

Draw one address example using element offsets and another using byte offsets, then identify the conversion explicitly. A software page capacity must be positive and its byte width must be representable by the chosen integer type. Do not reuse a hardware term as a variable name without recording its layer. Include object generation and device identity in the translation contract so an otherwise valid offset cannot select a different object's data.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LogicalAddress:
    object_id: int
    element_index: int

@dataclass
class PageHandle:
    slot_id: int
    generation: int

def translate(address, object_metadata, page_table):
    # Validate bounds and resolve a software slot, not a hardware frame.
```

```
    ...

def E00(config):
    # Draw layers, predict accounting, and validate CPU boundary cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a glossary with a falsifiable claim for each layer. Reject claims that a tensor's contiguous layout proves physical contiguity, or that a list of tensors is automatically usable as one dense CUDA tensor. Preserve prediction, observation, and interpretation separately. Export CPU scalar records without keeping live tensor references in the evidence log. No real hardware page fault, speedup, or allocation outcome may be inferred solely from the software model.

Ask a second reader to classify each diagram arrow as software lookup, payload access, or lower-level translation. Any arrow that implies direct control over hardware frames needs a separately implemented backend and support evidence. Record that backend as absent in the primary exercise; ordinary storage pointers cannot fill this evidence gap.

Part 7 - Engineering Interpretation and Philosophy

Explain which decisions the pager controls and which remain with PyTorch, CUDA, the driver, and the operating system. A precise boundary is essential: the project can demonstrate logical placement, sharing, and explicit migration without claiming a general virtual memory implementation or transparent support for every tensor operator.

19.35.2 Exercise 01

Exercise Title: Compare Contiguous Tensor Allocation Against Fixed-Size Paged Allocation and Identify Where Each Strategy Wastes Memory

Part 1 - Exercise Contract and Why It Matters

Compare two application allocation policies under an identical finite capacity: a contiguous interval allocator and a fixed-size slot allocator. Deliver traces that separate rounding waste, free-space dispersion, retained capacity, and metadata overhead. Add a real PyTorch payload implementation, but keep the controlled arena's conclusions scoped to its declared rules.

Part 2 - System and Memory Mental Model

Contiguous here means consecutive positions in the controlled arena, not adjacent hardware frames. Paging permits an object's logical pages to occupy separate available slots. Both policies still require actual backing capacity. A contiguous dense tensor can already be backed through lower-level virtual memory, so an application-level contiguous failure does not prove that a normal CUDA tensor needs contiguous physical VRAM. Pool slack and allocator cache retention are different accounting quantities.

Part 3 - Quantitative Prediction Before Execution

For requested lengths n_j, calculate useful payload $U = s\sum_j n_j$ and paged assigned capacity $C = sP\sum_j \lceil n_j/P \rceil$. Tail waste is $C - U$; it excludes free pool slots, table bytes, and cached backend allocations. Predict the largest contiguous arena interval and total free capacity for a

fragmented trace. Give one request each policy can satisfy and one neither can satisfy. Keep zero-length objects explicit instead of charging an unnecessary payload page.

Part 4 - Experimental Design and Instrumentation

Replay the same ordered allocation and release events through both policies. Use equal arena bytes, alignment, lifetime boundaries, and failure semantics. Include equal-size objects, a mixed-size distribution, and lengths just above a page boundary. Measure host bookkeeping time separately from completed CUDA payload initialization. Repeat with the same seed and additional seeds, and report startup separately from warmed reuse. Do not allow one policy to grow its arena during a nominally fixed-capacity comparison.

Include a contiguous policy with exact-length intervals and one with the same alignment as the paged policy. This separates placement effects from an unfair rounding advantage. Use a trace where all objects die together as a control, then another with staggered lifetimes. Label each denied request with the resource that was insufficient rather than using one undifferentiated failure count.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class AllocationEvent:
    operation: str
    object_id: int
    length: int

def replay_arena(events, policy, capacity_bytes):
    # Enforce equal capacity, ownership, and failure boundaries.
    ...

def compare_waste(contiguous_rows, paged_rows):
    # Keep tail slack, free holes, metadata, and backend metrics separate.
    ...

def E01(config):
    # Predict adversarial traces, then replay both allocation policies.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report raw requested lengths, assigned slots, contiguous free intervals, failed request size, and metadata scope. Validate that every accepted object contains the expected values and that no released object remains readable. A lower internal-waste ratio does not imply lower total

memory or faster execution. Mark a real allocator observation as a separate experiment; never rename an arena admission rejection a measured CUDA out-of-memory exception.

Recompute occupancy directly from the event trace instead of trusting the allocator's counters. Check that no live intervals overlap and no slot is assigned to two private objects. Compare the time at which memory becomes logically free with the time the backend is allowed to reuse it, especially if initialization or consumption is asynchronous.

Part 7 - Engineering Interpretation and Philosophy

Identify the workload assumptions under which each policy is attractive. Paging trades placement flexibility for translation, metadata, and often operator integration costs. Recommend a policy from measured useful work and complete capacity accounting rather than treating every retained byte as fragmentation.

19.35.3 Exercise 02

Exercise Title: Split a Large PyTorch Tensor into Fixed-Size Logical Pages and Reconstruct the Original Tensor Exactly

Part 1 - Exercise Contract and Why It Matters

Represent a dense tensor as fixed-capacity logical pages and reconstruct its original values and shape exactly. Implement both an aliasing view control and an owning-page variant so the evidence distinguishes slicing from copying. The owning representation becomes the basis for later independently managed payload slots.

Part 2 - System and Memory Mental Model

A slice can be a view of the original storage and retain the entire source allocation. Such a list is a logical partition, not independent backing blocks. Owning pages require explicit storage allocation and copying. The last page has a valid-length field; unused capacity is not part of the tensor. Rejoining with concatenation or another dense output materializes storage and must be counted. Reconstruction does not create a zero-copy dense view across arbitrary independent CUDA allocations.

Part 3 - Quantitative Prediction Before Execution

Predict page count, valid tail length, copied elements, and reconstruction output bytes for lengths 0, 1, $P - 1$, P, and $P + 1$. For each representation, list which storages remain live when the original tensor reference is dropped. Estimate the peak while source, independent pages, and reconstructed output coexist. State whether page construction or reconstruction dominates that peak for the chosen measurement boundary.

Part 4 - Experimental Design and Instrumentation

Use a bounded contiguous tensor first, then test noncontiguous input under an explicit normalization policy whose copy cost is measured. Preserve shape, dtype, and logical element order in metadata. Populate values that reveal page permutation and tail leakage. Compare reconstruction on CPU and CUDA when available, with deliberate completion boundaries. Retain only scalar checksums and mismatch summaries after validation, not every reconstructed tensor from every repetition.

Construct the owning variant with a source pattern that identifies both page number and element offset. Keep source and result lifetimes explicit when measuring peak memory; deleting

a Python name does not remove other views. For an empty source, define shape restoration without manufacturing an unnecessary payload page. Record any contiguous normalization performed before flattening a strided input.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class PagedImage:
    shape: tuple
    dtype: object
    page_elements: int
    valid_lengths: tuple
    pages: list

def split_pages(tensor, page_elements, ownership_policy):
    # Make aliasing or owning behavior explicit and preserve valid lengths.
    ...

def reconstruct(image):
    # Materialize only valid elements in their original logical order.
    ...

def E02(config):
    # Validate empty, boundary, layout, and ownership cases.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require elementwise equality for the supported finite test data. If claiming bitwise preservation, use an appropriate byte-level comparison and include signed zero and selected nonfinite encodings; ordinary equality treats NaNs differently. Explain any unsupported dtype or layout. Verify source mutation propagation for the view control and independence for owning pages. Report allocated and reserved CUDA peaks separately, including temporary reconstruction.

Inspect storage ownership separately from numerical equality. Two outputs can have identical values while one retains the source allocation and the other owns independent storage. Compare storage offsets as well as tensor pointers when diagnosing views. If validating exact raw encodings, avoid a comparison that normalizes or converts the values before checking them.

Part 7 - Engineering Interpretation and Philosophy

Explain why a correct round trip establishes representation correctness but not an allocation reduction. Identify when views suffice, when independent page ownership is necessary, and when reconstructing a dense result defeats the memory goal of a paged consumer.

19.35.4 Exercise 03

Exercise Title: Build a Physical Page Pool in PyTorch That Allocates and Releases Fixed-Size CUDA Blocks on Demand

Part 1 - Exercise Contract and Why It Matters

Build a bounded application page pool with acquire, release, and validation operations. Allocate fixed-capacity CUDA payload blocks when required and reuse released slots safely. Deliver a lifecycle ledger that distinguishes returning a slot to the application pool from returning memory to PyTorch or the driver.

Part 2 - System and Memory Mental Model

The pool's physical page is an owned tensor payload, not a chosen GPU frame. Choose independent blocks for the primary implementation. An optional slab backend must disclose that all slot views retain the slab and cannot release its individual backing allocations. A free-list entry is usable only when no logical owner or in-flight operation still depends on the slot. Generation numbers distinguish a reused slot from an old handle with the same index.

Part 3 - Quantitative Prediction Before Execution

For K fixed slots, predict payload capacity KPs, currently assigned pages, free pages, and pending-release pages. Require disjoint states and a count invariant covering every allocated slot. Predict backend allocation calls for a cold burst followed by equal-size reuse. Do not predict that reserved CUDA memory falls when the application merely appends a released slot to its free list. Include page metadata and temporary initialization bytes separately.

Part 4 - Experimental Design and Instrumentation

Start with one host thread and one CUDA stream, bounded requests, and explicit quiescent release. Test pool exhaustion through admission control before attempting unsafe real-device exhaustion. Assign recognizable payload patterns, release slots in a shuffled order, and verify later reacquisition. Add stale handle, double release, foreign handle, and wrong-device tests. Compare cold creation, warmed reuse, and final pool destruction with matching measurement boundaries and peak resets.

Add a bounded allocation-failure injector that rejects the third requested slot before any CUDA allocation is attempted. Verify that provisional state is cleaned without relying on a device-wide failure. Exercise both retained free slots and a policy that destroys independent free blocks after quiescence; these policies have different backend footprints even when their logical free counts match.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass(frozen=True)
class PageHandle:
    slot_id: int
    generation: int
```

```
class CudaPagePool:
    def __init__(self, page_elements, max_slots, device, dtype):
        # Establish bounded free, owned, and pending slot state.
        ...

    def acquire(self):
        # Validate admission and return a generation-checked handle.
        ...

    def release(self, handle, completion_token):
        # Reuse only after ownership and execution dependencies end.
        ...

    def audit(self):
        # Reconcile every slot and backend allocation.
        ...

def E03(config):
    # Exercise cold allocation, reuse, exhaustion, and invalid handles.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit state after every operation and compare values before and after reacquisition according to the initialization contract. Export live owned payload, free retained payload, pending payload, allocation-call counts, and backend allocated and reserved peaks. Report unsupported allocator counters rather than substituting zeros. If a slot is released with unfinished work, the implementation must defer reuse or reject the operation; reference deletion alone is not proof of completion.

Record generation changes across multiple acquire and release cycles, not just the first reuse. A raw pointer can repeat because the allocator reuses an address; that does not make a stale handle valid. Confirm that evidence logging stores scalar identifiers rather than tensor objects whose references would accidentally extend page lifetime.

Part 7 - Engineering Interpretation and Philosophy

Choose whether the pool optimizes predictable capacity, reduced allocator calls, or both. Explain the retained-memory cost of keeping free pages and why safe reuse depends on lifetime evidence beyond a Python free list.

19.35.5 Exercise 04

Exercise Title: Implement a Page Table That Maps Logical Tensor Pages to Noncontiguous Physical CUDA Blocks

Part 1 - Exercise Contract and Why It Matters

Implement logical page tables whose entries reference nonconsecutive pool slots. Deliver lookup, installation, replacement, and object destruction operations with checked bounds and

generations. Preserve a stable logical object identity even when its payload placement changes. This exercise manages software indirection without creating a contiguous CUDA virtual address range.

Part 2 - System and Memory Mental Model

An entry must describe a valid mapping, not merely contain an integer slot index. Record object length, page capacity, valid tail length, placement, generation, and access policy. Distinguish absent, resident, and invalid handles. The initial CPU-owned table may drive Python dispatch; it is not automatically available inside a CUDA kernel. A device table extension requires explicit representation, upload, and publication dependencies, all measured separately.

Part 3 - Quantitative Prediction Before Execution

Translate several indices around page boundaries through a deliberately permuted mapping. Calculate required entries and metadata bytes under a declared packed representation. Python object overhead cannot be inferred from the packed field widths alone. Predict the result of a stale mapping after slot reuse and identify the generation check that must reject it. Explain why two objects may use the same logical page number without sharing any backing.

Part 4 - Experimental Design and Instrumentation

Use independently initialized pool slots and install a randomized bijection for one object. Compare every translation against a CPU oracle. Test missing entries, negative indices under a reject policy, oversized indices, invalid object IDs, stale generations, and foreign pool handles. Define failure atomicity: a failed replacement leaves the old table and ownership intact. Keep host table updates serialized in the primary implementation before adding asynchronous table consumers.

Give one object a table whose logical pages map to slot IDs in descending order, and another a different permutation of separate slots. This makes an accidental identity mapping fail immediately. Define whether table replacement invalidates cached translations and how the consumer learns the new version. A debug lookup cache must not silently outlive the table generation that made its entry valid.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class MappingEntry:
    handle: object
    state: str
    valid_elements: int

class SoftwarePageTable:
    def lookup(self, object_id, logical_page):
        # Resolve a checked entry without inventing missing residency.
        ...

    def install(self, object_id, logical_page, entry):
```

```
        # Validate the mapping before publishing ownership changes.
        ...

    def replace(self, object_id, logical_page, expected, replacement):
        # Preserve the old mapping if preparation or validation fails.
        ...

def E04(config):
    # Validate shuffled placement, bounds, and stale generation rejection.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the mapping ledger to reconcile with pool ownership at every stable boundary. Verify translations independently from payload reads so a coincidental pattern cannot hide wrong placement. Report table construction and lookup time separately from CUDA work. If exposing a table snapshot to a consumer, specify how that snapshot remains valid until the consumer finishes. Never reuse an entry's slot while an older table version can still authorize access.

Test a replacement whose candidate belongs to the wrong pool despite having a numerically valid slot index. Require rejection before ownership changes. Then audit a successful replacement by recomputing table references and old slot release eligibility. If metadata lives on the device in an extension, include its publication event and allocated bytes in the evidence.

Part 7 - Engineering Interpretation and Philosophy

Explain how indirection decouples logical position from placement and why this benefit creates a publication and lifetime obligation. State which metadata would be needed for a future kernel implementation without claiming that the current Python table already supplies hardware translation.

19.35.6 Exercise 05

Exercise Title: Read a Logical Tensor Through Page-Table Translation Without Requiring Its Physical Blocks to Be Contiguous

Part 1 - Exercise Contract and Why It Matters

Read selected logical elements and ranges through the software page table. Support shuffled payload placement without first reconstructing the entire object. Deliver a correct explicit access path and quantify its translation, dispatch, and output-materialization costs. Restrict the primary path to read-only, non-autograd data with the established device and dtype contract.

Part 2 - System and Memory Mental Model

Each logical access resolves an object-relative page number and an offset, then reads the corresponding resident payload. A range crossing a boundary requires multiple page fragments. Gathered output is a new dense result unless a specific single-page view contract is chosen. Returning internal writable views would expose a mutation bypass, so define ownership and access rights before exposing them. Software translation adds work and does not make arbitrary PyTorch operators consume the pager transparently.

Part 3 - Quantitative Prediction Before Execution

For a range $[a, b)$, predict touched pages and valid fragment lengths, including an empty range and an unaligned final element. For an index list, compare access count with distinct page count. Repeated indices need repeated output values but need not require repeated page lookup. Estimate output bytes, translation metadata, and dispatch calls for scalar, per-page grouped, and full-reconstruction strategies before measuring any of them.

Part 4 - Experimental Design and Instrumentation

Construct a random physical placement with monotonically identifiable logical values. Test contiguous ranges, shuffled indices, duplicates, empty requests, and one request crossing every boundary. Compare results against a dense CPU oracle in the original requested order. Benchmark hot reads separately from fault handling, which has not been implemented yet. Use completed CUDA regions and include dense output allocation in the declared read cost. Keep translation instrumentation bounded and export only scalar summaries.

Use a request order that revisits pages after visiting distant ones, so a grouped implementation must restore original output order rather than return page-sorted values. Include a request whose last element is the final valid logical element. Define the lifetime of any single-page read view and whether it is a copied result or a managed lease; do not mix these meanings in one unlabeled benchmark.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class PagedReader:
    def read_range(self, object_id, start, stop):
        # Validate, split at boundaries, translate, and assemble valid data.
        ...

    def gather(self, object_id, logical_indices):
        # Preserve request order and duplicate reads under grouped dispatch.
        ...

def compare_read_paths(pager, dense_reference, requests):
    # Separate translation, payload work, output bytes, and full latency.
    ...

def E05(config):
    # Predict touched pages, then validate sparse and range access paths.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact values for the supported finite test data and explicitly compare output order. Record requested elements, unique touched pages, table lookups, output bytes, and completed

latency. A Python loop with many small CUDA launches may be slower than dense reconstruction; report that outcome. Reject nonresident or stale entries according to the current contract rather than reading arbitrary storage. State whether host index conversion or device index validation introduces synchronization.

Compare measured data movement with the required output payload, then explain extra full-page copies or temporary index buffers. An access that touches one element on every page can have low useful bytes and high dispatch overhead. Report that unfavorable case even if a large sequential read makes the same implementation appear efficient.

Part 7 - Engineering Interpretation and Philosophy

Decide when sparse logical access avoids enough materialization to justify indirection. Explain why correctness on small reads does not establish a competitive general tensor backend, and identify the workload that would justify a grouped kernel extension.

19.35.7 Exercise 06

Exercise Title: Write Through Logical Page Addresses and Verify That Updates Reach the Correct Physical CUDA Blocks

Part 1 - Exercise Contract and Why It Matters

Implement explicit writes through logical addresses while preserving all untouched values. Support ranges and a declared indexed-write policy. Verify that updates reach the mapped slots rather than assuming logical and physical page numbers coincide. Keep sharing and copy-on-write disabled until their later ownership contracts are implemented.

Part 2 - System and Memory Mental Model

A logical mutation can touch multiple independent payloads and may require several CUDA operations. Bounds checking and value-shape validation must precede mutation if the operation promises all-or-nothing admission. Repeated destination indices require a defined overwrite or reduction rule; unordered duplicate writes cannot be treated as deterministic last-writer behavior without an implementation that enforces that order. Autograd versioning and arbitrary external tensor aliases are outside the primary software pager contract.

Part 3 - Quantitative Prediction Before Execution

Predict the page fragments changed by a write starting at $P-1$ with length three. Identify all unchanged neighboring elements. Calculate useful write bytes versus page capacity touched, and distinguish initialization of a new page from rewriting a resident page. For a duplicate-index example, write the expected result under a deterministic sequential policy and contrast it with a commutative reduction policy whose floating-point ordering may still matter.

Part 4 - Experimental Design and Instrumentation

Initialize every page with distinct values and place sentinels around the valid logical region. Validate source values, destination bounds, dtype, and layout before dispatch. Test a single-page write, boundary crossing, empty write, full-object write, invalid tail access, and repeated indices. Compare the whole object with a CPU reference after each operation. Start with one stream and one writer, then add explicit completion evidence before exposing the object to a different stream.

Choose an initial write policy that rejects duplicate indices, then add a separately tested deterministic implementation if duplicate writes are needed. Make value broadcasting either

explicitly supported with reference checks or explicitly rejected. A permissive tensor copy primitive must not accidentally expand the pager's public contract. Record whether each write marks its page dirty even when the new value equals the previous value.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class PagedWriter:
    def write_range(self, object_id, start, values):
        # Validate the entire request before committing supported writes.
        ...

    def write_indices(self, object_id, indices, values, duplicate_policy):
        # Enforce the declared conflict rule rather than assuming ordering.
        ...

    def completion(self, operation_id):
        # Return evidence that downstream readers may safely consume data.
        ...

def E06(config):
    # Compare mapped updates and unchanged regions against a CPU oracle.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report logical bytes modified, pages touched, backend operations, temporary bytes, and completed latency. Check untouched regions and padding, not only the requested output. Inject an invalid index at the end of a request to verify the declared rejection boundary. Distinguish validation failures before publication from execution failures after partial work; do not promise general rollback of arbitrary asynchronous device errors.

Use a source tensor that would alias the destination under a proposed view extension and reject it until overlap semantics are defined. Partial self-copy can require a temporary snapshot. Check that a completed write is visible to a later reader on the supported stream dependency, rather than inferring visibility from a quickly returned Python method.

Part 7 - Engineering Interpretation and Philosophy

Explain why writable software memory needs a stronger contract than read-only translation. Choose the smallest deterministic mutation interface suitable for later copy-on-write and migration, and document every unsupported alias or concurrency pattern that could bypass it.

19.35.8 Exercise 07

Exercise Title: Allocate Variable-Length Logical Tensors from a Shared Fixed-Size Page Pool and Measure Internal Memory Waste

Part 1 - Exercise Contract and Why It Matters

Allocate many variable-length logical objects from one fixed-size page pool. Measure per-object tail waste, aggregate assigned capacity, retained free slots, and metadata separately. Produce a replayable lifetime trace rather than estimating total memory from average sequence length alone.

Part 2 - System and Memory Mental Model

Each nonempty object owns enough page mappings for its current length. Unused elements in its final page are internal slack under the chosen policy. An unassigned retained slot is pool capacity, not another object's tail waste. Small independent objects cannot share a tail slot unless a suballocation scheme is explicitly added; such a scheme changes translation and ownership and is outside this exercise. Shared page mappings are also excluded here so payload accounting remains directly auditable.

Part 3 - Quantitative Prediction Before Execution

For lengths 1, $P-1$, P, and $P+1$, derive assigned pages and slack. Calculate aggregate waste both as bytes and as a fraction of assigned payload capacity, leaving an empty denominator undefined. Compare two length distributions with the same mean but different boundary positions. Predict admission when free slots equal the required count and when they are one short. Include object-table metadata and peak simultaneous ownership.

Part 4 - Experimental Design and Instrumentation

Generate bounded short, long, and mixed object traces with fixed creation and destruction events. Preserve the same useful values and lifetime overlap across policy comparisons. Audit allocation and release after every event. Repeat with a shape distribution concentrated near page boundaries and a separate held-out distribution. Measure CPU bookkeeping, CUDA initialization, and steady reads independently before reporting complete useful-work time. Predeclare whether the pool grows on demand up to a maximum or starts fully allocated.

Keep object initialization policy constant when comparing size distributions. Zero-filled payloads and uninitialized allocations have different costs and correctness guarantees. Record each object's birth and death event so peak simultaneous assignment can be reconstructed independently. Add a distribution with many empty objects to expose metadata overhead that a payload-only metric would miss completely.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class LogicalObject:
    object_id: int
    length: int
    page_handles: list
```

```
def allocate_object(pool, length, initialization_policy):
    # Admit all required pages or leave pool ownership unchanged.
    ...

def waste_ledger(objects, pool):
    # Separate logical payload, tail slack, free slots, and metadata.
    ...

def E07(config):
    # Replay variable lengths and compare predictions with audited states.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report object count, length histogram, useful elements, assigned slots, free retained slots, pending slots, and rejected allocations. Reconcile all bytes using the same dtype and units. A reported small waste percentage is misleading if free capacity or table overhead is silently omitted from total residency. Validate that a failed multi-page allocation returns any provisional slots without corrupting earlier objects or exposing partially initialized data.

Audit the sum of each final page's valid length and slack against assigned capacity. An object with a length exactly divisible by page capacity has no tail waste. Report both per-object statistics and the byte-weighted aggregate; a simple average of waste percentages can rank workloads differently from aggregate wasted bytes.

Part 7 - Engineering Interpretation and Philosophy

Recommend a page size only for the tested length and lifetime distribution. Explain why low tail waste, high admission probability, and low total device residency are related but distinct objectives. Preserve the workload trace so later allocator changes can be compared fairly.

19.35.9 Exercise 08

Exercise Title: Sweep Page Size and Measure the Trade-Off Between Internal Fragmentation, Page-Table Size, Allocation Overhead, and Reuse Flexibility

Part 1 - Exercise Contract and Why It Matters

Sweep application page capacity and quantify the competing costs of tail slack, table entries, allocation activity, dispatch overhead, and reusable capacity. Select a tested operating point under explicit memory and latency constraints. Do not identify the software page size with an operating-system page size or CUDA VMM mapping granularity.

Part 2 - System and Memory Mental Model

Smaller software pages can reduce tail slack and improve placement flexibility while increasing mappings and per-page work. Larger pages can improve transfer and dispatch efficiency while wasting more capacity for short objects. Backend allocation rounding may make measured reserved memory differ from application payload calculations. A fixed byte budget implies a different maximum slot count for each page size, which must be reflected in admission comparisons.

Part 3 - Quantitative Prediction Before Execution

For each candidate P, calculate assigned capacity and mapping count from the same length trace. State a packed metadata model and separately measure actual host bookkeeping when possible. Predict page touches for the same range and random-access requests. Include a transfer-amplification estimate when a small update eventually requires moving a whole page. Identify candidates that violate the payload budget before running timed experiments.

Part 4 - Experimental Design and Instrumentation

Use a bounded geometric page-size sweep compatible with the supported dtype. Keep useful object lengths, access order, mutation pattern, and byte budget constant. Rebuild the pool for each candidate and separate cold creation from warmed reuse. Include short-object, long-object, and mixed traces. Repeat near the apparent optimum on a held-out trace rather than selecting from one noisy measurement. Report both per-operation latency and full completed useful work, including dense outputs or staging buffers that the consumer requires.

Keep software page capacity in elements and byte capacity beside it for every trial. Changing dtype while holding element capacity would change the byte budget, so treat dtype as fixed in the primary sweep. Use the same maximum logical object sizes and retain failed candidates in the report. A candidate cannot win by omitting requests that no longer fit its rounded capacity.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PageSizeTrial:
    page_elements: int
    payload_budget_bytes: int
    trace_id: str

def predict_page_costs(trial, lengths, accesses, dtype_bytes):
    # Compute separate capacity, table, touch, and transfer estimates.
    ...

def run_page_size_trial(trial, workload):
    # Rebuild equal-budget state and measure complete correct work.
    ...

def E08(config):
    # Evaluate feasible candidates and validate the selected compromise.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Keep raw lengths, bytes, mapping counts, allocator observations, failures, and timing distributions beside derived scores. Test a counterexample to the rule that smaller pages always save memory and another to the rule that larger pages are always faster. Mark unavailable metadata measurements explicitly. If the sweep changes backend allocation sizes and caching behavior, describe that additional mechanism instead of attributing every difference to tail fragmentation.

Inspect whether a smaller-page candidate reduces assigned payload but increases backend reserved memory or metadata. Explain that outcome using the recorded layers rather than treating it as contradictory. Include confidence intervals or repeated-run spreads around close latency rankings, and prefer a robust feasible point when the apparent optimum is noisy.

Part 7 - Engineering Interpretation and Philosophy

Choose a minimal justified policy for this project, possibly a single page size. Explain what evidence would justify multiple size classes and the extra ownership complexity they introduce. A benchmark optimum is conditional on its workload, budget, backend, and measurement region.

19.35.10 Exercise 09

Exercise Title: Reproduce External Fragmentation with Contiguous Allocation and Demonstrate How Noncontiguous Paging Avoids the Same Failure

Part 1 - Exercise Contract and Why It Matters

Construct a deterministic external-fragmentation failure in a bounded application arena, then replay the same lifetime trace with nonconsecutive page assignment. Demonstrate a request that paging admits despite lacking a sufficiently large contiguous free interval. Preserve equal total backing capacity and label the failure at the application admission layer.

Part 2 - System and Memory Mental Model

Use six equal arena slots as a minimal example. Allocate one object per slot, then release alternating objects. Three free slots exist but none are adjacent. A contiguous request for two slots fails under the arena's interval policy; a paged request can use two separate free slots. This says nothing about hardware frame adjacency or the current CUDA allocator's ability to grow, coalesce, or remap its own storage. The arena is deliberately fixed and its rules are part of the experiment.

Part 3 - Quantitative Prediction Before Execution

List free intervals and total free slots after every trace event. Predict both policy decisions for two-slot and four-slot requests. Explain why the four-slot request fails under either policy. Add a request requiring $P + 1$ elements so rounding is visible. Compare useful payload and admitted capacity without merging tail slack with separated free intervals. State the exact smallest trace that distinguishes the two admission rules.

Part 4 - Experimental Design and Instrumentation

Implement the arena model on CPU first and verify the expected decisions. Attach real CUDA payloads only to accepted slots in a separate execution phase. Prevent either policy from increasing arena capacity or silently compacting live objects. Keep initialization and logical value checks identical. If exploring real allocator fragmentation later, use an independent

bounded experiment with backend/version evidence; do not treat the controlled trace as a promised CUDA out-of-memory reproducer.

Visualize the arena with a table of slot index, current owner, and free-run identity after every event. The same slot table must drive both admission predictions and independent value checks. Add a compacting contiguous variant only as a separate comparison that accounts for moved payload and updated references; compaction is not free and changes the original failure model.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ArenaDecision:
    request_slots: int
    accepted: bool
    free_slots: int
    largest_free_run: int

def fragmented_trace(slot_count):
    # Construct and label the minimal alternating-release example.
    ...

def replay_fixed_arena(events, placement_policy):
    # Enforce fixed capacity and preserve all live object values.
    ...

def E09(config):
    # Compare predicted admission with CPU model and optional CUDA payloads.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require a complete event ledger and a value audit of every surviving object. Report policy rejection separately from actual backend allocation failure. Include an all-free control, a no-free control, and a fragmented case whose total capacity is still insufficient. A successful paged admission does not prove less total residency: mapping metadata and tail waste remain present. Do not fabricate a hardware outcome when CUDA is unavailable.

Demonstrate that numerical adjacency of CUDA pointers is irrelevant to the arena's declared consecutive-slot rule. Likewise, separated pointers do not reveal hardware frame placement. If an actual allocation unexpectedly succeeds or fails, retain that observation with its backend context rather than editing the controlled trace to manufacture agreement.

Part 7 - Engineering Interpretation and Philosophy

Explain the precise failure paging avoids and the capacity failures it cannot avoid. Use the controlled counterexample to challenge broad fragmentation claims, then identify the additional evidence needed before transferring the conclusion to a production allocator.

19.35.11 Exercise 10

Exercise Title: Grow a Logical Tensor Incrementally by Attaching New Physical Pages Without Reallocating or Copying Existing Pages

Part 1 - Exercise Contract and Why It Matters

Grow a logical object by appending mappings while retaining all existing page payloads. Preserve old logical values and handle identities, initialize newly exposed elements according to a declared policy, and support failure without publishing a partially grown object. This is logical growth through indirection rather than an in-place resize of one dense tensor storage.

Part 2 - System and Memory Mental Model

Growth within a partial tail can expose previously invalid elements without acquiring another slot. Crossing a page boundary requires additional pages. The logical length and table update must become visible only after required allocation and initialization dependencies are established. Growing a Python list or device page table may copy metadata even when no old payload page moves. Distinguish payload stability, table stability, and a reconstructed dense output's unrelated pointer.

Part 3 - Quantitative Prediction Before Execution

For an initial length $P - 2$, predict new slots needed after growth by one, three, and $P + 3$ elements in separate replays. Calculate payload initialization bytes and table changes. List which old slots and generations must remain unchanged. Predict peak provisional ownership while preparing a multi-page growth. If the pool cannot supply the complete request, specify the unchanged length, table, and values that rejection must preserve.

Part 4 - Experimental Design and Instrumentation

Use a deterministic append trace crossing multiple boundaries. Record old handles and checksums before each growth, then verify the entire prefix and newly exposed region afterward. Test zero growth, invalid negative growth, integer overflow, tail-only growth, and capacity rejection. Keep a separate reference implementation that reconstructs a dense object on every append, and compare complete cost while acknowledging that the two representations provide different operator interfaces. Do not expose uninitialized tail bytes as valid user data.

Choose newly exposed values from an append counter so tail-only growth cannot accidentally pass using old padding contents. Capture a scalar snapshot of the old mapping handles before preparation. If table growth allocates new metadata storage, report its transient coexistence with the old version. Keep previously issued consumer leases valid or reject concurrent growth under the initial serialized contract.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch
```

```
class GrowablePagedObject:
    def plan_growth(self, new_length):
        # Count tail exposure, new pages, metadata, and provisional capacity.
        ...

    def grow(self, new_length, initialization_policy):
        # Prepare dependencies and publish length/table coherently.
        ...

    def audit_prefix(self, previous_state):
        # Confirm original payload handles and values remain valid.
        ...

def E10(config):
    # Test boundary growth, initialization, and failure atomicity.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report old payload copies separately from new-element initialization and metadata movement. A claim of no copying applies only to preserved payloads, not to all work in the operation. Verify rejection leaves no leaked provisional pages. Benchmark after deliberate CUDA completion and reset peaks for the specified region. If growth shares a tail with another object in later extensions, require copy-on-write before modifying that shared page.

Verify prefix preservation after several growth and shrink cycles, not only a single append. A stable tensor pointer by itself does not prove the prefix was not overwritten; compare both identity and content. For an admission failure, inspect the provisional free list and ensure the next unrelated allocation can still use every legitimately free slot.

Part 7 - Engineering Interpretation and Philosophy

Explain when stable page payloads help incremental workloads and when indirection or a dense materialization remains expensive. State the exact stability guarantee that downstream consumers may rely on, including the conditions that invalidate previously obtained views or table snapshots.

19.35.12 Exercise 11

Exercise Title: Shrink a Logical Tensor and Return Only Its Unused Physical Pages to the Shared Free-Page Pool

Part 1 - Exercise Contract and Why It Matters

Shrink a logical object and return only wholly unused pages to the pool. Preserve retained values and apply explicit lifetime checks before reuse. Define truncation semantics so later regrowth cannot accidentally reveal data that the contract considers discarded or uninitialized.

Part 2 - System and Memory Mental Model

Shrinking changes valid length before it necessarily changes physical backing. The page containing the new final element remains owned even when most of it becomes slack. Removed

mappings release logical ownership, but pending readers, writes, transfers, or shared owners may still prevent slot reuse. Returning a slot to a retained pool does not guarantee a fall in allocator-reserved memory. A slab-backed pool cannot free one slot's backend allocation independently.

Part 3 - Quantitative Prediction Before Execution

For length $3P + 2$, compute retained pages after shrinking to $3P$, $P + 1$, P, and zero in separate trials. Distinguish removable mappings from actually reusable slots. Predict how much assigned slack remains after each shrink and which bytes a later regrowth must initialize. Include a case where a page has no logical mapping but still has an in-flight reader, so immediate reuse would violate correctness.

Part 4 - Experimental Design and Instrumentation

Fill objects with boundary-sensitive values, shrink them, and verify surviving prefixes against a CPU oracle. Test unchanged length, complete destruction, invalid larger target length, and repeated shrink requests. Start with quiescent single-owner objects, then use a controlled completion token to defer one release. Reacquire released slots for a different object and ensure the old object cannot access them through a stale table. Keep physical release policy separate from logical truncation.

Test shrinking by one element when the old final page remains necessary, and shrinking by one element when that change removes an entire page. These nearby lengths expose off-by-one reclamation errors. If readers hold leases to removed mappings, record retired state separately from the current object's table. Later completion must release that retired ownership without restoring the old logical length.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class ShrinkResult:
    retained_length: int
    removed_mappings: int
    reusable_slots: int
    deferred_slots: int

def shrink_object(pager, object_id, new_length):
    # Remove only unused mappings and preserve retained tail ownership.
    ...

def reclaim_completed(pool, completion_evidence):
    # Move deferred slots to free state only after all users finish.
    ...
```

```
def E11(config):
    # Validate prefix survival, stale access rejection, and later regrowth.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Audit free, mapped, and deferred counts after every shrink and completion. Report application-assigned capacity, pool-retained capacity, and backend metrics independently. Check that a truncated region is inaccessible and that regrowth obeys the initialization policy. If data sanitization is part of the chosen contract, measure it explicitly rather than equating release with erasure. Do not infer a leak merely because cached reserved memory stays high.

Destroy an object whose length is already zero and define whether the second destruction is a clear invalid-handle error. Avoid silent counter decrements. Check that a delayed completion for a retired page cannot free its new generation after reuse. This audit requires matching the completion token to the exact slot generation it protects.

Part 7 - Engineering Interpretation and Philosophy

Explain why logical deletion, ownership release, reusable capacity, and backend deallocation are distinct events. Choose a truncation and regrowth policy suitable for the later multi-object manager and document the consumer lifetime conditions required for safe reclamation.

19.35.13 Exercise 12

Exercise Title: Implement Page Reference Counting So Multiple Logical Tensors Can Safely Share Physical Pages

Part 1 - Exercise Contract and Why It Matters

Allow multiple logical objects to share payload pages using explicit mapping reference counts. Deliver checked share, unshare, destruction, and deferred reclamation operations. Keep mutation disabled for shared pages until the copy-on-write exercise defines the required behavior.

Part 2 - System and Memory Mental Model

A mapping reference count measures owning table entries, not arbitrary Python references and not the number of CUDA kernels still reading a page. Maintain in-flight use separately. A page becomes reusable only after its mapping count and outstanding use obligations both reach zero. Internal tensor views exposed outside the pager would create untracked aliases, so disallow them or define an explicit lease. Generation checks remain necessary after a slot is recycled.

Part 3 - Quantitative Prediction Before Execution

Start with two objects sharing three full pages and one object with a private tail. Calculate unique payload slots, total mappings, and counts per slot. Destroy the objects in different orders and predict which slots become reusable at each step. Add a retained read lease to one page and show why count zero alone cannot authorize reuse. Compare logical bytes across objects with unique backing bytes without double-counting shared payload.

Part 4 - Experimental Design and Instrumentation

Create shared objects through a single controlled API rather than copying table dictionaries directly. Verify each count against a recomputation from all live table entries. Test duplicate mappings within one object, partial sharing, complete sharing, destruction order, stale handles, and double unshare. Serialize host ownership changes initially. Record pending leases and their completion boundaries so the reference model can independently predict release. Keep random traces bounded to allow an audit after every event.

Create one object with two logical entries pointing to the same payload and another with one entry to it. Count three mapping references under this model, not two object references. State whether this alias pattern is supported for reads only until copy-on-write behavior is defined. Store mapping identities so repeated attach or detach calls cannot increment or decrement a counter twice without detection.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class SharedPageState:
    mapping_references: int
    inflight_leases: int
    generation: int

class PageOwnership:
    def attach(self, handle, mapping_id):
        # Validate and increment exactly once for a new owning mapping.
        ...

    def detach(self, handle, mapping_id):
        # Remove the mapping and defer reuse while leases remain.
        ...

    def audit(self, all_tables, active_leases):
        # Recompute ownership independently from the maintained counters.
        ...

def E12(config):
    # Exercise sharing and destruction orders against the ownership oracle.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require nonnegative counts, one ownership contribution per live mapping, and no free slot reachable from a valid mapping or lease. Demonstrate a counterexample where counting logical objects rather than mapping entries is wrong. Measure metadata overhead and avoided payload duplication separately. A reduced unique payload count does not establish total memory reduction if new tables or retained leases dominate the workload.

Use an independently generated multiset of mapping handles to recompute counts. Do not let the audit read the same maintained counters it is supposed to verify. Test a retained lease after all tables disappear, then complete that lease and check reclamation. This distinguishes logical reachability from outstanding execution lifetime.

Part 7 - Engineering Interpretation and Philosophy

Explain how sharing changes memory accounting and reclamation without making writes safe automatically. Define the ownership evidence that copy-on-write will need, and state why ordinary external aliases cannot be inferred completely from the pager's own mapping counters.

19.35.14 Exercise 13

Exercise Title: Implement Copy-on-Write for Shared PyTorch Pages and Allocate New Physical Storage Only When a Shared Page Is Modified

Part 1 - Exercise Contract and Why It Matters

Implement software copy-on-write for shared pages behind the pager's controlled write API. Preserve snapshot values for other logical owners while allowing a writer to modify its private version. Allocate replacement payload only for pages that require separation, and include allocation, copy, and publication costs in the evidence.

Part 2 - System and Memory Mental Model

PyTorch tensor writes do not automatically implement this project's page copy-on-write semantics. The manager must intercept every supported mutation. For a shared page, prepare private backing, copy the values that must survive, apply the update, and publish a coherent replacement mapping with correct ownership. A partial update usually needs the untouched old values. A complete valid-page overwrite may avoid that copy under a declared policy. Keep source pages and old table versions alive until all readers and copies finish.

Part 3 - Quantitative Prediction Before Execution

For two objects sharing four pages, predict new slots and copied bytes for a one-element write, a cross-boundary write, and a complete-page overwrite. Distinguish unique pages touched from number of elements written. Calculate peak ownership while old shared payloads and provisional private pages coexist. Show a pool-full case where copy-on-write must reject or defer the mutation; being able to read shared data does not imply enough space to privatize it.

Part 4 - Experimental Design and Instrumentation

Create two snapshots with identical logical values. Mutate one through only the controlled API and compare both complete objects against independent CPU references. Test repeated writes to an already private page, duplicate logical mappings, partial tail updates, and allocation failure. Serialize writers in the primary version; a concurrent extension requires locking or another defined publication protocol. Reject external writable view access that bypasses the manager. Start with no autograd rather than promising gradient preservation.

Define whether repeated aliases within one logical object belong to a shared mutation group or represent independent snapshot mappings. The selected copy-on-write behavior must preserve that declared relationship. For the primary snapshot model, page replacement affects only the targeted mapping unless the contract says otherwise. Do not infer snapshot semantics from a reference count without defining which mappings a write should update.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
import torch

class CopyOnWritePager:
    def plan_write(self, object_id, region):
        # Determine touched sharing groups and reserve transition capacity.
        ...

    def prepare_private_pages(self, plan):
        # Copy only required surviving values and retain old ownership.
        ...

    def commit_write(self, plan, values):
        # Apply supported mutation and publish checked mapping replacements.
        ...

def E13(config):
    # Validate snapshot isolation, copy accounting, and failure boundaries.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the unmodified snapshot to remain exactly unchanged and the writer to match its reference. Audit counts and generations after success and rejection. Report copied payload, newly initialized payload, provisional capacity, and steady unique backing. Distinguish admission atomicity from recovery after an unexpected asynchronous execution failure. No general transactional rollback of device faults is required or implied by this exercise.

Inject a failure after one of several replacement pages is prepared but before publication. Require provisional resources to be returned while old snapshots stay readable. On successful publication, preserve the old source until every copy and reader finishes. Record whole-page copy amplification for sparse writes so sharing savings are assessed alongside later mutation cost.

Part 7 - Engineering Interpretation and Philosophy

Explain when snapshot sharing defers rather than eliminates allocation. Recommend a mutation policy from the measured write density and available transition headroom, and identify why a transparent general tensor copy-on-write system would need stronger integration than this restricted manager.

19.35.15 Exercise 14

Exercise Title: Add CPU-Resident Pages and Implement Explicit GPU Page-In and Page-Out Operations Under a Fixed VRAM Page Budget

Part 1 - Exercise Contract and Why It Matters

Extend the pager with CPU backing and explicit GPU page-in and page-out under a fixed application CUDA slot budget. Preserve values across migration and make residency transitions observable. Distinguish the manager's payload budget from total device usage, which also includes outputs, workspaces, metadata, other allocations, and the caching allocator.

Part 2 - System and Memory Mental Model

A nonresident logical page retains an authoritative CPU version or another explicit reconstructible source. Track clean and dirty versions, transfer state, and backing ownership. Do not reuse a GPU slot until its latest values are safely backed and all device users finish. CPU backing consumes RAM; pinned staging consumes additional bounded capacity. Host-to-device submission is not transfer completion, and pinned sources must remain unchanged while transfers still depend on them.

Part 3 - Quantitative Prediction Before Execution

For K GPU payload slots and a larger logical page set, predict residency, CPU backing, dirty writeback bytes, and staging requirements for a short access trace. Count incoming reserved slots and outgoing slots still holding live data against the budget. A full pool may require completing an eviction before admitting a new page. Calculate both logical useful bytes and whole-page transfer amplification for the chosen access pattern.

Part 4 - Experimental Design and Instrumentation

Begin with synchronous migration at deliberate completion boundaries. Test clean eviction, dirty eviction, repeated page-in, a partial final page, and an object destroyed during a deferred transition under a defined cancellation policy. Compare all values with a CPU oracle. Add asynchronous transfers only after defining events, source lifetime, destination readiness, and slot reuse. Bound both host backing and staging. Measure cold population separately from steady migration, including writeback and synchronization cost.

Specify the authority rule for clean CPU-backed pages and dirty GPU pages. An old CPU copy cannot satisfy a fault for a newer version. If CPU backing is pageable, use a synchronous primary path or include a bounded pinned staging step with its own lifetime. Choose whether valid tail elements or full page capacity are transferred, and make the byte ledger follow that choice.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class ResidencyRecord:
    backing_version: int
    device_version: object
    state: str
    slot_handle: object
    transfer_token: object

class ExplicitPager:
```

```
    def page_in(self, page_id, consumer_stream):
        # Admit a slot, copy authoritative values, and publish readiness.
        ...

    def page_out(self, page_id):
        # Preserve dirty data and defer slot reuse until all work completes.
        ...

def E14(config):
    # Validate migration, versions, and every budget transition.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Export maximum simultaneous slot ownership, CPU backing bytes, pinned staging scope, transfer bytes by direction, and completed latency. Report backend device peaks separately from the application slot budget. Validate a round trip after mutation and demonstrate that a clean backed page can avoid unnecessary writeback. A slot returned to the pool may remain allocated or reserved by PyTorch; this does not invalidate a correctly scoped payload-budget claim.

Test a dirty page with multiple logical mappings under the chosen sharing policy, then verify the authoritative version after eviction and reload. Check both source and destination lifetime during asynchronous copies. A completed host method is insufficient evidence of completed device work; require the correct event or deliberate synchronization before reclaiming staging or payload slots.

Part 7 - Engineering Interpretation and Philosophy

Explain which memory pressure was relieved and which costs moved to CPU RAM, transfer bandwidth, or synchronization. State why explicit paging is a workload management technique rather than transparent CUDA Unified Memory or a hardware page-fault handler.

19.35.16 Exercise 15

Exercise Title: Trigger a Simulated Page Fault When a Required Logical Page Is Not Resident in VRAM and Restore It from CPU Memory

Part 1 - Exercise Contract and Why It Matters

Trigger an application-level simulated page fault when an explicit read or write requests a nonresident logical page. Restore the authoritative values from CPU backing, then resume the supported operation. Deliver fault records, correct retry behavior, and a clear distinction between software miss handling and hardware or operating-system page faults.

Part 2 - System and Memory Mental Model

The access API checks residency before dispatching payload work. A miss enters a controlled state machine rather than dereferencing an invalid CUDA pointer. Possible states include absent, loading, resident, evicting, and failed. A second request for a loading page must wait for the same operation or follow another explicit deduplication policy. Publishing an incomplete destination as resident can expose stale values even when its slot has already been allocated.

Part 3 - Quantitative Prediction Before Execution

For a trace of logical page requests, predict first-touch misses, later hits, repeated misses after eviction, and bytes transferred. Count fault requests separately from unique page-in operations. A range spanning two absent pages may generate two restorations. Derive the latency components of a blocking fault and identify which can overlap only after the later scheduler is added. Include a pool-full miss with no currently evictable victim.

Part 4 - Experimental Design and Instrumentation

Use a tiny bounded GPU slot count and a larger CPU-backed object. Force selected pages nonresident through the manager, then issue boundary reads and writes. Validate fault identity, restored version, resumed output, and unchanged neighbors. Simulate a page-in preparation failure before publication and require a coherent recoverable state. Never provoke an illegal device memory access to represent a software miss. Keep the primary host dispatcher serialized and define a bounded wait or admission failure when no victim can be reclaimed.

Issue two simulated requests for the same absent version before completing the first load in the transition simulator. Expect one page-in reservation and two dependent requests. Then cancel one requester and verify that the remaining requester can still complete. Define how the fault record refers to an object generation so an old request cannot resume against a new object with a recycled numeric identifier.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class FaultRecord:
    request_id: int
    page_id: int
    prior_state: str
    required_version: int
    outcome: str

class FaultDispatcher:
    def ensure_resident(self, page_id, access_mode):
        # Deduplicate transitions and return readiness or an explicit failure.
        ...

    def resume(self, logical_operation, readiness_tokens):
        # Execute only after all required pages are valid and available.
        ...

def E15(config):
    # Predict misses, force software faults, and validate resumed values.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report request misses, unique restorations, wait time, transfer bytes, retries, and failure phase without conflating them with OS fault counters. Check that a failed restoration does not install a valid mapping or leak a slot. Verify repeated requests do not allocate duplicate destinations for one version. Preserve unsupported concurrency cases as explicit limitations instead of assuming a Python dictionary alone implements a safe state machine.

Classify waiting for capacity separately from transferring data and waiting for an already scheduled restoration. These causes have different remedies. A timeout should report its blocked dependencies and preserve coherent state, not install a fabricated zero page. Test explicit failure reporting when the CPU backing version required by the request is unavailable.

Part 7 - Engineering Interpretation and Philosophy

Explain the benefit and overhead of moving residency checks into a controlled API. Identify which future operations can be resumed safely and why arbitrary PyTorch kernels cannot be intercepted by this software fault mechanism without additional integration.

19.35.17 Exercise 16

Exercise Title: Combine Page Prefetching and Page Eviction to Maintain a Dynamic GPU Working Set Without Exceeding the Physical Page Budget

Part 1 - Exercise Contract and Why It Matters

Add bounded prefetch and eviction scheduling while maintaining the declared GPU payload slot budget at every transition. Compare demand-only paging with lookahead policies using the same correct logical workload. Account for useful prefetch, wasted transfers, dirty writeback, waits, and scheduling overhead.

Part 2 - System and Memory Mental Model

Prefetch reserves capacity before use and may evict something needed sooner. An eviction candidate must satisfy ownership and completion rules, not simply have an old timestamp. Protect active leases and incomplete transfers. Maintain an explicit residency state machine and versioned table publication. Logical access order is a policy input; a host timestamp or kernel submission order alone does not establish when a device reader has finished with its payload.

Part 3 - Quantitative Prediction Before Execution

For a small slot budget, hand-simulate demand-only and one-page-lookahead execution on a sequential trace and an alternating working-set trace. Count misses, useful prefetched pages, evictions, writebacks, and peak reserved slots. Show a case where prefetch harms demand admission. Define a useful-prefetch ratio with an explicit lifetime window and leave an empty denominator undefined. Include the transition where an outgoing dirty page still occupies its slot.

Part 4 - Experimental Design and Instrumentation

Implement a conservative eviction baseline and bounded lookahead depth. Keep payload, staging, and outstanding-transfer limits separate. Start with synchronous scheduling, then add a transfer stream and event-based readiness. Require consumers to wait for the correct page generation and writers to respect migration state. Use the same finite trace for correctness and

separate repeated runs for timing. Compare unprofiled complete latency with a short diagnostic timeline; include prefetch setup and drain costs in end-to-end results.

Give demand and speculative work separate admission paths. A prefetched page that has not been consumed may be evicted under a declared policy, but an in-flight destination cannot be overwritten to satisfy demand. For dirty victims, reserve host backing or staging before starting writeback. Bound lookahead metadata and pending requests as well as payload slots so the controller cannot shift unbounded growth into a host queue.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class PagerBudgets:
    gpu_slots: int
    cpu_backing_bytes: int
    pinned_staging_bytes: int
    max_transfers: int

class WorkingSetScheduler:
    def plan(self, demand, lookahead, states):
        # Admit demand before speculative work within transition limits.
        ...

    def evictable(self, page_id, completion_evidence):
        # Exclude active, stale, dirty-unbacked, or in-flight dependencies.
        ...

    def advance(self, completed_tokens):
        # Publish finished transitions and reclaim only safe slots.
        ...

def E16(config):
    # Compare policies on sequential and adversarial working sets.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Require no interval where slot ownership exceeds the bound, including incoming reservations and outgoing live pages. Log a scalar transition ledger and independently audit it. Report wall time, demand stall intervals, useful work, transfer volume, writebacks, and wasted prefetch. Concurrent intervals must not be added as though they were serial. A low fault count can coexist with poor throughput if speculative transfers occupy bandwidth or block demand.

Compare a perfectly predicted sequential trace with a deliberately misleading lookahead trace. Record how often speculation delays demand and whether the fallback policy restores progress. Include a working set one page larger than capacity to expose thrashing. Check that

reported overlap actually shortens completed-work time rather than merely placing transfers on another stream.

Part 7 - Engineering Interpretation and Philosophy

Choose the smallest tested prefetch policy that improves useful work without weakening resource or correctness contracts. Explain the difference between hiding latency, reducing transfer volume, and reducing capacity demand; one policy need not improve all three.

19.35.18 Exercise 17

Exercise Title: Build a Multi-Sequence Page Allocator That Serves Many Dynamically Growing Tensor Objects from One Shared CUDA Page Pool

Part 1 - Exercise Contract and Why It Matters

Serve many growing and shrinking sequence objects from one page pool. Add per-object tables, generation-checked identities, lifecycle operations, and fair admission under shared capacity. Support selected shared prefixes and private suffixes only through the ownership and copy-on-write contracts already validated, without assuming a specialized attention kernel.

Part 2 - System and Memory Mental Model

Sequence identity, logical length, page mappings, shared groups, residency, and active leases belong to separate records. A destroyed object's identifier may be reused only with a new generation or another stale-reference defense. One sequence's partial tail remains its own capacity unless explicit sharing permits otherwise. Admission must consider transition headroom as well as steady pages, especially when a shared prefix is about to be modified.

Part 3 - Quantitative Prediction Before Execution

Predict peak unique backing for several sequences with a common full-page prefix and different private suffix lengths. Compare that with the sum of logical lengths and the fully duplicated baseline. Calculate required pages for simultaneous growth and identify an admission order that can starve a small request. Define the chosen fairness or priority rule and state whether it optimizes completed sequences, latency, or another useful-work objective.

Part 4 - Experimental Design and Instrumentation

Replay a bounded multi-sequence trace containing creation, append, read, mutation, shrink, share, and destruction. Preserve stable sequence IDs and expected values in a CPU reference. Compare equal-work isolated pools with the shared pool under equal aggregate payload capacity. Include simultaneous pending growth, cancellation before publication, a shared-tail restriction, and object-ID reuse. Separate allocation service from any model computation; if adding a model consumer, use only the manager's explicitly supported access interface and account for materialized dense inputs.

Use sequences with identical shared prefixes but different final partial pages, and initially permit prefix sharing only at complete-page boundaries. This keeps tail ownership explicit. Later expand sharing only with a reference model for valid lengths and mutation behavior. Label request priorities and record arrival order so a fairness claim can be checked against events rather than inferred from aggregate throughput.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each ... marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass(frozen=True)
class SequenceHandle:
    sequence_id: int
    generation: int

class MultiSequencePager:
    def create(self, length, shared_prefix=None):
        # Validate sharing boundaries and atomically admit initial mappings.
        ...

    def append(self, sequence, values):
        # Respect fairness, tail ownership, COW, and transition capacity.
        ...

    def destroy(self, sequence):
        # Retire the identity and safely release mappings and pending work.
        ...

def E17(config):
    # Audit the shared pool through mixed sequence lifecycle traces.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report accepted and rejected requests, wait times by sequence, unique payload, mapping count, tail slack, shared capacity saved, and transition peaks. Validate all surviving sequences after every event and ensure a cancelled operation cannot publish into a newly reused identity. A high aggregate throughput can hide starvation; report the worst waiting sequence and the tested fairness contract. Do not claim model-level acceleration from allocator-only timing.

Cancel a waiting sequence, reuse its numeric identifier with a new generation, and then complete the old sequence's outstanding transfer. The old completion must not modify the new sequence. Audit unique backing and reference counts through this interleaving. Check that a large sequence cannot consume all transition reservations indefinitely if the declared policy promises bounded service to smaller requests.

Part 7 - Engineering Interpretation and Philosophy

Explain where shared capacity improves admission and where contention or metadata erodes the benefit. Distinguish a general software sequence allocator from a complete paged attention implementation, and identify the required consumer integration before applying the design to a real model.

19.35.19 Exercise 18

Exercise Title: Stress-Test the Pager with Random Growth, Shrinkage, Sharing, Page Faults, Evictions, and Severe VRAM Pressure

Part 1 - Exercise Contract and Why It Matters

Stress-test the pager with reproducible randomized lifecycle and residency traces, including severe pressure within a small declared slot budget. Find minimal counterexamples to ownership, value, transition, and budget invariants. Separate deterministic fault injection from actual resource exhaustion and keep all real-device allocations bounded.

Part 2 - System and Memory Mental Model

The difficult failures combine individually valid operations: a shared page is being copied while one object shrinks, a dirty victim has pending readers, or a cancelled fault completes after object-ID reuse. A state machine must preserve version and generation identity across these transitions. Resource pressure can mean no admissible slot rather than a CUDA allocation failure. Do not force device-wide exhaustion when a small fixed application budget can exercise the same admission logic safely.

Part 3 - Quantitative Prediction Before Execution

Before execution, define invariants for every state and predict one valid and one invalid short trace. Calculate maximum transition capacity for growth, copy-on-write, page-in, and dirty eviction combinations. Define bounded waiting and progress expectations under a trace that eventually completes outstanding leases. A permanently pinned working set may make admission impossible; the correct result can be an explicit rejection rather than guaranteed progress.

Part 4 - Experimental Design and Instrumentation

Generate traces from a fixed seed with explicit operation probabilities, maximum lengths, page count, host backing limit, and transfer limit. Compare every stable state with a dense CPU oracle and recomputed ownership ledger. Add deterministic scheduler interleavings or completion-token simulation before running actual asynchronous streams. Inject preparation failures at named boundaries. Reduce any failing trace by replaying smaller subsequences while preserving dependencies, then save the smallest reproducible counterexample. Run additional seeds only after the primary trace is auditable.

Separate invalid-operation tests from valid randomized histories. An intentional stale handle should produce the expected rejection without being counted as a pager correctness failure. Save the exact scheduler decisions and completion order for asynchronous reproductions. A random seed alone may not reproduce real timing, so deterministic interleaving simulation is the primary tool for shrinking state-machine failures.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass

@dataclass
class StressLimits:
    max_objects: int
    max_length: int
    gpu_slots: int
    cpu_bytes: int
```

```
    steps: int

def generate_trace(seed, limits):
    # Produce bounded valid operations and labeled intentional violations.
    ...

def audit_state(pager, oracle, pending_operations):
    # Check values, counts, generations, versions, and all resource states.
    ...

def minimize_failure(trace, replay):
    # Preserve dependencies while finding a smaller reproducible failure.
    ...

def E18(config):
    # Test deterministic interleavings, then supported CUDA executions.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Report seeds, trace IDs, exact failure phase, last valid state, and whether reproduction succeeds. Include stale-handle rejection, double release, leaked provisional pages, invalid tail access, failed copy-on-write, duplicate page-in, and forbidden eviction controls. Distinguish a simulator pass from a CUDA execution pass. Export bounded CPU-only records and never invent hardware results when the execution environment lacks the required device or libraries.

When minimizing a trace, retain object creation, backing availability, and required sharing dependencies. A shortened trace that fails because its setup was removed is a different failure. Report the original and reduced histories with their invariant violations. Track pending work at shutdown so a test cannot appear to pass simply by exiting before delayed corruption becomes observable.

Part 7 - Engineering Interpretation and Philosophy

Explain which invariants survived the tested envelope and which remain unsupported. A randomized run without a failure is evidence about that run, not a proof of correctness under every interleaving. Recommend the next smallest experiment that addresses the most consequential unresolved risk.

19.35.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Virtual Tensor Memory Manager with Logical Addressing, Page Tables, Physical Page Pools, Sharing, Prefetching, and Eviction

Part 1 - Exercise Contract and Why It Matters

Integrate the restricted pager into one benchmarkable virtual tensor memory manager with logical addressing, checked tables, bounded pools, sharing, copy-on-write, CPU backing, explicit faults, prefetch, and eviction. Preserve the distinction between its software interface and

hardware virtual memory. Deliver a support matrix, reproducible traces, correctness evidence, and a workload-specific engineering recommendation.

Part 2 - System and Memory Mental Model

The manager coordinates object identity, mapping ownership, versions, residency, transfer completion, and admission. Use one source of authority for each record and explicit commit boundaries between prepared and published state. Ordinary PyTorch operators do not gain transparent paged access simply because a Python object exposes a familiar method name. The primary version supports a narrow no-autograd flat-value interface; shape metadata can be preserved without promising arbitrary views, gradients, layouts, or kernels.

Part 3 - Quantitative Prediction Before Execution

Predict complete payload residency, CPU backing, pinned staging, table bytes, tail slack, transition headroom, output materialization, and useful-work time for each benchmark trace. Compare dense materialization, a resident-only paged baseline, demand paging, and prefetch with equal useful values and supported semantics. Identify when a model larger than the GPU slot budget can be served and when its active working set or consumer outputs still make admission impossible. No paging policy creates additional bandwidth or physical capacity.

Part 4 - Experimental Design and Instrumentation

Freeze the support matrix and validate each subsystem before integration. Run short deterministic traces, randomized stress, and held-out sequential, sparse, shared-prefix, write-heavy, and thrashing workloads. Keep the same requests, outputs, and completion boundaries across baselines. Measure cold construction, warmed access, transition costs, and final drain separately. Ablate sharing, copy-on-write, prefetch, and eviction choices to identify mechanisms. Record device and software versions, dtype, page units, budgets, seeds, trace IDs, allocator backend, and initial-state identifiers.

Publish a supported-operation matrix before performance results: creation, range reads, indexed access, mutation, sharing, resizing, migration, and cancellation each need precise semantics. Mark unsupported layouts, external aliases, autograd, graph capture, and concurrent writers explicitly. Preserve one immutable benchmark trace per comparison and use scalar evidence IDs to link outputs, transitions, and resource observations without retaining their payloads.

Part 5 - PyTorch/CUDA Implementation

Complete the scaffold below. Each `...` marks required learner work; the implementation is intentionally incomplete and is not a finished solution.

```
from dataclasses import dataclass
import torch

@dataclass
class VirtualTensorContract:
    device: str
    dtype_name: str
    page_elements: int
    gpu_slots: int
    cpu_backing_bytes: int
    staging_bytes: int
```

```
    max_transfers: int
    supported_operations: tuple

class VirtualTensorMemoryManager:
    def __init__(self, contract):
        # Initialize authority, ownership, state machines, and bounded pools.
        ...

    def access(self, object_handle, request):
        # Validate, restore, translate, and dispatch supported operations.
        ...

    def mutate(self, object_handle, request, values):
        # Respect COW, versions, leases, and coherent publication.
        ...

    def schedule(self, demand, lookahead):
        # Enforce demand priority and every transition resource bound.
        ...

    def audit(self):
        # Recompute mappings, ownership, residency, versions, and budgets.
        ...

    def shutdown(self):
        # Finish or safely cancel owned work and report unreclaimed state.
        ...

def E19(config):
    # Validate the integrated contract before complete-work benchmarking.
    ...
    # Export evidence, counterexamples, limitations, and recommendation.
    ...
```

Part 6 - Measurement, Validation, and Failure Analysis

Acceptance requires exact supported values, coherent shared snapshots, checked stale identities, no unsafe reuse, truthful budget accounting, and bounded failure handling. Report useful completed operations, latency spread, slot peaks, host backing, backend allocated and reserved peaks, transfer bytes, faults, evictions, copies, metadata scope, and failure phases. Keep predictions, observations, and interpretations separate. A benchmark with incorrect results or omitted materialization cost cannot qualify as a performance improvement.

Include a workload where dense storage wins and another where the active set is too large for any permitted policy. Report rejection or poor performance honestly. Validate shutdown after normal completion and controlled cancellation, including old mappings and pending transfers. Separate measured delivered features from proposed kernel or VMM extensions so the final engineering recommendation cannot imply capabilities the scaffold leaves to the learner.

Part 7 - Engineering Interpretation and Philosophy

Recommend the smallest manager justified by the evidence, including a dense baseline when it wins. Explain which benefits came from software placement, sharing, reduced copying, or latency overlap. State what remains necessary for production integration, including supported kernels and stronger concurrency or autograd contracts, without presenting unimplemented extensions as delivered capabilities.

20

Conclusion of the Volume of Books

20.1 What next

The real goal is to delve deeper into artificial intelligence, machine learning, deep learning, and perhaps even self-programming in the future. Explore the philosophy of building mathematical models and move away from the notion that artificial intelligence will become uncontrollable. Research seeks solutions and development, not media attention. Focus on your research in artificial intelligence and create value in this world. What you've learned in these books is just a drop in the ocean. Artificial intelligence is like a black hole; once you get close to it, you'll be fascinated. And the strange thing is, you won't know if it has an end. Build your future with your own hands. Place yourself among the researchers. You are responsible for developing artificial intelligence. Be a role model for others.

20.2 Does this volume of books have an end

Yes, it has an end, and that's when the author dies. What I do is compile what I've learned throughout my life. Emirati society is my responsibility; I try to build a bright future for it, placing it among the ranks of the developed world. I believe we must expand our knowledge and compete with the rest of the world. The future must be bright, and bright, for the modern United Arab Emirates.

20.3 There are those who are smarter than you in artificial intelligence.

There are people who are smarter or more skilled than you, not because they learned more or started earlier, but because they learned something in a specific angle that you have not explored yet. There are also those who have studied artificial intelligence for many more years than you, and there is no shame in being late; the real problem begins when you say, "I know everything." The moment you feel that you have learned everything in AI, that is dangerous, because there is no such thing as learning everything in artificial intelligence. It is a vast world where learning never stops. Even when you specialize in one area, you will not say, "I know it all," but instead you will say, "There is a problem with no solution yet, so I must find one,"

and that is when you begin writing scientific papers and research. That is science: solving problems.
