All You Need

Everything You Need to Become an Artificial Intelligence Researcher

Abdulla Ali Khamis Alshamsi

Contents

Introduction of the Volume of Books **1**
0.1 Why am I writing this volume of books . . . 1
0.2 We must be at the forefront . . . 1
0.3 What will this volume of books contain . . . 1
0.4 Artificial Intelligence Departments . . . 16

1 Tensor Mathematics and Neural Networks Guide **18**
1.1 Introduction . . . 18
1.1.1 What will the book teach you . . . 18
1.1.2 The Chapters (T00 - T08) included in this book . . . 18
1.2 T00 - Tensor Algebra Laws . . . 19
1.2.1 Exercise 00 - Tensor Addition Law . . . 19
1.2.2 Exercise 01 - Tensor subtraction Law . . . 20
1.2.3 Exercise 02 - Tensor Hadamard Multiplication Law . . . 22
1.2.4 Exercise 03 - Tensor Division Law . . . 23
1.2.5 Exercise 04 - Tensor Power Law . . . 24
1.2.6 Exercise 05 - Tensor Square Root Law . . . 25
1.2.7 Exercise 06 - Tensor Absolute Value Law . . . 27
1.2.8 Exercise 07 - Tensor Negation Law . . . 28
1.2.9 Exercise 08 - Tensor Sign Law . . . 31
1.2.10 Exercise 09 - Tensor Clamp Law . . . 33
1.2.11 Exercise 10 - Tensor Round Law . . . 35
1.2.12 Exercise 11 - Tensor Floor Law . . . 36
1.2.13 Exercise 12 - Tensor Ceil Law . . . 37
1.2.14 Exercise 13 - Tensor Reciprocal Law . . . 39
1.2.15 Exercise 14 - Tensor Modulo Law . . . 40
1.2.16 Exercise 15 - Tensor Logical AND Law . . . 41
1.2.17 Exercise 16 - Tensor Logical OR Law . . . 43
1.2.18 Exercise 17 - Tensor Logical NOT Law . . . 44
1.2.19 Exercise 18 - Tensor Equality Law (Comparison) . . . 46
1.2.20 Exercise 19 - Tensor Not Equal Law (Comparison) . . . 48
1.2.21 Exercise 20 - Tensor Greater Than Law (Comparison) . . . 49
1.2.22 Exercise 21 - Tensor Less Than Law (Comparison) . . . 50
1.2.23 Exercise 22 - Tensor Greater or Equal Law (Comparison) . . . 51
1.2.24 Exercise 23 - Tensor Less or Equal Law (Comparison) . . . 53
1.3 T01 - Vector Laws (1D) . . . 54
1.3.1 Exercise 00 - 1D Dot Product Law . . . 54
1.3.2 Exercise 01 - 3D Cross Product Law . . . 56
1.3.3 Exercise 02 - 1D Norm Law . . . 58

1.3.4 Exercise 03 - 1D Normalize Law . . . 59
1.3.5 Exercise 04 - 1D Projection Law . . . 60
1.3.6 Exercise 05 - 1D Angle Law . . . 62
1.3.7 Exercise 06 - 1D Distance Law . . . 63
1.3.8 Exercise 07 - 1D Sum Reduction Law . . . 64
1.3.9 Exercise 08 - 1D Max Reduction Law . . . 66
1.3.10 Exercise 09 - 1D Min Reduction Law . . . 67
1.3.11 Exercise 10 - 1D Mean Reduction Law . . . 68
1.3.12 Exercise 11 - 1D Variance Law . . . 70
1.3.13 Exercise 12 - 1D Standard Deviation Law . . . 71
1.3.14 Exercise 13 - 1D Cumulative Sum Law . . . 72
1.3.15 Exercise 14 - 1D Cumulative Product Law . . . 74
1.4 T02 - Matrix Laws (2D) . . . 75
1.4.1 Exercise 00 - 2D Matrix Multiplication Law . . . 75
1.4.2 Exercise 01 - 2D Hadamard Matrix Law . . . 76
1.4.3 Exercise 02 - 2D Frobenius Inner Product Law . . . 78
1.4.4 Exercise 03 - 2D Determinant Law . . . 79
1.4.5 Exercise 04 - 2D Inverse Matrix Law . . . 81
1.4.6 Exercise 05 - 2D Transpose Law . . . 82
1.4.7 Exercise 06 - 2D Trace Law . . . 84
1.4.8 Exercise 07 - 2D Cofactor Law . . . 85
1.4.9 Exercise 08 - 2D Adjugate Law . . . 87
1.4.10 Exercise 09 - 2D Rank Law . . . 89
1.4.11 Exercise 10 - 2D Row Sum Law . . . 91
1.4.12 Exercise 11 - 2D Column Sum Law . . . 92
1.4.13 Exercise 12 - 2D Row Mean Law . . . 93
1.4.14 Exercise 13 - 2D Column Mean Law . . . 94
1.4.15 Exercise 14 - 2D Broadcasting Law . . . 95
1.5 T03 - Higher-Dimension Tensor Laws . . . 96
1.5.1 Exercise 00 - 3D Tensor Multiplication Law . . . 97
1.5.2 Exercise 01 - 3D Outer Product Law . . . 97
1.5.3 Exercise 02 - 3D Einstein Summation Law . . . 98
1.5.4 Exercise 03 - Batch Matrix Multiplication Law . . . 99
1.5.5 Exercise 04 - Tensor Contraction Law . . . 100
1.5.6 Exercise 05 - Tensor Repetition Law . . . 101
1.5.7 Exercise 06 - Tensor Tiling Law . . . 102
1.5.8 Exercise 07 - Tensor Broadcasting Law . . . 103
1.5.9 Exercise 08 - Tensor Indexing Law . . . 103
1.5.10 Exercise 09 - Tensor Advanced Slicing Law . . . 104
1.5.11 Exercise 10 - Tensor Padding Law . . . 105
1.5.12 Exercise 11 - Tensor Cropping Law . . . 106
1.5.13 Exercise 12 - Tensor Stacking Law . . . 107
1.5.14 Exercise 13 - Tensor Splitting Law . . . 108
1.5.15 Exercise 14 - Tensor Chunking Law . . . 108
1.6 T04 - Tensor shape Tranformation Laws . . . 109
1.6.1 Exercise 00 - Tensor Reshape Law . . . 109
1.6.2 Exercise 01 - Tensor View Law . . . 110
1.6.3 Exercise 02 - Tensor Permute Law . . . 111

1.6.4 Exercise 03 - Tensor Transpose Law . . . 112
1.6.5 Exercise 04 - Tensor Expand Law . . . 112
1.6.6 Exercise 05 - Tensor Repeat Law . . . 113
1.6.7 Exercise 06 - Tensor Flip Law . . . 114
1.6.8 Exercise 07 - Tensor Rotate Law . . . 115
1.6.9 Exercise 08 - Tensor Squeeze Law . . . 116
1.6.10 Exercise 09 - Tensor Unsqueeze Law . . . 116
1.6.11 Exercise 10 - Tensor Flatten Law . . . 117
1.6.12 Exercise 11 - Tensor Unflatten Law . . . 118
1.7 T05 - Differential Calculus Laws . . . 119
1.7.1 Exercise 00 - Gradient Law . . . 119
1.7.2 Exercise 01 - Jacobian Matrix Law . . . 119
1.7.3 Exercise 02 - Hessian Matrix Law . . . 120
1.7.4 Exercise 03 - Divergence Law . . . 121
1.7.5 Exercise 04 - Curl Law . . . 122
1.7.6 Exercise 05 - Laplacian Law . . . 122
1.7.7 Exercise 06 - Partial Derivative Law . . . 123
1.7.8 Exercise 07 - Chain Rule Law . . . 124
1.7.9 Exercise 08 - Product Rule Law . . . 124
1.7.10 Exercise 09 - Quotient Rule Law . . . 125
1.7.11 Exercise 10 - Power Rule Law . . . 126
1.7.12 Exercise 11 - Exponential Derivative Law . . . 127
1.7.13 Exercise 12 - Logarithmic Derivative Law . . . 128
1.7.14 Exercise 13 - Sigmoid Derivative Law . . . 128
1.7.15 Exercise 14 - Tanh Derivative Law . . . 129
1.7.16 Exercise 15 - ReLU Derivative Law . . . 130
1.7.17 Exercise 16 - LeakyReLU Derivative Law . . . 131
1.7.18 Exercise 17 - Softmax Derivative Law . . . 131
1.7.19 Exercise 18 - Loss Gradient Law . . . 132
1.8 T06 - Optimization Laws . . . 133
1.8.1 Exercise 00 - Gradient Descent Law . . . 133
1.8.2 Exercise 01 - Stochastic Gradient Descent Law . . . 134
1.8.3 Exercise 02 - Momentum Law . . . 135
1.8.4 Exercise 03 - RMSProp Law . . . 136
1.8.5 Exercise 04 - Adam Optimizer Law . . . 136
1.8.6 Exercise 05 - AdamW Law . . . 137
1.8.7 Exercise 06 - Nesterov Momentum Law . . . 138
1.8.8 Exercise 07 - Learning Rate Decay Law . . . 139
1.8.9 Exercise 08 - Weight Decay Law . . . 140
1.9 T07 - Statistics Probability Laws . . . 141
1.9.1 Exercise 00 - Mean Law . . . 141
1.9.2 Exercise 01 - Median Law . . . 141
1.9.3 Exercise 02 - Mode Law . . . 142
1.9.4 Exercise 03 - Variance Law . . . 143
1.9.5 Exercise 04 - Standard Deviation Law . . . 144
1.9.6 Exercise 05 - Covariance Law . . . 144
1.9.7 Exercise 06 - Correlation Law . . . 145
1.9.8 Exercise 07 - Probability Density Function Law . . . 146

1.9.9 Exercise 08 - Normal Distribution Law . . . 147
1.9.10 Exercise 09 - Uniform Distribution Law . . . 147
1.9.11 Exercise 10 - Bernoulli Law . . . 148
1.9.12 Exercise 11 - Softmax Probability Law . . . 149
1.9.13 Exercise 12 - Entropy Law . . . 150
1.9.14 Exercise 13 - KL Divergence Law . . . 150
1.9.15 Exercise 14 - Jensen Inequality Law . . . 151
1.10 T08 - Neural Network Transformatin Laws . . . 152
1.10.1 Exercise 00 - Linear Transformation Law . . . 152
1.10.2 Exercise 01 - Convolution Law . . . 153
1.10.3 Exercise 02 - Transposed Convolution Law . . . 153
1.10.4 Exercise 03 - Depthwise Convolution Law . . . 154
1.10.5 Exercise 04 - Softmax Activation Law . . . 155
1.10.6 Exercise 05 - Sigmoid Activation Law . . . 156
1.10.7 Exercise 06 - ReLU Activation Law . . . 156
1.10.8 Exercise 07 - GELU Activation Law . . . 157
1.10.9 Exercise 08 - Swish Activation Law . . . 158
1.10.10 Exercise 09 - Cross Entropy Loss Law . . . 159
1.10.11 Exercise 10 - MSE Loss Law . . . 160
1.10.12 Exercise 11 - L1 Loss Law . . . 160
1.10.13 Exercise 12 - Binary Cross Entropy Loss Law . . . 161
1.10.14 Exercise 13 - LogSoftmax Law . . . 162
1.10.15 Exercise 14 - LogSoftmax Gradient Law . . . 163

2 Applied Linear Algebra in Code 164
2.1 Introduction . . . 164
2.1.1 What will the book teach you . . . 164
2.1.2 The Chapters (ALA00 - ALA06) included in this book . . . 164
2.2 ALA00 - Tensor Operations in Code . . . 165
2.2.1 Exercise 00 - Basic Tensor Creation . . . 165
2.2.2 Exercise 01 - Tensor Shape Inspection . . . 166
2.2.3 Exercise 02 - Tensor Type Conversion . . . 167
2.2.4 Exercise 03 - Tensor Device Assignment . . . 167
2.2.5 Exercise 04 - Element-wise Addition . . . 168
2.2.6 Exercise 05 - Element-wise Multiplication . . . 169
2.2.7 Exercise 06 - Scalar-Tensor Operations . . . 170
2.2.8 Exercise 07 - Tensor Comparison Operations . . . 171
2.2.9 Exercise 08 - Boolean Masking Challenge . . . 172
2.2.10 Exercise 09 - Tensor Operation Chain Challenge . . . 172
2.2.11 Exercise 10 - Debugging Tensor Type Errors . . . 173
2.2.12 Exercise 11 - Tensor Operation Optimization Challenge . . . 174
2.3 ALA01 - Vector Dot & Norm Computation . . . 175
2.3.1 Exercise 00 - Manual Dot Product Implementation . . . 175
2.3.2 Exercise 01 - Dot Product Using PyTorch . . . 176
2.3.3 Exercise 02 - L2 Norm Calculation . . . 177
2.3.4 Exercise 03 - L1 Norm Calculation . . . 178
2.3.5 Exercise 04 - Vector Normalization . . . 179
2.3.6 Exercise 05 - Cosine Similarity Implementation . . . 179

2.3.7 Exercise 06 - Angle Between Two Vectors . . . 180
2.3.8 Exercise 07 - Batched Dot Product . . . 181
2.3.9 Exercise 08 - Stability Issues in Norm Computation . . . 182
2.3.10 Exercise 09 - Gradient-safe Dot Product Challenge . . . 183
2.3.11 Exercise 10 - Custom Similarity Metric Design . . . 184
2.4 ALA02 - Matrix Multiplication (matmul / mm) . . . 184
2.4.1 Exercise 00 - Basic Matrix Multiplication . . . 185
2.4.2 Exercise 01 - matmul vs mm Comparison . . . 185
2.4.3 Exercise 02 - Manual Matrix Multiplication . . . 186
2.4.4 Exercise 03 - Shape Compatibility Check . . . 187
2.4.5 Exercise 04 - Batched Matrix Multiplication . . . 188
2.4.6 Exercise 05 - High-Dimensional matmul Challenge . . . 189
2.4.7 Exercise 06 - Performance Comparison Challenge . . . 190
2.4.8 Exercise 07 - Matrix Multiplication Debugging . . . 191
2.4.9 Exercise 08 - Numerical Precision Challenge . . . 191
2.4.10 Exercise 09 - Custom Linear Layer Implementation . . . 192
2.5 ALA03 - Outer vs Inner Product . . . 193
2.5.1 Exercise 00 - Inner Product Coding Challenge . . . 193
2.5.2 Exercise 01 - Outer Product Coding Challenge . . . 194
2.5.3 Exercise 02 - Shape Interpretation Challenge . . . 195
2.5.4 Exercise 03 - Rank Analysis Challenge . . . 196
2.5.5 Exercise 04 - Feature Interaction Matrix Design . . . 197
2.5.6 Exercise 05 - Memory Cost Comparison Challenge . . . 198
2.5.7 Exercise 06 - Use-Case Driven Product Selection . . . 198
2.6 ALA04 - Broadcasting Rules & Mechanics . . . 199
2.6.1 Exercise 00 - Simple Broadcasting Addition . . . 200
2.6.2 Exercise 01 - Broadcasting Multiplication . . . 201
2.6.3 Exercise 02 - Broadcasting with Scalars . . . 202
2.6.4 Exercise 03 - Broadcasting Across Dimensions . . . 203
2.6.5 Exercise 04 - Invalid Broadcasting Detection . . . 204
2.6.6 Exercise 05 - Broadcasting Debugging Challenge . . . 205
2.6.7 Exercise 06 - Memory-efficient Broadcasting . . . 206
2.6.8 Exercise 07 - Broadcasting in Neural Layers . . . 207
2.7 ALA05 - Shape Reasoning & Dimension Flow . . . 208
2.7.1 Exercise 00 - Shape Tracking Basics . . . 208
2.7.2 Exercise 01 - Multi-step Shape Prediction . . . 209
2.7.3 Exercise 02 - Shape Mismatch Debugging . . . 210
2.7.4 Exercise 03 - Dynamic Shape Handling . . . 211
2.7.5 Exercise 04 - Shape-safe Function Design . . . 212
2.7.6 Exercise 05 - Model Shape Pipeline Validation . . . 213
2.8 ALA06 - Basis, Span & Projection (Applied) . . . 214
2.8.1 Exercise 00 - Vector Projection Implementation . . . 214
2.8.2 Exercise 01 - Orthogonal Projection . . . 215
2.8.3 Exercise 02 - Projection Error Measurement . . . 216
2.8.4 Exercise 03 - Subspace Projection Challenge . . . 217
2.8.5 Exercise 04 - Feature Space Reduction . . . 218
2.8.6 Exercise 05 - Projection-based Optimization Insight . . . 219

3 Autograd & Backprop Mechanics 221
3.1 Introduction . . . 221
3.1.1 What will the book teach you . . . 221
3.1.2 The Chapters (ABM00 - ABM06) included in this book . . . 221
3.2 ABM00 - Computational Graph Construction . . . 222
3.2.1 Exercise 00 - Tensor with requires_grad Setup . . . 222
3.2.2 Exercise 01 - Simple Operation Graph Creation . . . 223
3.2.3 Exercise 02 - Multi-Operation Graph Building . . . 223
3.2.4 Exercise 03 - Leaf vs Non-Leaf Tensor Detection . . . 224
3.2.5 Exercise 04 - Graph Retention After Backward . . . 225
3.2.6 Exercise 05 - Detaching Tensor from Graph . . . 226
3.2.7 Exercise 06 - Stop-Gradient Simulation Challenge . . . 227
3.2.8 Exercise 07 - Graph Reuse Error Debugging . . . 228
3.2.9 Exercise 08 - In-place Operation Graph Failure . . . 229
3.2.10 Exercise 09 - Manual Graph Reasoning Challenge . . . 230
3.3 ABM01 - Forward vs Backward Pass . . . 231
3.3.1 Exercise 00 - Forward Pass Value Tracking . . . 231
3.3.2 Exercise 01 - Backward Call on Scalar Loss . . . 232
3.3.3 Exercise 02 - Gradient Accumulation Observation . . . 233
3.3.4 Exercise 03 - Zeroing Gradients Correctly . . . 234
3.3.5 Exercise 04 - Multiple Backward Calls Challenge . . . 235
3.3.6 Exercise 05 - retain_graph Usage Challenge . . . 236
3.3.7 Exercise 06 - Backward Through Branching Graph . . . 237
3.3.8 Exercise 07 - Gradient Flow Order Reasoning . . . 238
3.3.9 Exercise 08 - Backward Error Debugging . . . 239
3.3.10 Exercise 09 - Custom Forward–Backward Trace . . . 240
3.4 ABM02 - Manual Gradient Calculation . . . 241
3.4.1 Exercise 00 - Derivative of Linear Function . . . 241
3.4.2 Exercise 01 - Manual Gradient vs Autograd Check . . . 242
3.4.3 Exercise 02 - Gradient of Quadratic Function . . . 243
3.4.4 Exercise 03 - Chain Rule Manual Verification . . . 244
3.4.5 Exercise 04 - Vector Gradient Computation . . . 245
3.4.6 Exercise 05 - Matrix Gradient Reasoning . . . 245
3.4.7 Exercise 06 - Broadcasting Gradient Challenge . . . 246
3.4.8 Exercise 07 - Gradient Shape Validation . . . 247
3.4.9 Exercise 08 - Numerical Gradient Approximation . . . 248
3.4.10 Exercise 09 - Gradient Mismatch Debugging . . . 249
3.5 ABM03 - Chain Rule in Code . . . 250
3.5.1 Exercise 00 - Single-Chain Gradient Flow . . . 250
3.5.2 Exercise 01 - Multi-Operation Chain Rule . . . 251
3.5.3 Exercise 02 - Nested Function Gradient Flow . . . 252
3.5.4 Exercise 03 - Chain Rule with Activation . . . 253
3.5.5 Exercise 04 - Branching Chain Rule Challenge . . . 254
3.5.6 Exercise 05 - Gradient Path Contribution Analysis . . . 255
3.5.7 Exercise 06 - Partial Gradient Blocking . . . 256
3.5.8 Exercise 07 - Detach Effect on Chain Rule . . . 257
3.5.9 Exercise 08 - Chain Rule Failure Debugging . . . 257
3.5.10 Exercise 09 - Full Graph Gradient Trace . . . 258

3.6 ABM04 - Autograd Engine in PyTorch . . . 259
3.6.1 Exercise 00 - Autograd Basic Usage . . . 260
3.6.2 Exercise 01 - grad_fn Inspection . . . 260
3.6.3 Exercise 02 - Gradient Accumulation Behavior . . . 261
3.6.4 Exercise 03 - No-Grad Context Manager . . . 262
3.6.5 Exercise 04 - Inference vs Training Mode Gradient . . . 263
3.6.6 Exercise 05 - Custom Autograd Function (Forward) . . . 264
3.6.7 Exercise 06 - Custom Autograd Function (Backward) . . . 265
3.6.8 Exercise 07 - Autograd Graph Memory Analysis . . . 266
3.6.9 Exercise 08 - Gradient Hook Implementation . . . 267
3.6.10 Exercise 09 - Autograd Failure Debugging . . . 268
3.7 ABM05 - Backprop Through Linear Layers . . . 269
3.7.1 Exercise 00 - Single Linear Layer Backprop . . . 269
3.7.2 Exercise 01 - Weight Gradient Verification . . . 270
3.7.3 Exercise 02 - Bias Gradient Verification . . . 271
3.7.4 Exercise 03 - Batch Linear Layer Backprop . . . 272
3.7.5 Exercise 04 - Manual vs Autograd Linear Backprop . . . 272
3.7.6 Exercise 05 - Gradient Scaling with Batch Size . . . 273
3.7.7 Exercise 06 - Frozen Layer Gradient Check . . . 274
3.7.8 Exercise 07 - Linear Stack Gradient Flow . . . 275
3.7.9 Exercise 08 - Numerical Stability in Backprop . . . 276
3.7.10 Exercise 09 - End-to-End Linear Backprop Challenge . . . 277
3.8 ABM06 - Gradient Flow Debugging . . . 278
3.8.1 Exercise 00 - Detecting Vanishing Gradients . . . 278
3.8.2 Exercise 01 - Detecting Exploding Gradients . . . 279
3.8.3 Exercise 02 - Gradient Norm Monitoring . . . 280
3.8.4 Exercise 03 - Layer-wise Gradient Inspection . . . 281
3.8.5 Exercise 04 - Broken Graph Debugging . . . 282
3.8.6 Exercise 05 - requires_grad Misuse Debugging . . . 283
3.8.7 Exercise 06 - Gradient Blocking Detection . . . 284
3.8.8 Exercise 07 - Hook-based Gradient Debugging . . . 285
3.8.9 Exercise 08 - Training Collapse Diagnosis . . . 286
3.8.10 Exercise 09 - Full Backprop Debugging Scenario . . . 287

4 Optimization in Code 289
4.1 Introduction . . . 289
4.1.1 What will the book teach you . . . 289
4.1.2 How to approach the exercises . . . 290
4.1.3 The Chapters (OC00 - OC06) included in this book . . . 290
4.2 OC00 - Gradient Descent Implementation . . . 290
4.2.1 Exercise 00 - Simple Gradient Descent Step . . . 291
4.2.2 Exercise 01 - Gradient Descent on Scalar Loss . . . 291
4.2.3 Exercise 02 - Gradient Descent on Vector Parameters . . . 292
4.2.4 Exercise 03 - Learning Rate Effect Observation . . . 293
4.2.5 Exercise 04 - Convergence vs Divergence Test . . . 294
4.2.6 Exercise 05 - Manual Parameter Update Loop . . . 295
4.2.7 Exercise 06 - Gradient Descent without Autograd . . . 296
4.2.8 Exercise 07 - Loss Curve Tracking Challenge . . . 297

4.2.9 Exercise 08 - Gradient Clipping Integration . . . 298
4.2.10 Exercise 09 - End-to-End Gradient Descent Challenge . . . 299
4.3 OC01 - Learning Rate Effects & Tuning . . . 300
4.3.1 Exercise 00 - Fixed Learning Rate Experiment . . . 300
4.3.2 Exercise 01 - Too-Small Learning Rate Scenario . . . 301
4.3.3 Exercise 02 - Too-Large Learning Rate Scenario . . . 302
4.3.4 Exercise 03 - Learning Rate Sweep Experiment . . . 302
4.3.5 Exercise 04 - Loss Oscillation Detection . . . 303
4.3.6 Exercise 05 - Adaptive Learning Rate Logic . . . 304
4.3.7 Exercise 06 - Learning Rate Scheduling Basics . . . 305
4.3.8 Exercise 07 - Warm-up Learning Rate Strategy . . . 306
4.3.9 Exercise 08 - Learning Rate Debugging Challenge . . . 307
4.3.10 Exercise 09 - Optimal Learning Rate Search . . . 308
4.4 OC02 - Momentum Update Rule . . . 309
4.4.1 Exercise 00 - Momentum Concept Implementation . . . 309
4.4.2 Exercise 01 - Velocity Term Tracking . . . 310
4.4.3 Exercise 02 - Momentum vs Vanilla GD . . . 311
4.4.4 Exercise 03 - Momentum Acceleration Effect . . . 311
4.4.5 Exercise 04 - Damped Oscillation Observation . . . 312
4.4.6 Exercise 05 - Momentum Coefficient Tuning . . . 313
4.4.7 Exercise 06 - Momentum on Noisy Gradients . . . 314
4.4.8 Exercise 07 - Custom Momentum Optimizer . . . 315
4.4.9 Exercise 08 - Momentum Failure Debugging . . . 316
4.4.10 Exercise 09 - Momentum Convergence Challenge . . . 317
4.5 OC03 - RMSProp Logic & Behavior . . . 318
4.5.1 Exercise 00 - RMSProp Accumulator Initialization . . . 318
4.5.2 Exercise 01 - Running Average of Squared Gradients . . . 319
4.5.3 Exercise 02 - RMSProp Update Step Implementation . . . 320
4.5.4 Exercise 03 - Effect of Decay Rate . . . 320
4.5.5 Exercise 04 - RMSProp vs Momentum Comparison . . . 321
4.5.6 Exercise 05 - Stability under High Gradient Variance . . . 322
4.5.7 Exercise 06 - RMSProp without Autograd . . . 323
4.5.8 Exercise 07 - Custom RMSProp Optimizer . . . 324
4.5.9 Exercise 08 - RMSProp Debugging Challenge . . . 325
4.5.10 Exercise 09 - RMSProp Convergence Evaluation . . . 326
4.6 OC04 - Adam Optimizer Math + Code . . . 327
4.6.1 Exercise 00 - Adam First Moment Initialization . . . 327
4.6.2 Exercise 01 - Adam Second Moment Initialization . . . 328
4.6.3 Exercise 02 - Bias Correction Implementation . . . 328
4.6.4 Exercise 03 - Adam Update Rule from Scratch . . . 329
4.6.5 Exercise 04 - Adam vs RMSProp Comparison . . . 330
4.6.6 Exercise 05 - Adam Hyperparameter Sensitivity . . . 331
4.6.7 Exercise 06 - Adam on Sparse Gradients . . . 332
4.6.8 Exercise 07 - Custom Adam Optimizer Class . . . 332
4.6.9 Exercise 08 - Adam Failure Case Debugging . . . 334
4.6.10 Exercise 09 - Adam End-to-End Training Challenge . . . 334
4.7 OC05 - Convergence & Stability . . . 335
4.7.1 Exercise 00 - Convergence Criteria Detection . . . 335

4.7.2 Exercise 01 - Loss Plateau Detection . . . 336
4.7.3 Exercise 02 - Divergence Pattern Identification . . . 337
4.7.4 Exercise 03 - Early Stopping Logic . . . 338
4.7.5 Exercise 04 - Gradient Explosion Mitigation . . . 339
4.7.6 Exercise 05 - Gradient Vanishing Mitigation . . . 340
4.7.7 Exercise 06 - Stability under Noisy Data . . . 341
4.7.8 Exercise 07 - Optimizer Comparison Experiment . . . 341
4.7.9 Exercise 08 - Stability Debugging Scenario . . . 342
4.7.10 Exercise 09 - Long-Run Training Stability Test . . . 343
4.8 OC06 - Weight Initialization Impact . . . 344
4.8.1 Exercise 00 - Zero Initialization Experiment . . . 344
4.8.2 Exercise 01 - Random Uniform Initialization . . . 345
4.8.3 Exercise 02 - Random Normal Initialization . . . 346
4.8.4 Exercise 03 - Xavier Initialization Implementation . . . 347
4.8.5 Exercise 04 - He Initialization Implementation . . . 348
4.8.6 Exercise 05 - Initialization Effect on Gradient Flow . . . 349
4.8.7 Exercise 06 - Initialization vs Convergence Speed . . . 349
4.8.8 Exercise 07 - Bad Initialization Failure Case . . . 350
4.8.9 Exercise 08 - Initialization Debugging Challenge . . . 351
4.8.10 Exercise 09 - End-to-End Initialization Comparison . . . 352

5 Loss Functions & Training Loop 354
5.1 Introduction . . . 354
5.1.1 What will the book teach you . . . 354
5.1.2 How to approach the exercises . . . 355
5.1.3 The Chapters (LFTL00 - LFTL06) included in this book . . . 356
5.2 LFTL00 - What is Loss and Why . . . 356
5.2.1 Exercise 00 - Define Loss for Simple Regression . . . 356
5.2.2 Exercise 01 - Compare Prediction vs Target . . . 357
5.2.3 Exercise 02 - Scalar Loss Computation . . . 357
5.2.4 Exercise 03 - Vector Loss Aggregation . . . 358
5.2.5 Exercise 04 - Mean Loss vs Sum Loss . . . 359
5.2.6 Exercise 05 - Loss Sensitivity Observation . . . 360
5.2.7 Exercise 06 - Loss Landscape Visualization . . . 361
5.2.8 Exercise 07 - Loss Scaling Effect . . . 362
5.2.9 Exercise 08 - Poor Loss Choice Failure Case . . . 362
5.2.10 Exercise 09 - Loss Design Reasoning Challenge . . . 363
5.3 LFTL01 - MSE Loss Implementation . . . 364
5.3.1 Exercise 00 - Manual MSE Formula Implementation . . . 364
5.3.2 Exercise 01 - MSE Using PyTorch . . . 365
5.3.3 Exercise 02 - Batch-wise MSE Computation . . . 366
5.3.4 Exercise 03 - MSE Gradient Inspection . . . 367
5.3.5 Exercise 04 - Effect of Outliers on MSE . . . 368
5.3.6 Exercise 05 - MSE Stability with Large Values . . . 368
5.3.7 Exercise 06 - Weighted MSE Loss Challenge . . . 369
5.3.8 Exercise 07 - MSE vs MAE Comparison . . . 370
5.3.9 Exercise 08 - MSE Debugging Challenge . . . 371
5.3.10 Exercise 09 - Custom MSE Loss Class . . . 372

5.4 LFTL02 - Cross-Entropy Logic . . . 373
5.4.1 Exercise 00 - Probability Output Validation . . . 373
5.4.2 Exercise 01 - One-Hot Target Encoding . . . 373
5.4.3 Exercise 02 - Manual Cross-Entropy Computation . . . 374
5.4.4 Exercise 03 - Cross-Entropy Using PyTorch . . . 375
5.4.5 Exercise 04 - LogSoftmax + NLL Breakdown . . . 376
5.4.6 Exercise 05 - Numerical Stability (Log-Sum-Exp) . . . 377
5.4.7 Exercise 06 - Batch Cross-Entropy Loss . . . 378
5.4.8 Exercise 07 - Wrong Target Shape Debugging . . . 379
5.4.9 Exercise 08 - Class Imbalance Effect . . . 379
5.4.10 Exercise 09 - Custom Cross-Entropy Loss . . . 380
5.5 LFTL03 - Building Training Loop Manually . . . 381
5.5.1 Exercise 00 - Single-Step Training Loop . . . 381
5.5.2 Exercise 01 - Forward + Loss + Backward Loop . . . 382
5.5.3 Exercise 02 - Parameter Update Integration . . . 383
5.5.4 Exercise 03 - Gradient Zeroing Placement . . . 384
5.5.5 Exercise 04 - Training Loop without Optimizer . . . 385
5.5.6 Exercise 05 - Loss Logging per Iteration . . . 386
5.5.7 Exercise 06 - Training Loop Bug Debugging . . . 387
5.5.8 Exercise 07 - Manual vs Optimizer Loop Comparison . . . 388
5.5.9 Exercise 08 - Gradient Explosion inside Loop . . . 388
5.5.10 Exercise 09 - End-to-End Manual Training Loop . . . 389
5.6 LFTL04 - Batching + Epochs . . . 390
5.6.1 Exercise 00 - Single-Batch Training . . . 390
5.6.2 Exercise 01 - Mini-Batch Training Setup . . . 391
5.6.3 Exercise 02 - Epoch Loop Construction . . . 392
5.6.4 Exercise 03 - Shuffling Data per Epoch . . . 393
5.6.5 Exercise 04 - Batch Size Effect Observation . . . 394
5.6.6 Exercise 05 - Gradient Accumulation across Batches . . . 395
5.6.7 Exercise 06 - Last Incomplete Batch Handling . . . 396
5.6.8 Exercise 07 - Performance vs Batch Size . . . 397
5.6.9 Exercise 08 - Batch-related Bug Debugging . . . 397
5.6.10 Exercise 09 - Full Epoch Training Challenge . . . 398
5.7 LFTL05 - Evaluation & Validation Split . . . 399
5.7.1 Exercise 00 - Train vs Eval Mode Difference . . . 399
5.7.2 Exercise 01 - Validation Dataset Separation . . . 400
5.7.3 Exercise 02 - Validation Loss Computation . . . 401
5.7.4 Exercise 03 - Overfitting Detection . . . 402
5.7.5 Exercise 04 - Early Stopping Trigger . . . 403
5.7.6 Exercise 05 - Metric vs Loss Comparison . . . 404
5.7.7 Exercise 06 - Evaluation without Gradient Tracking . . . 405
5.7.8 Exercise 07 - Validation Loop Bug Debugging . . . 405
5.7.9 Exercise 08 - Model Selection based on Validation . . . 406
5.7.10 Exercise 09 - Full Train–Validation Pipeline . . . 407
5.8 LFTL06 - Overfitting Prevention Methods . . . 408
5.8.1 Exercise 00 - Detecting Overfitting Pattern . . . 408
5.8.2 Exercise 01 - Regularization Concept Experiment . . . 409
5.8.3 Exercise 02 - Weight Decay Integration . . . 410

5.8.4 Exercise 03 - Dropout Effect Observation . . . 411
5.8.5 Exercise 04 - Data Augmentation Impact . . . 412
5.8.6 Exercise 05 - Early Stopping Implementation . . . 413
5.8.7 Exercise 06 - Bias–Variance Tradeoff Inspection . . . 414
5.8.8 Exercise 07 - Underfitting vs Overfitting Diagnosis . . . 414
5.8.9 Exercise 08 - Regularization Debugging Challenge . . . 415
5.8.10 Exercise 09 - Robust Training Pipeline Design . . . 416

6 SQL Lessons (PostgreSQL) 418
6.1 Introduction . . . 418
6.1.1 What will this book teach you . . . 418
6.1.2 How PostgreSQL supports artificial intelligence systems . . . 419
6.1.3 How to approach the exercises . . . 419
6.1.4 The Chapters (SQL00–SQL03) included in this book . . . 420
6.1.5 SQL00 - Relational Data Fundamentals . . . 420
6.1.6 SQL01 - Tables, Keys & Schemas . . . 420
6.1.7 SQL02 - Users, Plans & Limits Storage . . . 420
6.1.8 SQL03 - Query Logic & Transactions . . . 421
6.2 SQL00 - Relational Data Fundamentals . . . 421
6.2.1 Exercise 00 - Create Database + Connect Challenge . . . 421
6.2.2 Exercise 01 - Create Table with Correct Data Types . . . 422
6.2.3 Exercise 02 - Insert Rows + Verify with SELECT . . . 423
6.2.4 Exercise 03 - Basic WHERE Filtering Challenge . . . 424
6.2.5 Exercise 04 - ORDER BY + LIMIT + OFFSET Challenge . . . 425
6.2.6 Exercise 05 - UPDATE with Condition + Verification . . . 426
6.2.7 Exercise 06 - DELETE with Safety Condition . . . 427
6.2.8 Exercise 07 - NULL Handling + COALESCE Challenge . . . 428
6.2.9 Exercise 08 - Aggregate Basics (COUNT, SUM, AVG) . . . 429
6.2.10 Exercise 09 - Group By + Having Challenge . . . 430
6.3 SQL01 - Tables, Keys & Schemas . . . 432
6.3.1 Exercise 00 - Design Schema: users + plans + sessions . . . 432
6.3.2 Exercise 01 - Primary Key + Unique Constraint Challenge . . . 433
6.3.3 Exercise 02 - Foreign Key Relationship Setup . . . 434
6.3.4 Exercise 03 - ON DELETE Behavior (RESTRICT/CASCADE) . . . 435
6.3.5 Exercise 04 - CHECK Constraints for Data Validation . . . 436
6.3.6 Exercise 05 - Default Values + Timestamps . . . 437
6.3.7 Exercise 06 - Normalize: Split Table into 2NF/3NF . . . 438
6.3.8 Exercise 07 - Create Index + Explain Its Purpose . . . 439
6.3.9 Exercise 08 - Join Basics (INNER / LEFT) Challenge . . . 440
6.3.10 Exercise 09 - Query with Multi-Table Join + Filters . . . 441
6.4 SQL02 - Users, Plans & Limits Storage . . . 443
6.4.1 Exercise 00 - Implement Plans Table + Limits Columns . . . 443
6.4.2 Exercise 01 - Assign User to Plan + Enforce FK . . . 444
6.4.3 Exercise 02 - Track Usage Table (tokens/requests) . . . 445
6.4.4 Exercise 03 - Daily Usage Aggregation Query . . . 446
6.4.5 Exercise 04 - Check Limit Breach Query (Over Limit) . . . 447
6.4.6 Exercise 05 - Create View: user_current_limits . . . 448
6.4.7 Exercise 06 - Create View: user_usage_summary . . . 449

6.4.8 Exercise 07 - Plan Upgrade Transaction Challenge . . . 450
6.4.9 Exercise 08 - Audit Log Table for Plan Changes . . . 452
6.4.10 Exercise 09 - Report Query: Top Users by Usage . . . 453
6.5 SQL03 - Query Logic & Transactions . . . 454
6.5.1 Exercise 00 - Transaction Basics (BEGIN/COMMIT/ROLLBACK) . . . 454
6.5.2 Exercise 01 - Atomic Insert into Multiple Tables . . . 455
6.5.3 Exercise 02 - Consistency Check + Rollback on Failure . . . 456
6.5.4 Exercise 03 - Isolation Concept Simulation (Two Sessions) . . . 457
6.5.5 Exercise 04 - Locking Behavior Observation Challenge . . . 459
6.5.6 Exercise 05 - Upsert Pattern (INSERT...ON CONFLICT) . . . 460
6.5.7 Exercise 06 - Common Table Expression (CTE) Challenge . . . 461
6.5.8 Exercise 07 - Query Performance: EXPLAIN ANALYZE . . . 462
6.5.9 Exercise 08 - Index Impact Benchmark Challenge . . . 463
6.5.10 Exercise 09 - Transaction-Safe Usage Deduction Scenario . . . 464

7 NoSQL Lessons (MongoDB) 467
7.1 Introduction . . . 467
7.1.1 What will this book teach you . . . 467
7.1.2 How MongoDB supports artificial intelligence systems . . . 468
7.1.3 How to approach the exercises . . . 468
7.1.4 The Chapters (NOSQL00–NOSQL03) included in this book . . . 469
7.1.5 NOSQL00 - Document-Based Data Structures . . . 469
7.1.6 NOSQL01 - Chat History & Session Memory . . . 469
7.1.7 NOSQL02 - Dynamic Storage Models . . . 470
7.1.8 NOSQL03 - Scaling with Replica & Sharding . . . 470
7.2 NOSQL00 - Document-Based Data Structures . . . 470
7.2.1 Exercise 00 - Create Database and Collection . . . 470
7.2.2 Exercise 01 - Insert Single Document (insertOne) . . . 471
7.2.3 Exercise 02 - Insert Multiple Documents (insertMany) . . . 472
7.2.4 Exercise 03 - Basic Find Query with Filters . . . 473
7.2.5 Exercise 04 - Projection: Include / Exclude Fields . . . 474
7.2.6 Exercise 05 - Update Document with $set . . . 475
7.2.7 Exercise 06 - Update with $inc and $push . . . 476
7.2.8 Exercise 07 - Delete Document with Condition . . . 477
7.2.9 Exercise 08 - Nested Document Design Challenge . . . 478
7.2.10 Exercise 09 - Schema-less Design Pitfall Analysis . . . 479
7.3 NOSQL01 - Chat History & Session Memory . . . 480
7.3.1 Exercise 00 - Design Chat Message Document Structure . . . 480
7.3.2 Exercise 01 - Insert Chat Messages with Session ID . . . 481
7.3.3 Exercise 02 - Query Messages by Session and Time . . . 482
7.3.4 Exercise 03 - Sort Messages Chronologically . . . 483
7.3.5 Exercise 04 - Limit Chat History per Session . . . 484
7.3.6 Exercise 05 - Session Expiration using TTL Index . . . 485
7.3.7 Exercise 06 - Update Last-Active Timestamp . . . 487
7.3.8 Exercise 07 - Archive Old Sessions Strategy . . . 488
7.3.9 Exercise 08 - Aggregation: Messages Count per Session . . . 489
7.3.10 Exercise 09 - Session Memory Retrieval Pipeline . . . 490
7.4 NOSQL02 - Dynamic Storage Models . . . 491

7.4.1 Exercise 00 - Flexible Document Schema Design . . . 491
7.4.2 Exercise 01 - Optional Fields Handling . . . 492
7.4.3 Exercise 02 - Polymorphic Documents in One Collection . . . 493
7.4.4 Exercise 03 - Versioned Document Schema Strategy . . . 494
7.4.5 Exercise 04 - Partial Updates without Overwrite . . . 495
7.4.6 Exercise 05 - Embedded vs Referenced Documents . . . 496
7.4.7 Exercise 06 - Aggregation Pipeline with $group . . . 497
7.4.8 Exercise 07 - Data Migration between Schema Versions . . . 498
7.4.9 Exercise 08 - Indexing Strategy for Dynamic Fields . . . 500
7.4.10 Exercise 09 - Performance Tradeoff Evaluation . . . 501
7.5 NOSQL03 - Scaling with Replica & Sharding . . . 502
7.5.1 Exercise 00 - Create Index for High-Read Query . . . 502
7.5.2 Exercise 01 - Explain Query Execution Plan . . . 503
7.5.3 Exercise 02 - Replica Set Concept Simulation . . . 504
7.5.4 Exercise 03 - Read Preference Configuration . . . 505
7.5.5 Exercise 04 - Write Concern Configuration . . . 506
7.5.6 Exercise 05 - Shard Key Selection Challenge . . . 507
7.5.7 Exercise 06 - Chunk Distribution Observation . . . 508
7.5.8 Exercise 07 - Balancer Behavior Analysis . . . 509
7.5.9 Exercise 08 - Sharding vs Indexing Comparison . . . 511
7.5.10 Exercise 09 - Scalable Chat System Data Design . . . 512

8 Object Storage Lessons (MinIO) 514
8.1 Introduction . . . 514
8.1.1 What will this book teach you . . . 514
8.1.2 How object storage supports artificial intelligence systems . . . 515
8.1.3 How to approach the exercises . . . 515
8.1.4 The Chapters (OB00–OB03) included in this book . . . 516
8.1.5 OB00 - Binary Data & Large File Storage . . . 516
8.1.6 OB01 - Datasets, Weights & Checkpoints . . . 516
8.1.7 OB02 - Buckets & Access Structure . . . 517
8.1.8 OB03 - Distributed Mode & Fault Tolerance . . . 517
8.2 OB00 - Binary Data & Large File Storage . . . 517
8.2.1 Exercise 00 - Install MinIO and Start Server . . . 518
8.2.2 Exercise 01 - Create Bucket using CLI . . . 518
8.2.3 Exercise 02 - Upload Single File (Object Put) . . . 519
8.2.4 Exercise 03 - Download Object and Verify Integrity . . . 520
8.2.5 Exercise 04 - List Objects with Prefix Filtering . . . 521
8.2.6 Exercise 05 - Delete Object Safely . . . 522
8.2.7 Exercise 06 - Upload Large File using Multipart . . . 523
8.2.8 Exercise 07 - Metadata Attachment to Objects . . . 524
8.2.9 Exercise 08 - Versioning Enablement Challenge . . . 525
8.2.10 Exercise 09 - Binary Storage Performance Test . . . 526
8.3 OB01 - Datasets, Weights & Checkpoints . . . 528
8.3.1 Exercise 00 - Design Dataset Bucket Structure . . . 528
8.3.2 Exercise 01 - Upload Dataset with Folder Hierarchy . . . 529
8.3.3 Exercise 02 - Store Model Weights after Training . . . 530
8.3.4 Exercise 03 - Retrieve Checkpoint for Resume Training . . . 531

8.3.5 Exercise 04 - Versioned Model Checkpoints Strategy . . . 532
8.3.6 Exercise 05 - Atomic Model Save Operation . . . 533
8.3.7 Exercise 06 - Compare Local vs Object Storage IO . . . 534
8.3.8 Exercise 07 - Garbage Collection of Old Checkpoints . . . 535
8.3.9 Exercise 08 - Integrity Validation with Hashes . . . 536
8.3.10 Exercise 09 - Training Pipeline Object Integration . . . 537
8.4 OB02 - Buckets & Access Structure . . . 539
8.4.1 Exercise 00 - Bucket Policy Configuration . . . 539
8.4.2 Exercise 01 - Read-Only vs Read-Write Policy . . . 540
8.4.3 Exercise 02 - User and Access Key Creation . . . 541
8.4.4 Exercise 03 - Temporary Access using Presigned URL . . . 542
8.4.5 Exercise 04 - Private vs Public Object Access . . . 543
8.4.6 Exercise 05 - Folder-like Access Control Design . . . 544
8.4.7 Exercise 06 - Access Denial Debugging Challenge . . . 545
8.4.8 Exercise 07 - Multi-Bucket Permission Strategy . . . 546
8.4.9 Exercise 08 - Secure Credential Rotation . . . 547
8.4.10 Exercise 09 - Access Control Audit Scenario . . . 548
8.5 OB03 - Distributed Mode & Fault Tolerance . . . 550
8.5.1 Exercise 00 - Start MinIO in Distributed Mode . . . 550
8.5.2 Exercise 01 - Node Failure Simulation . . . 551
8.5.3 Exercise 02 - Data Replication Verification . . . 552
8.5.4 Exercise 03 - Healing Process Observation . . . 553
8.5.5 Exercise 04 - Disk Failure Recovery Scenario . . . 554
8.5.6 Exercise 05 - Erasure Coding Concept Experiment . . . 555
8.5.7 Exercise 06 - Performance Impact of Replication . . . 556
8.5.8 Exercise 07 - High Availability Configuration . . . 557
8.5.9 Exercise 08 - Disaster Recovery Backup Strategy . . . 558
8.5.10 Exercise 09 - End-to-End Fault Tolerance Test . . . 559

9 Vector Database Lessons (Qdrant) 562
9.1 Introduction . . . 562
9.1.1 What will this book teach you . . . 562
9.1.2 How Qdrant supports artificial intelligence systems . . . 563
9.1.3 How to approach the exercises . . . 564
9.1.4 The Chapters (QD00–QD03) included in this book . . . 564
9.1.5 QD00 - Embeddings & Semantic Meaning . . . 565
9.1.6 QD01 - Similarity Search Mechanics . . . 565
9.1.7 QD02 - RAG Integration Workflow . . . 565
9.1.8 QD03 - Indexing & Scalable Retrieval . . . 565
9.2 QD00 - Embeddings & Semantic Meaning . . . 566
9.2.1 Exercise 00 - Install Qdrant and Start Service . . . 566
9.2.2 Exercise 01 - Create Collection with Vector Size . . . 567
9.2.3 Exercise 02 - Generate Embeddings using Model . . . 568
9.2.4 Exercise 03 - Insert Single Vector Point . . . 569
9.2.5 Exercise 04 - Insert Batch of Vectors . . . 570
9.2.6 Exercise 05 - Attach Payload Metadata to Vectors . . . 571
9.2.7 Exercise 06 - Retrieve Vector by ID . . . 572
9.2.8 Exercise 07 - Vector Normalization Effect Test . . . 573

9.2.9 Exercise 08 - Semantic Meaning Drift Observation . . . 574
9.2.10 Exercise 09 - Embedding Quality Evaluation Challenge . . . 575
9.3 QD01 - Similarity Search Mechanics . . . 577
9.3.1 Exercise 00 - Cosine Similarity Search Query . . . 577
9.3.2 Exercise 01 - Euclidean Distance Search Query . . . 578
9.3.3 Exercise 02 - Compare Distance Metrics . . . 579
9.3.4 Exercise 03 - Top-K Nearest Neighbors Retrieval . . . 580
9.3.5 Exercise 04 - Similarity Threshold Filtering . . . 581
9.3.6 Exercise 05 - Payload-based Filtering in Search . . . 582
9.3.7 Exercise 06 - Hybrid Filter + Vector Search . . . 583
9.3.8 Exercise 07 - Search Performance Benchmark . . . 584
9.3.9 Exercise 08 - Search Result Ranking Analysis . . . 585
9.3.10 Exercise 09 - Similarity Debugging Scenario . . . 587
9.4 QD02 - RAG Integration Workflow . . . 588
9.4.1 Exercise 00 - Chunk Text Data for Embedding . . . 588
9.4.2 Exercise 01 - Store Document Chunks as Vectors . . . 589
9.4.3 Exercise 02 - Query Embedding Generation . . . 590
9.4.4 Exercise 03 - Retrieve Relevant Context Chunks . . . 591
9.4.5 Exercise 04 - Context Ranking by Similarity . . . 592
9.4.6 Exercise 05 - Metadata Filtering in RAG . . . 593
9.4.7 Exercise 06 - Limit Context Window Size . . . 594
9.4.8 Exercise 07 - Handle Empty Retrieval Case . . . 595
9.4.9 Exercise 08 - End-to-End RAG Pipeline Test . . . 597
9.4.10 Exercise 09 - RAG Failure Mode Analysis . . . 598
9.5 QD03 - Indexing & Scalable Retrieval . . . 599
9.5.1 Exercise 00 - HNSW Index Configuration . . . 599
9.5.2 Exercise 01 - Index Build vs Query Speed Tradeoff . . . 600
9.5.3 Exercise 02 - Payload Index Creation . . . 601
9.5.4 Exercise 03 - Large-Scale Vector Ingestion . . . 602
9.5.5 Exercise 04 - Shard Configuration Experiment . . . 603
9.5.6 Exercise 05 - Replication Factor Impact Test . . . 604
9.5.7 Exercise 06 - Consistency vs Performance Tradeoff . . . 606
9.5.8 Exercise 07 - Search Latency Monitoring . . . 607
9.5.9 Exercise 08 - Index Corruption Recovery Scenario . . . 609
9.5.10 Exercise 09 - Scalable Semantic Search System Design . . . 610

10 Linear Regression 613
10.1 Introduction . . . 613
10.1.1 What will the book teach you . . . 613
10.1.2 How to study this book . . . 615
10.1.3 The Chapters (LR00 - LR08) included in this book . . . 615
10.2 LR00 - Introduction to Linear Regression . . . 616
10.2.1 Exercise 00 - Define Linear Model $y = wx + b$ . . . 616
10.2.2 Exercise 01 - Implement Linear Function in PyTorch . . . 617
10.2.3 Exercise 02 - Tensor Shape Verification for Inputs . . . 617
10.2.4 Exercise 03 - Single Sample Forward Pass . . . 618
10.2.5 Exercise 04 - Batch Input Forward Pass . . . 619
10.2.6 Exercise 05 - Random Weight Initialization Test . . . 620

10.2.7 Exercise 06 - Effect of Bias Term Experiment . . . 621
10.2.8 Exercise 07 - Output Sensitivity to Weight Change . . . 622
10.2.9 Exercise 08 - Linear Model as Matrix Multiplication . . . 623
10.2.10 Exercise 09 - Manual Prediction vs PyTorch Output . . . 624
10.2.11 Exercise 10 - Move Model to CUDA Device . . . 626
10.2.12 Exercise 11 - CPU vs GPU Forward Pass Comparison . . . 627
10.2.13 Exercise 12 - Precision Difference (float32 vs float64) . . . 628
10.2.14 Exercise 13 - Multiple Feature Linear Model . . . 629
10.2.15 Exercise 14 - Verify Output Dimensions . . . 630
10.2.16 Exercise 15 - Linear Layer Using nn.Linear . . . 631
10.2.17 Exercise 16 - Inspect Weight and Bias Parameters . . . 632
10.2.18 Exercise 17 - Freeze Parameters Test . . . 633
10.2.19 Exercise 18 - Manual Forward Without nn.Module . . . 634
10.2.20 Exercise 19 - Forward Pass Failure Debugging . . . 635
10.3 LR01 - Model Structure and Components . . . 637
10.3.1 Exercise 00 - Separate Weights and Bias Tensors . . . 637
10.3.2 Exercise 01 - Parameter Registration in nn.Module . . . 638
10.3.3 Exercise 02 - Inspect requires_grad Flags . . . 639
10.3.4 Exercise 03 - Count Trainable Parameters . . . 640
10.3.5 Exercise 04 - Initialize Model on CUDA . . . 641
10.3.6 Exercise 05 - Verify Parameter Device Placement . . . 642
10.3.7 Exercise 06 - Manual Parameter Update Test . . . 643
10.3.8 Exercise 07 - Parameter Sharing Experiment . . . 644
10.3.9 Exercise 08 - Reinitialize Model Weights . . . 645
10.3.10 Exercise 09 - Effect of Bad Initialization . . . 646
10.3.11 Exercise 10 - Bias-only Model Behavior . . . 647
10.3.12 Exercise 11 - Weight-only Model Behavior . . . 648
10.3.13 Exercise 12 - Model Copy vs Reference Test . . . 649
10.3.14 Exercise 13 - State Dict Inspection . . . 651
10.3.15 Exercise 14 - Save and Load Model Weights . . . 652
10.3.16 Exercise 15 - Device Mismatch Error Debugging . . . 653
10.3.17 Exercise 16 - Gradient Flow Verification . . . 654
10.3.18 Exercise 17 - Manual Backward Call Test . . . 655
10.3.19 Exercise 18 - Parameter Update Order Inspection . . . 656
10.3.20 Exercise 19 - Model Structure Failure Case . . . 658
10.4 LR02 - Data Preparation and Feature Inputs . . . 659
10.4.1 Exercise 00 - Generate Synthetic Linear Dataset . . . 659
10.4.2 Exercise 01 - Add Noise to Dataset . . . 660
10.4.3 Exercise 02 - Feature Scaling Experiment . . . 661
10.4.4 Exercise 03 - Train/Test Split Implementation . . . 662
10.4.5 Exercise 04 - Batch Dataset Creation . . . 663
10.4.6 Exercise 05 - Shuffle Dataset per Epoch . . . 665
10.4.7 Exercise 06 - Move Dataset to CUDA . . . 666
10.4.8 Exercise 07 - DataLoader Integration . . . 667
10.4.9 Exercise 08 - Incorrect Shape Debugging . . . 668
10.4.10 Exercise 09 - Missing Feature Handling . . . 669
10.4.11 Exercise 10 - Bias Column Injection . . . 670
10.4.12 Exercise 11 - High-Dimensional Feature Test . . . 671

10.4.13 Exercise 12 - Collinearity Effect Observation . . . 672
10.4.14 Exercise 13 - Data Precision Impact Test . . . 673
10.4.15 Exercise 14 - Large Dataset GPU Transfer Cost . . . 674
10.4.16 Exercise 15 - Dataset Caching Strategy . . . 676
10.4.17 Exercise 16 - Dataset Integrity Check . . . 677
10.4.18 Exercise 17 - Manual Batch Iteration . . . 678
10.4.19 Exercise 18 - Data Leakage Detection . . . 679
10.4.20 Exercise 19 - Data Pipeline Failure Debugging . . . 680
10.5 LR03 - Prediction Function Implementation . . . 682
10.5.1 Exercise 00 - Define Predict(x) Function . . . 682
10.5.2 Exercise 01 - Vectorized Prediction . . . 683
10.5.3 Exercise 02 - Batch Prediction on CPU . . . 684
10.5.4 Exercise 03 - Batch Prediction on CUDA . . . 685
10.5.5 Exercise 04 - Shape-Safe Prediction . . . 686
10.5.6 Exercise 05 - Disable Grad in Inference . . . 687
10.5.7 Exercise 06 - Precision Switch During Inference . . . 688
10.5.8 Exercise 07 - Prediction Consistency Test . . . 689
10.5.9 Exercise 08 - Streaming Prediction Simulation . . . 690
10.5.10 Exercise 09 - Prediction Latency Benchmark . . . 691
10.5.11 Exercise 10 - Predict with Frozen Model . . . 692
10.5.12 Exercise 11 - CPU-to-GPU Prediction Sync Check . . . 693
10.5.13 Exercise 12 - Large Batch Prediction Stress Test . . . 694
10.5.14 Exercise 13 - Numerical Drift Detection . . . 696
10.5.15 Exercise 14 - Prediction with Missing Features . . . 697
10.5.16 Exercise 15 - Prediction Error Propagation . . . 698
10.5.17 Exercise 16 - TorchScript Prediction Export . . . 699
10.5.18 Exercise 17 - Inference Memory Profiling . . . 700
10.5.19 Exercise 18 - Prediction API Wrapper . . . 701
10.5.20 Exercise 19 - Prediction Failure Debugging . . . 702
10.6 LR04 - Error Measurement and Loss Definition . . . 704
10.6.1 Exercise 00 - Define MSE Loss Manually . . . 704
10.6.2 Exercise 01 - MSE via PyTorch . . . 705
10.6.3 Exercise 02 - Loss Reduction Modes . . . 706
10.6.4 Exercise 03 - Batch Loss Computation . . . 707
10.6.5 Exercise 04 - Loss on CUDA . . . 708
10.6.6 Exercise 05 - Loss Gradient Inspection . . . 709
10.6.7 Exercise 06 - Outlier Impact on Loss . . . 710
10.6.8 Exercise 07 - Loss Scaling Effects . . . 711
10.6.9 Exercise 08 - Loss Precision Comparison . . . 712
10.6.10 Exercise 09 - Loss Stability Test . . . 713
10.6.11 Exercise 10 - Custom Loss Class . . . 714
10.6.12 Exercise 11 - Loss with Masked Samples . . . 715
10.6.13 Exercise 12 - Loss Backward Pass Check . . . 716
10.6.14 Exercise 13 - Loss Accumulation Debugging . . . 717
10.6.15 Exercise 14 - Loss Memory Footprint . . . 719
10.6.16 Exercise 15 - CPU vs GPU Loss Parity . . . 720
10.6.17 Exercise 16 - Loss under Mixed Precision . . . 721
10.6.18 Exercise 17 - Loss Curve Logging . . . 722

10.6.19 Exercise 18 - Loss Exploding Case . . . 723
10.6.20 Exercise 19 - Loss Failure Debugging . . . 724
10.7 LR05 - Parameter Adjustment and Gradient . . . 726
10.7.1 Exercise 00 - Backward on Scalar Loss . . . 726
10.7.2 Exercise 01 - Inspect Weight Gradients . . . 727
10.7.3 Exercise 02 - Inspect Bias Gradients . . . 728
10.7.4 Exercise 03 - Zero Grad Correctly . . . 729
10.7.5 Exercise 04 - Manual Gradient Update . . . 730
10.7.6 Exercise 05 - Learning Rate Sensitivity . . . 731
10.7.7 Exercise 06 - Gradient Clipping . . . 732
10.7.8 Exercise 07 - Gradient Accumulation . . . 733
10.7.9 Exercise 08 - Gradient Noise Injection . . . 734
10.7.10 Exercise 09 - Gradient Check via Finite Difference . . . 735
10.7.11 Exercise 10 - Optimizer Step vs Manual Step . . . 737
10.7.12 Exercise 11 - CUDA Gradient Sync Check . . . 738
10.7.13 Exercise 12 - Frozen Parameter Gradient Test . . . 739
10.7.14 Exercise 13 - Gradient Explosion Scenario . . . 740
10.7.15 Exercise 14 - Gradient Vanishing Scenario . . . 741
10.7.16 Exercise 15 - Mixed Precision Backward . . . 742
10.7.17 Exercise 16 - Backward Graph Retention . . . 743
10.7.18 Exercise 17 - Gradient Memory Profiling . . . 744
10.7.19 Exercise 18 - Multi-Batch Gradient Behavior . . . 745
10.7.20 Exercise 19 - Gradient Debugging Case . . . 746
10.8 LR06 - Training Iterations and Convergence . . . 748
10.8.1 Exercise 00 - Single-Epoch Training . . . 748
10.8.2 Exercise 01 - Multi-Epoch Training Loop . . . 749
10.8.3 Exercise 02 - Convergence Criterion Check . . . 750
10.8.4 Exercise 03 - Divergence Detection . . . 751
10.8.5 Exercise 04 - Early Stopping . . . 752
10.8.6 Exercise 05 - Learning Rate Schedule . . . 754
10.8.7 Exercise 06 - Training on CUDA End-to-End . . . 755
10.8.8 Exercise 07 - CPU vs GPU Convergence . . . 756
10.8.9 Exercise 08 - Batch Size Impact . . . 757
10.8.10 Exercise 09 - Noise Robustness Test . . . 758
10.8.11 Exercise 10 - Reproducibility with Seeds . . . 759
10.8.12 Exercise 11 - Checkpoint Save per Epoch . . . 760
10.8.13 Exercise 12 - Resume Training from Checkpoint . . . 761
10.8.14 Exercise 13 - Long-Run Stability Test . . . 762
10.8.15 Exercise 14 - Loss Plateau Analysis . . . 764
10.8.16 Exercise 15 - Throughput Benchmark . . . 765
10.8.17 Exercise 16 - Gradient Drift Over Epochs . . . 766
10.8.18 Exercise 17 - Mixed Precision Training . . . 767
10.8.19 Exercise 18 - Training Failure Recovery . . . 768
10.8.20 Exercise 19 - Full Training Debug Scenario . . . 769
10.9 LR07 - Model Evaluation and Performance . . . 771
10.9.1 Exercise 00 - Compute RMSE Metric . . . 771
10.9.2 Exercise 01 - Compute MAE Metric . . . 772
10.9.3 Exercise 02 - Evaluation without Grad . . . 773

10.9.4 Exercise 03 - Train vs Eval Mode . . . 774
10.9.5 Exercise 04 - Overfitting Detection . . . 775
10.9.6 Exercise 05 - Cross-Validation Split . . . 776
10.9.7 Exercise 06 - Performance on Noisy Data . . . 777
10.9.8 Exercise 07 - Performance Scaling with Data Size . . . 778
10.9.9 Exercise 08 - Inference Throughput Test . . . 779
10.9.10 Exercise 09 - Latency Profiling on CUDA . . . 780
10.9.11 Exercise 10 - Memory Usage Profiling . . . 781
10.9.12 Exercise 11 - Error Distribution Analysis . . . 783
10.9.13 Exercise 12 - Residual Analysis . . . 784
10.9.14 Exercise 13 - Model Robustness Test . . . 785
10.9.15 Exercise 14 - Performance Regression Detection . . . 786
10.9.16 Exercise 15 - GPU Utilization Monitoring . . . 787
10.9.17 Exercise 16 - Metric Precision Comparison . . . 789
10.9.18 Exercise 17 - Evaluation Pipeline Automation . . . 790
10.9.19 Exercise 18 - Evaluation Failure Debugging . . . 791
10.9.20 Exercise 19 - Final Evaluation Report . . . 792
10.10LR08 - Result Visualization and Interpretation . . . 793
10.10.1 Exercise 00 - Plot Predictions vs Targets . . . 793
10.10.2 Exercise 01 - Plot Loss Curve . . . 795
10.10.3 Exercise 02 - Plot Residuals . . . 796
10.10.4 Exercise 03 - Visualization with Large Batches . . . 797
10.10.5 Exercise 04 - CPU vs GPU Visualization Parity . . . 798
10.10.6 Exercise 05 - Visualize Convergence Speed . . . 799
10.10.7 Exercise 06 - Hyperparameter Impact Plot . . . 800
10.10.8 Exercise 07 - Data Noise Visualization . . . 801
10.10.9 Exercise 08 - Error Distribution Plot . . . 802
10.10.10 Exercise 09 - Visualization Performance Cost . . . 804
10.10.11 Exercise 10 - Interactive Visualization . . . 805
10.10.12 Exercise 11 - Visualization from Checkpoints . . . 806
10.10.13 Exercise 12 - Multi-Run Comparison Plot . . . 807
10.10.14 Exercise 13 - Visualization Bug Debugging . . . 808
10.10.15 Exercise 14 - Interpret Weight Values . . . 810
10.10.16 Exercise 15 - Interpret Bias Effect . . . 811
10.10.17 Exercise 16 - Feature Contribution Analysis . . . 812
10.10.18 Exercise 17 - Explain Failure Cases . . . 813
10.10.19 Exercise 18 - Visualization Reproducibility . . . 814
10.10.20 Exercise 19 - Final Model Interpretation Report . . . 816

11 Logistic Regression 818
11.1 Introduction . . . 818
11.1.1 What will the book teach you . . . 818
11.1.2 How to study this book . . . 820
11.1.3 The Chapters (LG00 - LG08) included in this book . . . 821
11.2 LG00 - Introduction to Logistic Regression . . . 821
11.2.1 Exercise 00 - Define Binary Classification Problem . . . 822
11.2.2 Exercise 01 - Linear Output vs Probability Output . . . 823
11.2.3 Exercise 02 - Implement Sigmoid Function Manually . . . 824

11.2.4 Exercise 03 - Sigmoid Using PyTorch . . . 825
11.2.5 Exercise 04 - Probability Range Validation . . . 826
11.2.6 Exercise 05 - Single Sample Classification . . . 827
11.2.7 Exercise 06 - Batch Classification Forward Pass . . . 828
11.2.8 Exercise 07 - Decision Threshold Experiment . . . 829
11.2.9 Exercise 08 - Logit Interpretation Test . . . 830
11.2.10 Exercise 09 - Binary Output Failure Case . . . 831
11.2.11 Exercise 10 - Move Logistic Model to CUDA . . . 832
11.2.12 Exercise 11 - CPU vs GPU Probability Comparison . . . 833
11.2.13 Exercise 12 - Precision Effects on Sigmoid . . . 834
11.2.14 Exercise 13 - Saturation Behavior Observation . . . 836
11.2.15 Exercise 14 - Numerical Stability Breakdown . . . 837
11.2.16 Exercise 15 - Vectorized Binary Prediction . . . 838
11.2.17 Exercise 16 - Probability Calibration Check . . . 839
11.2.18 Exercise 17 - Frozen Logistic Model Test . . . 840
11.2.19 Exercise 18 - Manual Forward without nn.Module . . . 841
11.2.20 Exercise 19 - Forward Pass Failure Debugging . . . 842
11.3 LG01 - Binary Output and Decision Logic . . . 844
11.3.1 Exercise 00 - Convert Probability to Class Label . . . 844
11.3.2 Exercise 01 - Threshold Sensitivity Experiment . . . 845
11.3.3 Exercise 02 - Confusion Matrix Construction . . . 846
11.3.4 Exercise 03 - False Positive / False Negative Analysis . . . 847
11.3.5 Exercise 04 - Imbalanced Dataset Effect . . . 848
11.3.6 Exercise 05 - Dynamic Threshold Selection . . . 849
11.3.7 Exercise 06 - ROC Curve Concept Implementation . . . 851
11.3.8 Exercise 07 - AUC Metric Calculation . . . 852
11.3.9 Exercise 08 - Precision vs Recall Tradeoff . . . 853
11.3.10 Exercise 09 - Classification Failure Case . . . 854
11.3.11 Exercise 10 - CUDA Evaluation without Grad . . . 855
11.3.12 Exercise 11 - Batch-wise Decision Pipeline . . . 856
11.3.13 Exercise 12 - Prediction Consistency Test . . . 857
11.3.14 Exercise 13 - Threshold Drift Detection . . . 859
11.3.15 Exercise 14 - Metric Stability under Noise . . . 860
11.3.16 Exercise 15 - Classification Latency Benchmark . . . 861
11.3.17 Exercise 16 - Memory Profiling for Inference . . . 862
11.3.18 Exercise 17 - Misclassification Debugging . . . 864
11.3.19 Exercise 18 - Evaluation Pipeline Automation . . . 865
11.3.20 Exercise 19 - Decision Logic Failure Scenario . . . 866
11.4 LG02 - Sigmoid Activation Behavior . . . 868
11.4.1 Exercise 00 - Plot Sigmoid Curve . . . 868
11.4.2 Exercise 01 - Gradient of Sigmoid Inspection . . . 869
11.4.3 Exercise 02 - Vanishing Gradient Demonstration . . . 870
11.4.4 Exercise 03 - Saturation Region Detection . . . 871
11.4.5 Exercise 04 - Input Scaling Effect . . . 872
11.4.6 Exercise 05 - Large Logit Stability Test . . . 873
11.4.7 Exercise 06 - CUDA Gradient Comparison . . . 875
11.4.8 Exercise 07 - Float32 vs Float64 Gradient . . . 876
11.4.9 Exercise 08 - Backward Pass Visualization . . . 877

11.4.10 Exercise 09 - Activation Failure Debugging . . . 878
11.4.11 Exercise 10 - Custom Sigmoid Module . . . 879
11.4.12 Exercise 11 - Sigmoid vs Tanh Comparison . . . 880
11.4.13 Exercise 12 - Sigmoid in Deep Stack Simulation . . . 881
11.4.14 Exercise 13 - Gradient Noise Injection . . . 883
11.4.15 Exercise 14 - Autograd Graph Inspection . . . 884
11.4.16 Exercise 15 - Mixed Precision Backward Test . . . 885
11.4.17 Exercise 16 - Activation Profiling on GPU . . . 887
11.4.18 Exercise 17 - Stability under Extreme Inputs . . . 888
11.4.19 Exercise 18 - Activation Optimization Attempt . . . 889
11.4.20 Exercise 19 - Sigmoid Failure Report . . . 890
11.5 LG03 - Probability Interpretation Framework . . . 892
11.5.1 Exercise 00 - Likelihood Interpretation . . . 892
11.5.2 Exercise 01 - Log-Likelihood Computation . . . 893
11.5.3 Exercise 02 - Negative Log-Likelihood Concept . . . 894
11.5.4 Exercise 03 - Likelihood vs Loss Mapping . . . 895
11.5.5 Exercise 04 - Batch Likelihood Aggregation . . . 896
11.5.6 Exercise 05 - CUDA Likelihood Computation . . . 897
11.5.7 Exercise 06 - Likelihood Sensitivity Test . . . 898
11.5.8 Exercise 07 - Confidence Calibration Check . . . 899
11.5.9 Exercise 08 - Overconfident Prediction Detection . . . 901
11.5.10 Exercise 09 - Probability Misinterpretation Case . . . 902
11.5.11 Exercise 10 - Bayesian View Comparison . . . 903
11.5.12 Exercise 11 - Prior Effect Simulation . . . 904
11.5.13 Exercise 12 - Data Imbalance Impact . . . 905
11.5.14 Exercise 13 - Likelihood under Noise . . . 907
11.5.15 Exercise 14 - Probability Drift over Epochs . . . 908
11.5.16 Exercise 15 - Numerical Precision Effects . . . 909
11.5.17 Exercise 16 - Likelihood Visualization . . . 911
11.5.18 Exercise 17 - Probability Pipeline Debugging . . . 912
11.5.19 Exercise 18 - Confidence Failure Detection . . . 913
11.5.20 Exercise 19 - Final Probability Analysis Report . . . 915
11.6 LG04 - Classification Boundary Definition . . . 916
11.6.1 Exercise 00 - Linear Decision Boundary Plot . . . 916
11.6.2 Exercise 01 - Boundary Shift with Bias . . . 918
11.6.3 Exercise 02 - Multi-Feature Boundary Visualization . . . 919
11.6.4 Exercise 03 - Boundary on CUDA Computation . . . 920
11.6.5 Exercise 04 - Margin Concept Experiment . . . 922
11.6.6 Exercise 05 - Overlapping Classes Scenario . . . 923
11.6.7 Exercise 06 - Noise Impact on Boundary . . . 924
11.6.8 Exercise 07 - Boundary Stability Test . . . 926
11.6.9 Exercise 08 - Misclassified Region Detection . . . 927
11.6.10 Exercise 09 - Boundary Failure Case . . . 928
11.6.11 Exercise 10 - High-Dimensional Boundary Projection . . . 930
11.6.12 Exercise 11 - Boundary under Feature Scaling . . . 931
11.6.13 Exercise 12 - Regularization Effect on Boundary . . . 932
11.6.14 Exercise 13 - Boundary Drift over Training . . . 934
11.6.15 Exercise 14 - Boundary Sharpness Measurement . . . 936

11.6.16 Exercise 15 - Visualization Performance Cost . . . 937
11.6.17 Exercise 16 - Boundary Interpretation Report . . . 939
11.6.18 Exercise 17 - Decision Surface Debugging . . . 940
11.6.19 Exercise 18 - Boundary Robustness Test . . . 942
11.6.20 Exercise 19 - Final Boundary Analysis . . . 943
11.7 LG05 - Loss Representation for Classification . . . 945
11.7.1 Exercise 00 - Binary Cross Entropy Formula . . . 945
11.7.2 Exercise 01 - BCE via PyTorch . . . 946
11.7.3 Exercise 02 - Logits vs Probabilities Loss . . . 947
11.7.4 Exercise 03 - Numerical Stability (Log-Sum-Exp) . . . 948
11.7.5 Exercise 04 - BCE on CUDA . . . 949
11.7.6 Exercise 05 - Loss Gradient Inspection . . . 950
11.7.7 Exercise 06 - Class Imbalance Weighting . . . 951
11.7.8 Exercise 07 - Loss Scaling Effect . . . 952
11.7.9 Exercise 08 - Loss Explosion Scenario . . . 953
11.7.10 Exercise 09 - Loss Debugging Case . . . 954
11.7.11 Exercise 10 - Custom BCE Loss Class . . . 955
11.7.12 Exercise 11 - Masked Loss Computation . . . 956
11.7.13 Exercise 12 - Reduction Mode Comparison . . . 957
11.7.14 Exercise 13 - Mixed Precision Loss . . . 958
11.7.15 Exercise 14 - Loss Memory Profiling . . . 959
11.7.16 Exercise 15 - CPU vs GPU Loss Parity . . . 960
11.7.17 Exercise 16 - Loss Curve Logging . . . 961
11.7.18 Exercise 17 - Loss Drift Detection . . . 962
11.7.19 Exercise 18 - Failure Recovery Test . . . 963
11.7.20 Exercise 19 - Final Loss Report . . . 964
11.8 LG06 - Model Adjustment and Gradient Direction . . . 965
11.8.1 Exercise 00 - Backward Pass on BCE Loss . . . 965
11.8.2 Exercise 01 - Inspect Weight Gradients . . . 967
11.8.3 Exercise 02 - Inspect Bias Gradients . . . 968
11.8.4 Exercise 03 - Manual Gradient Update . . . 969
11.8.5 Exercise 04 - Learning Rate Sensitivity . . . 970
11.8.6 Exercise 05 - Gradient Clipping in Classification . . . 971
11.8.7 Exercise 06 - Gradient Noise Injection . . . 972
11.8.8 Exercise 07 - Optimizer Step Comparison . . . 973
11.8.9 Exercise 08 - CUDA Gradient Sync Check . . . 975
11.8.10 Exercise 09 - Gradient Explosion Scenario . . . 976
11.8.11 Exercise 10 - Gradient Vanishing Scenario . . . 977
11.8.12 Exercise 11 - Mixed Precision Backward . . . 978
11.8.13 Exercise 12 - Frozen Layer Gradient Test . . . 979
11.8.14 Exercise 13 - Gradient Accumulation . . . 980
11.8.15 Exercise 14 - Backward Graph Retention . . . 981
11.8.16 Exercise 15 - Gradient Memory Profiling . . . 983
11.8.17 Exercise 16 - Multi-Batch Gradient Behavior . . . 984
11.8.18 Exercise 17 - Gradient Drift Detection . . . 985
11.8.19 Exercise 18 - Debugging Gradient Failure . . . 986
11.8.20 Exercise 19 - End-to-End Gradient Report . . . 987
11.9 LG07 - Accuracy Validation and Output Analysis . . . 988

11.9.1 Exercise 00 - Accuracy Metric Implementation 988
11.9.2 Exercise 01 - Precision Metric 989
11.9.3 Exercise 02 - Recall Metric 990
11.9.4 Exercise 03 - F1 Score Computation 991
11.9.5 Exercise 04 - Evaluation without Grad 992
11.9.6 Exercise 05 - GPU Evaluation Throughput 993
11.9.7 Exercise 06 - Confusion Matrix Visualization 994
11.9.8 Exercise 07 - Metric Stability under Noise 995
11.9.9 Exercise 08 - Performance Scaling with Data Size 996
11.9.10 Exercise 09 - Latency Profiling on CUDA 997
11.9.11 Exercise 10 - Memory Usage Profiling 999
11.9.12 Exercise 11 - Error Distribution Analysis 1000
11.9.13 Exercise 12 - Threshold Sensitivity Analysis 1001
11.9.14 Exercise 13 - Metric Regression Detection 1002
11.9.15 Exercise 14 - Robustness Test 1003
11.9.16 Exercise 15 - Evaluation Pipeline Automation 1004
11.9.17 Exercise 16 - Evaluation Failure Debugging 1005
11.9.18 Exercise 17 - Multi-Run Metric Comparison 1006
11.9.19 Exercise 18 - Final Evaluation Report 1007
11.9.20 Exercise 19 - Production Metric Sanity Check 1008
11.10LG08 - Multi-Class Extension Concepts 1009
11.10.1 Exercise 00 - One-vs-Rest Logistic Strategy 1009
11.10.2 Exercise 01 - Softmax vs Sigmoid Comparison 1010
11.10.3 Exercise 02 - Multi-Class Dataset Preparation 1011
11.10.4 Exercise 03 - Cross-Entropy for Multi-Class 1012
11.10.5 Exercise 04 - CUDA Multi-Class Training 1013
11.10.6 Exercise 05 - Class Imbalance in Multi-Class 1014
11.10.7 Exercise 06 - Confusion Matrix for Multi-Class 1015
11.10.8 Exercise 07 - Macro vs Micro Metrics 1016
11.10.9 Exercise 08 - Probability Calibration Multi-Class 1017
11.10.10 Exercise 09 - Boundary Visualization Multi-Class 1018
11.10.11 Exercise 10 - Gradient Stability Multi-Class 1019
11.10.12 Exercise 11 - Mixed Precision Multi-Class 1020
11.10.13 Exercise 12 - Performance Scaling Classes 1021
11.10.14 Exercise 13 - Error Analysis per Class 1023
11.10.15 Exercise 14 - Metric Drift Detection 1024
11.10.16 Exercise 15 - End-to-End Multi-Class Pipeline 1025
11.10.17 Exercise 16 - Production Readiness Check 1026
11.10.18 Exercise 17 - Failure Recovery Scenario 1027
11.10.19 Exercise 18 - Scalability Stress Test 1028
11.10.20 Exercise 19 - Final Multi-Class Report 1029

12 Perceptron **1031**
12.1 Introduction 1031
12.1.1 What will the book teach you 1031
12.1.2 How to study this book 1034
12.1.3 The Chapters (PC00 - PC08) included in this book 1034
12.2 PC00 - Perceptron Concept and Motivation 1035

12.2.1 Exercise 00 - Understand the Limitation of Linear Regression for Classification 1035
12.2.2 Exercise 01 - Define the Perceptron as a Binary Decision Unit with Step Function 1036
12.2.3 Exercise 02 - Implement a Basic Perceptron Forward Pass Using Pure Python 1037
12.2.4 Exercise 03 - Translate Mathematical Perceptron Formula into PyTorch Operations 1038
12.2.5 Exercise 04 - Compare Linear Regression Output vs Perceptron Binary Output 1039
12.2.6 Exercise 05 - Analyze Why Perceptron Uses a Hard Decision Boundary 1040
12.2.7 Exercise 06 - Implement the Step Activation Function and Test Its Behavior 1041
12.2.8 Exercise 07 - Visualize Binary Decisions Generated by a Single Perceptron 1042
12.2.9 Exercise 08 - Test Perceptron on Linearly Separable Dataset 1043
12.2.10 Exercise 09 - Observe Failure on Non-Linearly Separable Data 1044
12.2.11 Exercise 10 - Move Perceptron Computation to CUDA and Verify Output Consistency 1045
12.2.12 Exercise 11 - Compare CPU vs GPU Execution for Perceptron Forward Pass 1046
12.2.13 Exercise 12 - Inspect Weight and Bias Initialization Effects on Decisions 1047
12.2.14 Exercise 13 - Analyze Sensitivity of Decision Boundary to Weight Changes 1048
12.2.15 Exercise 14 - Implement Perceptron without Using nn.Module 1050
12.2.16 Exercise 15 - Validate Output Shape and Data Type in Classification Pipeline 1051
12.2.17 Exercise 16 - Freeze Perceptron Parameters and Test Prediction Stability 1052
12.2.18 Exercise 17 - Debug Incorrect Binary Outputs Caused by Shape Mismatch 1053
12.2.19 Exercise 18 - Stress Test Perceptron with Large Batch Inputs 1054
12.2.20 Exercise 19 - Document Conceptual and Practical Failures of the Perceptron Model 1055
12.3 PC01 - Mathematical Structure of the Perceptron 1056
12.3.1 Exercise 00 - Express the Perceptron as a Vector Dot Product Plus Bias 1057
12.3.2 Exercise 01 - Rewrite the Perceptron Equation Using Matrix Notation .1058
12.3.3 Exercise 02 - Analyze the Geometric Meaning of the Weight Vector . .1059
12.3.4 Exercise 03 - Interpret the Bias Term as a Decision Boundary Shift . .1060
12.3.5 Exercise 04 - Compute the Signed Distance from a Point to the Decision Boundary 1061
12.3.6 Exercise 05 - Verify Perceptron Output Using Manual Vector Calculations 1062
12.3.7 Exercise 06 - Compare Multiple Weight Configurations and Their Boundaries 1063
12.3.8 Exercise 07 - Visualize Decision Hyperplane in 2D Feature Space 1064
12.3.9 Exercise 08 - Extend Decision Boundary Visualization to Higher Dimensions 1065
12.3.10 Exercise 09 - Investigate Numerical Precision Effects on Boundary Placement 1066
12.3.11 Exercise 10 - Implement Mathematical Perceptron Using CUDA Tensors 1067

12.3.12 Exercise 11 - Compare Float32 vs Float64 in Boundary Computation .1068
12.3.13 Exercise 12 - Detect Boundary Instability Under Small Input Noise . .1069
12.3.14 Exercise 13 - Analyze Scaling Effects on Weights and Inputs 1070
12.3.15 Exercise 14 - Validate Linear Separability Assumption Experimentally .1072
12.3.16 Exercise 15 - Demonstrate Failure Case with XOR Dataset 1073
12.3.17 Exercise 16 - Explain Why Single Perceptron Cannot Solve XOR . . .1074
12.3.18 Exercise 17 - Inspect Internal Tensor Operations During Forward Pass 1075
12.3.19 Exercise 18 - Stress Test Dot Product Computation on GPU 1076
12.3.20 Exercise 19 - Produce a Formal Mathematical Interpretation Report . .1077
12.4 PC02 - Perceptron Learning Rule and Updates 1078
12.4.1 Exercise 00 - Derive the Perceptron Weight Update Rule from Classification Errors 1078
12.4.2 Exercise 01 - Implement Manual Weight Update Based on Misclassified Samples 1079
12.4.3 Exercise 02 - Analyze the Role of Learning Rate in Perceptron Convergence Behavior 1080
12.4.4 Exercise 03 - Implement Bias Update Rule and Observe Its Effect on Decision Boundary 1081
12.4.5 Exercise 04 - Track Weight Evolution Across Multiple Training Iterations 1082
12.4.6 Exercise 05 - Compare Single-Sample Updates vs Batch Updates in Perceptron Training 1083
12.4.7 Exercise 06 - Detect and Analyze Oscillation in Non-Separable Datasets 1084
12.4.8 Exercise 07 - Implement Training Loop Without Using PyTorch Optimizers 1085
12.4.9 Exercise 08 - Observe Convergence Speed Under Different Data Orderings 1086
12.4.10 Exercise 09 - Investigate Failure to Converge on XOR-like Distributions 1087
12.4.11 Exercise 10 - Move Training Computation to CUDA and Verify Deterministic Behavior 1088
12.4.12 Exercise 11 - Compare CPU vs GPU Weight Update Numerical Differences 1089
12.4.13 Exercise 12 - Measure the Effect of Feature Scaling on Update Magnitude 1090
12.4.14 Exercise 13 - Analyze Sensitivity of Updates to Noisy Labels 1091
12.4.15 Exercise 14 - Implement Early Stopping Criterion Based on Zero Classification Errors 1092
12.4.16 Exercise 15 - Log and Visualize Weight Trajectories During Training 1093
12.4.17 Exercise 16 - Demonstrate Catastrophic Update with Large Learning Rate 1094
12.4.18 Exercise 17 - Validate Correctness of Update Rule Using Manual Calculations 1095
12.4.19 Exercise 18 - Stress Test Update Rule with High-Dimensional Feature Space 1096

12.4.20 Exercise 19 - Produce a Detailed Failure Analysis of the Learning Rule 1097
12.5 PC03 - Training Dynamics and Convergence Theory 1098
12.5.1 Exercise 00 - Define Formal Convergence Criteria for the Perceptron Algorithm 1098
12.5.2 Exercise 01 - Experimentally Verify the Perceptron Convergence Theorem .1099
12.5.3 Exercise 02 - Analyze the Effect of Margin Size on Training Stability .1100
12.5.4 Exercise 03 - Measure Number of Updates Until Convergence 1101
12.5.5 Exercise 04 - Study the Impact of Data Ordering on Convergence Speed .1102
12.5.6 Exercise 05 - Investigate Training Behavior on Nearly Separable Data .1103
12.5.7 Exercise 06 - Demonstrate Divergence on Non-Separable Datasets 1103
12.5.8 Exercise 07 - Compare Deterministic vs Randomized Sample Ordering .1104
12.5.9 Exercise 08 - Observe Weight Norm Growth During Training 1105
12.5.10 Exercise 09 - Analyze the Relationship Between Margin and Generalization 1106
12.5.11 Exercise 10 - Run Long-Horizon Training on CUDA for Stability Observation 1107
12.5.12 Exercise 11 - Compare Float Precision Effects on Convergence 1108
12.5.13 Exercise 12 - Detect Numerical Drift in Extended Training Runs 1109
12.5.14 Exercise 13 - Visualize Convergence Trajectories in Parameter Space . .1110
12.5.15 Exercise 14 - Investigate Overfitting Behavior in Linearly Separable Data .1111
12.5.16 Exercise 15 - Analyze Training Failure Modes and Their Root Causes .1112
12.5.17 Exercise 16 - Compare Convergence Between CPU and GPU Implementations 1113
12.5.18 Exercise 17 - Stress Test Convergence with Large-Scale Synthetic Data 1114
12.5.19 Exercise 18 - Validate Theoretical Claims Using Empirical Results . . .1115
12.5.20 Exercise 19 - Write a Formal Convergence and Stability Report 1116
12.6 PC04 - Perceptron Loss Perspective and Errors 1117
12.6.1 Exercise 00 - Interpret Perceptron Learning as Error-Driven Optimization .1117
12.6.2 Exercise 01 - Define Implicit Loss Function Used by the Perceptron . .1118
12.6.3 Exercise 02 - Compare Perceptron Loss with Hinge Loss 1119
12.6.4 Exercise 03 - Analyze Zero-One Loss Limitations in Optimization . . .1120
12.6.5 Exercise 04 - Visualize Loss Landscape for Simple Perceptron Models .1120
12.6.6 Exercise 05 - Implement Perceptron Loss Manually in PyTorch 1121
12.6.7 Exercise 06 - Compare Gradient-Free Updates vs Gradient-Based Losses .1122
12.6.8 Exercise 07 - Observe Non-Smooth Loss Behavior at Decision Boundary .1123
12.6.9 Exercise 08 - Analyze Sensitivity of Loss to Margin Violations 1124
12.6.10 Exercise 09 - Study Error Accumulation Across Epochs 1125
12.6.11 Exercise 10 - Implement Loss Computation on CUDA 1126
12.6.12 Exercise 11 - Compare CPU vs GPU Loss Evaluation Consistency . . .1126
12.6.13 Exercise 12 - Examine Numerical Stability of Loss Under Extreme Values .1127
12.6.14 Exercise 13 - Relate Loss Behavior to Classification Performance 1128
12.6.15 Exercise 14 - Debug Unexpected Loss Values During Training 1129
12.6.16 Exercise 15 - Visualize Loss Evolution Over Training Iterations 1130
12.6.17 Exercise 16 - Contrast Loss-Based Training with Backprop-Based Models .1131
12.6.18 Exercise 17 - Evaluate Robustness of Loss to Label Noise 1132
12.6.19 Exercise 18 - Identify Scenarios Where Loss Minimization Fails 1133

12.6.20 Exercise 19 - Produce a Critical Analysis of Perceptron Loss Limitations 1134
12.7 PC05 - Multi-Class Perceptron Extensions 1135
12.7.1 Exercise 00 - Extend Binary Perceptron to One-vs-Rest Multi-Class Setting 1135
12.7.2 Exercise 01 - Implement Class-Specific Weight Vectors for Multi-Class Output 1136
12.7.3 Exercise 02 - Define Prediction Rule for Multi-Class Perceptron . . . 1137
12.7.4 Exercise 03 - Implement Multi-Class Training Loop with Error Updates 1137
12.7.5 Exercise 04 - Analyze Decision Regions in Multi-Class Feature Space 1138
12.7.6 Exercise 05 - Compare One-vs-Rest and One-vs-One Strategies 1139
12.7.7 Exercise 06 - Handle Class Imbalance in Multi-Class Perceptron Training 1140
12.7.8 Exercise 07 - Evaluate Multi-Class Accuracy and Confusion Matrix . . 1141
12.7.9 Exercise 08 - Observe Training Instability with Increasing Number of Classes 1142
12.7.10 Exercise 09 - Visualize Multi-Class Decision Boundaries 1143
12.7.11 Exercise 10 - Execute Multi-Class Perceptron Training on CUDA . . . 1144
12.7.12 Exercise 11 - Compare CPU vs GPU Scaling with Number of Classes 1144
12.7.13 Exercise 12 - Measure Memory Growth with Class Count 1145
12.7.14 Exercise 13 - Investigate Error Propagation Across Classes 1146
12.7.15 Exercise 14 - Analyze Misclassification Patterns in Multi-Class Setting 1147
12.7.16 Exercise 15 - Implement Weight Regularization for Multi-Class Stability 1148
12.7.17 Exercise 16 - Compare Multi-Class Perceptron with Softmax Regression 1149
12.7.18 Exercise 17 - Stress Test Multi-Class Model with High-Dimensional Inputs 1150
12.7.19 Exercise 18 - Debug Class-Specific Training Failures 1151
12.7.20 Exercise 19 - Produce a Comprehensive Multi-Class Analysis Report 1152
12.8 PC06 - Computational Performance and CUDA Effects 1153
12.8.1 Exercise 00 - Benchmark Perceptron Forward Pass on CPU vs GPU . . 1153
12.8.2 Exercise 01 - Benchmark Training Throughput on CUDA 1154
12.8.3 Exercise 02 - Measure Memory Usage During Training on GPU 1155
12.8.4 Exercise 03 - Analyze Kernel Launch Overhead for Small Batches 1156
12.8.5 Exercise 04 - Evaluate Scaling Behavior with Increasing Batch Size . . 1157
12.8.6 Exercise 05 - Compare Float32 vs Mixed Precision Performance 1158
12.8.7 Exercise 06 - Identify Performance Bottlenecks in Training Loop 1159
12.8.8 Exercise 07 - Profile CUDA Execution Using PyTorch Tools 1160
12.8.9 Exercise 08 - Optimize Data Transfer Between Host and Device 1161
12.8.10 Exercise 09 - Investigate Synchronization Overhead 1161
12.8.11 Exercise 10 - Stress Test GPU with Large-Scale Synthetic Data 1162
12.8.12 Exercise 11 - Compare Multi-GPU vs Single-GPU Perceptron Execution 1163
12.8.13 Exercise 12 - Measure Determinism Across GPU Runs 1164
12.8.14 Exercise 13 - Analyze Precision-Induced Performance Variations 1165
12.8.15 Exercise 14 - Benchmark Perceptron vs Logistic Regression Performance 1166
12.8.16 Exercise 15 - Identify When GPU Usage Is Counterproductive 1167
12.8.17 Exercise 16 - Evaluate Energy Efficiency of GPU Execution 1168
12.8.18 Exercise 17 - Optimize Training Loop for Throughput 1169
12.8.19 Exercise 18 - Detect Performance Regression After Code Changes . . . 1170
12.8.20 Exercise 19 - Produce a Performance Optimization Report 1171

12.9 PC07 - Generalization and Theoretical Limits 1172
12.9.1 Exercise 00 - Analyze Generalization Capability of the Perceptron Model 1173
12.9.2 Exercise 01 - Study the Impact of Margin on Generalization Performance 1173
12.9.3 Exercise 02 - Compare Training Accuracy vs Test Accuracy 1174
12.9.4 Exercise 03 - Investigate Overfitting in Linearly Separable Data 1175
12.9.5 Exercise 04 - Evaluate Robustness to Input Noise 1176
12.9.6 Exercise 05 - Analyze Sensitivity to Label Noise 1177
12.9.7 Exercise 06 - Explore the Effect of Regularization on Generalization . .1178
12.9.8 Exercise 07 - Compare Perceptron Generalization to Logistic Regression 1179
12.9.9 Exercise 08 - Study Bias-Variance Tradeoff in Simple Models 1180
12.9.10 Exercise 09 - Identify Scenarios Where Perceptron Generalization Fails 1181
12.9.11 Exercise 10 - Evaluate Generalization on High-Dimensional Sparse Data 1182
12.9.12 Exercise 11 - Measure Stability Across Different Random Seeds 1183
12.9.13 Exercise 12 - Compare Deterministic vs Stochastic Training Outcomes .1184
12.9.14 Exercise 13 - Analyze Generalization Under Distribution Shift 1185
12.9.15 Exercise 14 - Investigate Adversarial-Like Perturbations 1185
12.9.16 Exercise 15 - Produce Empirical Evidence Supporting Theoretical Claims 1186
12.9.17 Exercise 16 - Document Limitations of Perceptron in Real-World Data 1187
12.9.18 Exercise 17 - Compare Perceptron to Modern Linear Classifiers 1188
12.9.19 Exercise 18 - Evaluate Suitability of Perceptron for Production Use . .1189
12.9.20 Exercise 19 - Write a Critical Theoretical Review of the Perceptron . .1190
12.10PC08 - Transition to Multi-Layer Networks 1191
12.10.1 Exercise 00 - Demonstrate the Inability of Single Perceptron to Model XOR 1191
12.10.2 Exercise 01 - Manually Combine Two Perceptrons to Solve XOR 1192
12.10.3 Exercise 02 - Interpret Hidden Units as Feature Transformers 1193
12.10.4 Exercise 03 - Build a Two-Layer Perceptron Network Manually 1194
12.10.5 Exercise 04 - Compare Single-Layer vs Multi-Layer Expressiveness . . .1195
12.10.6 Exercise 05 - Analyze Decision Boundaries Formed by Two-Layer Models 1196
12.10.7 Exercise 06 - Observe Emergent Non-Linearity in Hidden Representations 1197
12.10.8 Exercise 07 - Implement Simple Two-Layer Network in PyTorch 1197
12.10.9 Exercise 08 - Compare Manual Network vs nn.Module Implementation 1198
12.10.10 Exercise 09 - Train Two-Layer Network Using Gradient-Based Optimization 1199
12.10.11 Exercise 10 - Execute Two-Layer Training on CUDA 1200
12.10.12 Exercise 11 - Visualize Hidden Layer Activations 1201
12.10.13 Exercise 12 - Study Gradient Flow Through Multiple Layers 1202
12.10.14 Exercise 13 - Analyze Training Stability in Multi-Layer Networks . . .1203
12.10.15 Exercise 14 - Compare Perceptron Training to Backpropagation 1204
12.10.16 Exercise 15 - Identify Failure Modes in Shallow Neural Networks 1205
12.10.17 Exercise 16 - Evaluate Expressive Power Gain with Additional Layers .1206
12.10.18 Exercise 17 - Bridge Conceptual Gap Between Perceptron and MLP . .1207
12.10.19 Exercise 18 - Stress Test Multi-Layer Perceptron with Complex Data .1208
12.10.20 Exercise 19 - Produce a Final Transition Report Toward Neural Networks 1209

13 MLP (Feed-Forward Network) 1211
13.1 Introduction 1211

13.1.1 What will the book teach you 1211
13.1.2 Why this book comes after the Perceptron 1213
13.1.3 How to study this book 1213
13.1.4 The Chapters (MLP00 - MLP08) included in this book 1213
13.2 MLP00 - Conceptual Foundation of MLP 1214
13.2.1 Exercise 00 - Understand Why Single Perceptron Is Insufficient for Complex Functions 1214
13.2.2 Exercise 01 - Define Feed-Forward Network as Layered Function Composition 1215
13.2.3 Exercise 02 - Interpret Hidden Layers as Learned Feature Transformers 1216
13.2.4 Exercise 03 - Compare Linear Model Output vs Multi-Layer Non-Linear Output 1216
13.2.5 Exercise 04 - Visualize Information Flow Through Multiple Layers . . .1217
13.2.6 Exercise 05 - Implement a Two-Layer Network Using Pure Tensor Operations 1218
13.2.7 Exercise 06 - Translate Mathematical MLP Formulation into PyTorch Code 1219
13.2.8 Exercise 07 - Analyze the Role of Non-Linearity Between Linear Layers 1220
13.2.9 Exercise 08 - Verify Dimensional Consistency Across All Layers 1221
13.2.10 Exercise 09 - Identify Common Conceptual Misunderstandings About Hidden Layers 1222
13.2.11 Exercise 10 - Execute Forward Pass of MLP on CUDA Device 1223
13.2.12 Exercise 11 - Compare CPU vs GPU Forward Execution Outputs . . .1223
13.2.13 Exercise 12 - Inspect Intermediate Activations at Each Hidden Layer .1224
13.2.14 Exercise 13 - Analyze the Effect of Depth on Representational Power .1225
13.2.15 Exercise 14 - Implement Forward Pass Without Using nn.Module 1226
13.2.16 Exercise 15 - Debug Shape Errors in Multi-Layer Tensor Computations 1227
13.2.17 Exercise 16 - Stress Test Forward Pass with Large Batch Sizes 1228
13.2.18 Exercise 17 - Validate Determinism of Forward Pass Under Fixed Seeds 1229
13.2.19 Exercise 18 - Examine Numerical Stability of Deep Forward Computation 1230
13.2.20 Exercise 19 - Write a Conceptual Summary Explaining Why MLP Enables Universal Approximation 1231
13.3 MLP01 - Architecture Design and Layer Composition 1233
13.3.1 Exercise 00 - Design a Configurable MLP Architecture with Variable Depth 1233
13.3.2 Exercise 01 - Implement MLP Using nn.Module and nn.Linear Layers .1234
13.3.3 Exercise 02 - Dynamically Build Network from Layer Configuration List 1235
13.3.4 Exercise 03 - Register Parameters Correctly for Arbitrary Network Depth 1235
13.3.5 Exercise 04 - Verify Parameter Count for Custom Architectures 1237
13.3.6 Exercise 05 - Inspect Weight and Bias Shapes for Each Layer 1238
13.3.7 Exercise 06 - Implement Forward Hook to Capture Intermediate Outputs 1238
13.3.8 Exercise 07 - Compare Shallow vs Deep Architectures on Same Task 1239
13.3.9 Exercise 08 - Analyze Trade-Off Between Width and Depth 1240

13.3.10 Exercise 09 - Detect Architecture-Induced Bottlenecks 1241
13.3.11 Exercise 10 - Move Entire Architecture to CUDA and Validate Placement 1242
13.3.12 Exercise 11 - Debug Device Mismatch Errors in Multi-Layer Networks 1243
13.3.13 Exercise 12 - Test Forward Compatibility with Different Input Shapes 1244
13.3.14 Exercise 13 - Clone Architecture and Compare Parameter Independence 1245
13.3.15 Exercise 14 - Save and Reload Architecture with State Dict 1246
13.3.16 Exercise 15 - Stress Test Architecture Creation with Large Layer Counts 1247
13.3.17 Exercise 16 - Evaluate Memory Footprint of Deep Architectures 1248
13.3.18 Exercise 17 - Compare Manual Tensor Implementation vs nn.Module 1250
13.3.19 Exercise 18 - Identify Architectural Failure Modes Early 1251
13.3.20 Exercise 19 - Produce an Architecture Design Rationale Document 1252
13.4 MLP02 - Activation Functions and Non-Linearity 1253
13.4.1 Exercise 00 - Implement ReLU Activation and Observe Its Piecewise Behavior 1253
13.4.2 Exercise 01 - Compare ReLU, Sigmoid, and Tanh in Forward Propagation 1254
13.4.3 Exercise 02 - Visualize Activation Output Distributions Across Layers 1255
13.4.4 Exercise 03 - Analyze Gradient Flow for Different Activation Choices 1256
13.4.5 Exercise 04 - Demonstrate Vanishing Gradient in Deep Sigmoid Networks 1257
13.4.6 Exercise 05 - Demonstrate Dying ReLU Phenomenon Experimentally 1258
13.4.7 Exercise 06 - Implement LeakyReLU and Compare Gradient Behavior 1259
13.4.8 Exercise 07 - Test GELU Activation in Deep Networks 1260
13.4.9 Exercise 08 - Evaluate Activation Choice Impact on Training Stability 1261
13.4.10 Exercise 09 - Debug Activation-Induced Training Failures 1262
13.4.11 Exercise 10 - Execute Activation Functions on CUDA and Compare Performance 1263
13.4.12 Exercise 11 - Compare Float Precision Effects on Activation Output 1264
13.4.13 Exercise 12 - Track Activation Saturation Across Layers 1265
13.4.14 Exercise 13 - Instrument Network to Log Activation Statistics 1266
13.4.15 Exercise 14 - Replace Activation Mid-Training and Observe Effects 1267
13.4.16 Exercise 15 - Analyze Activation Interaction with Weight Initialization 1268

13.4.17 Exercise 16 - Compare Custom Activation vs Built-In PyTorch Activation 1269
13.4.18 Exercise 17 - Stress Test Activations Under Extreme Inputs 1270
13.4.19 Exercise 18 - Identify Scenarios Where Activation Choice Dominates Performance 1271
13.4.20 Exercise 19 - Write an Activation Function Selection Guide Based on Experiments 1272
13.5 MLP03 - Backpropagation Mechanics in MLP 1273
13.5.1 Exercise 00 - Perform a Full Forward Pass and Confirm Autograd Graph Construction 1273
13.5.2 Exercise 01 - Compute Loss and Trigger Backward Pass Through Multiple Layers 1274
13.5.3 Exercise 02 - Inspect Gradients of Each Layer and Verify Their Tensor Shapes 1275
13.5.4 Exercise 03 - Validate Gradient Flow by Checking Non-Zero Gradients in Hidden Layers 1276
13.5.5 Exercise 04 - Demonstrate Vanishing Gradients in Deep Networks Using Saturating Activations 1277
13.5.6 Exercise 05 - Demonstrate Exploding Gradients and Apply Gradient Clipping Correctly 1278
13.5.7 Exercise 06 - Compare Manual Gradient Computation vs Autograd for a Small Network 1279
13.5.8 Exercise 07 - Verify Backward Correctness Using Finite Difference Gradient Checking 1280
13.5.9 Exercise 08 - Detect and Fix Common Backprop Bugs Caused by Detached Tensors 1281
13.5.10 Exercise 09 - Debug Gradient Mismatch Caused by Wrong Loss Reduction Mode 1282
13.5.11 Exercise 10 - Execute Backward Pass on CUDA and Validate Gradient Consistency 1283
13.5.12 Exercise 11 - Investigate CPU vs GPU Gradient Parity Under Different Random Seeds 1284
13.5.13 Exercise 12 - Compare float32 vs float64 Gradients for Stability and Precision Insights 1285
13.5.14 Exercise 13 - Use Autograd Hooks to Log Gradient Norms Layer by Layer During Training 1287
13.5.15 Exercise 14 - Prove the Need for zero_grad by Demonstrating Gradient Accumulation Errors 1288
13.5.16 Exercise 15 - Analyze the Effect of Batch Size on Gradient Variance and Update Stability 1289
13.5.17 Exercise 16 - Demonstrate Graph Retention Costs Using retain_graph and Memory Profiling 1290
13.5.18 Exercise 17 - Debug Device Mismatch Errors During Backward Computation on CUDA 1291
13.5.19 Exercise 18 - Stress Test Backpropagation with Deep Architecture and Large Batch Inputs 1292
13.5.20 Exercise 19 - Write a Full Backprop Debugging Playbook Based on Observed Failure Modes 1293

13.6 MLP04 - Weight Initialization and Training Stability 1295
13.6.1 Exercise 00 - Implement Zero Initialization and Observe Symmetry Failure in Hidden Units 1295
13.6.2 Exercise 01 - Compare Random Uniform vs Random Normal Initialization in Early Training 1296
13.6.3 Exercise 02 - Implement Xavier Initialization and Validate Activation Variance Preservation 1297
13.6.4 Exercise 03 - Implement He Initialization and Validate ReLU-Compatible Gradient Flow 1298
13.6.5 Exercise 04 - Track Activation Statistics to Confirm Initialization Quality Across Layers 1299
13.6.6 Exercise 05 - Track Gradient Statistics to Detect Early Instability from Bad Initialization 1300
13.6.7 Exercise 06 - Demonstrate Training Collapse Caused by Extreme Initialization Scale 1301
13.6.8 Exercise 07 - Compare Training Speed Under Different Initializations Using the Same Dataset 1302
13.6.9 Exercise 08 - Analyze How Initialization Interacts with Activation Choice (ReLU vs Tanh) 1303
13.6.10 Exercise 09 - Debug NaN Loss Caused by Unstable Initialization and Fix the Root Cause 1304
13.6.11 Exercise 10 - Run Initialization Experiments on CUDA and Profile Startup Training Stability 1305
13.6.12 Exercise 11 - Compare float32 vs mixed precision Training Stability for Each Initialization 1306
13.6.13 Exercise 12 - Implement Custom Parameter Initializer for Arbitrary Network Depth 1307
13.6.14 Exercise 13 - Measure Layer-Wise Signal Propagation Depth Before Saturation Occurs 1308
13.6.15 Exercise 14 - Diagnose Dying ReLU Caused by Initialization and Apply LeakyReLU Fix 1309
13.6.16 Exercise 15 - Show How Bias Initialization Influences Early Learning and Decision Boundaries 1309
13.6.17 Exercise 16 - Compare Built-In PyTorch init Methods with Your Manual Implementations 1310
13.6.18 Exercise 17 - Stress Test Initialization with Very Deep Networks and Monitor Memory Usage 1311
13.6.19 Exercise 18 - Create a Reproducible Initialization Benchmark Report with Controlled Seeds 1313
13.6.20 Exercise 19 - Produce a Practical Initialization Selection Guide for Real Training Projects 1314
13.7 MLP05 - Optimizers and Learning Rate Dynamics 1315
13.7.1 Exercise 00 - Implement Manual SGD Updates and Verify Parameter Changes Step by Step 1315
13.7.2 Exercise 01 - Compare SGD vs Momentum and Observe Convergence Differences 1316
13.7.3 Exercise 02 - Implement Adam Optimizer and Track Bias Correction Behavior 1317

13.7.4 Exercise 03 - Compare Adam vs AdamW and Identify Weight Decay Differences in Practice 1318
13.7.5 Exercise 04 - Perform Learning Rate Sweep and Identify Divergence Threshold 1319
13.7.6 Exercise 05 - Implement Learning Rate Scheduler and Validate Step Timing and Effects 1319
13.7.7 Exercise 06 - Diagnose Slow Convergence Caused by Too-Low Learning Rate and Fix It 1320
13.7.8 Exercise 07 - Diagnose Divergence Caused by Too-High Learning Rate and Stabilize Training 1321
13.7.9 Exercise 08 - Implement Gradient Clipping and Measure Its Effect on Optimization Stability 1322
13.7.10 Exercise 09 - Compare Optimization Under Different Batch Sizes to Observe Noise Benefits 1323
13.7.11 Exercise 10 - Execute Optimizer Steps on CUDA and Validate Parameter Device Placement 1323
13.7.12 Exercise 11 - Profile Optimizer Overhead on GPU and Identify Bottlenecks in Update Step 1324
13.7.13 Exercise 12 - Compare Mixed Precision vs Full Precision Optimization Dynamics on the Same Task 1325
13.7.14 Exercise 13 - Implement Gradient Accumulation to Simulate Larger Batch Size on Limited GPU Memory 1326
13.7.15 Exercise 14 - Verify Determinism and Reproducibility Under Fixed Seeds and Controlled Settings 1327
13.7.16 Exercise 15 - Detect and Fix Silent Training Bugs Caused by Missing zero_grad or Wrong Order 1328
13.7.17 Exercise 16 - Implement Weight Decay Correctly and Demonstrate Difference from L2 Regularization 1329
13.7.18 Exercise 17 - Benchmark Convergence Speed for Multiple Optimizers and Summarize Results 1330
13.7.19 Exercise 18 - Monitor Gradient Norms and Parameter Norms to Detect Impending Instability Early 1330
13.7.20 Exercise 19 - Write an Optimization Debugging Checklist Covering All Common Training Failures 1331
13.8 MLP06 - Loss Functions, Training Loop, and Logging 1332
13.8.1 Exercise 00 - Build a Minimal Training Loop with Proper Train/Eval Separation and Correct Modes 1332
13.8.2 Exercise 01 - Implement Classification Training Using CrossEntropyLoss and Validate Label Encoding 1333
13.8.3 Exercise 02 - Implement Regression Training Using MSELoss and Validate Output Shapes 1334
13.8.4 Exercise 03 - Add Accurate Metric Tracking and Ensure Metrics Match Ground Truth Calculations 1335
13.8.5 Exercise 04 - Implement Validation Loop and Detect Overfitting Using Train vs Val Curves 1336
13.8.6 Exercise 05 - Add Early Stopping Logic and Confirm It Prevents Wasteful Training Iterations 1337

13.8.7 Exercise 06 - Add Checkpoint Saving and Restore Training from Checkpoint Without Drift 1338
13.8.8 Exercise 07 - Implement Resume Training with Scheduler and Optimizer State Preservation 1339
13.8.9 Exercise 08 - Add Structured Logging and Verify Logs Are Correct for Every Epoch 1339
13.8.10 Exercise 09 - Debug Training Loop Bugs That Produce Good Loss but Bad Accuracy 1340
13.8.11 Exercise 10 - Train Entire Pipeline on CUDA and Ensure Data, Model, and Loss Are on Same Device 1341
13.8.12 Exercise 11 - Measure GPU Utilization During Training and Identify Under-Utilization Root Causes 1342
13.8.13 Exercise 12 - Implement Mixed Precision Training with GradScaler and Detect Silent Overflow Issues 1343
13.8.14 Exercise 13 - Create a Reproducible Experiment Template with Seeds, Configs, and Version Logs 1344
13.8.15 Exercise 14 - Implement Gradient Accumulation in Training Loop and Validate Equivalent Results 1345
13.8.16 Exercise 15 - Handle NaN Loss During Training by Adding Detection and Immediate Diagnostics 1346
13.8.17 Exercise 16 - Implement Batch-Level Debug Mode to Inspect Failing Samples During Training 1347
13.8.18 Exercise 17 - Benchmark Training Throughput Under Different DataLoader Settings and Pin Memory 1348
13.8.19 Exercise 18 - Validate End-to-End Training Correctness by Overfitting a Tiny Dataset on Purpose 1349
13.8.20 Exercise 19 - Produce a Full Training Loop Debugging and Verification Report 1350
13.9 MLP07 - Regularization, Dropout, and Generalization 1351
13.9.1 Exercise 00 - Demonstrate Overfitting in MLP by Training on Small Dataset Without Regularization 1351
13.9.2 Exercise 01 - Apply L2 Regularization and Measure Its Effect on Train vs Validation Gap 1351
13.9.3 Exercise 02 - Apply Weight Decay Correctly and Compare It Against L2 Regularization Implementation 1352
13.9.4 Exercise 03 - Implement Dropout Layer and Verify Behavior Differs Between Train and Eval Modes 1353
13.9.5 Exercise 04 - Tune Dropout Probability and Identify Underfitting vs Overfitting Patterns 1354
13.9.6 Exercise 05 - Combine Dropout with Weight Decay and Analyze Interaction Effects 1355
13.9.7 Exercise 06 - Implement Early Stopping and Compare Against Regularization Techniques 1356
13.9.8 Exercise 07 - Study the Effect of Model Capacity (Depth/Width) on Generalization Behavior 1357
13.9.9 Exercise 08 - Demonstrate Data Augmentation Concept for Non-Image Tabular Tasks 1357

13.9.10 Exercise 09 - Debug Regularization Misuse That Causes Training Collapse or No Learning 1358
13.9.11 Exercise 10 - Execute Regularized Training on CUDA and Measure Runtime Overhead of Dropout 1359
13.9.12 Exercise 11 - Compare Regularization Outcomes Under Mixed Precision Training 1360
13.9.13 Exercise 12 - Analyze Generalization Under Label Noise and Apply Robust Training Strategies 1361
13.9.14 Exercise 13 - Study the Effect of Input Feature Normalization on Generalization Stability 1362
13.9.15 Exercise 14 - Implement K-Fold Cross Validation and Compare Model Stability Across Folds 1363
13.9.16 Exercise 15 - Diagnose Underfitting and Identify Whether It Comes from Regularization or Capacity Limits 1363
13.9.17 Exercise 16 - Build a Generalization Report with Error Breakdown and Residual Analysis 1364
13.9.18 Exercise 17 - Evaluate Robustness Under Distribution Shift and Document Observed Failure Patterns 1365
13.9.19 Exercise 18 - Implement Model Ensembling of Multiple MLP Runs and Compare Generalization Gains 1366
13.9.20 Exercise 19 - Write a Practical Regularization Strategy Guide for Real Training Projects 1367
13.10MLP08 - Scaling, Profiling, and Production Readiness 1368
13.10.1 Exercise 00 - Profile MLP Training Performance and Identify Whether Compute or Data Is the Bottleneck 1368
13.10.2 Exercise 01 - Measure DataLoader Impact Using num_workers and Pin Memory Configuration 1369
13.10.3 Exercise 02 - Implement Gradient Accumulation for Memory-Constrained GPUs and Validate Equivalence 1370
13.10.4 Exercise 03 - Implement Mixed Precision Training and Quantify Speed vs Stability Tradeoffs 1371
13.10.5 Exercise 04 - Compare Different Batch Sizes and Identify the Throughput-Optimal Configuration 1372
13.10.6 Exercise 05 - Monitor GPU Utilization and Fix Under-Utilization Caused by Input Pipeline Issues 1372
13.10.7 Exercise 06 - Benchmark Inference Latency and Throughput for Production Deployment Settings 1373
13.10.8 Exercise 07 - Export MLP Model Using TorchScript or torch.compile and Validate Output Parity 1374
13.10.9 Exercise 08 - Implement Checkpoint Rotation and Storage Strategy for Long Training Runs 1375
13.10.10 Exercise 09 - Detect Memory Leaks and Unexpected GPU Growth Across Long Training Sessions 1376
13.10.11 Exercise 10 - Integrate Model Saving into Object Storage Workflow and Validate Retrieval Correctness 1377
13.10.12 Exercise 11 - Build a Minimal Inference API Wrapper and Validate Input Validation and Error Handling 1378

13.10.13 Exercise 12 - Implement Deterministic Training Controls and Explain Remaining Sources of Non-Determinism 1379
13.10.14 Exercise 13 - Add Full Experiment Tracking and Ensure Reproducibility Across Machines and GPUs 1380
13.10.15 Exercise 14 - Stress Test Training at Scale with Large Synthetic Dataset and Monitor System Limits 1381
13.10.16 Exercise 15 - Validate Correctness by Intentionally Overfitting Tiny Dataset and Confirming Perfect Fit 1382
13.10.17 Exercise 16 - Implement Regression Tests That Detect Training Quality Degradation After Refactors 1382
13.10.18 Exercise 17 - Build a Production Readiness Checklist Covering Performance, Stability, and Monitoring 1383
13.10.19 Exercise 18 - Simulate Failure Recovery by Resuming from Checkpoint After Forced Interruption 1384
13.10.20 Exercise 19 - Produce a Final End-to-End MLP Engineering Report with Lessons Learned and Best Practices 1385

14 CNN (Convolutional Neural Networks) 1387
14.1 Introduction 1387
14.1.1 What will the book teach you 1387
14.1.2 Why this book comes after the MLP 1389
14.1.3 How to study this book 1389
14.1.4 The Chapters (CNN00 - CNN08) included in this book 1390
14.2 CNN00 - Convolution Concept and Intuition 1390
14.2.1 Exercise 00 - Understand Convolution as Local Pattern Detection Instead of Global Fully-Connected Mixing 1390
14.2.2 Exercise 01 - Implement a Simple 2D Convolution Using Explicit Nested Loops for Full Transparency 1391
14.2.3 Exercise 02 - Implement Cross-Correlation and Explain Why Deep Learning Calls It Convolution 1392
14.2.4 Exercise 03 - Visualize How a Kernel Slides Over an Image and Produces a Feature Map 1393
14.2.5 Exercise 04 - Verify Convolution Output Shape by Manual Calculation Using Kernel Size and Stride 1394
14.2.6 Exercise 05 - Compare Different Kernel Sizes and Observe How Receptive Field Changes 1395
14.2.7 Exercise 06 - Demonstrate the Effect of Stride on Downsampling and Information Loss 1396
14.2.8 Exercise 07 - Demonstrate the Effect of Padding on Border Information Preservation and Output Size 1397

14.2.9 Exercise 08 - Implement Convolution with torch.nn.functional.conv2d and Validate It Against Manual Output 1398
14.2.10 Exercise 09 - Create Multiple Filters and Observe How Each Detects Different Visual Patterns 1399
14.2.11 Exercise 10 - Move Convolution to CUDA and Confirm Numerical Parity with CPU Results 1400
14.2.12 Exercise 11 - Benchmark CPU vs GPU Convolution Runtime for Small and Large Input Tensors 1401
14.2.13 Exercise 12 - Compare float32 and float16 Convolution Outputs and Detect Precision-Sensitive Cases 1402
14.2.14 Exercise 13 - Understand Channels-First Format (N,C,H,W) and Debug Common Shape Mistakes 1402
14.2.15 Exercise 14 - Implement 1x1 Convolution and Explain Channel Mixing Without Spatial Mixing 1403
14.2.16 Exercise 15 - Demonstrate Convolution as Matrix Multiplication with im2col on a Tiny Example 1404
14.2.17 Exercise 16 - Stress Test Convolution with Large Batches and Monitor GPU Memory Consumption 1405
14.2.18 Exercise 17 - Debug Device Mismatch and Non-Contiguous Tensor Issues in Convolution Pipelines 1406
14.2.19 Exercise 18 - Validate Determinism Settings and Observe When CUDA Convolution Becomes Non-Deterministic 1407
14.2.20 Exercise 19 - Write a Conceptual Report Explaining Why Convolution Is the Core Inductive Bias for Vision 1408
14.3 CNN01 - Feature Maps, Filters, and Receptive Fields 1409
14.3.1 Exercise 00 - Compute Feature Map Dimensions for Multiple Conv Layers Using Manual Step-by-Step Formula 1409
14.3.2 Exercise 01 - Visualize How Receptive Field Grows with Depth Using a Simple Layer Stack 1410
14.3.3 Exercise 02 - Show How Increasing Channels Raises Representation Capacity Without Increasing Resolution 1411
14.3.4 Exercise 03 - Implement Multi-Channel Convolution and Explain the Channel Summation Mechanism Clearly 1412

14.3.5 Exercise 04 - Verify Kernel Tensor Shape (out_channels,in_channels,kH,kW) and Debug Wrong Ordering Bugs 1413
14.3.6 Exercise 05 - Compare Edge-Detector Kernels on Synthetic Pattern Images and Observe Their Responses 1414
14.3.7 Exercise 06 - Create Custom Kernels to Detect Horizontal, Vertical, and Diagonal Structures 1415
14.3.8 Exercise 07 - Demonstrate Translation Equivariance by Shifting Input and Observing Shifted Feature Maps 1416
14.3.9 Exercise 08 - Demonstrate When Translation Equivariance Breaks Due to Padding or Stride Choices 1417
14.3.10 Exercise 09 - Analyze How Stride Impacts Aliasing and Feature Map Quality Using Visual Examples 1417
14.3.11 Exercise 10 - Run Feature Map Extraction on CUDA and Verify Output Shape and Device Placement 1418
14.3.12 Exercise 11 - Benchmark Different Kernel Sizes and Strides on GPU to Measure Real Performance Differences 1419
14.3.13 Exercise 12 - Investigate Numerical Differences Between CPU and GPU Feature Maps Under Various Seeds 1420
14.3.14 Exercise 13 - Implement Depthwise Convolution Manually and Explain How It Differs from Standard Convolution 1421
14.3.15 Exercise 14 - Implement Grouped Convolution and Prove It Reduces Parameters While Preserving Some Representation Power 1422
14.3.16 Exercise 15 - Compare Standard, Depthwise, and Grouped Convolutions in Parameters, Speed, and Feature Quality 1423
14.3.17 Exercise 16 - Detect and Fix Shape Errors When Switching Between RGB and Grayscale Inputs 1424
14.3.18 Exercise 17 - Stress Test a Very Deep Conv Stack and Monitor Activation Magnitudes for Stability Issues 1425
14.3.19 Exercise 18 - Build a Receptive Field Calculator and Validate It Against Empirical Behavior 1426
14.3.20 Exercise 19 - Produce a Receptive Field and Feature Map Interpretation Guide for Future Debugging 1427
14.4 CNN02 - Pooling, Downsampling, and Invariance 1428

14.4.1 Exercise 00 - Implement Max Pooling Manually and Verify It Matches torch.nn.functional.max_pool2d 1428
14.4.2 Exercise 01 - Implement Average Pooling and Compare Its Behavior to Max Pooling on the Same Input 1429
14.4.3 Exercise 02 - Explain and Demonstrate Why Pooling Introduces Local Translation Invariance 1430
14.4.4 Exercise 03 - Compare Pooling and Strided Convolution for Downsampling and Measure Quality Differences 1431
14.4.5 Exercise 04 - Analyze Pooling Window Size, Information Loss, and Classification Performance 1432
14.4.6 Exercise 05 - Visualize Aliasing from Aggressive Downsampling Without Anti-Aliasing 1433
14.4.7 Exercise 06 - Implement Global Average Pooling and Explain Its Role in Modern CNN Classifier Heads 1434
14.4.8 Exercise 07 - Demonstrate Adaptive Pooling with Variable Input Image Sizes 1435
14.4.9 Exercise 08 - Compare Feature Map Statistics Before and After Pooling to Understand Signal Compression 1436
14.4.10 Exercise 09 - Debug Output Shape Mistakes from Pooling and Stride Interactions in Complex Networks 1437
14.4.11 Exercise 10 - Run Pooling on CUDA and Confirm Correctness and Speed Benefits 1438
14.4.12 Exercise 11 - Benchmark Pooling and Strided Convolution Runtime and GPU Memory Usage 1439
14.4.13 Exercise 12 - Investigate Pooling Precision Under float16 Mixed Precision Settings 1440
14.4.14 Exercise 13 - Implement Anti-Aliased Pooling and Compare It with Standard Pooling 1441
14.4.15 Exercise 14 - Implement Blur Pooling and Measure Its Effect on Robustness 1441
14.4.16 Exercise 15 - Analyze When Pooling Helps or Hurts Based on Dataset Structure 1442
14.4.17 Exercise 16 - Stress Test Deep Downsampling Stacks and Detect Feature Collapse or Excessive Information Loss 1443
14.4.18 Exercise 17 - Build a Shape-Tracking Utility for Spatial Changes Through a CNN Pipeline 1444
14.4.19 Exercise 18 - Create a Downsampling Strategy Comparison Report Using Multiple Configurations 1445
14.4.20 Exercise 19 - Write a Practical Guide for Selecting Pooling, Stride, or Global Pooling in Real CNNs 1446
14.5 CNN03 - CNN Forward Architecture and Implementation 1447

14.5.1 Exercise 00 - Build a Minimal CNN Classifier and Verify Forward Pass Output Dimensions 1448
14.5.2 Exercise 01 - Implement CNN with nn.Sequential and Compare It to Explicit Forward Function Style 1449
14.5.3 Exercise 02 - Add ReLU Between Conv Layers and Confirm Non-Linearity Changes Representation 1450
14.5.4 Exercise 03 - Implement Flatten Correctly and Debug Batch Dimension Mistakes 1450
14.5.5 Exercise 04 - Replace Flatten and Fully Connected Head with Global Average Pooling and Compare Cost 1451
14.5.6 Exercise 05 - Add Dropout to the CNN Classifier Head and Verify Train and Eval Behavior 1452
14.5.7 Exercise 06 - Implement Batch Normalization and Verify Running Statistics and Mode Switching 1453
14.5.8 Exercise 07 - Add a Residual-Like Skip Connection and Verify Shape Compatibility 1454
14.5.9 Exercise 08 - Inspect Intermediate Feature Maps with Forward Hooks and Save Them for Debugging 1455
14.5.10 Exercise 09 - Debug CNN Forward Failures: Shape Mismatch, NaNs, and Wrong Channel Ordering 1456
14.5.11 Exercise 10 - Move a Full CNN Forward Pass to CUDA and Confirm Shared Device Placement 1457
14.5.12 Exercise 11 - Benchmark Forward Throughput and Identify Expensive Layers on GPU 1458
14.5.13 Exercise 12 - Compare float32 and Mixed Precision Forward Outputs and Detect Sensitive Layers 1459
14.5.14 Exercise 13 - Implement a Configurable CNN Builder from a Layer Specification List 1460
14.5.15 Exercise 14 - Validate Parameter Count and Memory Footprint for Multiple CNN Architecture Variants 1461
14.5.16 Exercise 15 - Test CNN Forward Robustness Across Input Sizes with Adaptive Pooling 1462
14.5.17 Exercise 16 - Create Unit Tests for Output Shapes and Dtypes at Every CNN Layer 1463
14.5.18 Exercise 17 - Stress Test CNN Forward with Large Batches and Monitor GPU Memory Peaks 1464

14.5.19 Exercise 18 - Implement a Minimal CNN Inference Wrapper and Validate Preprocessing Requirements 1465
14.5.20 Exercise 19 - Produce a CNN Forward Design Report Explaining Architecture Choices and Their Effects 1466
14.6 CNN04 - CNN Training Loop, Loss, and Backpropagation 1466
14.6.1 Exercise 00 - Build a Complete CNN Training Loop with Correct Train/Eval Modes and Loss Computation 1467
14.6.2 Exercise 01 - Overfit a Tiny Dataset to Validate End-to-End CNN Correctness 1468
14.6.3 Exercise 02 - Compare CrossEntropyLoss and BCEWithLogitsLoss for Binary Image Classification 1468
14.6.4 Exercise 03 - Inspect Layer-Wise Gradients and Detect Vanishing or Exploding Patterns 1469
14.6.5 Exercise 04 - Validate Backpropagation with Finite Differences on a Tiny CNN 1470
14.6.6 Exercise 05 - Debug NaN Loss by Checking Inputs, Initialization, and Learning Rate 1471
14.6.7 Exercise 06 - Implement Gradient Clipping and Measure Its Stabilizing Effect 1472
14.6.8 Exercise 07 - Implement Learning Rate Scheduling and Verify Step Timing and Outcome 1473
14.6.9 Exercise 08 - Compare SGD and Adam on the Same CNN and Explain Outcome Differences 1474
14.6.10 Exercise 09 - Debug Training Where Loss Improves but Accuracy Does Not Improve 1474
14.6.11 Exercise 10 - Train CNN on CUDA with Correct DataLoader Transfer and Pinned Memory 1475
14.6.12 Exercise 11 - Profile GPU Utilization and Fix Training Under-Utilization Bottlenecks 1476
14.6.13 Exercise 12 - Implement Mixed Precision CNN Training and Detect Silent Overflow or Underflow 1477
14.6.14 Exercise 13 - Validate Determinism Options and Explain CNN Training Non-Determinism 1478
14.6.15 Exercise 14 - Implement Checkpoint Resume with Optimizer and Scheduler State Preservation 1479
14.6.16 Exercise 15 - Benchmark Training Throughput Across Batch Sizes and Find the Best Trade-Off 1480

14.6.17 Exercise 16 - Implement Gradient Accumulation for Memory-Constrained Large-Batch Training 1481
14.6.18 Exercise 17 - Build Debug Mode That Saves Misclassified Images and Confidence Scores 1482
14.6.19 Exercise 18 - Validate Training by Reaching Near-Perfect Accuracy on a Simple Synthetic Task 1483
14.6.20 Exercise 19 - Produce a Full CNN Training Debugging Playbook Covering Common Failure Scenarios 1483
14.7 CNN05 - Data Pipeline and Augmentation for Vision 1484
14.7.1 Exercise 00 - Implement Image Dataset Loading with Correct Normalization and Tensor Conversion 1484
14.7.2 Exercise 01 - Validate Channel Ordering and Normalization by Visualizing a Preprocessed Batch 1485
14.7.3 Exercise 02 - Implement Train and Test Splits and Confirm No Data Leakage 1486
14.7.4 Exercise 03 - Implement Random Crop and Horizontal Flip and Measure Generalization Impact 1487
14.7.5 Exercise 04 - Implement Color Jitter and Analyze When It Helps or Hurts Specific Datasets 1488
14.7.6 Exercise 05 - Implement Random Rotation and Analyze Its Effect on Model Invariance 1488
14.7.7 Exercise 06 - Implement Random Erasing or Cutout and Evaluate Its Regularization Effect 1489
14.7.8 Exercise 07 - Implement MixUp or CutMix and Compare with Standard Augmentation 1490
14.7.9 Exercise 08 - Optimize DataLoader with num_workers and pin_memory and Benchmark It 1491
14.7.10 Exercise 09 - Debug Data Pipeline Bugs Causing Wrong Labels or Broken Image Tensors 1491
14.7.11 Exercise 10 - Move the Data Pipeline to CUDA Efficiently and Measure Transfer Overhead 1492
14.7.12 Exercise 11 - Implement Prefetching and Compare It with a Baseline DataLoader 1493
14.7.13 Exercise 12 - Analyze Image Resolution Trade-Offs in Accuracy, Speed, and GPU Memory 1494
14.7.14 Exercise 13 - Detect Augmentation Bugs That Destroy Class Semantics or Introduce Label Noise 1494
14.7.15 Exercise 14 - Implement Balanced Sampling for Imbalanced Image Datasets 1495

14.7.16 Exercise 15 - Build an Augmentation Ablation Study and Identify What Actually Helps 1496
14.7.17 Exercise 16 - Compare Per-Dataset and Per-Image Normalization Strategies 1497
14.7.18 Exercise 17 - Create a Data Quality Report for Corruption, Duplicates, and Outliers 1498
14.7.19 Exercise 18 - Stress Test DataLoader Throughput and Debug Crashes or Deadlocks 1498
14.7.20 Exercise 19 - Produce a Practical Vision Data Pipeline Checklist for Training-Ready Datasets 1499
14.8 CNN06 - Regularization, Normalization, and Robustness 1500
14.8.1 Exercise 00 - Demonstrate CNN Overfitting Without Regularization and Observe the Generalization Gap 1500
14.8.2 Exercise 01 - Apply Weight Decay and Quantify Training Stability and Validation Performance 1501
14.8.3 Exercise 02 - Compare Dropout in the Classifier Head and Convolutional Blocks 1502
14.8.4 Exercise 03 - Implement BatchNorm and Explain Its Effect on Optimization and Gradient Flow 1502
14.8.5 Exercise 04 - Compare BatchNorm and LayerNorm in CNN Settings and Explain When Each Fits 1503
14.8.6 Exercise 05 - Diagnose Instability from Wrong Normalization Placement and Fix the Root Cause 1504
14.8.7 Exercise 06 - Evaluate Robustness to Input Noise and Blurring and Compare Degradation Patterns 1504
14.8.8 Exercise 07 - Evaluate Random Occlusion and Test Use of Global Context 1505
14.8.9 Exercise 08 - Implement Label Smoothing and Measure Overconfidence and Calibration 1506
14.8.10 Exercise 09 - Debug Regularization Misconfiguration Causing Underfitting or Failure to Learn 1506
14.8.11 Exercise 10 - Train Regularized CNN on CUDA and Measure Technique Runtime and Memory Overhead 1507
14.8.12 Exercise 11 - Compare Mixed Precision Stability With and Without Normalization Layers 1508
14.8.13 Exercise 12 - Perform a Regularization Ablation Study and Identify What Actually Helps 1508

14.8.14 Exercise 13 - Detect Distribution Shift Under Changed Lighting or Color and Measure Generalization Failure 1509
14.8.15 Exercise 14 - Implement Test-Time Augmentation and Decide Whether It Adds Robustness or Noise 1510
14.8.16 Exercise 15 - Evaluate Adversarial-Like Perturbations and Document CNN Sensitivity Patterns 1510
14.8.17 Exercise 16 - Build a Robustness Report Grouping Misclassifications by Failure Type and Confidence 1511
14.8.18 Exercise 17 - Analyze Calibration Error and Build a Reliability Diagram for Overconfidence 1512
14.8.19 Exercise 18 - Implement CNN Ensembling and Quantify Accuracy and Robustness Improvements 1512
14.8.20 Exercise 19 - Write a Practical CNN Regularization Strategy Guide for Training and Deployment 1513
14.9 CNN07 - Modern CNN Blocks and Architectural Patterns 1514
14.9.1 Exercise 00 - Implement a VGG-Style Block and Analyze Parameters and Feature Behavior 1514
14.9.2 Exercise 01 - Implement a Residual Block and Explain Improved Gradient Flow 1514
14.9.3 Exercise 02 - Validate Residual Addition Shapes and Debug Channel Mismatch Errors 1515
14.9.4 Exercise 03 - Implement a Bottleneck Residual Block and Compare Its Efficiency with a Standard Block 1516
14.9.5 Exercise 04 - Implement Depthwise Separable Convolution and Quantify Parameter and FLOPs Reduction 1516
14.9.6 Exercise 05 - Implement a MobileNetV2-Style Inverted Residual and Explain the Expansion Ratio 1517
14.9.7 Exercise 06 - Implement Squeeze-and-Excitation Attention and Measure Feature Selectivity 1517
14.9.8 Exercise 07 - Compare Standard, Depthwise Separable, and Grouped Convolution Speed on GPU 1518
14.9.9 Exercise 08 - Build a Small CNN with Modern Blocks and Validate Its Forward Pass 1519
14.9.10 Exercise 09 - Debug Stride Placement and Residual Path Misalignment Bugs 1519
14.9.11 Exercise 10 - Train a Modern-Block CNN on CUDA and Benchmark It Against a Simple Baseline 1520
14.9.12 Exercise 11 - Profile GPU Utilization and Identify Block-Level Bottlenecks 1520

14.9.13 Exercise 12 - Compare Memory Usage of VGG-Style and Residual Architectures 1521
14.9.14 Exercise 13 - Implement Stochastic Depth and Observe Regularization in Deep Residual Networks 1522
14.9.15 Exercise 14 - Implement DropPath and Verify It Activates Only During Training 1522
14.9.16 Exercise 15 - Compare Accuracy and Robustness Across Architectural Pattern Choices 1523
14.9.17 Exercise 16 - Build an Ablation Study Removing One Block Type at a Time and Measure Impact 1523
14.9.18 Exercise 17 - Create an Architecture Summary with Parameters, FLOPs, Speed, and Accuracy 1524
14.9.19 Exercise 18 - Stress Test a Deep Modern CNN for NaNs, Instability, and Memory Blowups 1525
14.9.20 Exercise 19 - Produce a Modern CNN Architecture Guide for Efficient Vision Models 1525
14.10CNN08 - Deployment, Export, and Production Readiness 1526
14.10.1 Exercise 00 - Benchmark CNN Inference Latency and Throughput Under Production-Like Batch and Precision Settings . . .1526
14.10.2 Exercise 01 - Export CNN Using TorchScript and Validate Output Parity Across Exported and Native Models 1527
14.10.3 Exercise 02 - Export CNN Using ONNX and Validate Correctness Across Different Runtime Backends 1527
14.10.4 Exercise 03 - Use torch.compile for CNN and Measure Speed Gains vs Compilation Overhead 1528
14.10.5 Exercise 04 - Implement Quantization Conceptually and Measure Accuracy Drop vs Performance Gain 1529
14.10.6 Exercise 05 - Implement Batch Inference Pipeline with Efficient Transfer and Memory Reuse 1529
14.10.7 Exercise 06 - Build a Minimal Inference Service Wrapper with Input Validation and Error Handling 1530
14.10.8 Exercise 07 - Implement Model Versioning and Backward-Compatible Checkpoint Loading 1531
14.10.9 Exercise 08 - Add Monitoring Hooks for Confidence Drift and Data Distribution Shift 1531
14.10.10 Exercise 09 - Build Batch Failure Handling That Skips Corrupt Inputs Without Breaking the Pipeline 1532

14.10.11 Exercise 10 - Run Deployment-Oriented CUDA Inference and Measure Real GPU Utilization Under Load 1533
14.10.12 Exercise 11 - Compare float32, float16, and int8 Inference Accuracy and Performance Trade-Offs 1533
14.10.13 Exercise 12 - Build a Reproducible Deployment Benchmark Suite with Fixed Inputs and Seeds 1534
14.10.14 Exercise 13 - Implement Checkpoint Integrity Verification and Detect Corrupted Weight Files Early 1535
14.10.15 Exercise 14 - Simulate NaN Production Incident and Build an Automatic Rollback Strategy 1536
14.10.16 Exercise 15 - Validate Training–Serving Preprocessing Parity and Detect Silent Mismatch Bugs 1536
14.10.17 Exercise 16 - Implement A/B Testing for Two CNN Models on the Same Input Stream 1537
14.10.18 Exercise 17 - Create an End-to-End Production Readiness Checklist for Performance, Monitoring, and Stability 1538
14.10.19 Exercise 18 - Stress Test Inference Service for Memory Leaks and Tail Latency Spikes 1538
14.10.20 Exercise 19 - Produce a Final CNN Engineering Report Covering Architecture, Training, Deployment, and Failures 1539

15 RNN (Recurrent Neural Networks) 1541
15.1 Introduction 1541
15.1.1 What will the book teach you 1541
15.1.2 How to study this book 1545
15.1.3 The Chapters (RNN00 - RNN08) included in this book 1545
15.2 RNN00 - Sequence Modeling and Core RNN Intuition 1546
15.2.1 Exercise 00 - Understand Why Sequence Data Requires Memory Beyond Standard Feed-Forward Networks 1546
15.2.2 Exercise 01 - Represent a Sequence as Time Steps and Define the Input–Output Mapping Precisely 1546
15.2.3 Exercise 02 - Implement a Simple RNN Forward Pass Using Pure Python Recurrence 1547
15.2.4 Exercise 03 - Translate the RNN Recurrence Equation into PyTorch Tensor Operations 1548
15.2.5 Exercise 04 - Explain Hidden State as Compact Memory and Test Its Effect on Output Prediction 1549

15.2.6 Exercise 05 - Demonstrate Weight Sharing Across Time Steps and Explain Why It Matters 1549
15.2.7 Exercise 06 - Build a Tiny Synthetic Sequence Task Where History Is Required to Predict Correctly 1550
15.2.8 Exercise 07 - Compare One-Step Prediction vs Full-Sequence Prediction in a Controlled Experiment 1551
15.2.9 Exercise 08 - Implement Many-to-One RNN for Sequence Classification and Validate Output Shapes 1551
15.2.10 Exercise 09 - Implement Many-to-Many RNN for Sequence Labeling and Validate Temporal Alignment 1552
15.2.11 Exercise 10 - Move RNN Forward Computation to CUDA and Validate Output Parity with CPU Results 1553
15.2.12 Exercise 11 - Benchmark RNN Forward Speed on CPU vs GPU for Different Sequence Lengths 1553
15.2.13 Exercise 12 - Compare float32 vs float16 RNN Forward Outputs and Identify Precision-Sensitive Cases 1554
15.2.14 Exercise 13 - Understand Tensor Shapes for RNN Inputs (seq_len, batch, input_size) and Debug Mistakes 1555
15.2.15 Exercise 14 - Implement RNN with batch_first Option and Verify Shape Conversions Correctly 1556
15.2.16 Exercise 15 - Implement a Manual Unroll of RNN Over Time and Compare to torch.nn.RNN Behavior 1556
15.2.17 Exercise 16 - Stress Test RNN Forward with Long Sequences and Monitor GPU Memory and Runtime 1557
15.2.18 Exercise 17 - Debug Device Mismatch and Hidden-State Placement Errors in CUDA RNN Pipelines 1558
15.2.19 Exercise 18 - Validate Determinism Settings and Observe When CUDA RNN Becomes Non-Deterministic 1559
15.2.20 Exercise 19 - Write a Conceptual Report Explaining RNN Memory, Weight Sharing, and Temporal Computation 1559
15.3 RNN01 - Hidden State Dynamics and Temporal Behavior 1560
15.3.1 Exercise 00 - Visualize Hidden State Evolution Over Time for a Simple Repeating Pattern Sequence 1560
15.3.2 Exercise 01 - Analyze How Initial Hidden State Choice Affects Early Predictions and Convergence 1561

15.3.3 Exercise 02 - Implement Learnable Initial Hidden State and Compare Against Zero Initialization 1562
15.3.4 Exercise 03 - Demonstrate Information Decay Over Long Sequences Using Hidden State Probing 1562
15.3.5 Exercise 04 - Compare Single-Layer vs Multi-Layer RNN Hidden State Representations 1563
15.3.6 Exercise 05 - Implement Stacked RNN and Confirm Correct Hidden State Shape at Each Layer 1564
15.3.7 Exercise 06 - Investigate the Effect of Hidden Size on Memory Capacity and Sequence Accuracy 1565
15.3.8 Exercise 07 - Implement Bidirectional RNN and Verify Forward and Backward State Concatenation 1565
15.3.9 Exercise 08 - Compare Bidirectional vs Unidirectional RNN for a Sequence Labeling Task 1566
15.3.10 Exercise 09 - Debug Hidden State Shape Bugs in Multi-Layer and Bidirectional RNN Setups 1567
15.3.11 Exercise 10 - Move Hidden State Analysis to CUDA Without Excess Host–Device Transfers 1568
15.3.12 Exercise 11 - Benchmark Hidden State Computation Cost for Increasing Hidden Size on GPU 1568
15.3.13 Exercise 12 - Compare Floating-Point Precision Effects on Hidden State Stability and Temporal Drift 1569
15.3.14 Exercise 13 - Use Forward Hooks to Save Hidden States and Build a Visualization Pipeline 1570
15.3.15 Exercise 14 - Probe Hidden States to Detect Whether Past Information Is Encoded or Forgotten 1571
15.3.16 Exercise 15 - Implement Teacher Forcing Conceptually and Observe Its Impact on Sequence Generation 1571
15.3.17 Exercise 16 - Investigate Exposure Bias in Autoregressive Sequence Generation with RNN 1572
15.3.18 Exercise 17 - Stress Test Very Long Sequences and Identify Practical Limits for Vanilla RNN Memory 1573
15.3.19 Exercise 18 - Build a Hidden State Debugging Checklist for Shapes, Devices, and Temporal Alignment 1574
15.3.20 Exercise 19 - Produce a Detailed Report Explaining Hidden State Dynamics and Their Failure Modes 1575
15.4 RNN02 - Backpropagation Through Time (BPTT) 1575

15.4.1 Exercise 00 - Define Backpropagation Through Time and Explain How It Extends Standard Backprop 1575
15.4.2 Exercise 01 - Implement an RNN Training Loop and Confirm Gradients Flow Through Time Steps 1576
15.4.3 Exercise 02 - Inspect Gradient Norms Across Time and Detect Vanishing Gradient Behavior 1577
15.4.4 Exercise 03 - Inspect Gradient Norms Across Time and Detect Exploding Gradient Behavior 1578
15.4.5 Exercise 04 - Apply Gradient Clipping and Measure Its Stabilization Effect Quantitatively 1579
15.4.6 Exercise 05 - Implement Truncated BPTT and Compare Memory Usage and Accuracy Trade-Offs 1579
15.4.7 Exercise 06 - Compare Full BPTT vs Truncated BPTT on the Same Synthetic Long-Dependency Task 1580
15.4.8 Exercise 07 - Debug Silent Errors Caused by Hidden State Detaching at the Wrong Time 1581
15.4.9 Exercise 08 - Perform Finite Difference Gradient Checking for a Tiny RNN to Validate Backward Correctness 1582
15.4.10 Exercise 09 - Demonstrate Why Vanilla RNN Struggles with Long-Term Dependencies in Practice 1583
15.4.11 Exercise 10 - Execute BPTT on CUDA and Validate Gradient Consistency with CPU Under Controlled Settings 1583
15.4.12 Exercise 11 - Profile GPU Memory During BPTT and Identify Graph Retention Bottlenecks 1584
15.4.13 Exercise 12 - Compare float32 vs Mixed-Precision RNN Training and Detect Overflow or Underflow 1585
15.4.14 Exercise 13 - Use Autograd Hooks to Log Gradient Norms at Each Time Step and Summarize Results 1586
15.4.15 Exercise 14 - Demonstrate Gradient Accumulation When Forgetting zero_grad in an RNN Training Loop 1587
15.4.16 Exercise 15 - Analyze Batch Size Impact on Gradient Noise and Convergence in RNN Training 1587
15.4.17 Exercise 16 - Debug NaN Loss by Checking Learning Rate, Initialization, and Sequence Length 1588

15.4.18 Exercise 17 - Stress Test BPTT with Long Sequences and Large Hidden Size to Observe Practical Limits 1589
15.4.19 Exercise 18 - Build a BPTT Debugging Checklist for Detach Strategy, Truncation, and Gradient Clipping 1590
15.4.20 Exercise 19 - Write a Full BPTT Engineering Report Explaining Experimental Failures and Fixes 1591
15.5 RNN03 - Sequence Data Preparation and Batching 1592
15.5.1 Exercise 00 - Convert Raw Sequential Data into Sliding Windows and Validate Correct Input–Target Alignment 1592
15.5.2 Exercise 01 - Implement a Custom Dataset for Sequence Pairs and Validate getitem Correctness 1593
15.5.3 Exercise 02 - Implement Padding for Variable-Length Sequences and Explain Why Padding Is Needed 1594
15.5.4 Exercise 03 - Implement Packed Sequences with pack_padded_sequence and Validate Correctness 1595
15.5.5 Exercise 04 - Debug Packing Bugs from Wrong Length Sorting and Misaligned Outputs 1595
15.5.6 Exercise 05 - Compare Padded vs Packed Training and Measure Speed and Memory Differences 1596
15.5.7 Exercise 06 - Build a Collate Function That Produces Batch-First Tensors with Correct Padding Masks 1597
15.5.8 Exercise 07 - Validate Masking So Loss Ignores Padding Time Steps Correctly 1598
15.5.9 Exercise 08 - Create a Variable-Length Synthetic Dataset and Verify the Training Pipeline Handles It 1599
15.5.10 Exercise 09 - Debug Training Instability from Incorrect Padding Masks or Wrong Loss Reduction 1600
15.5.11 Exercise 10 - Move the Sequence Batching Pipeline to CUDA Efficiently and Minimize Host-to-Device Transfers 1601
15.5.12 Exercise 11 - Benchmark DataLoader Throughput with num_workers and pin_memory Settings 1602
15.5.13 Exercise 12 - Implement Gradient Accumulation for Long Sequences Under Limited GPU Memory 1603
15.5.14 Exercise 13 - Validate Reproducibility of Sequence Batching Under Random Shuffling and Fixed Seeds 1604
15.5.15 Exercise 14 - Implement a Train–Validation Split Without Leakage in Sequential Time-Series Data 1605

15.5.16 Exercise 15 - Implement Teacher-Forcing Dataset Format for Sequence-to-Sequence Tasks 1606
15.5.17 Exercise 16 - Implement Stateful RNN Batching and Decide When to Reset Hidden States Correctly 1607
15.5.18 Exercise 17 - Detect and Fix Alignment Bugs That Make an RNN Learn the Wrong Target Shift 1607
15.5.19 Exercise 18 - Build a Sequence Data Pipeline Checklist Covering Padding, Packing, and Masking 1608
15.5.20 Exercise 19 - Produce a Full Sequence Data Preparation Report with Verified Edge Cases 1609
15.6 RNN04 - Language Modeling with Vanilla RNN 1610
15.6.1 Exercise 00 - Implement Character-Level Tokenization and Build a Vocabulary with Correct Index Mapping 1610
15.6.2 Exercise 01 - Build a Simple Character-Level RNN Language Model and Verify Output Logit Shapes 1611
15.6.3 Exercise 02 - Implement Cross-Entropy Loss for Next-Character Prediction and Validate Target Alignment 1612
15.6.4 Exercise 03 - Train a Tiny RNN Language Model Until It Overfits a Small Text Sample on Purpose 1613
15.6.5 Exercise 04 - Generate Text Autoregressively and Observe Repetition and Instability Patterns 1614
15.6.6 Exercise 05 - Implement Temperature Sampling and Analyze Diversity vs Coherence 1615
15.6.7 Exercise 06 - Implement Top-k Sampling and Compare with Temperature-Only Sampling 1616
15.6.8 Exercise 07 - Debug Generation Bugs Caused by Incorrect Hidden-State Reset Behavior 1617
15.6.9 Exercise 08 - Compare Sequence Length and Its Effect on Learning Short vs Long Patterns 1618
15.6.10 Exercise 09 - Evaluate an RNN Language Model with Perplexity and Interpret What the Number Means 1619
15.6.11 Exercise 10 - Train a Character RNN on CUDA and Measure Speed Improvement over a CPU Baseline 1620
15.6.12 Exercise 11 - Profile GPU Utilization and Fix Language-Model Input Pipeline Bottlenecks 1620

15.6.13 Exercise 12 - Implement Mixed-Precision Training and Detect Instability in Long-Sequence Language Modeling 1621
15.6.14 Exercise 13 - Compare Vanilla RNN with GRU or LSTM and Document Why Vanilla RNN Fails 1622
15.6.15 Exercise 14 - Implement Truncated BPTT for Language Modeling and Quantify Memory Savings 1623
15.6.16 Exercise 15 - Debug Training Divergence through Learning Rate, Clipping, and Initialization 1624
15.6.17 Exercise 16 - Build a Generation Evaluation Script for Repetition and Novelty Metrics 1625
15.6.18 Exercise 17 - Create a Controlled Long-Term Dependency Failure Experiment for Vanilla RNN 1626
15.6.19 Exercise 18 - Stress Test Language Modeling with Longer Text and Identify GPU Memory and Speed Limits 1627
15.6.20 Exercise 19 - Produce a Full Character-Level RNN Language Modeling Report with Failure Analysis and Fixes 1628
15.7 RNN05 - Time Series Forecasting with Vanilla RNN 1629
15.7.1 Exercise 00 - Convert Time Series into Supervised Windows and Verify the Correct Target Horizon 1629
15.7.2 Exercise 01 - Implement Feature Scaling for Time Series and Explain How It Prevents Training Instability 1630
15.7.3 Exercise 02 - Build a Simple RNN Forecaster and Validate Output Shapes for Multi-Step Prediction 1630
15.7.4 Exercise 03 - Compare One-Step and Multi-Step Forecasting and Explain Error Accumulation 1631
15.7.5 Exercise 04 - Train an RNN on Synthetic Seasonal Data and Confirm It Learns Periodicity 1632
15.7.6 Exercise 05 - Implement Autoregressive Multi-Step Forecasting and Observe Drift over Time 1633
15.7.7 Exercise 06 - Implement Teacher Forcing for Forecasting and Compare with Pure Autoregressive Training 1634
15.7.8 Exercise 07 - Evaluate Forecast Accuracy with MAE and MSE and Interpret Their Different Penalties 1635

15.7.9 Exercise 08 - Debug Forecasting Bugs from Wrong Windowing or Misaligned Targets 1636
15.7.10 Exercise 09 - Diagnose Overfitting in Forecasting and Apply Regularization or Early Stopping 1637
15.7.11 Exercise 10 - Train a Time-Series RNN on CUDA and Benchmark End-to-End Throughput Including the Data Pipeline 1638
15.7.12 Exercise 11 - Profile GPU Memory and Runtime for Sequence Length and Hidden-Size Scaling 1639
15.7.13 Exercise 12 - Implement Mixed Precision for Forecasting and Identify Stability Failures 1640
15.7.14 Exercise 13 - Compare Vanilla RNN and LSTM Forecasting and Document Long-Term Dependency Gains 1641
15.7.15 Exercise 14 - Implement Truncated BPTT for Long Forecasting Windows and Quantify Memory Savings 1642
15.7.16 Exercise 15 - Build a Forecast Visualization Tool for Predictions and Ground Truth across Multiple Horizons 1643
15.7.17 Exercise 16 - Diagnose Instability from Seasonal Scale and Fix It with Normalization 1644
15.7.18 Exercise 17 - Create Walk-Forward Validation to Avoid Temporal Leakage in Forecast Evaluation 1645
15.7.19 Exercise 18 - Stress Test the Forecasting Pipeline with Large Data and Identify Practical Limits 1646
15.7.20 Exercise 19 - Produce a Full Time-Series RNN Forecasting Report with Failure Cases and Engineering Fixes 1647
15.8 RNN06 - Regularization and Stabilization for RNNs 1648
15.8.1 Exercise 00 - Demonstrate Overfitting in RNN and Measure Train vs Validation Gap in Sequence Tasks 1648
15.8.2 Exercise 01 - Apply Dropout in RNN and Compare Input Dropout with Dropout Between Recurrent Layers 1649
15.8.3 Exercise 02 - Use Weight Decay and Analyze Its Effect on RNN Stability and Generalization 1650
15.8.4 Exercise 03 - Implement Gradient Clipping and Compare Different Clip Norm Values Experimentally 1650
15.8.5 Exercise 04 - Implement Layer Normalization in RNN and Measure Hidden-State Stability 1651

15.8.6 Exercise 05 - Diagnose NaN Loss and Build Automatic Early-Failure Diagnostics for RNN Training 1652
15.8.7 Exercise 06 - Compare Recurrent Weight Initializations and Observe Training Differences 1653
15.8.8 Exercise 07 - Compare SGD and Adam for RNNs and Explain Optimizer Sensitivity 1654
15.8.9 Exercise 08 - Implement Learning-Rate Scheduling and Confirm Reduced Instability in RNN Training 1655
15.8.10 Exercise 09 - Debug Cases Where Loss Decreases but Sequence Quality Does Not 1656
15.8.11 Exercise 10 - Train a Stabilized RNN on CUDA and Measure Regularization Runtime Overhead 1657
15.8.12 Exercise 11 - Compare Mixed-Precision Stability With and Without Gradient Scaling in RNNs 1658
15.8.13 Exercise 12 - Analyze Generalization Under Label Noise and Sequence-Noise Propagation 1659
15.8.14 Exercise 13 - Perform an Ablation Study to Identify Which Stabilization Methods Actually Help 1660
15.8.15 Exercise 14 - Implement Early Stopping and Compare It with Regularization and Dropout 1661
15.8.16 Exercise 15 - Build a Comprehensive Debugging Checklist for RNN Training Stability 1662
15.8.17 Exercise 16 - Evaluate Robustness Under Time-Series Distribution Shift and Document Failure Modes 1663
15.8.18 Exercise 17 - Build Calibration and Confidence Analysis for RNN Predictions Across Time Steps 1664
15.8.19 Exercise 18 - Stress Test Very Long Sequences and Observe When Regularization Stops Helping 1665
15.8.20 Exercise 19 - Write a Practical RNN Stabilization Strategy Guide for Real Engineering Projects 1666
15.9 RNN07 - Efficiency, Profiling, and CUDA Performance 1666
15.9.1 Exercise 00 - Benchmark Vanilla RNN vs GRU vs LSTM Runtime and Memory to Understand Engineering Tradeoffs 1667
15.9.2 Exercise 01 - Profile RNN Training with PyTorch Profiler and Identify Kernel and Memory Bottlenecks 1668

15.9.3 Exercise 02 - Optimize Data Transfer by Minimizing Host-to-Device Copies in Sequence Training 1669
15.9.4 Exercise 03 - Measure Sequence-Length Impact on Throughput and Find the Practical GPU Limit 1670
15.9.5 Exercise 04 - Compare Packed vs Padded Sequence Performance and Measure Speedup and Memory Changes 1670
15.9.6 Exercise 05 - Evaluate batch_first and Its Effect on Memory Layout and Performance 1671
15.9.7 Exercise 06 - Benchmark Hidden Sizes and Layer Counts and Build a Scaling Curve 1672
15.9.8 Exercise 07 - Diagnose an Under-Utilized GPU and Fix DataLoader or Padding Bottlenecks 1673
15.9.9 Exercise 08 - Compare float32 and Mixed-Precision Speed and Document Stability Constraints 1674
15.9.10 Exercise 09 - Measure Gradient-Clipping Overhead and Decide Whether It Is Worth It 1675
15.9.11 Exercise 10 - Implement Gradient Accumulation and Compare It with True Large-Batch Training 1676
15.9.12 Exercise 11 - Run CUDA Efficiency Tests and Produce Reproducible Benchmark Tables 1677
15.9.13 Exercise 12 - Investigate Non-Determinism in cuDNN RNN Kernels and Document When It Appears 1678
15.9.14 Exercise 13 - Compare Stateful and Stateless RNN Training Efficiency and Explain Hidden-State Reset Costs 1679
15.9.15 Exercise 14 - Implement RNN Checkpointing and Resume and Measure Restart-Time Loss 1680
15.9.16 Exercise 15 - Build a Production RNN Inference Benchmark Across Batch Sizes 1681
15.9.17 Exercise 16 - Export an RNN with TorchScript and Validate Output Parity and Speed 1682
15.9.18 Exercise 17 - Test ONNX Export and Identify Unsupported Operators or Shape Edge Cases 1682
15.9.19 Exercise 18 - Stress Test Long-Sequence Inference and Detect Memory Leaks or Latency Spikes 1683
15.9.20 Exercise 19 - Produce a Complete RNN Engineering Performance Report with Scaling Curves and Best Practices 1684
15.10RNN08 - Transition to Gated RNNs (Why LSTM Exists) 1685

15.10.1 Exercise 00 - Demonstrate Long-Term Dependency Failure in Vanilla RNN with a Controlled Memory Task 1685
15.10.2 Exercise 01 - Explain Vanishing Gradients as Repeated Jacobian Multiplication 1686
15.10.3 Exercise 02 - Implement a Simple GRU Cell Manually and Compare It with Vanilla RNN Behavior 1687
15.10.4 Exercise 03 - Compare Vanilla RNN, GRU, and LSTM on the Same Long-Dependency Task 1688
15.10.5 Exercise 04 - Analyze Hidden-State Updates and Explain Why Gates Preserve Useful Gradients 1689
15.10.6 Exercise 05 - Implement a Minimal LSTM Cell and Verify Gate Shapes and Ranges Step by Step 1690
15.10.7 Exercise 06 - Train GRU and LSTM and Compare Stability, Convergence Speed, and Final Accuracy 1691
15.10.8 Exercise 07 - Debug Gate Misconfiguration Bugs Causing No Learning or Constant Outputs 1692
15.10.9 Exercise 08 - Run GRU and LSTM Experiments on CUDA and Measure Memory and Runtime Tradeoffs 1693
15.10.10 Exercise 09 - Explain Why LSTM and GRU Are Engineering Solutions to Vanilla RNN Limits 1694
15.10.11 Exercise 10 - Ablate the Forget Gate and Observe Memory Collapse . . .1695
15.10.12 Exercise 11 - Find the Sequence Length Where LSTM Clearly Outperforms Vanilla RNN 1696
15.10.13 Exercise 12 - Compare Gated and Vanilla Models Under Distribution Shift 1697
15.10.14 Exercise 13 - Implement Truncated BPTT for GRU and LSTM and Compare Memory Savings with Vanilla RNN 1697
15.10.15 Exercise 14 - Profile RNN and LSTM GPU Utilization and Explain Kernel-Level Differences 1698
15.10.16 Exercise 15 - Build a Checklist for Choosing RNN, GRU, or LSTM in Real Projects 1699
15.10.17 Exercise 16 - Export GRU and LSTM and Compare Deployment Complexity with Vanilla RNN 1700
15.10.18 Exercise 17 - Stress Test Gated Models with Long Sequences and Large Hidden Sizes 1701

15.10.19 Exercise 18 - Create an Ablation Report Quantifying What Gates Improve and Why 1702
15.10.20 Exercise 19 - Produce the Final RNN Track Report with Concepts, Experiments, Failures, and Next Steps 1703

16 LSTM (Long Short-Term Memory) 1705
16.1 Introduction 1705
16.1.1 What will the book teach you 1705
16.2 LSTM00 - LSTM Intuition and Why Gates Exist 1709
16.2.1 Exercise 00 - Explain Why Vanilla RNN Fails on Long Dependencies and Why LSTM Was Designed as a Fix 1709
16.2.2 Exercise 01 - Define Hidden State vs Cell State and Their Roles in Memory Preservation 1710
16.2.3 Exercise 02 - Write LSTM Update Equations and Map Every Term to Memory Control 1711
16.2.4 Exercise 03 - Implement One LSTM Time Step with Pure Torch Tensors Without nn.LSTM 1712
16.2.5 Exercise 04 - Validate Sigmoid and Tanh Gate Ranges Precisely 1713
16.2.6 Exercise 05 - Compare LSTM and Vanilla RNN Forward Behavior on the Same Sequence 1714
16.2.7 Exercise 06 - Force Forget-Gate Extremes and Observe Memory Retention 1714
16.2.8 Exercise 07 - Force Input-Gate Extremes and Observe Memory Writing 1715
16.2.9 Exercise 08 - Force Output-Gate Extremes and Observe newline Hidden-State Exposure 1716
16.2.10 Exercise 09 - Verify Gate and State Shapes for Batch-First and Time-First Layouts 1717
16.2.11 Exercise 10 - Run the Manual LSTM Step on CUDA and Confirm CPU Parity 1718
16.2.12 Exercise 11 - Benchmark Manual LSTM vs nn.LSTM and Explain Kernel Fusion Benefits 1719
16.2.13 Exercise 12 - Compare float32 and float16 LSTM Outputs and Find Precision-Sensitive Gate Cases 1720
16.2.14 Exercise 13 - Debug Gate Order, Concatenation, and newline Weight-Shape Mistakes 1721
16.2.15 Exercise 14 - Manually Unroll LSTM Through Time and Compare with nn.LSTM 1721
16.2.16 Exercise 15 - Stress Test Long-Sequence LSTM Forward Runtime and GPU Memory 1722
16.2.17 Exercise 16 - Investigate cuDNN LSTM Non-Determinism and Document It 1723
16.2.18 Exercise 17 - Build a Long-Memory Synthetic Task and Confirm LSTM Outperforms RNN 1724
16.2.19 Exercise 18 - Find the Smallest Hidden Size That Retains Long Dependencies 1725

16.2.20 Exercise 19 - Explain How Gates Enable More Stable Gradient Flow Through Time 1726
16.3 LSTM01 - LSTM Architecture Variants and Configurations 1727
16.3.1 Exercise 00 - Implement a Many-to-One LSTM Classifier and Select the Last Hidden State Correctly 1727
16.3.2 Exercise 01 - Implement Many-to-Many LSTM Sequence Labeling and Validate Temporal Alignment 1728
16.3.3 Exercise 02 - Implement a Stacked LSTM and Confirm Multi-Layer Hidden and Cell Shapes 1729
16.3.4 Exercise 03 - Implement Bidirectional LSTM and Verify Concatenation and Output Dimensions 1730
16.3.5 Exercise 04 - Compare Unidirectional and Bidirectional LSTM for Sequence Labeling 1731
16.3.6 Exercise 05 - Use batch_first and Keep Shapes Consistent Across the Pipeline 1732
16.3.7 Exercise 06 - Implement Inter-Layer Dropout and Verify the num_layers Condition 1732
16.3.8 Exercise 07 - Build a Capacity Curve Across Hidden Sizes and Layer Counts 1733
16.3.9 Exercise 08 - Implement LSTM Projection and Explain Why It Helps .1734
16.3.10 Exercise 09 - Debug Shape Errors in Multi-Layer and Bidirectional LSTM1735
16.3.11 Exercise 10 - Move the Complete LSTM Architecture to CUDA and Validate State Device Placement 1736
16.3.12 Exercise 11 - Benchmark LSTM Across Sequence Lengths and Find Practical GPU Limits 1737
16.3.13 Exercise 12 - Compare float32 and Mixed-Precision Stability and Find fp16 Gate Failures 1738
16.3.14 Exercise 13 - Wrap nn.LSTM in a Debuggable Module That Exposes States 1739
16.3.15 Exercise 14 - Create Unit Tests for LSTM Shapes Across Configurations1740
16.3.16 Exercise 15 - Validate LSTM Determinism and Reproducibility Across Runs and Machines 1741
16.3.17 Exercise 16 - Stress Test Deep Stacked LSTM for Gradient and Memory Limits 1742
16.3.18 Exercise 17 - Compare LSTM and GRU Parameter Cost with Accuracy1743
16.3.19 Exercise 18 - Build an Architecture Selection Checklist for Depth, Width, and Directionality 1744
16.3.20 Exercise 19 - Produce an LSTM Architecture Engineering Report . . .1744
16.4 LSTM02 - Backpropagation Through Time in LSTM 1745
16.4.1 Exercise 00 - Confirm Gradients Flow Through Hidden and Cell-State Paths 1745
16.4.2 Exercise 01 - Compare Temporal Gradient Norms with Vanilla RNN . .1746
16.4.3 Exercise 02 - Create Exploding Gradients and Apply Clipping Correctly1747
16.4.4 Exercise 03 - Implement Truncated BPTT and Measure Its Tradeoffs .1748
16.4.5 Exercise 04 - Debug Detach Strategies That Break Long-Term Learning1749
16.4.6 Exercise 05 - Finite-Difference Check a Tiny LSTM Cell 1750

16.4.7 Exercise 06 - Monitor Gate Gradients and Detect Saturation 1750
16.4.8 Exercise 07 - Fix Forget-Gate Saturation with Initialization and LR . .1751
16.4.9 Exercise 08 - Fix Input-Gate Saturation with Normalization or Initialization 1752
16.4.10 Exercise 09 - Diagnose NaN Loss from Precision, LR, and Sequence Length 1753
16.4.11 Exercise 10 - Validate CUDA and CPU Gradient Parity 1754
16.4.12 Exercise 11 - Profile BPTT Memory and Graph-Retention Bottlenecks 1754
16.4.13 Exercise 12 - Detect Mixed-Precision Overflow and Underflow 1755
16.4.14 Exercise 13 - Log Gate Gradient Norms with Autograd Hooks 1756
16.4.15 Exercise 14 - Demonstrate and Fix the zero_grad Accumulation Bug .1757
16.4.16 Exercise 15 - Analyze Batch Size, Gradient Noise, and Convergence . .1758
16.4.17 Exercise 16 - Stress Very Long Sequences and Locate LSTM Forgetting1759
16.4.18 Exercise 17 - Compare Full and Truncated BPTT on Long Dependencies1759
16.4.19 Exercise 18 - Build an LSTM-Specific BPTT newline Debugging Checklist 1760
16.4.20 Exercise 19 - Produce the Complete LSTM BPTT Engineering Report 1761
16.5 LSTM03 - Sequence Data Handling for LSTM 1762
16.5.1 Exercise 00 - Build Variable-Length Sequence Dataset and Validate Targets 1762
16.5.2 Exercise 01 - Implement Padding and Masks and Prove Loss Ignores Padding 1763
16.5.3 Exercise 02 - Implement Packed Sequences and Validate Benefits 1764
16.5.4 Exercise 03 - Debug Sorting, Length, and Packed-Output Bugs 1765
16.5.5 Exercise 04 - Compare Padded and Packed Training on CUDA 1765
16.5.6 Exercise 05 - Build a Clean Variable-Length Collate Function 1766
16.5.7 Exercise 06 - Implement Masked Sequence Loss and Match Manual Computation 1767
16.5.8 Exercise 07 - Implement Stateful Batching and Correct State Resets . .1768
16.5.9 Exercise 08 - Prevent Time-Series Leakage with Chronological Splits . .1769
16.5.10 Exercise 09 - Debug Instability from Masks and Loss Reduction 1770
16.5.11 Exercise 10 - Move the Sequence Pipeline to CUDA Efficiently 1771
16.5.12 Exercise 11 - Benchmark DataLoader Workers for Variable Sequences .1772
16.5.13 Exercise 12 - Accumulate Gradients for Long Sequences with Limited Memory 1772
16.5.14 Exercise 13 - Validate Reproducibility with Variable-Length Batches . .1773
16.5.15 Exercise 14 - Format Teacher-Forcing Data newline for LSTM Seq2Seq 1774
16.5.16 Exercise 15 - Build a Complete Sequence-Data Checklist 1775
16.5.17 Exercise 16 - Detect and Fix Off-by-One Target Alignment 1776
16.5.18 Exercise 17 - Create a Task That Fails Without Packing 1776
16.5.19 Exercise 18 - Stress Test a Large Variable-Length Pipeline 1777
16.5.20 Exercise 19 - Produce the LSTM Sequence-Data Engineering Report .1778
16.6 LSTM04 - Language Modeling and Text Generation with LSTM 1779
16.6.1 Exercise 00 - Build Character-Level Tokenization and Vocabulary . . .1779
16.6.2 Exercise 01 - Implement LSTM Language Model and Verify Logit Shapes1780
16.6.3 Exercise 02 - Implement Cross-Entropy Loss and Confirm Target Alignment 1781

16.6.4 Exercise 03 - Overfit a Tiny Text as a Correctness Test 1782
16.6.5 Exercise 04 - Generate Text Autoregressively and Analyze Repetition .1783
16.6.6 Exercise 05 - Implement Temperature Sampling and Measure the Tradeoff1784
16.6.7 Exercise 06 - Implement Top-k Sampling and Compare Stability 1785
16.6.8 Exercise 07 - Implement Nucleus Sampling and Compare p Values . . .1785
16.6.9 Exercise 08 - Debug Hidden and Cell State Carry-Over 1786
16.6.10 Exercise 09 - Evaluate the Language Model with Perplexity 1787
16.6.11 Exercise 10 - Train on CUDA and Benchmark Against CPU 1788
16.6.12 Exercise 11 - Profile GPU Utilization and Fix Pipeline Bottlenecks . .1789
16.6.13 Exercise 12 - Implement Mixed Precision and Identify Instability 1790
16.6.14 Exercise 13 - Compare LSTM and GRU for Language Modeling 1791
16.6.15 Exercise 14 - Implement Truncated BPTT for Longer Contexts 1792
16.6.16 Exercise 15 - Debug Divergence with Learning Rate, Clipping, and Gates1793
16.6.17 Exercise 16 - Build a Generation Evaluation Script 1794
16.6.18 Exercise 17 - Prove LSTM Captures a Controlled Long Dependency . .1795
16.6.19 Exercise 18 - Stress Test Long-Prompt Text Generation 1796
16.6.20 Exercise 19 - Produce the Full LSTM Language Modeling Report . . .1797
16.7 LSTM05 - Time Series Forecasting with LSTM 1798
16.7.1 Exercise 00 - Build Multi-Feature Time Series Windows 1798
16.7.2 Exercise 01 - Implement Feature Scaling Strategy 1798
16.7.3 Exercise 02 - Build a One-Step LSTM Forecaster 1799
16.7.4 Exercise 03 - Extend the Forecaster to Multi-Step Prediction 1800
16.7.5 Exercise 04 - Learn Long Seasonality Better Than a Vanilla RNN . . .1800
16.7.6 Exercise 05 - Compare Teacher Forcing and Autoregressive Generation 1801
16.7.7 Exercise 06 - Evaluate Forecast Accuracy with MAE, MSE, and MAPE1802
16.7.8 Exercise 07 - Debug Windowing and Alignment Bugs 1802
16.7.9 Exercise 08 - Diagnose and Reduce Forecasting Overfitting 1803
16.7.10 Exercise 09 - Build Walk-Forward Validation without Leakage 1804
16.7.11 Exercise 10 - Train the Full Pipeline on CUDA 1804
16.7.12 Exercise 11 - Profile Sequence Length and Hidden Size 1805
16.7.13 Exercise 12 - Implement Mixed Precision and Detect Gate Saturation .1806
16.7.14 Exercise 13 - Compare LSTM and GRU Forecasting 1806
16.7.15 Exercise 14 - Implement Truncated BPTT for Long Windows 1807
16.7.16 Exercise 15 - Build a Multi-Horizon Forecast Visualization 1808
16.7.17 Exercise 16 - Measure Robustness under Seasonal Shift 1808
16.7.18 Exercise 17 - Estimate Probabilistic Forecast Uncertainty 1809
16.7.19 Exercise 18 - Stress Test the Large Forecasting Pipeline 1810
16.7.20 Exercise 19 - Produce the Full Forecasting Engineering Report 1810
16.8 LSTM06 - Regularization, Stabilization,
and Robustness 1811
16.8.1 Exercise 00 - Demonstrate LSTM Overfitting and Measure the Gap . .1811
16.8.2 Exercise 01 - Compare Inter-Layer and Input Dropout 1812
16.8.3 Exercise 02 - Implement and Evaluate Weight Decay 1813
16.8.4 Exercise 03 - Compare Gradient Clipping Norms 1813
16.8.5 Exercise 04 - Apply Layer Normalization inside LSTM 1814
16.8.6 Exercise 05 - Diagnose NaN Loss and Numerical Failure 1815
16.8.7 Exercise 06 - Compare SGD, Adam, and AdamW 1816
16.8.8 Exercise 07 - Schedule Learning Rate and Prevent Late Divergence . .1816

16.8.9 Exercise 08 - Analyze Batch Size and Gradient Noise 1817
16.8.10 Exercise 09 - Debug Improving Loss but Poor Predictions 1818
16.8.11 Exercise 10 - Measure CUDA Overhead of Stabilization 1818
16.8.12 Exercise 11 - Compare Mixed Precision with and without GradScaler .1819
16.8.13 Exercise 12 - Perform a Stabilization Ablation Study 1820
16.8.14 Exercise 13 - Evaluate Robustness under Distribution Shift 1820
16.8.15 Exercise 14 - Calibrate Sequence Predictions over Time 1821
16.8.16 Exercise 15 - Compare Early Stopping and Regularization 1822
16.8.17 Exercise 16 - Create an LSTM Failure Debugging Checklist 1822
16.8.18 Exercise 17 - Analyze Long-Sequence Generalization Limits 1823
16.8.19 Exercise 18 - Stress Test Very Long and Wide LSTMs 1824
16.8.20 Exercise 19 - Write a Practical LSTM Stabilization Guide 1824
16.9 LSTM07 - Efficiency, Profiling, and Deployment 1825
16.9.1 Exercise 00 - Benchmark LSTM vs GRU Runtime and Memory 1825
16.9.2 Exercise 01 - Profile LSTM Training with PyTorch Profiler 1826
16.9.3 Exercise 02 - Reduce Padding Waste and Improve GPU Utilization . .1827
16.9.4 Exercise 03 - Compare Packed and Padded Runtime 1827
16.9.5 Exercise 04 - Measure Sequence-Length Scaling 1828
16.9.6 Exercise 05 - Compare batch_first and Memory Layout 1829
16.9.7 Exercise 06 - Scale Hidden Size and Layer Count 1829
16.9.8 Exercise 07 - Diagnose an Under-Utilized GPU 1830
16.9.9 Exercise 08 - Compare float32 and Mixed Precision 1831
16.9.10 Exercise 09 - Measure Gradient-Clipping Overhead 1831
16.9.11 Exercise 10 - Use Gradient Accumulation under Memory Limits 1832
16.9.12 Exercise 11 - Build Reproducible CUDA Benchmark Tables 1833
16.9.13 Exercise 12 - Investigate cuDNN LSTM Non-Determinism 1833
16.9.14 Exercise 13 - Export LSTM with TorchScript 1834
16.9.15 Exercise 14 - Export LSTM to ONNX 1835
16.9.16 Exercise 15 - Build a Production Inference Benchmark 1835
16.9.17 Exercise 16 - Checkpoint and Resume Training 1836
16.9.18 Exercise 17 - Stress Test Stateful Long-Sequence Inference 1837
16.9.19 Exercise 18 - Build a Deployment Readiness Checklist 1837
16.9.20 Exercise 19 - Produce the LSTM Performance Report 1838
16.10LSTM08 - Bridge to Attention and Why Transformers Win 1839
16.10.1 Exercise 00 - Demonstrate Very-Long-Context LSTM Failure 1839
16.10.2 Exercise 01 - Explain Sequential Computation Limits 1839
16.10.3 Exercise 02 - Add Simple Additive Attention 1840
16.10.4 Exercise 03 - Implement Dot-Product Attention 1841
16.10.5 Exercise 04 - Visualize Attention over Time 1841
16.10.6 Exercise 05 - Build an LSTM Encoder-Decoder with Attention 1842
16.10.7 Exercise 06 - Compare Copy Task with and without Attention 1843
16.10.8 Exercise 07 - Diagnose Attention Mask and Softmax Bugs 1843
16.10.9 Exercise 08 - Measure CUDA Cost and Quality of Attention 1844
16.10.10 Exercise 09 - Produce the Bridge-to-Transformers Report 1845
16.10.11 Exercise 10 - Quantify the Encoder-Decoder Bottleneck 1845
16.10.12 Exercise 11 - Masked Attention for Variable Lengths 1846
16.10.13 Exercise 12 - Compare Attention Distributions by Length 1847
16.10.14 Exercise 13 - Profile Parallelism Added by Attention 1847

16.10.15 Exercise 14 - Clip Gradients in LSTM plus Attention 1848
16.10.16 Exercise 15 - Choose LSTM, LSTM plus Attention, or Transformer . .1849
16.10.17 Exercise 16 - Export LSTM plus Attention 1849
16.10.18 Exercise 17 - Stress Test Long Attention Sequences 1850
16.10.19 Exercise 18 - Ablate Attention Components 1851
16.10.20 Exercise 19 - Produce the Final LSTM Track Report 1851

17 Transformers 1853
17.1 Introduction 1853
17.1.1 What will the book teach you 1853
17.1.2 Why this book comes after the LSTM 1856
17.1.3 How to study this book 1856
17.1.4 The Chapters (TRF00 - TRF08) included in this book 1857
17.2 TRF00 1858
17.2.1 Exercise 00 1858
17.2.2 Exercise 01 1861
17.2.3 Exercise 02 1864
17.2.4 Exercise 03 1867
17.2.5 Exercise 04 1870
17.2.6 Exercise 05 1873
17.2.7 Exercise 06 1876
17.2.8 Exercise 07 1879
17.2.9 Exercise 08 1882
17.2.10 Exercise 09 1885
17.2.11 Exercise 10 1888
17.2.12 Exercise 11 1890
17.2.13 Exercise 12 1893
17.2.14 Exercise 13 1895
17.2.15 Exercise 14 1898
17.2.16 Exercise 15 1900
17.2.17 Exercise 16 1903
17.2.18 Exercise 17 1905
17.2.19 Exercise 18 1908
17.2.20 Exercise 19 1910
17.3 TRF01 1913
17.3.1 Exercise 00 1913
17.3.2 Exercise 01 1916
17.3.3 Exercise 02 1919
17.3.4 Exercise 03 1921
17.3.5 Exercise 04 1923
17.3.6 Exercise 05 1925
17.3.7 Exercise 06 1927
17.3.8 Exercise 07 1930
17.3.9 Exercise 08 1932
17.3.10 Exercise 09 1934
17.3.11 Exercise 10 1937
17.3.12 Exercise 11 1939
17.3.13 Exercise 12 1941

17.3.14 Exercise 13 1943
17.3.15 Exercise 14 1945
17.3.16 Exercise 15 1948
17.3.17 Exercise 16 1950
17.3.18 Exercise 17 1952
17.3.19 Exercise 18 1954
17.3.20 Exercise 19 1957
17.4 TRF02 1959
17.4.1 Exercise 00 1959
17.4.2 Exercise 01 1962
17.4.3 Exercise 02 1964
17.4.4 Exercise 03 1966
17.4.5 Exercise 04 1968
17.4.6 Exercise 05 1970
17.4.7 Exercise 06 1973
17.4.8 Exercise 07 1975
17.4.9 Exercise 08 1977
17.4.10 Exercise 09 1979

Introduction of the Volume of Books

0.1 Why am I writing this volume of books

One day I decided to learn artificial intelligence programming. What happened was strange; I discovered that the more I delved, the more I realized there was still so much to learn. The deeper I explored this world, the more I understood that I hadn't learned anything, or that what I had learned was just a drop in the ocean. That's why I decided to write down everything I learned on my journey to learning artificial intelligence programming.

What I saw in this science confirmed that we in the UAE need a lot of learning. Therefore, I will use this book to teach future generations in the UAE how to program artificial intelligence, based on the principle of self-learning, just as I implemented it at School 42 Abu Dhabi. What we need is to organize our ideas and begin.

0.2 We must be at the forefront

The competition between Saudi Arabia and the UAE to acquire artificial intelligence is a drop in the ocean compared to what companies like OpenAI, Google, and other major American firms are doing. We must accelerate development because the capabilities these companies possess rival those of most countries in the world. As Emiratis and residents of the UAE, we must expedite the development of this community in programming and advancing advanced artificial intelligence.

It's true we have educational and infrastructure projects, but we lack a huge number of educated personnel. That's why I decided to write this book for them—a solid foundation upon which to build this national workforce, and even for residents of the UAE.

0.3 What will this volume of books contain

Book 1: Tensor Mathematics and Neural Networks Guide

You will learn the fundamentals of mathematics and how to program it using Pytorch. While the first challenge will be easy, the second chapter will be quite difficult if you're new to this field. This isn't because it's impossible to grasp, but because you need four things to overcome the difficulties: first, understand the equation; then, write it using Pytorch; then, ask yourself what its application is in artificial intelligence; and finally, practice creating equations using it. Pay attention: you must complete all four of these points together in every chapter. Don't skip or skip any challenge without completing these four points, because the learning system is

built upon what you've learned previously.

Book 2: Applied Linear Algebra in Code

This book moves the reader from understanding mathematical laws to implementing and reasoning about them in code. Knowing an equation on paper is important, but artificial intelligence requires an additional ability: translating that equation into tensor operations that are mathematically correct, computationally efficient, and compatible with the dimensions of the data. The reader will therefore work directly with PyTorch tensors while learning how values, shapes, data types, and devices influence every operation.

The book begins with essential tensor operations, including tensor creation, shape inspection, type conversion, device assignment, element-wise operations, comparisons, and Boolean masking. These topics may appear simple, but they form the language through which every later model will be constructed. A small misunderstanding involving a tensor's shape, data type, or device can stop an entire training pipeline or, more dangerously, allow the program to run while producing an incorrect result. For this reason, the exercises require the reader to inspect and reason about tensors instead of treating them as ordinary lists of numbers.

The reader will then study vector dot products, norms, normalization, cosine similarity, angles, matrix multiplication, inner products, outer products, broadcasting, and dimension flow. These operations are not isolated mathematical tricks. They appear throughout artificial intelligence in similarity measurement, feature interaction, linear transformations, attention mechanisms, loss calculations, and neural-network layers. The exercises will require both manual implementations and PyTorch implementations so the reader understands what the framework performs internally.

Special attention is given to shape reasoning. Before executing an operation, the reader should be able to predict the shape of its output and explain why the operation is valid. This habit is essential because many problems in artificial intelligence programming are dimension problems disguised as coding problems. Broadcasting, batched matrix multiplication, and high-dimensional tensor operations become manageable only when the reader can follow how every dimension moves through the computation.

The final part of the book introduces basis, span, and projection through applied exercises. These concepts explain how information can be represented, compared, decomposed, and reduced inside a feature space. By completing this book, the reader should no longer see tensors as containers of numbers. Instead, they should see them as structured mathematical objects whose dimensions and operations describe how information flows through an artificial intelligence system.

Book 3: Autograd and Backprop Mechanics

This book explains how an artificial intelligence model learns from its mistakes. In the previous books, the reader learned how tensors are created and transformed. Here, those operations are connected into computational graphs that PyTorch can differentiate automatically. The objective is not merely to call `backward()`, but to understand what is constructed during the forward pass, what happens during the backward pass, and why a gradient may be correct, missing, accumulated, blocked, or numerically unstable.

The book begins with computational graph construction. The reader will learn the role of `requires_grad`, the difference between leaf and non-leaf tensors, how operations connect ten-

sors to their gradient functions, and what happens when a tensor is detached from the graph. These distinctions are fundamental. If the graph is broken unintentionally, the model cannot learn; if the graph is retained unnecessarily, memory consumption can increase significantly. The exercises will therefore require the reader to inspect and reason about graph behavior instead of treating automatic differentiation as an invisible process.

The forward pass computes predictions and intermediate values, while the backward pass propagates information about the final error toward the parameters that produced it. The reader will observe gradient accumulation, learn when gradients must be cleared, study repeated backward calls, and understand the purpose of `retain_graph`. Branching graphs will show that a parameter may influence the output through several paths and that its final gradient is the sum of all relevant path contributions.

Manual gradient calculation remains an essential part of this book. The reader will calculate derivatives of linear, quadratic, vector, and matrix operations before comparing those results with PyTorch Autograd. This is necessary because automatic differentiation can compute a result, but it cannot confirm that the mathematical function itself was designed correctly. Numerical gradient approximation will provide another method for checking suspicious gradients and identifying mismatches between theoretical and computed results.

The chain rule connects the entire learning process. The reader will trace gradients through sequences of operations, nested functions, activation functions, and branching paths. They will also investigate how detaching a tensor, using an in-place operation, or disabling gradient tracking changes the graph. By following each contribution from the loss back to a parameter, the reader will understand backpropagation as a structured application of the chain rule rather than as a mysterious framework command.

The later exercises examine PyTorch's Autograd engine, custom automatic-differentiation functions, gradient hooks, memory behavior, and backpropagation through linear layers. The book concludes with gradient-flow debugging, including vanishing gradients, exploding gradients, frozen layers, broken graphs, and training collapse. By the end, the reader should be able to explain not only how gradients are computed, but also why learning succeeds or fails inside a real computational graph.

Book 4: Optimization in Code

Computing gradients tells a model how its loss changes, but gradients alone do not train the model. Optimization determines how those gradients are converted into parameter updates. This book studies the mathematical rules, implementation details, and behavioral consequences of optimization algorithms. The reader will learn that choosing an optimizer is not simply selecting a PyTorch class; it is choosing a system that controls the direction, size, memory, and stability of every learning step.

The book begins with gradient descent implemented from first principles. The reader will update scalar and vector parameters manually, observe how the learning rate changes the optimization path, and compare convergence with divergence. These experiments are important because the same gradient can produce slow progress, stable learning, oscillation, or complete failure depending on the size of the update. Tracking the loss curve will teach the reader to interpret optimization as a process that develops over time rather than as a single calculation.

Learning-rate experiments will demonstrate why there is no universally correct step size. A very small learning rate may produce stable but impractically slow progress, while a very large one may repeatedly cross the minimum or cause the loss to explode. The reader will

explore fixed rates, learning-rate sweeps, schedules, warm-up strategies, and adaptive logic. The purpose is to develop the ability to recognize learning-rate problems from evidence such as loss curves, gradient behavior, and parameter movement.

Momentum introduces memory into parameter updates. Instead of responding only to the current gradient, the optimizer maintains a velocity that combines information from previous steps. The reader will investigate acceleration, damped oscillation, noisy gradients, momentum coefficients, and custom optimizer implementations. This prepares the reader to understand why optimization algorithms maintain internal states and how those states influence future updates.

RMSProp and Adam add adaptive scaling based on gradient history. RMSProp tracks a running average of squared gradients, while Adam combines first-moment and second-moment estimates with bias correction. The reader will implement these mechanisms step by step before using their PyTorch equivalents. Particular attention will be given to numerical stability, epsilon values, decay rates, sparse gradients, and hyperparameter sensitivity. This prevents the algorithms from becoming formulas that are memorized but not understood.

Optimization must also be evaluated through convergence and stability. The reader will detect plateaus, divergence, vanishing gradients, exploding gradients, and instability caused by noisy data. Early stopping, gradient clipping, and optimizer comparisons will be used as diagnostic tools rather than automatic solutions. The book also studies weight initialization because the starting point of optimization can determine whether gradients travel through a network effectively. Zero, uniform, normal, Xavier, and He initialization will be compared through controlled experiments.

By the end of this book, the reader should be able to implement major optimization rules, interpret their internal states, identify unstable training behavior, and justify the selection of an optimizer and its hyperparameters. The goal is to replace random trial and error with experiments supported by mathematical reasoning and observable evidence.

Book 5: Loss Functions and Training Loop

This book brings the previous mathematical and computational components together into a complete learning process. A model cannot learn merely because it produces an output. It requires a loss function that measures the difference between its prediction and the desired target, a backward pass that computes gradients, an optimizer that updates parameters, and a training loop that repeats this process correctly. A mistake in any one of these components can make the entire system unreliable.

The book begins by examining what a loss represents and why its design matters. The reader will compare predictions with targets, calculate scalar and vector losses, and study different aggregation methods. Mean and sum reductions may appear interchangeable, but they change the scale of the loss and its gradients. The reader will also investigate loss sensitivity, scaling effects, and loss landscapes to understand how the selected objective shapes the behavior that the model is encouraged to learn.

Mean Squared Error will be implemented manually and through PyTorch. The reader will examine its batch behavior, gradient, sensitivity to outliers, and numerical stability when values become large. Weighted MSE and comparisons with Mean Absolute Error will show that every loss function expresses assumptions about which errors matter and how strongly they should be penalized. Choosing a loss is therefore part of defining the problem, not merely a technical step after creating the model.

Cross-entropy introduces the logic of classification. The reader will work with probabilities,

class indices, one-hot targets, logarithms, LogSoftmax, and Negative Log-Likelihood. Numerical stability will receive special attention through the log-sum-exp principle. The reader must understand whether a function expects logits or probabilities and whether the target should contain class indices or encoded vectors. Incorrect assumptions about these inputs can produce errors or silently train the wrong objective.

After studying individual losses, the reader will construct a training loop manually. Every iteration must follow a deliberate order: obtain a batch, clear old gradients, perform the forward pass, calculate the loss, run backpropagation, and update the parameters. The reader will examine why changing this order causes gradient accumulation, stale updates, or misleading loss values. Manual parameter updates will then be compared with optimizer-based updates so the relationship between mathematical rules and framework tools remains visible.

The book then expands the loop to mini-batches and epochs. The reader will learn how to shuffle data, handle the final incomplete batch, calculate epoch-level loss correctly, and understand the effect of batch size on memory, speed, and gradient noise. Accumulating batch means without considering batch size can produce an incorrect epoch statistic, so sample counts and reduction rules must remain explicit throughout the pipeline.

Training performance alone cannot establish whether a model has learned a general pattern. The reader will therefore separate training, validation, and evaluation responsibilities. They will use the correct model modes, disable gradient tracking during evaluation, calculate validation loss, compare loss with task-specific metrics, detect overfitting, and select the best model based on validation evidence. The test set must remain untouched until model and hyperparameter decisions have been completed.

The final part focuses on preventing overfitting. The reader will study regularization, weight decay, dropout, data augmentation, early stopping, and the bias–variance tradeoff. They will distinguish underfitting from overfitting and debug cases where a regularization method is implemented incorrectly. These exercises emphasize that regularization is not a collection of switches to activate blindly; every method changes the learning process and must be evaluated through controlled experiments.

By completing this book, the reader should be able to build a robust training and validation pipeline from beginning to end. They should understand how predictions become losses, how losses produce gradients, how optimizers update parameters, how batches form epochs, and how validation protects the model from false confidence. At this stage, the reader will have assembled the fundamental mechanism through which neural networks learn.

Book 6: SQL Lessons (PostgreSQL)

This book moves the reader from files and in-memory objects into the disciplined world of relational data. PostgreSQL is used because it exposes the central ideas of database engineering without hiding them behind an application framework: tables, rows, columns, keys, constraints, joins, transactions, indexes, execution plans, and access control. The objective is not merely to memorize SQL syntax. It is to learn how to represent facts so that the database can preserve their meaning even when applications fail, requests arrive concurrently, or the dataset grows beyond what can be inspected manually.

The opening chapters establish relational thinking. The reader will design schemas, choose data types, distinguish primary keys from business identifiers, model one-to-one, one-to-many, and many-to-many relationships, and use constraints to reject invalid states. They will practice inserts, updates, deletes, filters, ordering, aggregation, subqueries, common table expressions, and joins while continuously checking whether the returned rows answer the intended ques-

tion. Special attention is given to `NULL`, duplicate rows, referential integrity, and the difference between a query that runs and a query that is logically correct.

The book then connects SQL to AI-oriented systems. Experiments model users, conversations, messages, datasets, model versions, training runs, metrics, and audit events. The reader will learn when normalized tables protect consistency, when denormalization may reduce read cost, and how to design reliable boundaries between relational metadata and large binary artifacts stored elsewhere. Transactions and isolation levels are explored through concurrent update scenarios so that atomicity, consistency, isolation, and durability become observable behaviors rather than definitions learned in isolation.

Performance work begins only after correctness is established. The reader will create indexes, compare sequential and indexed access, inspect query plans, identify unnecessary scans, and study the tradeoffs introduced by every additional index. Pagination, bulk insertion, connection management, prepared statements, backup, restoration, roles, permissions, and safe migration practices are included because a useful database must survive change as well as serve queries. Failure exercises expose missing constraints, accidental Cartesian products, ineffective indexes, lock contention, and transaction boundaries that are too wide or too weak.

By completing this book, the reader should be able to design and operate a PostgreSQL database that acts as a trustworthy system of record. They should know how to translate application requirements into schemas, prove data integrity through constraints and transactions, diagnose slow or incorrect queries with evidence, and decide which information belongs in relational storage. This foundation becomes essential when later books combine structured metadata with document stores, object storage, vector databases, and model-serving pipelines.

Book 7: NoSQL Lessons (MongoDB)

This book introduces document-oriented storage as a deliberate modeling choice rather than as an escape from schema design. MongoDB stores records as flexible BSON documents, allowing related fields and nested structures to remain close to the application objects that use them. That flexibility is powerful for rapidly evolving products, conversational histories, event records, and heterogeneous metadata, but it also transfers important responsibilities to the engineer. The reader will learn that “schema-less” never means “structure-less”: every production collection still has assumptions that must be documented, validated, indexed, and migrated.

The first part develops a precise understanding of documents, collections, identifiers, embedded objects, arrays, and references. The reader will insert, retrieve, update, and delete documents; query nested fields; use projections and aggregation pipelines; and examine how document shape affects both clarity and performance. Controlled comparisons between embedding and referencing reveal the central design tradeoff: embedding can make a complete object cheap to read, while references can reduce duplication and prevent oversized or frequently rewritten documents.

Chat history and session memory provide a practical setting for these decisions. The exercises organize conversations, messages, roles, timestamps, tool calls, user preferences, and evolving metadata. The reader will investigate bounded versus unbounded arrays, atomic document updates, time-based retention, indexes for recent-history retrieval, and safeguards against duplicated events. Dynamic storage experiments then introduce validation rules, optional fields, schema version tags, backward-compatible readers, and migration strategies for documents created by older application versions.

The final chapters move from a single process to operational reliability. Readers exam-

ine compound indexes, explain plans, replica sets, read and write concerns, failover, sharding keys, chunk distribution, and the consequences of uneven access patterns. They also study authentication, least-privilege roles, backup and restoration, idempotent writes, and consistency expectations across replicas. Failure scenarios are designed to expose silent problems such as unindexed queries, hot shards, documents that grow without limit, and application code that assumes every historical document has the newest shape.

By the end of the book, the reader should be able to decide when MongoDB is a better fit than a relational database and when it is not. They should be capable of designing document models that evolve safely, building efficient query and aggregation paths, preserving session and conversational data, and planning replication and sharding from actual workload behavior. The lasting lesson is that flexibility is valuable only when it is paired with explicit invariants, observability, and disciplined operational choices.

Book 8: Object Storage Lessons (MinIO)

This book addresses a class of data that does not fit naturally inside ordinary database rows: datasets, images, audio, archives, model weights, checkpoints, exported artifacts, and other large binary objects. MinIO provides an S3-compatible environment in which the reader can learn object storage locally while working with concepts that transfer directly to larger cloud systems. The key conceptual shift is from editing files inside a shared filesystem to storing immutable or versioned objects under bucket and key namespaces and accessing them through network APIs.

The opening exercises establish the object lifecycle. Readers install and start the service, configure a client, create buckets, upload and download individual objects, list keys by prefix, inspect metadata, and verify integrity with hashes. They will distinguish an object key from a real directory path, understand content types and object metadata, and observe why large transfers require streaming or multipart uploads. Experiments with retries and interrupted transfers make idempotency and integrity checking concrete.

The next stage connects object storage to machine-learning work. Datasets, model weights, and checkpoints are organized using predictable naming and versioning strategies. The reader will implement atomic-style save workflows in which an incomplete artifact is never mistaken for a valid checkpoint, retrieve the latest approved version, resume a training run, compare local and remote I/O behavior, and remove obsolete checkpoints without deleting required recovery points. Hash manifests and metadata records are used to detect corruption or accidental replacement.

Security and scale are treated as part of the storage design. The reader will configure bucket policies, create users and access keys, compare read-only and read-write permissions, generate temporary presigned URLs, rotate credentials, and audit denied requests. Distributed-mode experiments introduce erasure coding, replication, node and disk failure, healing, availability, backup, and disaster recovery. These exercises clarify the difference between redundancy and backup: a replicated mistake or deletion is still a mistake unless independent recovery material exists.

By completing this book, the reader should be able to build a reliable artifact layer for AI systems. They should understand how to structure buckets and keys, protect credentials, transfer large files safely, validate integrity, retain useful versions, and recover from infrastructure failures. They will also know how object storage complements PostgreSQL or MongoDB: databases hold searchable state and metadata, while MinIO holds the large immutable payloads referenced by that state.

Book 9: Vector Database Lessons (Qdrant)

This book introduces a different way of retrieving information. Traditional databases answer exact conditions such as identifiers, ranges, and field equality; a vector database can retrieve items whose numerical representations are close in meaning. Qdrant is used to make this process inspectable from end to end. The reader will learn that semantic search is not magic inside the database: it is a pipeline whose quality depends on the embedding model, vector dimensions, distance metric, metadata, indexing configuration, and evaluation procedure.

The first chapters build the representation layer. Readers create collections with explicit vector size and distance settings, generate embeddings, insert individual and batched points, attach payload metadata, and retrieve records by identifier. Experiments examine normalization, cosine similarity, Euclidean distance, and semantic drift. The reader will test near and distant examples, inspect unexpected neighbors, and separate an embedding-model failure from a database configuration failure.

Similarity search is then studied as a ranking mechanism. The exercises perform top-k retrieval, apply score thresholds, filter by payload, combine semantic and structured constraints, and measure ranking stability. Rather than accepting a plausible first result, the reader will construct small relevance sets and calculate whether the desired items appear at useful ranks. Performance benchmarks show how collection size, vector dimension, filtering selectivity, and search parameters change latency and recall.

The RAG chapters connect retrieval to document-grounded generation. Text is chunked with explicit overlap and provenance, embedded, stored, queried, ranked, filtered, and limited to a controlled context budget. Empty retrieval, conflicting chunks, duplicated passages, stale documents, and weak queries are handled as first-class failure modes. The final scaling work introduces HNSW configuration, payload indexes, batch ingestion, shards, replication, consistency, monitoring, snapshot recovery, and the difference between index speed and retrieval quality.

By the end of the book, the reader should be able to engineer and evaluate a semantic retrieval system instead of merely calling a search endpoint. They should understand how meaning becomes a vector, how approximate nearest-neighbor indexes trade recall for speed, how metadata narrows semantic results, and how retrieval quality constrains the final answer of a RAG system. This prepares the ground for models that consume, transform, and generate representations at a much deeper level.

Book 10: Linear Regression

This book begins the model-centered portion of the curriculum with the simplest trainable relationship that still contains the complete logic of machine learning. Linear regression expresses a prediction as a weighted combination of input features plus a bias. Because the model is transparent, every tensor, parameter, prediction, error, gradient, and update can be inspected directly. The simplicity is intentional: the reader can concentrate on the learning mechanism without losing the causal chain inside a large architecture.

The early chapters translate $y = wx + b$ from notation into PyTorch. Readers verify shapes for single samples and batches, extend the formula to multiple features through matrix multiplication, compare manual tensor operations with `nn.Linear`, inspect registered parameters, freeze and copy models, save state dictionaries, and move models safely between CPU and CUDA. Precision and device experiments reveal why two mathematically equivalent implementations may still behave differently in actual software.

Data preparation then becomes part of the model argument. The reader generates synthetic datasets with known parameters, adds controlled noise, scales features, builds train and test splits, uses data loaders, and detects leakage or target misalignment. Collinearity, missing features, high dimensionality, caching, transfer cost, and incorrect batch shapes are explored because a correct formula cannot compensate for a broken input pipeline.

The central chapters connect predictions to mean squared error and gradients. Readers implement MSE manually, compare reduction modes, inspect loss gradients, observe the disproportionate effect of outliers, perform manual parameter updates, verify gradients through finite differences, and compare hand-written steps with optimizers. Full training loops introduce epochs, convergence criteria, divergence detection, learning-rate schedules, early stopping, checkpoints, reproducible seeds, mixed precision, and recovery after interruption.

Evaluation completes the story. RMSE, MAE, residuals, error distributions, cross-validation, throughput, latency, and memory are measured on held-out data. Visualizations of predictions, residuals, loss curves, feature contributions, weights, and bias turn numeric output into evidence about model behavior. By completing the book, the reader should be able to explain exactly how a differentiable model learns, diagnose each stage of its pipeline, and distinguish a low training loss from a model that genuinely represents the underlying relationship.

Book 11: Logistic Regression

This book transforms the linear score into a probabilistic classifier. Logistic regression begins with the same weighted sum used in linear regression, but interprets that raw value as a logit and maps it through the sigmoid function. The result lies between zero and one and can be converted into a class decision through a threshold. This apparently small change introduces many of the central ideas of classification: probabilities, decision boundaries, likelihood, calibration, class imbalance, asymmetric errors, and threshold-dependent metrics.

The reader first implements sigmoid manually and with PyTorch, checks its numerical range, studies saturation under extreme logits, and compares CPU, CUDA, `float32`, and `float64` behavior. Single-sample and vectorized batch predictions make the relationship between tensor shape and output meaning explicit. Threshold experiments show that the model produces a probability-like score while the application chooses the decision rule; changing the threshold changes false positives and false negatives without retraining the weights.

Probability is then connected to likelihood and loss. Readers calculate likelihood, log-likelihood, negative log-likelihood, binary cross-entropy, and the stable logits-based form used by `BCEWithLogitsLoss`. They observe why taking a logarithm of a rounded probability can fail, how class weights affect imbalanced data, and how confidence can be poorly calibrated even when accuracy appears high. The geometry of the linear decision boundary is visualized as weights, bias, scaling, noise, overlap, and regularization change.

Training and evaluation chapters inspect gradients, optimizer updates, clipping, accumulation, mixed precision, and failure cases such as vanishing gradients caused by sigmoid saturation. Confusion matrices, precision, recall, F1, ROC, AUC, threshold sweeps, calibration checks, latency, and memory profiling are implemented from their definitions. A multi-class extension compares one-versus-rest sigmoid models with softmax and cross-entropy, making clear which assumptions change when classes are mutually exclusive.

By the end of the book, the reader should be able to build a numerically stable classification pipeline and defend its decision threshold using the costs of real errors. They should understand the distinction among logits, probabilities, labels, likelihood, and loss; recognize when accuracy is misleading; and analyze both a model's ranking ability and the reliability of its confidence.

This creates a direct bridge from regression into neural classification.

Book 12: Perceptron

This book studies the perceptron as both a historical foundation and a precise boundary between what one linear decision unit can and cannot represent. A perceptron computes a weighted sum plus bias and applies a hard step rule. Unlike logistic regression, it does not attempt to produce a smooth probability. Its prediction is a direct binary decision, and its learning rule responds to classification errors by moving the decision boundary toward a configuration that separates the observed classes.

Readers begin by implementing the forward calculation in pure Python and PyTorch, inspecting the step activation, and comparing continuous linear output, sigmoid probability, and hard binary output. The vector dot product, bias term, signed distance, weight direction, and hyperplane geometry are developed carefully. Two-dimensional plots make each parameter change visible, while higher-dimensional tensor experiments preserve the same mathematical interpretation.

The learning rule is derived from misclassified samples and then implemented without an optimizer. Readers track weights and bias after every update, compare online and batch-style variants, vary the learning rate and sample order, verify updates manually, and observe oscillation under noisy labels. The perceptron convergence theorem is tested on linearly separable data by measuring the number of mistakes and relating stability to the separating margin.

Limitations receive equal attention. XOR and overlapping classes demonstrate why no single hyperplane can solve a non-linearly separable problem. Perceptron loss, hinge loss, and zero-one loss are compared to reveal why smooth or margin-based objectives are easier to optimize. Multi-class strategies, class-specific weight vectors, generalization, regularization, robustness, high-dimensional behavior, CPU/GPU execution, and performance profiling broaden the model without hiding its assumptions.

The final chapter manually combines multiple perceptrons to form non-linear decision regions and solve XOR. This is the conceptual step from a single artificial neuron to a network. By completing the book, the reader should be able to derive and implement the perceptron, state precisely when it converges, diagnose why it fails, and explain why hidden layers and differentiable training are necessary for more expressive models.

Book 13: MLP (Feed-Forward Neural Networks)

This book turns individual linear units into a trainable multi-layer system. A multilayer perceptron composes affine transformations with non-linear activation functions so that each hidden layer can construct a new representation for the next. The central insight is that stacking linear layers without non-linearity remains only one linear transformation; expressive power arises from the interaction among depth, width, learned features, and non-linear activation.

The reader builds two-layer networks from raw tensor operations before using `nn.Module`, `nn.Linear`, and configurable layer lists. Parameter registration, shapes, hooks, copying, serialization, device placement, and architecture validation are treated explicitly. Shallow and deep networks are compared on the same task so that width, depth, bottlenecks, parameter count, memory, and representation capacity become measurable design choices rather than abstract preferences.

Activation and initialization experiments expose the internal health of a network. ReLU, LeakyReLU, sigmoid, tanh, and GELU are compared through activation distributions and gra-

dient flow. Dying ReLUs, saturated sigmoid units, vanishing gradients, and exploding gradients are produced intentionally. Zero, uniform, normal, Xavier, and He initialization are tested while layer-wise statistics show whether signals and gradients remain usable as depth increases.

Backpropagation is then followed through every layer. Readers inspect the autograd graph, calculate a small example manually, perform finite-difference gradient checks, use hooks to record gradient norms, and debug detached tensors, missing `zero_grad`, incorrect loss reduction, device mismatches, and retained graphs. Optimizer chapters compare SGD, momentum, Adam, and AdamW; explore learning-rate schedules, clipping, accumulation, weight decay, mixed precision, and silent update-order bugs; and measure convergence under controlled seeds.

The final portion assembles complete classification and regression pipelines with training, validation, checkpointing, logging, regularization, dropout, early stopping, cross-validation, profiling, export, inference wrappers, object-storage integration, and recovery tests. By completing this book, the reader should be able to design an MLP, observe its internal dynamics, stabilize its optimization, and prepare it for reproducible deployment. More importantly, they will possess a reusable debugging method that carries directly into deeper architectures.

Book 14: Convolutional Neural Networks (CNN)

This book introduces the architectural bias that made deep learning especially effective for images. A fully connected layer mixes every input location globally, while convolution applies shared local filters across space. This structure exploits locality, repeated visual patterns, and translation-related behavior while using far fewer parameters. Readers do not begin with a large pretrained network; they first implement the operation with nested loops so that every pixel, kernel value, stride, padding choice, and output position can be accounted for.

The foundations include cross-correlation, kernel sliding, channels-first tensors, feature maps, receptive fields, padding, stride, dilation, and output-shape formulas. Manual results are checked against PyTorch convolution. Multiple input and output channels reveal how kernels combine spatial and channel information, while custom edge detectors make feature responses visible. Depthwise, grouped, and 1×1 convolutions demonstrate different ways to trade computation and parameters for representational capacity.

Pooling and downsampling chapters examine max pooling, average pooling, global average pooling, adaptive pooling, strided convolution, aliasing, and information loss. The reader constructs full CNN forward architectures with activation functions, flattening or global pooling, classifier heads, batch normalization, dropout, hooks, and residual connections. Shape-tracking utilities and unit tests are used to catch the channel-order and spatial-dimension bugs that frequently appear before training begins.

Training is developed together with the vision data pipeline. Readers load and normalize images, prevent split leakage, apply crops, flips, rotations, color changes, erasing, MixUp or CutMix, balanced sampling, and augmentation ablations. They inspect gradients, overfit a tiny dataset as a correctness test, diagnose NaNs and misleading accuracy, tune optimizers and schedules, use CUDA and mixed precision, and profile data-transfer or DataLoader bottlenecks. Regularization, normalization, calibration, robustness to blur, noise, occlusion, and distribution shift are evaluated through categorized failure examples.

Modern blocks and deployment complete the track. VGG-style stacks, residual bottlenecks, depthwise-separable blocks, inverted residuals, squeeze-and-excitation, stochastic depth, and DropPath are implemented and compared by parameters, FLOPs, memory, speed, and accuracy. Export, compilation, quantization, versioning, monitoring, rollback, and inference-service stress tests connect research code to production constraints. By the end, the reader should

be able to explain what a CNN sees, build and train one reliably, select efficient blocks, and diagnose failures from raw inputs through deployment.

Book 15: Recurrent Neural Networks (RNN)

This book introduces models whose computation carries state through time. Sequence data cannot always be understood by treating each observation independently: the meaning of a word, signal, or event may depend on what appeared earlier. A recurrent neural network addresses this by combining the current input with a hidden state produced at the previous time step. The same weights are reused across the sequence, creating a compact memory and allowing one model to process inputs of different lengths.

The reader implements the recurrence first in pure Python and then with tensors, manually unrolls it through time, and compares the result with `nn.RNN`. Many-to-one and many-to-many mappings, batch-first layouts, stacked and bidirectional variants, hidden-state initialization, and shape rules are examined in detail. Synthetic tasks reveal whether the hidden state actually stores useful history, how information decays, and how hidden size affects memory capacity.

Backpropagation through time exposes both the power and the weakness of the architecture. Readers inspect gradients at successive time steps, reproduce vanishing and exploding behavior, apply clipping, perform finite-difference checks, and implement truncated BPTT. Detaching state at the wrong boundary, retaining graphs accidentally, forgetting to clear gradients, and carrying state across unrelated sequences are treated as concrete engineering failures with observable consequences.

Sequence preparation receives a complete pipeline of its own. Sliding windows, variable lengths, padding, masks, packed sequences, collate functions, teacher forcing, stateful batching, temporal train/validation splits, and target alignment are validated through small edge cases. Character-level language modeling and time-series forecasting then provide two complementary applications. Sampling temperature, top-k, perplexity, autoregressive drift, forecast horizons, walk-forward evaluation, and temporal leakage connect recurrent mechanics to real output quality.

The final chapters examine regularization, normalization, initialization, CUDA performance, mixed precision, profiling, export, and reproducibility. Long-dependency experiments show where vanilla recurrence fails even when code is correct. By completing the book, the reader should be able to build and debug an RNN pipeline, understand the computational and gradient paths through time, and explain from evidence why gated architectures such as GRU and LSTM were needed.

Book 16: Long Short-Term Memory (LSTM)

This book studies the LSTM as an engineering response to the fragile memory of the vanilla RNN. Instead of forcing all past information through one repeatedly transformed hidden state, an LSTM introduces a cell state and learned gates that regulate forgetting, writing, and exposure. The architecture does not grant unlimited memory, but it creates a more stable path through time and gives the model explicit mechanisms for preserving or discarding information.

Readers derive the forget, input, candidate, and output equations and implement a single LSTM cell with raw Torch tensors. Gate ranges, concatenation order, weight shapes, hidden state, and cell state are verified at every step. Forced gate values reveal causal behavior: a closed input gate prevents writing, an open forget gate preserves memory, and the output gate controls what becomes visible. A manual temporal unroll is compared with `nn.LSTM` on CPU

and CUDA.

Architecture chapters cover many-to-one and many-to-many mappings, stacked and bidirectional models, projection layers, dropout between layers, batch-first layouts, and custom wrappers that expose internal state. Backpropagation experiments measure gradients through both hidden and cell paths, identify gate saturation, apply clipping, compare full and truncated BPTT, and diagnose detach strategies that silently destroy long-term learning. Precision, initialization, sequence length, and learning rate are varied to show that an LSTM can still become unstable or forget.

The data and application sections revisit variable-length packing, masking, state reset, teacher forcing, character language modeling, text sampling, time-series forecasting, multi-step drift, and walk-forward validation at greater memory depth. Comparisons with RNN and GRU clarify where additional gates justify their parameter and runtime cost. Regularization, calibration, distribution shift, profiler traces, CUDA utilization, checkpoint recovery, TorchScript, ONNX, and deployment benchmarks turn the model into a complete engineering system.

The closing chapter adds attention on top of LSTM outputs. The reader observes how attention relaxes the encoder bottleneck by retrieving information from multiple time steps directly, while also seeing that the recurrent core still limits parallel execution. By completing the book, the reader should understand not only how LSTM gates work, but why they improve gradient flow, where they remain insufficient, and how their remaining limits lead naturally to attention and Transformers.

Book 17: Transformers

This book introduces the architecture that replaces sequential recurrence with content-based interaction among tokens. Attention allows each position to retrieve a weighted combination of information from other positions, making dependencies explicit and permitting the sequence to be processed in parallel during training. The reader will not treat the Transformer as an opaque library component. Every major tensor transformation is built, measured, tested, and related to the model's ability to represent context.

The opening chapters define queries, keys, and values and implement scaled dot-product attention from raw Torch operations. Shape reasoning follows the full `(batch, heads, sequence, dimension)` layout. Stable softmax, padding masks, causal masks, dropout, scaling by $\sqrt{d_k}$, and attention visualizations are validated through properties rather than example outputs alone. Runtime and memory experiments reveal the quadratic cost of dense attention as sequence length grows.

Multi-head attention, token embeddings, positional information, residual paths, layer normalization, and feed-forward sublayers are assembled into complete encoder and decoder blocks. Readers inspect head diversity, projection matrices, pre-norm and post-norm behavior, positional extrapolation, mask broadcasting, and gradient flow through residual connections. Small copy, classification, and next-token tasks provide controlled environments in which a wrong axis or mask produces a clear failure signal.

Training chapters cover tokenization boundaries, batching variable-length text, cross-entropy alignment, teacher forcing, autoregressive decoding, learning-rate warmup, weight decay, clipping, mixed precision, checkpointing, and reproducibility. Encoder-only, decoder-only, and encoder–decoder architectures are compared by information access and task objective. Profiling then connects theory to hardware through memory peaks, fused attention kernels, compilation, gradient checkpointing, sequence packing, caching, and throughput under realistic batch and context sizes.

By completing this book, the reader should be able to implement a small Transformer from first principles, prove that its masks prevent forbidden information flow, train it on controlled tasks, and identify failures in attention, positions, normalization, or optimization. They should also understand why Transformers displaced recurrent networks at scale and what their advantages cost in memory, data, and computation. This creates the architectural foundation needed to study large language models as systems rather than as mysterious text generators.

Book 18: Large Language Models (LLMs)

This book completes the volume by expanding the Transformer from a small inspectable model into the full lifecycle of a large language model. The scale changes more than the parameter count. Data construction, tokenization, distributed optimization, evaluation, alignment, inference memory, serving, monitoring, and safety become coupled parts of one system. The goal is to give the reader a rigorous map of these parts while preserving the experimental habit developed throughout the earlier books.

The first stage explains how text becomes training examples. Readers examine subword tokenization, vocabulary tradeoffs, context windows, document boundaries, deduplication, filtering, contamination, mixtures of data sources, and next-token prediction. Scaling experiments connect parameters, tokens, batch size, compute, and validation loss without implying that lower pretraining loss automatically produces a useful or trustworthy assistant. Checkpoints and optimizer states are treated as large distributed artifacts with explicit storage and recovery requirements.

Post-training then changes model behavior. Supervised instruction tuning, prompt formats, response masking, preference data, reward modeling, direct preference methods, and human evaluation are introduced through small reproducible analogues. Readers distinguish capability from instruction following, style from factuality, and refusal behavior from genuine safety. Dataset bias, reward hacking, catastrophic forgetting, and benchmark contamination are investigated as failure modes that can produce impressive metrics while weakening real-world reliability.

Inference chapters reveal why serving an LLM is a systems problem. Autoregressive decoding, temperature, top-k, top-p, repetition controls, KV caching, batching, streaming, quantization, memory estimation, latency, throughput, and context growth are measured together. Retrieval-augmented generation, tool calling, structured outputs, and agent loops connect the model to PostgreSQL, MongoDB, MinIO, Qdrant, and the engineering foundations established earlier. Every external action is surrounded by validation, permissions, provenance, timeouts, and failure handling.

Evaluation and production readiness form the final discipline. Readers build task suites, compare automatic and human judgments, test hallucination, calibration, robustness, prompt injection, data leakage, harmful output, distribution shift, and performance regression. Monitoring, versioning, red-team cases, rollback, cost accounting, and incident analysis prevent a successful demonstration from being mistaken for a dependable product. By completing the book, the reader should be able to reason about an LLM across data, architecture, training, alignment, inference, tools, evaluation, and deployment—and to identify which layer of the system must change when behavior fails.

Book 19: Dynamic Memory Management

This book treats memory as an active computational resource rather than a passive capacity limit. Modern PyTorch systems do not operate inside GPU memory alone: tensors, parameters, gradients, optimizer states, activations, input batches, and inference caches move through a hierarchy that includes CUDA VRAM, pinned and pageable system RAM, memory-mapped storage, and NVMe. Performance and correctness therefore depend not only on how many bytes exist, but on where those bytes reside, when they are created, how long they remain live, whether they can be reused, and what synchronization protects them while computation is in flight. Across fifty chapters and one thousand exercises, the reader constructs a measurable theory of this hierarchy and then turns it into a working dynamic-memory runtime.

The opening chapters establish the evidence layer. Readers learn to distinguish allocated, reserved, active, inactive, peak, free, and total memory; predict tensor storage from shape and dtype; and reconcile PyTorch counters with device-level observations. Operator profiling, caching-allocator behavior, detailed allocator statistics, and memory snapshots expose increasingly precise views of the same system. Instead of diagnosing every rise in reserved memory as a leak, the reader reconstructs segments, blocks, allocation histories, stack traces, retry events, and fragmentation. Pinned host buffers, non-blocking transfers, CUDA streams, events, prefetching, and compute–copy overlap then connect memory state to the physical data path between CPU and GPU. Every timing experiment separates submission latency, device execution, synchronization, page-locking cost, and end-to-end throughput so that asynchronous work cannot produce misleading measurements.

The middle of the book turns observation into control. Readers design eviction policies, dynamic tensor and parameter placement, layer offloading, CPU and NVMe offloading, and out-of-core execution across a three-tier hierarchy. Activation checkpointing and activation offloading trade storage for recomputation or transfer, while mixed precision, dynamic loss scaling, gradient accumulation, and adaptive batch sizing change the memory budget during training. Controlled CUDA out-of-memory experiments lead to recovery policies, memory-aware scheduling, buffer pools, fragmentation management, tensor reuse, in-place operations, and storage-alias analysis. Meta-device construction, lazy parameter materialization, memory-mapped datasets, DataLoader optimization, and virtualized or paged tensor storage show how large systems can be assembled without allocating every object at once.

The LLM and distributed chapters apply these principles where memory pressure becomes architectural. Readers implement paged KV caches, move cache blocks between VRAM and RAM, quantize cached keys and values, and design eviction policies that balance context retention against latency and capacity. Fully Sharded Data Parallel, ZeRO-style partitioning, tensor parallelism, pipeline scheduling, and multi-GPU balancing are studied as memory-placement algorithms rather than as unexplained framework switches. Parameters, gradients, optimizer states, activations, temporary communication buffers, and uneven device capacities are accounted for explicitly. Experiments are designed to run on one machine with the available GPUs while still revealing the ownership, communication, synchronization, and failure principles that govern larger distributed systems.

The closing chapters unite measurement and policy as one engineering discipline. CUDA events and bandwidth profiling establish trustworthy timing boundaries; leak investigations connect persistent references to Python source; autograd analysis reconstructs saved tensors and graph lifetimes; and detach, no-grad, and inference mode are treated as distinct controls with distinct correctness consequences. The reader then builds a custom PyTorch memory manager and a final offload engine that observes pressure, chooses placement, reuses bounded buffers, schedules transfers, applies backpressure, recovers from predictable failures, and vali-

dates numerical outputs after every optimization. By completing this book, the reader should be able to explain every major MiB used by a workload, locate the source of memory growth, distinguish capacity failure from fragmentation or lifetime failure, and design a runtime that adapts across VRAM, RAM, and storage without sacrificing correctness, stability, or reproducibility.

0.4 Artificial Intelligence Departments

When you start learning about artificial intelligence, you might encounter some problems, or in short, you'll fall into a black hole and won't know why this is happening, who I am, or what's around me.

At every step, you must know which AI specialization you are currently studying, because this is the simplest and most important question that helps you understand the AI world without confusion. When you clearly know where you are, learning becomes focused and stable, and you stop mixing theory with systems or tools that belong to a different stage. The harder questions, such as why you are studying this or what learning structure you want, can come later, but without first knowing your current specialization, progress feels chaotic even when you are moving forward. Knowing where you stand gives context, sets boundaries, and makes the entire learning journey intentional and clear.

For this reason, readers will notice that I explicitly show the AI specializations inside the book itself. These specializations are placed there intentionally so the reader always knows which domains they are focusing on, independent of the book title. By seeing the specializations clearly, the reader can immediately understand what they are learning at that moment and which part of the AI landscape they are operating in, making the learning process structured, contextual, and free from confusion.

1- Mathematics and Theory

This specialization focuses on the mathematical foundations that govern artificial intelligence, including linear algebra, probability theory, optimization, and information theory. It provides the formal language used to describe models, learning dynamics, and convergence behavior, making it essential for understanding why algorithms work, not just how to use them.

2- Models and Training

This specialization covers the design, training, and optimization of AI models such as neural networks, transformers, and other learning architectures. It includes loss functions, backpropagation, optimization strategies, and training stability, forming the core process through which models learn from data.

3- Data Engineering for AI

This specialization focuses on preparing data for machine learning systems, including data collection, cleaning, transformation, labeling, and feature engineering. Since model performance

is heavily dependent on data quality, this area plays a critical role in the success or failure of AI systems.

4- AI Evaluation and Experimentation

This specialization is concerned with measuring and validating model performance using metrics, benchmarks, validation strategies, and controlled experiments. It ensures that models generalize correctly, avoid overfitting, and behave as expected under different conditions.

5- Applied AI and Deployment

This specialization deals with integrating trained models into real-world applications. It includes inference pipelines, APIs, latency optimization, monitoring, and system reliability, transforming research models into usable and scalable AI products.

6- AI Systems and Distributed Training

This specialization focuses on scaling AI training and inference across multiple devices or machines. It includes distributed training techniques, parallelism strategies, memory optimization, and communication frameworks, which become necessary when working with large models or datasets.

7- AI Infrastructure and Hardware

This specialization addresses the underlying hardware and infrastructure that support AI workloads. It includes GPUs, accelerators, memory hierarchies, networking, and low-level software stacks, enabling efficient computation at scale.

8- AI Safety / Ethics / Alignment

This specialization examines the risks, limitations, and societal impact of AI systems. It covers topics such as bias, robustness, alignment with human intent, misuse prevention, and regulatory considerations, ensuring AI systems are safe and responsible.

9- AI + Domain Specialization

This specialization focuses on applying AI techniques to specific fields such as medicine, finance, cybersecurity, physics, or robotics. It combines AI knowledge with domain expertise, enabling the creation of effective and meaningful solutions within real-world contexts.

Book 1

Tensor Mathematics and Neural Networks Guide

1.1 Introduction

1.1.1 What will the book teach you

Before entering the world of artificial intelligence programming, you must understand the mathematical and programming foundations that make intelligent systems possible. This book begins with the most fundamental tensor operations and gradually progresses toward higher-dimensional tensor laws, differential calculus, optimization, probability, statistics, and neural-network transformations using PyTorch.

The purpose of this book is to build a strong connection between mathematical theory and practical implementation. You will learn how equations describe tensor operations, how tensor shapes control valid computations, and how these laws appear inside neural networks. Every chapter builds on the knowledge from the chapters before it, so you should understand each lesson and complete every exercise before moving forward.

The book consists of many exercises. Each exercise explains why a mathematical law matters, presents its mathematical form, provides hints and helpful PyTorch tools, and gives you an incomplete Python code skeleton. The complete solution will not be provided. You must analyse the problem, complete the code, test your implementation, and correct any mistakes yourself.

This approach may feel challenging, but it is designed to develop independent reasoning and genuine problem-solving ability. The objective is not simply to memorize equations or copy code. You must understand what each operation does, why its dimensions are valid, how it affects data, and where it is used in artificial intelligence. This book will establish the mathematical foundation required for the practical and advanced AI books that follow.

1.1.2 The Chapters (T00 - T08) included in this book

- T00 - Tensor Algebra Laws
- T01 - Vector Laws (1D)

- T02 - Matrix Laws (2D)
- T03 - Higher-Dimension Tensor Laws
- T04 - Tensor Shape Transformation Laws
- T05 - Differential Calculus Laws
- T06 - Optimization Laws
- T07 - Statistics Probability Laws
- T08 - Neural Network Transformation Laws

1.2 T00 - Tensor Algebra Laws

Mathematics and Theory

1.2.1 Exercise 00 - Tensor Addition Law

Part 1 - why this matters

Tensor addition is the first operation used to combine numerical information in artificial intelligence systems. It appears in almost every model, from adding bias terms to accumulating gradients during training. Understanding this operation is essential before moving to more complex tensor transformations.

Part 2 - Mathematical form

Mathematical Definition

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor (matrix) addition is a binary operator defined as:

$$+ : \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} + \mathbf{Y}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the operation is defined component-wise by:

$$Z_{i,j} = X_{i,j} + Y_{i,j} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

Tensor addition in PyTorch is performed using the built-in function `torch.add(x, y)`. This operation applies element-wise addition and requires both tensors to have the same shape.

Before performing any tensor operation, ensure that the inputs are PyTorch tensors created using `torch.tensor()`. Understanding how tensors are constructed is essential before manipulating them.

PyTorch tensors can exist on different devices:

- CPU (default)
- GPU (CUDA-enabled devices)

When working with multiple tensors, both tensors must be located on the same device. Mixing CPU and GPU tensors will result in a runtime error.

To deepen your understanding, explore:

- How to create tensors using `torch.tensor()`
- How to check the device of a tensor
- How to move tensors between CPU and GPU

This exercise assumes CPU-based tensors, but the same logic applies to GPU tensors when explicitly moved to a CUDA device.

Part 4 - Python code skeleton

```
import torch

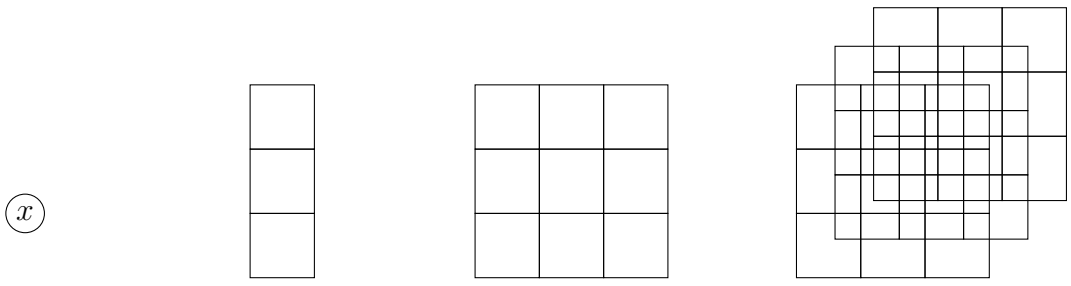
def E00(x,y):
    z = torch...
    return z

def main():
    x = torch.tensor...
    y = torch.tensor...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.2.2 Exercise 01 - Tensor subtraction Law

Part 0 - Before we begin



Scalar **Vector** **Matrix** **Tensor**

All numerical data in artificial intelligence is ultimately represented using the same underlying structure; the difference lies only in how many dimensions the data has.

- **Scalar**: A single numerical value with no dimensions.
- **Vector**: A one-dimensional collection of ordered values.
- **Matrix**: A two-dimensional grid of values arranged in rows and columns.
- **Tensor**: A generalization to three or more dimensions, used to represent complex data such as images, sequences, or batches.

Part 1 - why this matters

This operation has the same importance as the previous exercise. The only difference is that subtraction is used instead of addition. Understanding this change is essential before moving to more advanced tensor operations.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor (matrix) subtraction is a binary operator defined as:

$$- : \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} - \mathbf{Y}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the operation is defined component-wise by:

$$Z_{i,j} = X_{i,j} - Y_{i,j} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, tensor subtraction is performed using the built-in function `torch.sub(x, y)`. The reader is encouraged to search for this function and understand how it applies element-wise subtraction between tensors.

Part 4 - Python code skeleton

```
import torch

def E01(x,y):
    z = torch...
    return z

def main():
    x = torch.tensor...
    y = torch.tensor...
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.2.3 Exercise 02 - Tensor Hadamard Multiplication Law

Part 1 - why this matters

This exercise continues the logical progression of tensor operations. After learning how tensors are combined through addition and how differences are expressed through subtraction, Hadamard multiplication introduces a new concept: controlling how information is scaled rather than simply accumulated or removed.

Unlike addition and subtraction, element-wise multiplication directly modifies the strength of each individual value. Each component can be amplified, reduced, or completely suppressed depending on the corresponding value in the second tensor. This changes the behavior of the data itself, not just its numerical total.

Understanding this operation is essential because it represents a foundational mechanism used later in more advanced tensor transformations. Mastering this concept at an early stage makes the transition to complex model structures more intuitive and coherent.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Hadamard multiplication (element-wise multiplication) is a binary operator defined as:

$$\odot : \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \odot \mathbf{Y}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the operation is defined component-wise by:

$$Z_{i,j} = X_{i,j} \cdot Y_{i,j} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, Hadamard (element-wise) multiplication can be performed using the built-in operator `x * y`.

The reader is encouraged to search for a function called `torch.mul()` and understand how it performs element-wise multiplication between tensors.

Part 4 - Python code skeleton

```
import torch

def E02(x,y):
    z = torch...
    return z

def main():
    x = torch.tensor...
    y = torch.tensor...
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.2.4 Exercise 03 - Tensor Division Law

Part 0 - The weight

In artificial intelligence, a weight represents the strength of influence that an input has on the model's internal computation and final decision. Each input signal is multiplied by a weight, allowing the model to emphasize important information and suppress irrelevant or noisy signals. Learning in neural networks is therefore the process of continuously adjusting these weights to reflect how much the model should trust each input.

$$2000 \times 2000 = 4{,}000{,}000$$

$$0.2 \times 0.2 = 0.04$$

The large numerical gap produced by unscaled weights leads to unstable matrix computations, where values grow too fast and dominate subsequent operations. Keeping weights within a controlled and close numerical range ensures stable tensor operations, preserves relative relationships between features, and allows learning algorithms to update weights smoothly without numerical explosion or loss of precision.

Part 1 - why this matters

Tensor Division Law is required because repeated multiplication and accumulation in neural networks cause values to either explode or vanish, and division is used to rescale tensors into a numerical range where learning remains stable.

In normalization, division is not applied merely to modify data values, but to decouple magnitude from structure, allowing the model to learn patterns rather than be dominated by raw numerical scale.

When working with ratios, probabilities, and feature weights, division transforms absolute values into relative relationships, enabling meaningful comparison and scale-independent decision making.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Division Law (element-wise):

$$\oslash : \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \oslash \mathbf{Y}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \frac{X_{i,j}}{Y_{i,j}} \quad \text{for } i,j \in \{1,2,3\}, \quad Y_{i,j} \neq 0.$$

Part 3 - Hints and Helper

In PyTorch, tensor division (element-wise division) can be performed using the built-in operator `x / y`.

The reader is encouraged to search for a function called `torch.div()` and understand how it performs element-wise division between tensors.

Part 4 - Python code skeleton

```
import torch

def E03(x,y):
    z = torch...
    return z

def main():
    x = torch.tensor...
    y = torch.tensor...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.2.5 Exercise 04 - Tensor Power Law

Part 0 - The Magnitude

In artificial intelligence, knowing whether a value is positive or negative is often less important than understanding its magnitude relative to zero. Magnitude represents the size or intensity of an error or deviation without regard to direction, since a model must measure how large an error is rather than where it lies.

For this reason, power-based operations are used to represent magnitude in a numerically stable form, enabling reliable measurement and optimization of error and deviation.

Part 1 - why this matters

In artificial intelligence, it is essential to distinguish between the influence of a signal controlled by weights and the magnitude of a value measured independently of its direction.

The Tensor Power Law is used to convert values into measurable magnitudes, enabling stable numerical evaluation of error and deviation.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Power Law (element-wise) is defined as:

$$\circledast : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \circledast 2$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = (X_{i,j})^2 \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, tensor power (element-wise exponentiation) can be performed using the built-in operator `x ** 2`.

The reader is encouraged to search for a function called `torch.pow()` and understand how it applies element-wise power operations between tensors or between a tensor and a scalar.

Part 4 - Python code skeleton

```
import torch

def E04(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.2.6 Exercise 05 - Tensor Square Root Law

Part 0 - The element-wise

What "element-wise" means. An **element-wise** operation applies the same rule to each entry of a tensor *independently*, so the value at one position is computed only from the value(s) at the *same position*. As a result, the output typically has the **same shape** as the input (or the broadcasted shape if broadcasting is used).

Shape requirement (matrix × matrix). For two matrices, an element-wise binary law is defined only when the shapes match:

$$\odot : \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}, \qquad Z_{i,j} = X_{i,j} \odot Y_{i,j}.$$

Here, each output entry $Z_{i,j}$ depends only on $X_{i,j}$ and $Y_{i,j}$.

Why we use element-wise laws in AI. Element-wise laws are used to transform or scale data *without mixing information* across positions. They are essential for operations such as normalization, magnitude measurement (e.g., squaring), and pointwise non-linear transformations, where we want to adjust values while preserving the tensor structure.

Why $\mathbb{R}^{3\times3}$ and $\mathbb{R}^{3\times2}$ is not element-wise. If $\mathbf{X} \in \mathbb{R}^{3\times3}$ and $\mathbf{Y} \in \mathbb{R}^{3\times2}$, then an element-wise binary operation is **not defined** because there is no one-to-one alignment between entries:

$$\mathbb{R}^{3\times3} \not\odot \mathbb{R}^{3\times2} \quad \text{(shape mismatch)}.$$

So your intuition is correct: this is **not** an element-wise operation. However, this does **not** automatically mean it is a different "type of operation" by itself; it is simply a **shape mismatch** for element-wise binary laws. (Only if a broadcasting rule applies can some mismatched shapes still work, but 3×3 and 3×2 do not broadcast to a common shape.)

Part 1 - why this matters

In artificial intelligence, operations like squaring are used to measure intensity or error without being affected by sign, but they also change the measurement unit and push values into a much larger numerical range than the original scale. The Tensor Square Root Law restores values back to their natural scale after magnitude-based computations, making results interpretable and comparable by returning them to the same "unit" as the original signal rather than leaving them in squared units. Additionally, the square root compresses the numerical range and mitigates the growth caused by squaring and accumulation, improving tensor-level numerical stability and reducing the risk of explosion or precision loss during training.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$ with $X_{i,j} \geq 0$.

Tensor Square Root Law (element-wise) is defined as:

$$\sqrt{\cdot} : \mathbb{R}^{3\times3}_{\geq 0} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \sqrt{\mathbf{X}}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \sqrt{X_{i,j}} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, tensor square root (element-wise square root) can be performed using the built-in function `torch.sqrt()`.

The reader is encouraged to explore how `torch.sqrt()` applies the square root operation element-wise on tensors and to understand its role in restoring scale after magnitude-based operations.

Part 4 - Python code skeleton

```
import torch

def E05(x):
    z = torch...
    return z

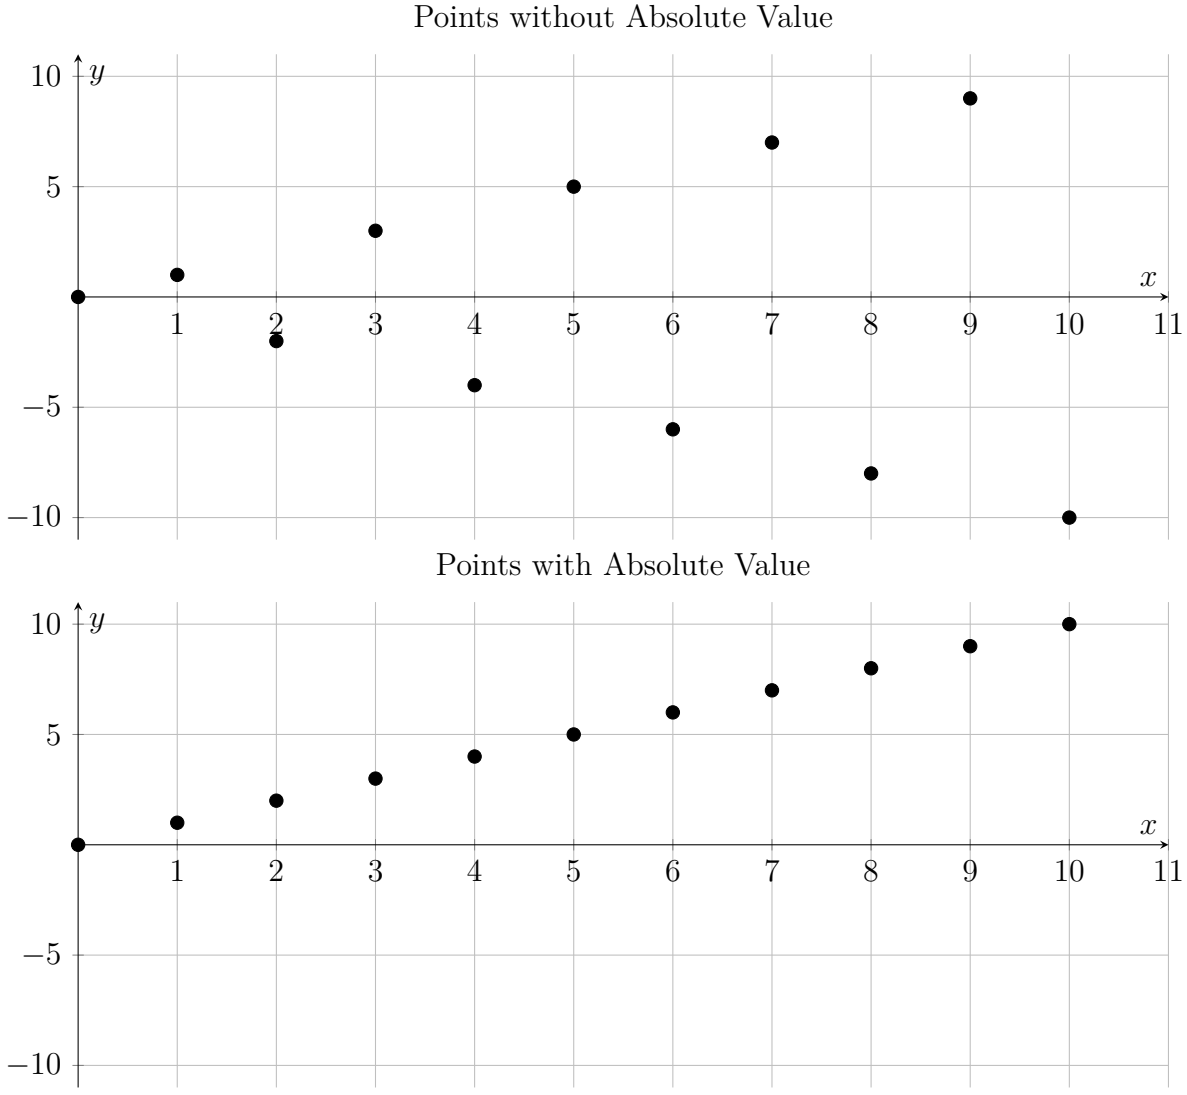
def main():
    x = torch.tensor...
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.2.7 Exercise 06 - Tensor Absolute Value Law

Part 1 - why this matters

In artificial intelligence equations, the goal is not always to determine the direction of an error or the sign of a value, but rather to measure its true magnitude regardless of whether it is positive or negative. Positive and negative values represent different directions around a reference point, but when evaluating model performance or computing deviation, the sign can be misleading because it allows errors to cancel each other out during aggregation. For this reason, it becomes necessary to remove the sign and convert values to non-negative quantities, so that every deviation is counted as an independent contribution reflecting its actual intensity rather than its direction. This transformation ensures that no error disappears simply because an opposite error exists.



The absolute value provides a precise and straightforward way to achieve this goal without altering the numerical scale of values or artificially amplifying them. Unlike squaring, which changes the measurement unit and exaggerates large differences, the absolute value preserves linear relationships between values and enables direct, numerically stable measurement of deviation. This is why it is widely used in artificial intelligence equations whenever a fair and

balanced assessment of error or distance is required, especially in scenarios where excessive influence from large values must be avoided or clear interpretability of results is desired. In this sense, removing the sign is not a mathematical simplification, but a deliberate choice to separate measurement from direction within the model.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Absolute Value Law (element-wise) is defined as:

$$|\cdot| : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = |\mathbf{X}|$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = |X_{i,j}| \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor absolute value (element-wise absolute value) can be computed using the built-in function `torch.abs()`.

The reader is encouraged to explore how `torch.abs()` removes the sign of each element independently and how it is commonly used in error measurement and magnitude-related computations.

Part 4 - Python code skeleton

```
import torch

def E06(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.2.8 Exercise 07 - Tensor Negation Law

Part 0.1 - Optimization and Gradients

In artificial intelligence, the term Optimization is not used in its general linguistic sense. Instead, it refers to the controlled adjustment of a model's numerical parameters within a high-dimensional mathematical space. Researchers treat the model as a purely numerical system

governed by a single objective function, and optimization defines how this system evolves over time toward configurations that reduce error according to a predefined criterion.

From a research perspective, Optimization transforms learning into a process that can be precisely managed and analyzed. Rather than being an abstract or emergent behavior, learning becomes a sequence of small, measurable parameter updates. This framing allows researchers to design learning algorithms whose behavior can be studied, compared, and refined, making model training both predictable and interpretable.

Within artificial intelligence research, the Gradient is understood as a mathematical sensing mechanism rather than merely a derivative. It provides local information about how sensitive the model is to small changes in its internal parameters, revealing the directions in which the objective function changes most rapidly.

In practice, the Gradient serves as raw directional information rather than a decision rule. Researchers do not follow it blindly; instead, they manipulate its influence through additional operations such as negation, scaling, or constraint enforcement. Thus, the Gradient supplies the signal, while Optimization defines how that signal is used to guide the learning process.

Part 0.2 - Difference and Error Function

In artificial intelligence, Difference is not understood as a simple subtraction operation, but as a foundational concept that signals the existence of a gap between two states: what the model produces and what it is expected to produce. Researchers treat Difference as the first mathematical acknowledgment that the current system deviates from its objective, without yet explaining the cause of that deviation.

From a research standpoint, Difference is the most primitive representation of error before any further processing. Once the difference is formulated, it can be treated as an independent mathematical object that can be scaled, transformed, sign-inverted, or passed through additional functions. For this reason, Difference is not the end of computation but its starting point, forming the basis for all subsequent correction steps.

The Error Function represents the next conceptual layer beyond Difference. In the researcher's view, an Error Function is a deliberate definition of what constitutes error and how severely it should be penalized. It is not merely a computational formula, but a formal policy that encodes the learning objective and determines which deviations matter and which can be ignored.

At a deeper level, the Error Function governs the long-term behavior of the model. It shapes the optimization landscape by deciding how raw differences are aggregated and weighted, thereby influencing the direction and stability of learning. As a result, changing the Error Function can fundamentally alter the learning dynamics of a system, even when the data and model architecture remain unchanged.

Part 0.3 - Signal directions and Opposition

In artificial intelligence, the direction of a signal is as important as its numerical magnitude. Researchers treat each signal as a force that pushes the model in a specific direction within the

solution space. The same numerical value can be beneficial or harmful depending on its sign, which means that model behavior cannot be understood by magnitude alone without considering direction.

From a training perspective, signal direction determines whether a proposed change moves the model closer to its objective or farther away from it. For this reason, many learning procedures prioritize controlling the direction of change before adjusting its strength. An incorrect direction, even if small, can accumulate over time and lead to significant divergence during training.

The concept of Opposition in artificial intelligence does not imply rejection, but rather a deliberate decision to act against a given signal direction. Researchers recognize that certain signals may carry valid information about the system while still leading to undesirable behavior if followed directly. Opposition allows this information to be used while preventing harmful movement.

At a deeper research level, opposition represents the point at which control is imposed on model behavior. Through operations such as negation, the learning process can exploit directional information without being dominated by it. This idea underlies practices like reversing the gradient during optimization and explains why tensor-level operations such as negation appear early and repeatedly in learning algorithms.

Part 1 - why this matters

The primary purpose of the Tensor Negation Law is to provide a simple and consistent way to reverse the effect of values without altering the structure or layout of the data. In many artificial intelligence systems, we do not need to introduce new information; instead, we need to express that an existing contribution should act in the opposite direction. Negation achieves this by preserving the same tensor shape and positions while inverting the sign of each value.

Tensor negation is used extensively because many core operations are based on comparison and correction. When computing differences between model outputs and target values, or when updating parameters during training, negation is required to move against an undesired direction. Without negation, it would be impossible to formally represent error, opposition, or corrective movement in a clean and structured mathematical way.

Most importantly, Tensor Negation preserves the tensor's internal structure. The dimensionality, alignment, and positional meaning of the data remain unchanged, while only the sign is inverted. This makes negation a safe and essential operation in learning systems, as it modifies numerical behavior without breaking the integrity of tensor-based representations or mixing information across locations.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Negation Law (element-wise) is defined as:

$$- : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = -\mathbf{X}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = -\,X_{i,j} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, tensor negation (element-wise sign inversion) can be performed using the built-in function `torch.neg()`, or equivalently by applying the unary minus operator `-x`.

The reader is encouraged to explore how unary negation acts independently on each tensor entry without changing the tensor shape, and to compare the explicit use of `torch.neg()` with the operator form to understand their equivalence at the tensor level.

Part 4 - Python code skeleton

```
import torch

def E07(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.2.9 Exercise 08 - Tensor Sign Law

Part 1 - why this matters

In artificial intelligence systems, numerical values are constantly used to control decisions, updates, and internal signals. However, not every operation requires knowing the exact magnitude of a value. In many situations, what truly matters is the *direction* of influence rather than its size. Positive and negative values indicate opposite effects within the model, and identifying this direction alone is often sufficient to guide learning or adjustment processes.

Neural networks, in particular, repeatedly update their parameters based on signals that may vary widely in scale. Large values can cause unstable behavior, while very small values may become negligible during aggregation. By extracting only the sign of a tensor, the model can ignore harmful scale differences and focus solely on whether each component pushes the system forward, backward, or not at all. This leads to more stable and interpretable behavior in parts of the learning process where controlled directional movement is preferred over exact measurement.

Mathematically, the Tensor Sign Law allows the model to separate *decision* from *measurement*. Instead of treating numbers as precise quantities, the law converts them into directional indicators. This is especially useful in optimization and control-related operations, where consistent movement in the correct direction is more important than reacting strongly to large but possibly noisy values.

The Tensor Sign Law can be expressed in its simplest form as:

$$z = \text{sign}(x)$$

where:

- x represents a real-valued scalar or a single element of a tensor.
- $\text{sign}(x)$ extracts the direction of x.
- $z = 1$ if $x > 0$, indicating a positive direction.
- $z = -1$ if $x < 0$, indicating a negative direction.
- $z = 0$ if $x = 0$, indicating no directional influence.

When applied element-wise to tensors, this operation enables neural networks to reason about directional behavior independently of magnitude, forming a foundation for stable updates, directional analysis, and simplified control mechanisms within artificial intelligence models.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Sign Law (element-wise) is defined as:

$$\text{sign}(\cdot) : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \text{sign}(\mathbf{X})$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} > 0 \\ 0 & \text{if } X_{i,j} = 0 \\ -1 & \text{if } X_{i,j} < 0 \end{cases} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor sign operation (element-wise sign extraction) can be computed using the built-in function `torch.sign()`.

The reader is encouraged to explore how `torch.sign()` separates *direction* from *magnitude*, returning only the sign of each element, and how this operation is commonly paired with absolute value or norm based laws in optimization, gradient analysis, and control of update direction.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.2.10 Exercise 09 - Tensor Clamp Law

Part 0 - conceptual overview

In a neural network, all numerical behavior revolves around a small set of interconnected quantities: weights, activations, scores, and gradients. These elements do not exist independently; instead, they form a continuous feedback loop that drives learning and decision-making within the model.

Weights represent the internal parameters of the network and determine how input information is transformed. Activations are the intermediate signals produced when inputs are combined with weights and passed through nonlinear functions. Scores are the final numerical outputs of the network before interpretation, often representing confidence, preference, or likelihood. Together, weights and activations shape the scores produced by the model.

Gradients complete the loop by measuring how changes in weights affect the final scores and error. They flow backward through the network and guide how weights should be adjusted. Because activations, scores, and gradients can grow unbounded or become unstable, controlling their numerical range becomes essential. Understanding this relationship explains why mechanisms such as clamping are needed to keep all components operating within safe and meaningful limits.

Part 1 - why this matters

Artificial intelligence systems continuously generate numerical values while processing data, updating parameters, and producing outputs. These values are not inherently constrained and can easily grow too large or become too small during training or inference. When such uncontrolled values propagate through a neural network, they may cause numerical instability, saturation, or unreliable behavior that degrades the overall performance of the model.

The Tensor Clamp Law introduces explicit boundaries that restrict values to a predefined and meaningful range. By enforcing lower and upper limits, the model is protected from extreme values that do not carry additional useful information. This controlled restriction allows learning processes to remain stable while still preserving the essential structure of the data. Instead of eliminating information, clamping preserves valid values and only corrects those that

exceed acceptable limits.

Within neural networks, clamping is commonly used to maintain safe operating ranges for activations, gradients, and outputs. It ensures that numerical values remain interpretable and physically or logically valid throughout computation. In this sense, the Tensor Clamp Law acts as a stabilizing mechanism that enables artificial intelligence systems to learn effectively without being disrupted by unbounded numerical behavior.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$ and let $a, b \in \mathbb{R}$ with $a \leq b$.
Tensor Clamp Law (element-wise) is defined as:

$$\text{clamp}_{[a,b]}(\cdot) : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \text{clamp}_{[a,b]}(\mathbf{X})$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} a & \text{if } X_{i,j} < a \\ X_{i,j} & \text{if } a \leq X_{i,j} \leq b \\ b & \text{if } X_{i,j} > b \end{cases} \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor clamp operation (element-wise value limiting) can be computed using the built-in function `torch.clamp()`.

The reader is encouraged to explore how `torch.clamp()` enforces lower and upper bounds on each tensor element independently, preventing values from exceeding predefined limits and ensuring numerical stability during computation.

Part 4 - Python code skeleton

```
import torch

def E09(x, m, M):
    z = torch...
    return z

def main():
    x = torch.tensor...
    m =...
    M =...
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.2.11 Exercise 10 - Tensor Round Law

Part 1 - why this matters

Neural networks operate primarily in a continuous numerical space, where values such as weights, activations, and scores can take any real number. This continuous representation is essential for learning and optimization, but it does not always align with the requirements of decision-making or real-world execution. In many situations, a model must eventually produce discrete, integer-based outcomes rather than continuous values.

The Tensor Round Law provides a controlled way to convert continuous values into stable integer representations. By rounding values to the nearest integer, small numerical fluctuations are removed without introducing large distortions. This is particularly important when values are close to decision boundaries, where minor changes could otherwise cause inconsistent or unstable behavior.

Within artificial intelligence systems, rounding is commonly used when transitioning from internal numerical processing to final outputs, counters, or index-based operations. It enables models to move from soft, approximate representations to clear and interpretable decisions, ensuring that continuous learning processes can be safely integrated with discrete system requirements.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Round Law (element-wise) is defined as:

$$\text{round}(\cdot) : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \text{round}(\mathbf{X})$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \text{round}(X_{i,j}) \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor rounding operation (element-wise rounding to the nearest integer) can be computed using the built-in function `torch.round()`.

The reader is encouraged to explore how `torch.round()` converts continuous values into discrete ones by rounding each element independently, and how this operation is commonly used when transitioning from continuous representations to discrete decisions or stabilized numerical outputs.

Part 4 - Python code skeleton

```
import torch

def E10(x):
```

```
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.2.12 Exercise 11 - Tensor Floor Law

Part 1 - why this matters

Artificial intelligence systems often work with continuous numerical values, yet many decisions and operations within these systems require discrete and strictly bounded outcomes. In such cases, fractional values cannot be interpreted directly, and a clear rule is needed to convert continuous quantities into valid integers without violating system constraints.

The Tensor Floor Law provides a conservative transformation by mapping each value to the largest integer that is less than or equal to it. This guarantees that the result never exceeds the original value, making it suitable for situations where upper limits must be respected. By consistently rounding downward, the operation prevents unintended overestimation that could lead to invalid decisions or resource misuse.

Within artificial intelligence pipelines, floor-based transformations are used when values represent counts, indices, or execution steps that must remain within safe and allowable bounds. The Tensor Floor Law ensures that continuous numerical outputs can be safely translated into discrete, actionable values while preserving logical consistency throughout the system.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Floor Law (element-wise) is defined as:

$$\lfloor \cdot \rfloor : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \lfloor \mathbf{X} \rfloor$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \lfloor X_{i,j} \rfloor \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor floor operation (element-wise rounding down to the nearest integer) can be computed using the built-in function `torch.floor()`.

The reader is encouraged to explore how `torch.floor()` consistently rounds values downward regardless of their fractional part, and how this operation is commonly used when enforcing conservative or lower-bound numerical decisions in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E11(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.2.13 Exercise 12 - Tensor Ceil Law

Part 0 - Conservation and Safeguarding

Artificial intelligence systems are fundamentally numerical systems that rely on continuous values to represent uncertainty, estimates, and learned behavior. However, these systems do not operate in isolation; they must eventually interact with finite computational resources, discrete execution steps, and real-world constraints. As a result, numerical decisions in artificial intelligence are not only mathematical choices but also design decisions that reflect how the system handles risk, error, and failure.

Two fundamental design philosophies emerge when continuous values must be converted into discrete decisions: *conservation* and *safeguarding*. These philosophies define how an artificial intelligence system reacts when faced with uncertainty in numerical estimation. Rather than optimizing for mathematical elegance, they optimize for system reliability and practical correctness.

Conservation represents a cautious approach that prioritizes efficiency and resource control. Under this philosophy, the system avoids allocating or executing more than what is strictly justified by the current numerical estimate. The underlying assumption is that overestimation is more harmful than underestimation. Conservation is therefore used when excessive allocation, unnecessary computation, or inflated execution can degrade performance, increase cost, or destabilize the system.

Safeguarding represents a complementary but fundamentally different philosophy. Instead of minimizing usage, it prioritizes completeness and correctness. Under this approach, the system ensures that requirements are fully met, even if this means allocating slightly more resources or executing additional steps. The core assumption of safeguarding is that underestimation is more dangerous than overestimation, especially when missing data, incomplete processing, or early termination can lead to silent failures.

In artificial intelligence development, neither philosophy is universally superior. Each reflects a different tolerance for risk. Conservation accepts the possibility of doing less in exchange for efficiency, while safeguarding accepts controlled excess in exchange for reliability. The choice between them is not a mathematical preference but a system-level judgment about which type

of failure is unacceptable in a given context.

These philosophies directly influence how numerical transformations are applied within neural networks and AI pipelines. When values represent optional capacity, iterative refinement, or expandable processes, conservation-oriented decisions are often appropriate. When values represent mandatory coverage, irreversible decisions, or completeness requirements, safeguarding-oriented decisions become essential.

Understanding conservation and safeguarding as design principles allows AI developers to reason more clearly about numerical transformations such as floor and ceiling operations. Rather than viewing these operations as simple rounding rules, they can be understood as explicit expressions of system intent, encoding how the model chooses to balance efficiency against reliability within its computational logic.

Part 1 - why this matters

Artificial intelligence systems frequently work with continuous numerical values that represent estimated quantities such as required steps, resource usage, or data coverage. However, many execution-level decisions within these systems cannot operate on fractional values and must rely on integer-based quantities that fully satisfy the underlying requirement.

The Tensor Ceil Law provides a safe transformation by mapping each value to the smallest integer greater than or equal to it. This guarantees that the resulting value never underestimates the original quantity. By enforcing upward rounding, the model avoids incomplete processing, missed data, or insufficient allocation that could otherwise occur when fractional estimates are truncated.

Within artificial intelligence pipelines, ceiling-based transformations are used when full coverage and completeness are more important than minimizing numerical overhead. The Tensor Ceil Law ensures that continuous estimates are converted into discrete decisions that meet or exceed required thresholds, enabling reliable and robust system behavior.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$.

Tensor Ceil Law (element-wise) is defined as:

$$\lceil \cdot \rceil : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \lceil \mathbf{X} \rceil$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \lceil X_{i,j} \rceil \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor ceiling operation (element-wise rounding up to the nearest integer) can be computed using the built-in function `torch.ceil()`.

The reader is encouraged to explore how `torch.ceil()` consistently maps each value to the smallest integer greater than or equal to it, and how this operation is used when enforcing upward-safe or minimum-satisfying numerical decisions in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E12(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E12(...))

if __name__ == "__main__":
    main()
```

1.2.14 Exercise 13 - Tensor Reciprocal Law

Part 1 - why this matters

Artificial intelligence systems frequently rely on numerical values that represent relative importance, distance, confidence, or influence. In many such cases, a larger numerical value does not necessarily imply a stronger or more desirable effect. Instead, certain relationships require an inverse interpretation, where smaller values should exert greater influence and larger values should contribute less to the final outcome.

The Tensor Reciprocal Law enables this inverse relationship by transforming each value into its multiplicative inverse. Through this transformation, large values are attenuated while small values are amplified, allowing the model to rebalance the contribution of different elements. This is particularly useful when values encode penalties, distances, or uncertainty measures, where dominance by large magnitudes would otherwise distort the model's behavior.

Within artificial intelligence pipelines, reciprocal-based transformations are used to regulate influence, normalize contributions, and prevent disproportionate effects from dominating learning or decision processes. By explicitly reversing the numerical relationship, the Tensor Reciprocal Law provides a principled way to express inverse dependence, enabling more stable and meaningful interactions between numerical components in neural networks and related systems.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$ such that $X_{i,j} \neq 0$ for all $i, j \in \{1, 2, 3\}$.
Tensor Reciprocal Law (element-wise) is defined as:

$$(\cdot)^{-1} : \mathbb{R}^{3\times3} \setminus \{0\} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X}^{-1}$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \frac{1}{X_{i,j}} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor reciprocal operation (element-wise inversion) can be computed using the built-in function `torch.reciprocal()`.

The reader is encouraged to explore how `torch.reciprocal()` computes the inverse of each element independently, and why special care must be taken to avoid zero values, as division by zero leads to undefined or unstable numerical behavior in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E13(x):
    z = torch...
    return z

def main():
    x = torch.tensor...
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.2.15 Exercise 14 - Tensor Modulo Law

Part 1 - why this matters

Artificial intelligence systems often manipulate numerical values that grow unbounded through accumulation, iteration, or repeated updates. While such growth is mathematically valid, it is not always meaningful for the behavior the model is intended to represent. In many scenarios, the absolute size of a value is less important than its position within a fixed and repeating range.

The Tensor Modulo Law provides a principled way to map unbounded values back into a bounded, periodic domain. By computing the remainder of a division, the operation preserves the relative position of a value within a cycle while discarding the number of completed cycles. This allows models to reason about states, phases, or positions without being affected by uncontrolled numerical growth.

Within artificial intelligence pipelines, modulo-based transformations are used whenever periodic structure, bounded indexing, or cyclic behavior is required. They enable models to operate within finite domains, prevent numerical overflow, and encode repeating patterns directly into mathematical formulations. In this sense, the Tensor Modulo Law is not merely a

numerical convenience, but a formal mechanism for expressing periodicity and controlled value spaces in artificial intelligence systems.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{3\times3}$ and let $m \in \mathbb{R}$ with $m \neq 0$.
Tensor Modulo Law (element-wise) is defined as:

$$\mathrm{mod}_m(\cdot) : \mathbb{R}^{3\times3} \to \mathbb{R}^{3\times3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \bmod m$$

where $\mathbf{Z} \in \mathbb{R}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = X_{i,j} \bmod m \quad \text{for } i, j \in \{1, 2, 3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor modulo operation (element-wise remainder computation) can be performed using the built-in function `torch.remainder()`.

The reader is encouraged to explore how `torch.remainder()` computes the remainder of each tensor element with respect to a given modulus, and how this operation is commonly used in periodic behavior, index wrapping, and bounded numerical representations within artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E14(x, m):
    z = torch...
    return z

def main():
    x = torch.tensor...
    m =...
    print(E14(...))

if __name__ == "__main__":
    main()
```

1.2.16 Exercise 15 - Tensor Logical AND Law

Part 1 - why this matters

Artificial intelligence systems frequently make decisions based on multiple conditions rather than a single numerical value. In many scenarios, an action, update, or computation should only occur when several requirements are satisfied simultaneously. This necessity cannot be

expressed through standard arithmetic operations alone and requires an explicit logical mechanism.

The Tensor Logical AND Law provides a formal way to encode simultaneous validity within mathematical expressions. By combining multiple boolean conditions into a single logical outcome, the operation ensures that a result is considered valid only when all contributing conditions are true. This allows decision rules to be represented directly inside tensor-based computations, rather than being handled externally through procedural logic.

Within artificial intelligence pipelines, logical AND operations are widely used to construct masks, enforce constraints, and control conditional execution. They enable models to selectively activate or deactivate elements based on multiple criteria at once, ensuring consistency and correctness in complex decision processes. In this sense, the Tensor Logical AND Law serves as a foundational tool for integrating logical reasoning into numerical and tensor-based AI systems.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \{0,1\}^{3\times 3}$.

Tensor Logical AND Law (element-wise) is defined as:

$$\wedge : \{0,1\}^{3\times 3} \times \{0,1\}^{3\times 3} \to \{0,1\}^{3\times 3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \wedge \mathbf{Y}$$

where $\mathbf{Z} \in \{0,1\}^{3\times 3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} = 1 \text{ and } Y_{i,j} = 1 \\ 0 & \text{otherwise} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor logical AND operation (element-wise logical conjunction) can be computed using the built-in function `torch.logical_and()`.

The reader is encouraged to explore how `torch.logical_and()` evaluates each pair of tensor elements independently, and how logical conjunction is used to enforce simultaneous conditions, masks, and rule-based constraints in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E15(X, Y):
    z = torch...
    return z

def main():
    X = torch.tensor...
    Y = torch.tenosr...
```

```
    print(E15(...))

if __name__ == "__main__":
    main()
```

1.2.17 Exercise 16 - Tensor Logical OR Law

Part 1 - why this matters

Artificial intelligence systems often operate in environments where information is incomplete, uncertain, or noisy. In such contexts, requiring all conditions to be satisfied simultaneously can make decision processes overly rigid and fragile. Instead, many AI systems must allow actions or conclusions to be validated through alternative acceptable conditions.

The Tensor Logical OR Law provides a formal mechanism for expressing such flexibility within mathematical formulations. By evaluating multiple conditions and accepting a result when at least one condition is true, the operation enables models to continue functioning even when some inputs or criteria fail. This supports robustness and adaptability in complex or imperfect environments.

Within artificial intelligence pipelines, logical OR operations are commonly used to construct fallback rules, permissive masks, and alternative decision paths. They allow models to represent "either–or" logic directly within tensor-based computations, ensuring that decision-making remains resilient without sacrificing logical clarity.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \{0,1\}^{3\times 3}$.

Tensor Logical OR Law (element-wise) is defined as:

$$\vee : \{0,1\}^{3\times 3} \times \{0,1\}^{3\times 3} \to \{0,1\}^{3\times 3}$$

Define:

$$\mathbf{Z} = \mathbf{X} \vee \mathbf{Y}$$

where $\mathbf{Z} \in \{0,1\}^{3\times 3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} = 1 \text{ or } Y_{i,j} = 1 \\ 0 & \text{otherwise} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor logical OR operation (element-wise logical disjunction) can be computed using the built-in function `torch.logical_or()`.

The reader is encouraged to explore how `torch.logical_or()` evaluates each pair of tensor elements independently, and how logical disjunction is used to represent alternative conditions, fallback rules, and flexible masking in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E16(X, Y):
    z = torch...
    return z

def main():
    X = torch.tensor...
    Y = torch.tenosr...
    print(E16(...))

if __name__ == "__main__":
    main()
```

1.2.18 Exercise 17 - Tensor Logical NOT Law

Part 0 - combined logical reasoning

Artificial intelligence systems rarely make decisions based on a single condition. Instead, real-world decision-making requires evaluating multiple constraints, allowing alternatives, and explicitly excluding invalid states. Logical operators such as AND, OR, and NOT each capture a distinct aspect of this process, but none of them alone is sufficient to express complete decision logic.

Combining logical AND, OR, and NOT into a single mathematical expression allows an AI system to represent full decision policies rather than isolated rules. Logical AND enforces simultaneous validity, ensuring that all required conditions are satisfied. Logical OR introduces flexibility by allowing multiple acceptable paths to a valid outcome. Logical NOT provides exclusion by explicitly rejecting states or conditions that must not occur. Together, these operators form a complete logical language for decision control.

The benefit of combining these operators lies in clarity and correctness. A single unified logical equation explicitly defines when an action is permitted, when it is rejected, and when alternative conditions are acceptable. This eliminates hidden assumptions, scattered conditional logic, and ambiguous decision pathways that often arise when logic is implemented procedurally rather than mathematically.

In artificial intelligence pipelines, such combined logical expressions are commonly used to construct complex masks, enforce hierarchical constraints, and control conditional execution within tensor-based computations. By embedding logical structure directly into mathematical formulations, models can apply decision rules efficiently and consistently across large-scale data structures.

Moreover, representing logic as a single equation enables analysis and verification. The combined expression can be simplified, tested for completeness, and examined for edge cases. This makes the decision process more transparent and robust, which is essential when AI systems operate in uncertain or safety-critical environments.

Ultimately, the combination of AND, OR, and NOT transforms logical reasoning from a set of disconnected checks into a coherent decision framework. Rather than asking isolated questions such as "is this condition true?", the system evaluates a complete policy that defines acceptance, rejection, and permissible alternatives in a unified and mathematically rigorous manner.

Part 1 - why this matters

Artificial intelligence systems frequently rely on boolean conditions to control execution, enforce constraints, and construct decision logic. In many situations, it is not sufficient to check whether a condition is true; the system must also reason about when a condition is explicitly false. This requires a formal way to invert logical states within mathematical expressions.

The Tensor Logical NOT Law provides a precise mechanism for logical negation, allowing models to reverse boolean values in a consistent and interpretable manner. By transforming true conditions into false ones and vice versa, the operation enables artificial intelligence systems to express exclusion, invalidation, and complementary conditions directly within tensor computations.

Within artificial intelligence pipelines, logical NOT operations are commonly used to deactivate masks, exclude invalid states, and construct complementary rules. They allow models to reason not only about what is permitted, but also about what must be explicitly rejected, ensuring clarity and completeness in logical decision-making processes.

Part 2 - Mathematical form

Let $\mathbf{X} \in \{0,1\}^{3\times 3}$.

Tensor Logical NOT Law (element-wise) is defined as:

$$\neg : \{0,1\}^{3\times 3} \to \{0,1\}^{3\times 3}$$

Define:

$$\mathbf{Z} = \neg \mathbf{X}$$

where $\mathbf{Z} \in \{0,1\}^{3\times 3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} = 0 \\ 0 & \text{if } X_{i,j} = 1 \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor logical NOT operation (element-wise logical negation) can be computed using the built-in function `torch.logical_not()`.

The reader is encouraged to explore how `torch.logical_not()` inverts each boolean tensor element independently, and how logical negation is used to exclude conditions, reverse masks, and express complementary constraints in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E17(X):
    z = torch...
    return z

def main():
    X = torch.tensor...
    print(E17(...))

if __name__ == "__main__":
    main()
```

1.2.19 Exercise 18 - Tensor Equality Law (Comparison)

Part 0 - comparison vs logical operations

Artificial intelligence systems rely on both numerical evaluation and logical decision-making. Although comparison operations and logical operations may appear similar at a surface level, they serve fundamentally different roles within AI pipelines. Understanding the distinction between them is essential for designing clear, correct, and interpretable decision mechanisms.

Comparison operations are concerned with evaluating relationships between values. They answer questions such as whether two values are equal, or whether one value is greater or smaller than another. The result of a comparison is a boolean outcome derived directly from numerical properties. In this sense, comparison acts as a bridge between continuous numerical representations and discrete decision boundaries.

Logical operations, on the other hand, do not evaluate numerical relationships. Instead, they operate on boolean conditions that already represent decisions, validity, or state membership. Logical AND, OR, and NOT combine, relax, or invert these boolean states to construct higher-level decision logic. Their purpose is not to measure or compare, but to control how conditions interact.

In artificial intelligence workflows, comparison operations typically appear first. Numerical outputs from models are compared against thresholds, targets, or reference values to produce boolean indicators. These indicators alone are often insufficient to represent complex decision policies, as real-world decisions rarely depend on a single condition.

Logical operations are then applied to the results of comparisons. They combine multiple boolean signals, enforce constraints, allow alternatives, or exclude invalid states. This separation of roles ensures clarity: comparisons define elementary conditions, while logical operators define how those conditions govern behavior.

Treating comparison and logical operations as distinct stages prevents conceptual confusion and improves system design. Comparisons define "what is true" at the numerical level, while logical operations define "what should be done" at the decision level. Together, they form a structured pathway from raw numerical outputs to coherent and controllable artificial intelli-

gence behavior.

Part 1 - why this matters

Artificial intelligence systems frequently need to determine whether two values represent the same state, outcome, or decision rather than measuring how far apart they are. In such situations, numerical distance is less relevant than exact agreement, and a clear boundary must be drawn between matching and non-matching values.

The Tensor Equality Law provides a formal mechanism for performing exact comparisons within tensor-based computations. By converting element-wise comparisons into boolean outcomes, the operation allows models to identify matching conditions, validate predictions, and construct decision masks that separate valid states from invalid ones.

Within artificial intelligence pipelines, equality comparisons are essential for evaluation, rule enforcement, and conditional execution. They enable systems to verify correctness, trigger specific actions, and control subsequent processing steps based on precise matching criteria. In this sense, the Tensor Equality Law serves as a foundational tool for transforming numerical outputs into explicit logical decisions.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Equality Law (element-wise comparison) is defined as:

$$=: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} = \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} = Y_{i,j} \\ 0 & \text{if } X_{i,j} \neq Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor equality comparison (element-wise equality check) can be performed using the built-in function `torch.eq()`.

The reader is encouraged to explore how `torch.eq()` compares each pair of tensor elements independently and produces a boolean tensor that represents exact equality, which is commonly used for masking, condition checking, and rule-based logic in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E18(X, Y):
    z = torch...
```

```
    return z

def main():
    X = torch...
    Y = torch...
    print(E18(...))

if __name__ == "__main__":
    main()
```

1.2.20 Exercise 19 - Tensor Not Equal Law (Comparison)

Part 1 - why this matters

Artificial intelligence systems must not only confirm correct or expected states, but also detect when deviations occur. In many scenarios, meaningful actions are triggered not by agreement, but by difference. Identifying mismatches between values is therefore essential for monitoring, correction, and adaptive behavior.

The Tensor Not Equal Law provides a formal mechanism for detecting discrepancies within tensor-based computations. By producing a boolean outcome for each comparison, the operation highlights where values diverge from references, targets, or prior states. This allows models to isolate irregularities and focus attention on elements that require intervention.

Within artificial intelligence pipelines, not-equal comparisons are commonly used for error detection, change tracking, and conditional filtering. They enable systems to respond explicitly to unexpected outcomes rather than silently accepting them. In this sense, the Tensor Not Equal Law transforms numerical differences into actionable signals that guide correction and control within AI systems.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Not Equal Law (element-wise comparison) is defined as:

$$\neq: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} \neq \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} \neq Y_{i,j} \\ 0 & \text{if } X_{i,j} = Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor not-equal comparison (element-wise inequality check) can be computed using the built-in function `torch.ne()`.

The reader is encouraged to explore how `torch.ne()` compares each pair of tensor elements independently and produces a boolean tensor that highlights mismatched values, which is commonly used for masking, filtering, and error detection in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E19(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E19(...))

if __name__ == "__main__":
    main()
```

1.2.21 Exercise 20 - Tensor Greater Than Law (Comparison)

Part 1 - why this matters

Artificial intelligence systems often rely on threshold-based decisions rather than exact matches. In many cases, the precise value of a quantity is less important than whether it exceeds a certain level. Such comparisons are fundamental when determining activation, eligibility, or dominance within a model.

The Tensor Greater Than Law enables artificial intelligence systems to identify values that surpass reference points or constraints. By converting numerical comparisons into boolean outcomes, the operation allows models to distinguish significant signals from insignificant ones and to trigger decisions based on exceeding predefined criteria.

Within artificial intelligence pipelines, greater-than comparisons are commonly used to enforce thresholds, activate conditional logic, and control flow based on magnitude. They provide a clear and interpretable boundary between acceptable and insufficient values, making them essential for decision-oriented numerical processing.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Greater Than Law (element-wise comparison) is defined as:

$$>: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} > \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} > Y_{i,j} \\ 0 & \text{if } X_{i,j} \leq Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor greater-than comparison (element-wise comparison) can be computed using the built-in function `torch.gt()`.

The reader is encouraged to explore how `torch.gt()` compares tensor elements independently and produces a boolean tensor that identifies values exceeding a given reference, which is commonly used for thresholding, masking, and conditional execution in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E20(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E20(...))

if __name__ == "__main__":
    main()
```

1.2.22 Exercise 21 - Tensor Less Than Law (Comparison)

Part 1 - why this matters

Artificial intelligence systems frequently make decisions based on identifying insufficient, weak, or sub-threshold values rather than dominant ones. In many scenarios, recognizing when a value falls below a certain level is essential for filtering, suppression, or corrective action within a model.

The Tensor Less Than Law allows artificial intelligence systems to detect values that do not meet required criteria. By converting numerical comparisons into boolean outcomes, the operation enables models to isolate underperforming signals, enforce lower-bound constraints, and control behavior based on insufficiency rather than excess.

Within artificial intelligence pipelines, less-than comparisons are commonly used to deactivate elements, identify low-confidence regions, and regulate conditional execution. They provide a clear mechanism for detecting when values fail to reach necessary thresholds, supporting stable and controlled decision-making.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Less Than Law (element-wise comparison) is defined as:

$$<: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} < \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} < Y_{i,j} \\ 0 & \text{if } X_{i,j} \geq Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor less-than comparison (element-wise comparison) can be computed using the built-in function `torch.lt()`.

The reader is encouraged to explore how `torch.lt()` evaluates each tensor element independently and produces a boolean tensor that highlights values below a given reference, which is commonly used for thresholding, masking, and conditional suppression in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E21(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E21(...))

if __name__ == "__main__":
    main()
```

1.2.23 Exercise 22 - Tensor Greater or Equal Law (Comparison)

Part 1 - why this matters

Artificial intelligence systems often rely on inclusive threshold decisions, where meeting a requirement is sufficient even if the value does not exceed it. In many practical scenarios, equality with a boundary condition is just as valid as surpassing it. Ignoring this distinction can lead to unnecessary rejection of valid states or premature suppression of meaningful signals.

The Tensor Greater or Equal Law allows artificial intelligence systems to express inclusive dominance by treating equality and superiority as acceptable outcomes. By converting numerical comparisons into boolean results, the operation ensures that values meeting or exceeding

a reference are treated consistently within decision logic.

Within artificial intelligence pipelines, greater-or-equal comparisons are commonly used to enforce minimum requirements, validate eligibility, and activate conditional execution when values reach acceptable thresholds. This inclusive comparison supports stable decision boundaries and prevents unintended exclusion at critical limits.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Greater or Equal Law (element-wise comparison) is defined as:

$$\geq: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} \geq \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} \geq Y_{i,j} \\ 0 & \text{if } X_{i,j} < Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor greater-or-equal comparison (element-wise comparison) can be computed using the built-in function `torch.ge()`.

The reader is encouraged to explore how `torch.ge()` evaluates tensor elements independently and produces a boolean tensor that identifies values meeting or exceeding a given reference, which is commonly used for thresholding, masking, and inclusive condition enforcement in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E22(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E22(...))

if __name__ == "__main__":
    main()
```

1.2.24 Exercise 23 - Tensor Less or Equal Law (Comparison)

Part 1 - why this matters

Artificial intelligence systems often require inclusive lower-bound decisions, where values are considered acceptable not only when they are strictly smaller than a reference, but also when they exactly meet it. In many practical settings, reaching a boundary condition is sufficient and should not be treated as failure.

The Tensor Less or Equal Law allows artificial intelligence systems to express inclusive insufficiency by treating equality and inferiority as valid outcomes. By converting numerical comparisons into boolean results, the operation ensures that values below or equal to a reference are handled consistently within decision logic.

Within artificial intelligence pipelines, less-or-equal comparisons are commonly used to enforce upper limits, suppress excessive values, and validate constraints that allow boundary equality. This inclusive comparison supports stable control mechanisms and prevents unnecessary rejection at critical thresholds.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{3\times3}$.

Tensor Less or Equal Law (element-wise comparison) is defined as:

$$\leq: \mathbb{R}^{3\times3} \times \mathbb{R}^{3\times3} \to \{0,1\}^{3\times3}$$

Define:

$$\mathbf{Z} = (\mathbf{X} \leq \mathbf{Y})$$

where $\mathbf{Z} \in \{0,1\}^{3\times3}$ and the law is defined component-wise by:

$$Z_{i,j} = \begin{cases} 1 & \text{if } X_{i,j} \leq Y_{i,j} \\ 0 & \text{if } X_{i,j} > Y_{i,j} \end{cases} \quad \text{for } i,j \in \{1,2,3\}.$$

Part 3 - Hints and Helper

In PyTorch, the tensor less-or-equal comparison (element-wise comparison) can be computed using the built-in function `torch.le()`.

The reader is encouraged to explore how `torch.le()` evaluates tensor elements independently and produces a boolean tensor that identifies values below or equal to a given reference, which is commonly used for constraint enforcement, masking, and boundary-aware decision logic in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E23(X, Y):
    z = torch...
```

```
    return z

def main():
    X = torch...
    Y = torch...
    print(E23(...))

if __name__ == "__main__":
    main()
```

1.3 T01 - Vector Laws (1D)

Mathematics and Theory

1.3.1 Exercise 00 - 1D Dot Product Law

Part 0.1 - similarity

In artificial intelligence, similarity refers to how closely two pieces of information resemble each other in meaning or behavior. When data is represented as vectors, similarity is no longer judged by visual inspection or direct value comparison, but by how strongly two vectors align in the same direction. Vectors that point in similar directions are considered similar, even if their individual components differ in magnitude.

The dot product provides a natural mathematical foundation for measuring similarity between vectors. By combining corresponding elements and aggregating their interaction into a single scalar value, the dot product captures the degree of alignment between two representations. This makes it a fundamental tool for evaluating similarity in embedding spaces, feature representations, and learned vector models used throughout artificial intelligence systems.

Part 0.2 - relevance

Relevance in artificial intelligence describes how important or meaningful one vector is with respect to another. Unlike similarity, which focuses on mutual alignment, relevance is often asymmetric: one vector represents a query or context, while the other represents a candidate or response. The goal is to measure how strongly the candidate responds to the context.

The dot product is widely used to compute relevance scores by projecting one vector onto another. When the dot product is large, the candidate vector aligns strongly with the direction defined by the context, indicating high relevance. This principle underlies many scoring mechanisms in artificial intelligence, where decisions are made based on how strongly inputs activate learned patterns encoded in weight vectors.

Part 0.3 - matching

Matching refers to the process of determining whether two vectors correspond to each other under a specific criterion or task. In artificial intelligence, this often involves comparing an input representation against multiple candidates and selecting the best match. Unlike strict

equality, matching is based on degrees of compatibility rather than exact correspondence.

The dot product enables matching by producing comparable scalar scores across multiple vector pairs. By evaluating how well each candidate aligns with a given input, artificial intelligence systems can rank, select, or filter candidates based on their matching strength. This mechanism is central to tasks such as retrieval, classification, and association, where the goal is to identify the most compatible vector among many alternatives.

Part 1 - why this matters

Artificial intelligence systems represent information as vectors in order to capture structure, relationships, and meaning. However, representing data as vectors alone is not sufficient; models must also evaluate how these vectors interact with one another. The dot product provides a fundamental mechanism for measuring this interaction by converting two vectors into a single scalar value.

The 1D dot product quantifies the degree of alignment between two vectors. When the resulting value is large, the vectors exhibit strong agreement; when it is zero, they are orthogonal and unrelated; and when it is negative, they represent opposing directions. This ability to measure alignment makes the dot product a core operation for similarity evaluation, relevance scoring, and directional decision-making in artificial intelligence systems.

Within artificial intelligence pipelines, the dot product serves as the backbone of linear models, neural networks, and attention mechanisms. It enables models to combine inputs with learned weights, transform high-dimensional interactions into interpretable scalar scores, and make decisions based on the strength of vector relationships. In this sense, the dot product is not merely a mathematical tool, but a foundational operation that translates vector interactions into meaningful computational judgments.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^n$ be two one-dimensional vectors of the same length.

1D Dot Product Law is defined as:

$$\cdot : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$$

Define:

$$z = \mathbf{X} \cdot \mathbf{Y}$$

where $z \in \mathbb{R}$ and the dot product is defined as:

$$z = \sum_{i=1}^{n} X_i \, Y_i$$

The operation computes a scalar value by multiplying corresponding elements of the two vectors and summing the results.

Part 3 - Hints and Helper

In PyTorch, the dot product between two one-dimensional tensors can be computed using the built-in function `torch.dot()`.

The reader is encouraged to explore how `torch.dot()` requires both input vectors to have the same length and produces a single scalar value, which is widely used in similarity measurement, projection, and interaction modeling in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E00(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.3.2 Exercise 01 - 3D Cross Product Law

Part 1 - why this matters

Artificial intelligence systems that operate in three-dimensional environments must reason not only about magnitude or similarity, but also about orientation and spatial structure. In such settings, understanding how vectors relate to one another in space requires more than measuring alignment; it requires identifying directions that are perpendicular to given surfaces or motions.

The 3D cross product provides a fundamental mechanism for generating a new vector that is orthogonal to two input vectors. This operation enables artificial intelligence systems to determine surface normals, orientation, and rotational direction, all of which are essential for geometric reasoning in three-dimensional space. Unlike the dot product, which reduces vector interaction to a scalar, the cross product creates a new directional entity that encodes spatial information absent from the original inputs.

Within artificial intelligence pipelines, the cross product is widely used in tasks involving 3D perception, robotics, physical simulation, and computer vision. It allows models to reason about facing direction, angular relationships, and spatial consistency, making it a critical operation whenever intelligent systems must interact with or interpret the physical structure of their environment.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^3$ be two three-dimensional vectors, where

$$\mathbf{X} = (X_1, X_2, X_3), \quad \mathbf{Y} = (Y_1, Y_2, Y_3).$$

3D Cross Product Law is defined as:

$$\times : \mathbb{R}^3 \times \mathbb{R}^3 \to \mathbb{R}^3$$

Define:

$$\mathbf{Z} = \mathbf{X} \times \mathbf{Y}$$

where $\mathbf{Z} \in \mathbb{R}^3$ is given by:

$$\mathbf{Z} = \begin{pmatrix} X_2Y_3 - X_3Y_2 \\ X_3Y_1 - X_1Y_3 \\ X_1Y_2 - X_2Y_1 \end{pmatrix}.$$

The resulting vector $\mathbf{Z}$ is orthogonal to both $\mathbf{X}$ and $\mathbf{Y}$, and its magnitude represents the area of the parallelogram spanned by the two input vectors.

The magnitude of the resulting vector is given by:

$$\|\mathbf{Z}\| = \|\mathbf{X} \times \mathbf{Y}\| = \|\mathbf{X}\| \, \|\mathbf{Y}\| \sin(\theta),$$

where θ is the angle between $\mathbf{X}$ and $\mathbf{Y}$.

This magnitude represents the area of the parallelogram spanned by the two vectors.

Part 3 - Hints and Helper

In PyTorch, the cross product between two three-dimensional tensors can be computed using the built-in function `torch.cross()`.

The reader is encouraged to explore how `torch.cross()` operates only on three-dimensional vectors, why the order of operands matters, and how the result represents a vector perpendicular to the input vectors. This operation is commonly used in geometric reasoning, orientation detection, and physics-inspired computations within artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E01(X, Y):
    z = torch...
    return z

def main():
    X = torch...
    Y = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.3.3 Exercise 02 - 1D Norm Law

Part 0 - Magnitude

In vector-based representations, magnitude describes the strength or intensity of a vector independent of its direction. While a vector's direction encodes meaning or orientation, its magnitude reflects how strongly that information is expressed. Separating magnitude from direction allows artificial intelligence systems to analyze the scale of signals without conflating it with semantic alignment.

Magnitude plays a central role in controlling numerical behavior within models. Large magnitudes may dominate computations, while very small magnitudes may become negligible. By explicitly reasoning about magnitude, artificial intelligence systems can regulate signal strength, stabilize computations, and prepare vectors for fair comparison and transformation.

Part 1 - why this matters

Artificial intelligence systems frequently operate on vectors whose direction encodes meaning and whose magnitude encodes strength. Without explicitly measuring magnitude, models cannot distinguish between weak and dominant signals, even when they point in similar directions. This can lead to biased comparisons, unstable learning, or misleading similarity measurements.

The 1D norm provides a principled way to extract the magnitude of a vector as a single non-negative scalar. This enables artificial intelligence systems to monitor signal strength, normalize representations, and control numerical scale before applying further operations such as dot products or similarity measures. By isolating magnitude from direction, the norm supports stable, interpretable, and well-conditioned vector computations within artificial intelligence pipelines.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Norm Law is defined as:

$$\|\cdot\| : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$z = \|\mathbf{X}\|$$

where $z \in \mathbb{R}$ and the norm is defined as:

$$z = \sqrt{\sum_{i=1}^{n} X_i^2}$$

The norm maps a vector to a non-negative scalar representing its magnitude independent of direction.

Part 3 - Hints and Helper

In PyTorch, the norm of a one-dimensional tensor can be computed using the built-in function `torch.norm()`.

The reader is encouraged to explore how `torch.norm()` collapses a vector into a single scalar value that represents its length, and how this operation is commonly used for normalization, scaling, and magnitude-based comparisons in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E02(X):
    z = torch...
    return z

def main():
    X = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.3.4 Exercise 03 - 1D Normalize Law

Part 1 - Why this matters

Artificial intelligence systems frequently compare and combine vectors to evaluate similarity, relevance, or alignment. However, raw vectors often differ significantly in magnitude due to scale, frequency, or accumulated effects. When magnitude is left uncontrolled, larger vectors can dominate computations and distort meaningful comparisons, even when their directional information is similar.

Normalization addresses this issue by enforcing a common scale across vectors. By rescaling each vector to unit length, artificial intelligence systems ensure that comparisons focus on direction rather than numerical dominance. This allows models to reason about relative orientation, semantic alignment, and structural relationships without bias introduced by vector magnitude.

Within artificial intelligence pipelines, normalization is a critical step before similarity measurements, attention scoring, and distance-based reasoning. It stabilizes computations, improves interpretability, and enables fair and consistent vector interactions. In this sense, normalization is not merely a numerical adjustment, but a foundational operation that shapes how intelligent systems interpret and compare vector representations.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector with $\|\mathbf{X}\| \neq 0$.

1D Normalize Law is defined as:

$$\text{normalize}(\cdot) : \mathbb{R}^n \to \mathbb{R}^n$$

Define:

$$\mathbf{Z} = \frac{\mathbf{X}}{\|\mathbf{X}\|}$$

where $\mathbf{Z} \in \mathbb{R}^n$ and satisfies:

$$\|\mathbf{Z}\| = 1.$$

This operation rescales the vector so that its magnitude becomes one, while preserving its original direction.

Part 3 - Hints and Helper

In PyTorch, vector normalization can be implemented by dividing a tensor by its norm, which is commonly computed using `torch.norm()`.

The reader is encouraged to explore how normalization rescales vectors to unit length while preserving direction, and why checking that the norm is non-zero is essential to avoid undefined operations. Normalization is widely used to ensure stable similarity measurements, fair comparisons, and numerically balanced computations in artificial intelligence systems.

Part 4 - Python code skeleton

```
import torch

def E03(X):
    norm = torch...
    z...
    return z

def main():
    X = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.3.5 Exercise 04 - 1D Projection Law

Part 1 - Why this matters

In artificial intelligence systems, information is rarely used in its raw form. High-dimensional vectors often contain a mixture of relevant structure and incidental variation, and treating all components equally can obscure meaningful relationships. Projection provides a principled way to isolate the portion of a vector that aligns with a specific direction, allowing models to focus on the information that truly contributes to a given representation or decision.

Unlike similarity measures that only quantify how related two vectors are, projection extracts the exact component of one vector that lies along another. This distinction is critical in mechanisms such as attention, feature weighting, and embedding analysis, where the goal is not merely to measure alignment, but to use it. By transforming relational scores into directional components, projection turns abstract similarity into actionable geometric structure.

From an interpretability perspective, projection offers a clear geometric explanation of how information flows through a model. It reveals how much of a signal contributes along a chosen axis, separating meaningful influence from orthogonal noise. In this sense, projection is not just a mathematical tool, but a lens through which artificial intelligence systems can reason about

structure, relevance, and decision-making in high-dimensional spaces.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^n$ be two one-dimensional vectors, with $\mathbf{Y} \neq \mathbf{0}$.

1D Projection Law describes how to project vector $\mathbf{X}$ onto vector $\mathbf{Y}$, extracting the component of $\mathbf{X}$ that lies in the direction of $\mathbf{Y}$.

The projection operator is defined as:

$$\text{proj}_{\mathbf{Y}}(\mathbf{X}) : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}^n$$

Define:

$$\mathbf{Z} = \frac{\mathbf{X} \cdot \mathbf{Y}}{\|\mathbf{Y}\|^2} \mathbf{Y}$$

where:

$$\mathbf{Z} \in \mathbb{R}^n$$

This operation computes the scalar contribution of $\mathbf{X}$ along $\mathbf{Y}$ using the dot product, then rescales $\mathbf{Y}$ accordingly. The resulting vector represents the directional component of $\mathbf{X}$ aligned with $\mathbf{Y}$.

Part 3 - Hints and Helper

PyTorch does not provide a single dedicated function for vector projection. Instead, projection is constructed explicitly using a combination of `torch.dot()` and `torch.norm()`, which together mirror the mathematical definition directly.

The reader is encouraged to express the projection formula explicitly using PyTorch tensor operations rather than searching for a built-in projection operator. This approach preserves clarity, avoids hidden abstractions, and reinforces understanding of how dot products and norms interact to form the projection. Care must be taken to ensure that the reference vector has a non-zero norm to prevent undefined divisions.

Part 4 - Python code skeleton

```
import torch

def E04(X, Y):
    scalar = torch...
    z = (...)
    return z

def main():
    X = torch...
    Y = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.3.6 Exercise 05 - 1D Angle Law

Part 1 - Why this matters

In artificial intelligence systems, understanding how vectors relate to each other goes beyond measuring magnitude or extracting directional components. The angle between vectors provides a direct geometric interpretation of their relationship, revealing whether two representations point in similar, opposing, or orthogonal directions.

Angle-based reasoning is fundamental in similarity analysis, embedding spaces, and representation learning. When vectors are normalized, the angle between them becomes a pure measure of directional alignment, independent of scale. This allows artificial intelligence systems to compare patterns, concepts, or features based solely on orientation rather than numerical dominance.

From a modeling perspective, angle measurements enable robust comparisons in high-dimensional spaces where raw distances may be misleading. By reasoning in terms of angles, models gain a stable and interpretable way to assess alignment, separation, and opposition between learned representations, reinforcing both geometric intuition and analytical clarity.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^n$ be two one-dimensional vectors, with $\mathbf{X} \neq \mathbf{0}$ and $\mathbf{Y} \neq \mathbf{0}$.

1D Angle Law defines the angle between two vectors using their dot product and magnitudes.

The angle operator is defined as:

$$\text{angle}(\cdot, \cdot) : \mathbb{R}^n \times \mathbb{R}^n \to [0, \pi]$$

Define:

$$\theta = \arccos\left(\frac{\mathbf{X} \cdot \mathbf{Y}}{\|\mathbf{X}\| \, \|\mathbf{Y}\|}\right)$$

where:

$$\theta \in [0, \pi]$$

This formulation expresses the geometric angle between two vectors, capturing their directional alignment independently of their magnitudes.

Part 3 - Hints and Helper

In PyTorch, the angle between two vectors is constructed explicitly using `torch.dot()`, `torch.norm()`, and an inverse cosine operation applied to the resulting scalar. These tensor operations directly reflect the mathematical definition of the angle between vectors.

The reader is encouraged to rely on PyTorch's dot product and norm functions to compute the cosine of the angle, then apply an inverse trigonometric operation to recover the angle itself. Ensuring that both vectors have non-zero norms and that the cosine value remains within a valid numerical range is essential to avoid undefined or unstable results.

Part 4 - Python code skeleton

```
import torch

def E05(X, Y):
```

```
        cos_theta = torch...
        theta = (...)
        return theta

    def main():
        X = torch...
        Y = torch...
        print(E05(...))

    if __name__ == "__main__":
        main()
```

1.3.7 Exercise 06 - 1D Distance Law

Part 1 - Why this matters

In artificial intelligence systems, comparing representations often requires more than understanding direction or alignment. Distance provides a direct measure of separation between vectors, capturing how far apart two representations are within a given space. This notion is fundamental when models must reason about similarity, clustering, or deviation from a reference state.

Distance-based reasoning plays a central role in optimization, anomaly detection, and embedding analysis. During training, loss functions frequently rely on distance to quantify error, guiding models toward desired targets. In representation spaces, distance determines neighborhood structure, influencing how models group, separate, or prioritize information.

From an interpretability perspective, distance offers an intuitive geometric signal: small distances indicate closeness or similarity, while large distances signal divergence. By grounding comparisons in geometric separation, artificial intelligence systems gain a stable and scalable way to evaluate relationships between vectors across high-dimensional spaces.

Part 2 - Mathematical form

Let $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^n$ be two one-dimensional vectors.
1D Distance Law defines the distance between two vectors as the norm of their difference. The distance operator is defined as:

$$\text{dist}(\cdot, \cdot) : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$$

Define:

$$d = \|\mathbf{X} - \mathbf{Y}\|$$

where:

$$d \in \mathbb{R}, \quad d \geq 0$$

This formulation measures the geometric separation between two vectors, independent of their orientation, and reduces to the standard Euclidean distance in vector space.

Part 3 - Hints and Helper

In PyTorch, distance computation is expressed using tensor subtraction followed by a norm operation. There is no requirement for a dedicated distance function when the mathematical definition can be written directly using basic tensor operations.

The reader is encouraged to compute the vector difference explicitly and apply `torch.norm()` to obtain the distance. This approach maintains clarity, avoids unnecessary abstraction, and reinforces the geometric interpretation of distance as magnitude of separation.

Part 4 - Python code skeleton

```
import torch

def E06(X, Y):
    diff = X ...
    d = torch...
    return d

def main():
    X = torch...
    Y = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.3.8 Exercise 07 - 1D Sum Reduction Law

Part 0 - Loss Functions

Loss functions quantify how far a model's predictions deviate from their target values during training. At early stages of learning, this deviation is often large, reflecting poor alignment between prediction and ground truth. As the model updates its parameters through optimization, the accumulated deviation is gradually reduced, driving the loss toward smaller values. For example, an initial error magnitude of 5.0 may decrease progressively through training iterations until it reaches a value such as 0.5, indicating improved model performance. This reduction process can be viewed as a sequence of deviation points:

$$5.0 \rightarrow 4.2 \rightarrow 3.6 \rightarrow 2.8 \rightarrow 2.1 \rightarrow 1.5 \rightarrow 1.0 \rightarrow 0.5$$

Each step represents a reduction in overall error achieved by aggregating individual deviations through a loss function and applying corrective updates. In this sense, loss reduction is not instantaneous, but a gradual convergence from high deviation toward minimal error.

Part 1 - Why this matters

In artificial intelligence systems, information is often represented in a distributed form across multiple dimensions. While this distributed structure is essential for capturing detailed patterns and local relationships, models ultimately require a mechanism to collapse these representations into a single signal that can guide decisions, comparisons, or optimization objectives.

Sum reduction provides this mechanism by aggregating all components of a vector into one scalar value. This operation transforms dispersed information into a global measure, enabling artificial intelligence systems to reason about total activation, accumulated error, or overall contribution without preserving positional detail. In doing so, sum reduction acts as a bridge between local computations and global model behavior.

From a learning perspective, sum reduction underpins many loss formulations and optimization processes. It allows models to evaluate collective outcomes rather than isolated components, ensuring that training signals reflect the full scope of model responses. In this sense, sum reduction is not merely a numerical convenience, but a structural operation that enables artificial intelligence systems to transition from representation to decision.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Sum Reduction Law defines the operation of reducing a vector to a single scalar by summing all of its components.

The sum reduction operator is defined as:

$$\text{sum}(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$s = \sum_{i=1}^{n} X_i$$

where:

$$s \in \mathbb{R}$$

This operation collapses the vector dimension by aggregating all elements into a single scalar, preserving total magnitude while discarding positional structure.

Part 3 - Hints and Helper

In PyTorch, sum reduction is expressed using a dedicated reduction operation applied to a tensor. This operation directly reflects the mathematical summation of vector components and avoids manual iteration.

The reader is encouraged to use PyTorch's built-in summation functionality to reduce a one-dimensional tensor to a scalar, ensuring clarity and consistency with tensor-based computation. Care should be taken to understand how reduction operations alter tensor shape and dimensionality.

Part 4 - Python code skeleton

```
import torch

def E07(X):
    s = torch...
    return s

def main():
    X = torch...
```

```
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.3.9 Exercise 08 - 1D Max Reduction Law

Part 1 - Why this matters

In artificial intelligence systems, not all information contributes equally to a decision. In many scenarios, the strongest signal within a set of values carries the most meaningful insight, while smaller contributions may represent noise or secondary effects. Max reduction enables models to focus on this dominant signal by selecting the largest component of a vector and discarding the rest.

This behavior is especially important in pattern detection and feature analysis, where the presence of a strong activation can be more informative than the overall distribution of values. By preserving only the maximum response, max reduction allows artificial intelligence systems to highlight salient features, trigger decisions, or identify critical evidence without dilution from weaker signals.

From a structural perspective, max reduction performs a decisive dimensional collapse. It transforms a distributed representation into a single value that reflects peak influence rather than aggregate behavior. In this sense, max reduction is not merely a numerical shortcut, but a selective operation that shapes how models prioritize information and respond to the most influential components within high-dimensional representations.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Max Reduction Law defines the operation of reducing a vector to a single scalar by selecting its maximum component.

The max reduction operator is defined as:

$$\max(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$m = \max_{1 \le i \le n} X_i$$

where:

$$m \in \mathbb{R}$$

This operation collapses the vector dimension by preserving only the largest value, discarding all other components and their relative structure.

Part 3 - Hints and Helper

In PyTorch, max reduction is performed using `torch.max()`, which applies a reduction operation over the elements of a tensor. This function directly reflects the mathematical definition of selecting the maximum component of a vector.

The reader is encouraged to use `torch.max()` to reduce a one-dimensional tensor to its largest value, while being mindful that the function may also return auxiliary information such as the index of the maximum element. When only the reduced scalar is required, attention should be focused on extracting the value component of the operation.

Part 4 - Python code skeleton

```
import torch

def E08(X):
    m = torch...
    return m

def main():
    X = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.3.10 Exercise 09 - 1D Min Reduction Law

Part 1 - Why this matters

In artificial intelligence systems, not all information signals are valuable in the same way. While some operations focus on dominant or peak values, others require identifying the weakest or most constrained component within a set of values. Min reduction enables models to isolate this limiting factor by selecting the smallest element of a vector and discarding all others.

This operation is particularly important in optimization, constraint handling, and safety-sensitive reasoning. By focusing on the minimum value, artificial intelligence systems can detect bottlenecks, identify failure conditions, or evaluate worst-case scenarios where the weakest signal determines overall behavior. In such contexts, the smallest component carries disproportionate importance.

From a structural perspective, min reduction performs a decisive dimensional collapse centered on limitation rather than dominance. It transforms a distributed representation into a single scalar that reflects the most restrictive element of the system. In this sense, min reduction is not merely a numerical counterpart to max reduction, but a complementary operation that enables artificial intelligence systems to reason about constraints, risk, and lower bounds within high-dimensional representations.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Min Reduction Law defines the operation of reducing a vector to a single scalar by selecting its minimum component.

The min reduction operator is defined as:

$$\min(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$m = \min_{1 \le i \le n} X_i$$

where:

$$m \in \mathbb{R}$$

This operation collapses the vector dimension by preserving only the smallest value, discarding all other components and their relative structure.

Part 3 - Hints and Helper

In PyTorch, min reduction is performed using `torch.min()`, which applies a reduction operation over the elements of a tensor. This function directly reflects the mathematical definition of selecting the minimum component of a vector.

The reader is encouraged to use `torch.min()` to reduce a one-dimensional tensor to its smallest value, while being aware that the function may also return auxiliary information such as the index of the minimum element. When only the reduced scalar is required, attention should be focused on extracting the value component of the operation.

Part 4 - Python code skeleton

```
import torch

def E09(X):
    m = torch...
    return m

def main():
    X = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.3.11 Exercise 10 - 1D Mean Reduction Law

Part 0.1 - Batch

In artificial intelligence training, data is often processed in batches rather than as individual samples. A batch represents a group of examples evaluated together in a single forward and backward pass, enabling efficient computation and stable learning. By operating on batches, models can estimate gradients more reliably while balancing memory constraints and training speed, making batch processing a fundamental concept in modern optimization workflows.

Part 0.2 - Workflows

In artificial intelligence systems, workflows describe the structured sequence of operations through which data moves from input to output during training or inference. A workflow typically includes data loading, batch processing, model evaluation, loss computation, and parameter updates, forming a coherent pipeline that governs how learning unfolds. By organizing computation into clear workflows, artificial intelligence systems ensure consistency,

reproducibility, and efficient coordination between individual operations within complex models.

Part 1 - Why this matters

In artificial intelligence systems, performance must be evaluated in a way that is independent of scale and data quantity. When representations vary in length or when training is performed over batches of different sizes, relying on total accumulated values can distort interpretation. Mean reduction addresses this challenge by providing a normalized measure that reflects average behavior rather than total magnitude.

By averaging components, mean reduction allows models to reason about quality instead of quantity. This is especially important in learning processes, where loss values, activations, and errors must remain comparable across iterations and datasets. Unlike sum reduction, which grows with vector size, mean reduction maintains a stable range, enabling consistent optimization and controlled parameter updates.

From a structural perspective, mean reduction performs a balanced dimensional collapse. It transforms a distributed representation into a single scalar while preserving proportional contribution from all components. In this sense, mean reduction is not merely a convenience, but a foundational operation that ensures fair evaluation, stable learning dynamics, and reliable comparison within artificial intelligence systems.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector, with $n \geq 1$.

1D Mean Reduction Law defines the operation of reducing a vector to a single scalar by computing the average of its components.

The mean reduction operator is defined as:

$$\text{mean}(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$\mu = \frac{1}{n} \sum_{i=1}^{n} X_i$$

where:

$$\mu \in \mathbb{R}$$

This operation collapses the vector dimension by aggregating all elements into a single scalar while normalizing by the number of components, preserving average magnitude rather than total or peak values.

Part 3 - Hints and Helper

In PyTorch, mean reduction is performed using `torch.mean()`, which computes the average value of all elements in a tensor. This function directly implements the mathematical definition of mean reduction.

The reader is encouraged to use `torch.mean()` to reduce a one-dimensional tensor to a scalar, while understanding that mean reduction differs conceptually from sum reduction by normalizing the result with respect to the vector length. Care should be taken to ensure the tensor is non-empty to avoid undefined behavior.

Part 4 - Python code skeleton

```
import torch

def E10(X):
    mu = torch...
    return mu

def main():
    X = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.3.12 Exercise 11 - 1D Variance Law

Part 1 - Why this matters

In artificial intelligence systems, evaluating performance or behavior based solely on average values can be misleading. Two sets of representations may share the same mean while exhibiting fundamentally different levels of stability and reliability. Variance addresses this limitation by measuring how widely values are distributed around their average, revealing information that mean values alone cannot capture.

By quantifying dispersion, variance allows artificial intelligence systems to distinguish between stable signals and fluctuating ones. Low variance indicates consistency and predictable behavior, while high variance signals noise, instability, or sensitivity to input changes. This distinction is critical in training dynamics, data quality assessment, and model robustness analysis.

From a structural perspective, variance performs a dimensional collapse focused on deviation rather than magnitude. It transforms a distributed representation into a single scalar that reflects variability around a central tendency. In this sense, variance is not merely a statistical quantity, but a foundational measure that enables artificial intelligence systems to reason about stability, noise, and reliability within high-dimensional representations.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector, with $n \geq 1$.

1D Variance Law defines the operation of measuring how widely the components of a vector are spread around their mean.

The variance operator is defined as:

$$\mathrm{var}(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^{n} (X_i - \mu)^2$$

where:

$$\mu = \frac{1}{n} \sum_{i=1}^{n} X_i, \quad \sigma^2 \in \mathbb{R}, \quad \sigma^2 \geq 0$$

This formulation quantifies dispersion by averaging the squared deviations from the mean, collapsing the vector into a single scalar that reflects variability rather than magnitude.

Part 3 - Hints and Helper

In PyTorch, variance is computed using `torch.var()`, which internally combines mean subtraction and squared deviation reduction into a single operation. This function directly corresponds to the mathematical definition of variance.

The reader is encouraged to use `torch.var()` to compute variance over a one-dimensional tensor, while being mindful of normalization conventions. In particular, attention should be paid to whether the operation uses population normalization or an unbiased estimate, as this choice affects the scaling of the result.

Part 4 - Python code skeleton

```
import torch

def E11(X):
    var = torch...
    return var

def main():
    X = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.3.13 Exercise 12 - 1D Standard Deviation Law

Part 1 - Why this matters

In artificial intelligence systems, understanding average behavior is not sufficient to characterize how a model or dataset behaves in practice. Standard deviation provides a direct and interpretable measure of how far individual values typically deviate from the mean, offering insight into the spread and stability of representations.

Unlike variance, which expresses dispersion in squared units, standard deviation operates in the same scale as the original data. This makes it particularly valuable for reasoning about noise, consistency, and sensitivity within models. A small standard deviation indicates tightly clustered values and stable behavior, while a large standard deviation signals fluctuation and uncertainty.

From a structural perspective, standard deviation performs a dimensional collapse that preserves interpretability. It transforms a distributed vector into a single scalar that reflects typical deviation rather than extreme or aggregate behavior. In this sense, standard deviation serves as a practical bridge between statistical measurement and intuitive understanding in artificial intelligence systems.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector, with $n \geq 1$.

1D Standard Deviation Law defines the operation of measuring the typical magnitude of deviation of vector components from their mean.

The standard deviation operator is defined as:

$$\text{std}(\cdot) : \mathbb{R}^n \to \mathbb{R}$$

Define:

$$\sigma = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(X_i - \mu)^2}$$

where:

$$\mu = \frac{1}{n}\sum_{i=1}^{n} X_i, \quad \sigma \in \mathbb{R}, \quad \sigma \geq 0$$

This formulation expresses dispersion in the same units as the original data, making standard deviation directly interpretable as an average distance from the mean.

Part 3 - Hints and Helper

In PyTorch, standard deviation is computed using `torch.std()`, which internally relies on variance computation followed by a square root operation. This function corresponds directly to the mathematical definition of standard deviation.

The reader is encouraged to use `torch.std()` to compute dispersion over a one-dimensional tensor, while paying attention to normalization conventions. In particular, understanding whether population or unbiased normalization is used is important, as it affects the scale of the resulting value.

Part 4 - Python code skeleton

```
import torch

def E12(X):
    std = torch...
    return std

def main():
    X = torch...
    print(E12(...))

if __name__ == "__main__":
    main()
```

1.3.14 Exercise 13 - 1D Cumulative Sum Law

Part 1 - Why this matters

In artificial intelligence systems, many forms of information cannot be fully understood when treated as isolated values. Data often arrives as a sequence, where each element gains meaning from what came before it. Cumulative sum addresses this need by transforming momentary values into a representation that encodes historical accumulation.

By allowing each element of the output vector to reflect all preceding inputs, cumulative sum introduces a simple yet powerful notion of memory. This makes it possible for artificial intelligence systems to reason about trends, growth, and long-term influence without relying on learned parameters or complex recurrent structures. In this sense, cumulative sum provides a foundational mechanism for capturing temporal context.

From a structural perspective, cumulative sum preserves dimensionality while changing interpretation. It converts a vector of independent values into a progressive representation where each position carries contextual information. This transformation enables artificial intelligence systems to analyze sequences, monitor convergence, and model accumulation processes in a transparent and deterministic manner.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Cumulative Sum Law defines the operation of transforming a vector into a new vector where each element represents the running total up to that position.

The cumulative sum operator is defined as:

$$\text{cumsum}(\cdot) : \mathbb{R}^n \to \mathbb{R}^n$$

Define:

$$Z_k = \sum_{i=1}^{k} X_i, \quad k = 1, 2, \ldots, n$$

where:

$$\mathbf{Z} = [Z_1, Z_2, \ldots, Z_n] \in \mathbb{R}^n$$

This operation preserves dimensionality while encoding progressive accumulation, allowing each position to reflect all preceding contributions.

Part 3 - Hints and Helper

In PyTorch, cumulative summation is performed using `torch.cumsum()`, which computes running totals along a specified dimension of a tensor. This function directly corresponds to the mathematical definition of cumulative summation.

The reader is encouraged to use `torch.cumsum()` to accumulate values along the one-dimensional axis, while understanding that unlike reduction operations, cumulative sum does not collapse dimensionality. Each output element depends on all previous elements in the sequence.

Part 4 - Python code skeleton

```
import torch

def E13(X):
    Z = torch...
    return Z

def main():
    X = torch...
```

```
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.3.15 Exercise 14 - 1D Cumulative Product Law

Part 1 - Why this matters

In artificial intelligence systems, not all processes evolve through additive accumulation. Some dynamics grow, decay, or amplify multiplicatively, where the effect of each element compounds over time. Cumulative product captures this behavior by allowing each value to influence all subsequent values through multiplication rather than addition.

By encoding multiplicative history, cumulative product enables artificial intelligence systems to model growth rates, decay processes, scaling effects, and probabilistic chains. This is particularly important in scenarios where relative change matters more than absolute difference, such as likelihood propagation, signal attenuation, and sequential scaling.

From a structural perspective, cumulative product preserves dimensionality while introducing compounding dependency. Each output element reflects the entire multiplicative past, transforming a vector of independent factors into a progressive representation that encodes long-term influence and amplification effects.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^n$ be a one-dimensional vector.

1D Cumulative Product Law defines the operation of transforming a vector into a new vector where each element represents the running product up to that position.

The cumulative product operator is defined as:

$$\text{cumprod}(\cdot) : \mathbb{R}^n \to \mathbb{R}^n$$

Define:

$$Z_k = \prod_{i=1}^{k} X_i, \quad k = 1, 2, \ldots, n$$

where:

$$\mathbf{Z} = [Z_1, Z_2, \ldots, Z_n] \in \mathbb{R}^n$$

This operation preserves vector length while encoding multiplicative accumulation, allowing each position to reflect compounded influence from all preceding elements.

Part 3 - Hints and Helper

In PyTorch, cumulative product is performed using `torch.cumprod()`, which computes running products along a specified tensor dimension. This function directly corresponds to the mathematical definition of cumulative product.

The reader is encouraged to use `torch.cumprod()` along the one-dimensional axis, while being mindful that unlike reduction operations, this law does not collapse dimensionality. Each output element depends on all prior elements, and special care should be taken when vectors contain zeros or negative values, as these can significantly alter subsequent results.

Part 4 - Python code skeleton

```
import torch

def E14(X):
    Z = torch...
    return Z

def main():
    X = torch...
    print(E14(...))

if __name__ == "__main__":
    main()
```

1.4 T02 - Matrix Laws (2D)

Mathematics and Theory

1.4.1 Exercise 00 - 2D Matrix Multiplication Law

Part 1 - Why this matters

In artificial intelligence systems, raw data rarely holds value in its original form. Learning emerges from the ability to transform representations into new spaces where meaningful patterns become accessible. Two-dimensional matrix multiplication provides the fundamental mechanism for this transformation by combining multiple features through structured, weighted interactions.

By applying matrix multiplication, artificial intelligence models can process entire batches of data simultaneously, mapping input features to learned representations in a consistent and scalable manner. Each output element encodes a weighted aggregation of inputs, allowing models to capture relationships, dependencies, and correlations that cannot be expressed through one-dimensional operations alone.

From a structural perspective, matrix multiplication establishes the bridge between data and learning. It formalizes how parameters influence representations and defines how information flows through layers of a model. In this sense, two-dimensional matrix multiplication is not merely a computational operation, but the core transformation law that enables artificial intelligence systems to learn, generalize, and reason across high-dimensional spaces.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times p}$ be two two-dimensional matrices.

2D Matrix Multiplication Law defines the operation of combining two matrices by computing dot products between rows of the first matrix and columns of the second matrix.

The matrix multiplication operator is defined as:

$$(\cdot) : \mathbb{R}^{m \times n} \times \mathbb{R}^{n \times p} \rightarrow \mathbb{R}^{m \times p}$$

Define:

$$\mathbf{C} = \mathbf{AB}$$

with elements:

$$C_{ij} = \sum_{k=1}^{n} A_{ik}\, B_{kj}$$

where:

$$\mathbf{C} \in \mathbb{R}^{m \times p}$$

This operation combines rows of $\mathbf{A}$ with columns of $\mathbf{B}$, producing a new matrix whose entries encode weighted interactions between both inputs.

Part 3 - Hints and Helper

In PyTorch, matrix multiplication is performed using `torch.matmul()`, which automatically applies the correct multiplication rule based on tensor dimensionality. For two-dimensional tensors, this function implements standard matrix multiplication as defined mathematically.

The reader is encouraged to use `torch.matmul()` when multiplying matrices, rather than element-wise operations. Special attention should be paid to matrix shapes, as the inner dimensions must match for the multiplication to be valid.

Part 4 - Python code skeleton

```
import torch

def E00(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.4.2 Exercise 01 - 2D Hadamard Matrix Law

Part 1 - Why this matters

In artificial intelligence systems, not all operations aim to transform data into new representations. In many scenarios, the objective is to regulate, filter, or modulate existing information without altering its structural form. Hadamard matrix multiplication provides this capability by enabling direct, element-wise control over matrix values.

By applying Hadamard multiplication, artificial intelligence models can selectively amplify, suppress, or mask individual elements within a matrix. This operation is essential in mechanisms such as masking, gating, and attention control, where decisions are made locally at the level of each element rather than through global aggregation or transformation.

From a structural perspective, Hadamard multiplication preserves dimensionality while modifying semantic influence. It allows models to intervene in information flow without reshaping or reprojecting data, making it a critical tool for fine-grained control within neural architectures. In this sense, the Hadamard matrix law complements matrix multiplication by enabling precision and control where transformation alone is insufficient.

Part 2 - Mathematical form

Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{m \times n}$ be two matrices of the same shape.

2D Hadamard Matrix Law defines element-wise multiplication between two matrices, where each element in the output matrix is obtained by multiplying corresponding elements from the input matrices.

The Hadamard multiplication operator is defined as:

$$\odot : \mathbb{R}^{m \times n} \times \mathbb{R}^{m \times n} \rightarrow \mathbb{R}^{m \times n}$$

Define:

$$\mathbf{C} = \mathbf{A} \odot \mathbf{B}$$

with elements:

$$C_{ij} = A_{ij} \cdot B_{ij}$$

where:

$$\mathbf{C} \in \mathbb{R}^{m \times n}$$

This operation requires both matrices to have identical dimensions and applies multiplication independently to each corresponding pair of elements.

Part 3 - Hints and Helper

In PyTorch, Hadamard (element-wise) matrix multiplication is performed using the `*` operator or the function `torch.mul()`. Both approaches apply element-wise multiplication and require the input matrices to share the same shape.

The reader is encouraged to distinguish clearly between Hadamard multiplication and standard matrix multiplication. Unlike `torch.matmul()`, Hadamard multiplication does not combine rows and columns and does not perform any form of dimensional reduction or aggregation.

Part 4 - Python code skeleton

```
import torch

def E01(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.4.3 Exercise 02 - 2D Frobenius Inner Product Law

Part 1 - Why this matters

In artificial intelligence systems, matrices often represent batches of data, learned parameters, feature maps, attention scores, or intermediate activations. Comparing these matrices requires an operation that measures how strongly their entries align while preserving the structure of the original representations. The two-dimensional Frobenius inner product provides this mechanism by combining corresponding entries from two matrices into a single scalar value.

By applying the Frobenius inner product, artificial intelligence models can measure similarity, interaction, and agreement between matrix-valued representations. Each pair of corresponding entries contributes to the final result, allowing the operation to summarize the global relationship between two matrices without discarding the contribution of any individual position.

From a learning perspective, the Frobenius inner product appears naturally in loss functions, matrix similarity measures, optimization objectives, and gradient-based methods. It also provides the matrix-space extension of the standard vector dot product. In this sense, the two-dimensional Frobenius inner product is not merely a reduction operation, but a fundamental law for measuring alignment between structured representations in artificial intelligence systems.

Part 2 - Mathematical form

Let $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{m \times n}$ be two two-dimensional matrices with identical shapes.

2D Frobenius Inner Product Law defines the operation of multiplying corresponding entries from both matrices and summing all resulting products.

The Frobenius inner product operator is defined as:

$$\langle \cdot, \cdot \rangle_F : \mathbb{R}^{m \times n} \times \mathbb{R}^{m \times n} \to \mathbb{R}$$

Define:

$$c = \langle \mathbf{A}, \mathbf{B} \rangle_F$$

Then:

$$c = \sum_{i=1}^{m} \sum_{j=1}^{n} A_{ij} B_{ij}$$

Equivalently:

$$\langle \mathbf{A}, \mathbf{B} \rangle_F = \operatorname{tr}\left(\mathbf{A}^{\mathsf{T}} \mathbf{B}\right)$$

where:

$$c \in \mathbb{R}$$

This operation measures the global alignment between $\mathbf{A}$ and $\mathbf{B}$ by accumulating the products of all corresponding matrix entries into a single scalar.

Part 3 - Hints and Helper

In PyTorch, the Frobenius inner product can be computed by combining element-wise multiplication with a reduction over all matrix entries. The functions `torch.mul()` and `torch.sum()` may be used to express these two stages explicitly.

The reader should verify that both input tensors have the same shape before performing the operation. Special attention should also be paid to the difference between the Frobenius inner product and matrix multiplication: the Frobenius inner product multiplies corresponding entries and returns a scalar, whereas matrix multiplication combines rows and columns and generally returns a matrix.

Part 4 - Python code skeleton

```
import torch

def E02(A, B):
    C = torch...
    c = torch...
    return c

def main():
    A = torch...
    B = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.4.4 Exercise 03 - 2D Determinant Law

Part 1 - Why this matters

In artificial intelligence systems, matrices frequently describe linear transformations applied to data, features, parameters, and learned representations. Understanding whether such a transformation preserves information or collapses part of the input space is essential when analyzing the behavior of a model. The two-dimensional determinant provides a single scalar value that summarizes this structural property for a square matrix.

The magnitude of the determinant describes how a matrix transformation scales area in two dimensions and, more generally, volume in higher-dimensional spaces. Its sign indicates whether the transformation preserves or reverses orientation. A determinant equal to zero reveals that the transformation compresses the space into a lower dimension, causing information to be lost and making the matrix non-invertible.

From a learning perspective, determinants appear in probabilistic models, normalizing flows, covariance analysis, change-of-variable formulas, and numerical methods involving matrix invertibility. In this sense, the two-dimensional determinant is not merely a matrix calculation, but a fundamental diagnostic law for understanding how learned transformations scale, preserve, or destroy information.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be a two-dimensional square matrix.

2D Determinant Law defines an operation that maps a square matrix to a single scalar representing the signed scaling factor of the corresponding linear transformation.

The determinant operator is defined as:

$$\det : \mathbb{R}^{n \times n} \to \mathbb{R}$$

Define:

$$\delta = \det(\mathbf{A})$$

For a general $n \times n$ matrix, the determinant is defined by the Leibniz formula:

$$\delta = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \prod_{i=1}^{n} A_{i,\sigma(i)}$$

where S_n is the set of all permutations of $\{1, 2, \ldots, n\}$ and $\operatorname{sgn}(\sigma)$ is the sign of the permutation σ.

For the special case:

$$\mathbf{A} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathbb{R}^{2 \times 2}$$

the determinant is:

$$\det(\mathbf{A}) = ad - bc$$

where:

$$\delta \in \mathbb{R}$$

If $\det(\mathbf{A}) \neq 0$, then $\mathbf{A}$ is invertible. If $\det(\mathbf{A}) = 0$, then $\mathbf{A}$ is singular and its transformation collapses at least one dimension of the input space.

Part 3 - Hints and Helper

In PyTorch, the determinant of a square matrix is computed using `torch.linalg.det()`. This function applies a numerically appropriate matrix-factorization method rather than directly expanding the full Leibniz formula.

The reader should verify that the input tensor is two-dimensional and square, meaning that its number of rows equals its number of columns. The tensor should also use a supported floating-point or complex data type. Special attention should be paid to matrices whose determinant is equal or very close to zero, as they may be singular or numerically ill-conditioned.

Part 4 - Python code skeleton

```
import torch

def E03(A):
    determinant = torch...
    return determinant

def main():
    A = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.4.5 Exercise 04 - 2D Inverse Matrix Law

Part 1 - Why this matters

In artificial intelligence systems, matrices are used to transform data from one representation space into another. When a transformation preserves enough information to be reversed, its inverse matrix provides the mechanism for recovering the original representation. This reversibility is essential for understanding whether a learned transformation can be undone without losing information.

By applying an inverse matrix, artificial intelligence models and numerical algorithms can recover unknown variables, reverse coordinate transformations, and solve systems of linear equations. Inverse transformations also appear in probabilistic modeling, covariance-based methods, optimization, and invertible neural network architectures, where information must pass through a sequence of reversible mappings.

From a structural perspective, the existence of an inverse distinguishes information-preserving transformations from singular transformations that collapse one or more dimensions. In this sense, the two-dimensional inverse matrix law is not merely a method for reversing matrix multiplication, but a fundamental condition for determining whether a matrix transformation preserves the full structure of its input space.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be a two-dimensional square matrix satisfying:

$$\det(\mathbf{A}) \neq 0$$

2D Inverse Matrix Law defines the unique matrix $\mathbf{A}^{-1}$ that reverses the transformation produced by $\mathbf{A}$.

The inverse operator is defined over the set of invertible matrices as:

$$(\cdot)^{-1} : \mathrm{GL}_n(\mathbb{R}) \to \mathrm{GL}_n(\mathbb{R})$$

Define:

$$\mathbf{B} = \mathbf{A}^{-1}$$

Then:

$$\mathbf{AB} = \mathbf{BA} = \mathbf{I}_n$$

where:

$$\mathbf{B} \in \mathbb{R}^{n \times n}$$

and $\mathbf{I}_n$ is the $n \times n$ identity matrix.

The inverse may also be expressed as:

$$\mathbf{A}^{-1} = \frac{1}{\det(\mathbf{A})} \operatorname{adj}(\mathbf{A})$$

For the special case:

$$\mathbf{A} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

with $ad - bc \neq 0$, the inverse is:

$$\mathbf{A}^{-1} = \frac{1}{ad - bc} \begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$$

If $\det(\mathbf{A}) = 0$, then the inverse does not exist and $\mathbf{A}$ is called a singular matrix.

Part 3 - Hints and Helper

In PyTorch, the inverse of a square matrix is computed using `torch.linalg.inv()`. The function returns a matrix with the same shape as the input and requires the input matrix to be invertible.

The reader should verify that the input tensor is two-dimensional, square, and stored using a supported floating-point or complex data type. Special attention should be paid to matrices whose determinants are zero or very close to zero, because singular or ill-conditioned matrices may cause an error or produce numerically unstable results. When solving a system such as $\mathbf{Ax} = \mathbf{b}$, directly solving the system is generally more stable than explicitly forming $\mathbf{A}^{-1}$.

Part 4 - Python code skeleton

```
import torch

def E04(A):
    A_inverse = torch...
    return A_inverse

def main():
    A = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.4.6 Exercise 05 - 2D Transpose Law

Part 1 - Why this matters

In artificial intelligence systems, matrices organize information along rows and columns, with each axis often representing a different semantic role. Rows may represent observations while columns represent features, or one axis may represent input units while the other represents output units. The two-dimensional transpose provides the fundamental operation for exchanging these roles without changing the values stored in the matrix.

By applying the transpose, artificial intelligence models can align matrix shapes for multiplication, compare features across observations, and reverse the direction in which relationships are represented. Transposition appears in linear layers, attention mechanisms, covariance calculations, gradient expressions, and inner-product operations where rows must interact with columns in a mathematically valid form.

From a structural perspective, transposition reorganizes a matrix by reflecting its entries across the main diagonal. It changes the orientation of a representation while preserving all of its information. In this sense, the two-dimensional transpose is not merely a shape manipulation, but a fundamental law for aligning, interpreting, and combining matrix-valued representations in artificial intelligence systems.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix.

2D Transpose Law defines the operation of exchanging the row and column indices of a matrix.

The transpose operator is defined as:

$$(\cdot)^{\mathsf{T}} : \mathbb{R}^{m \times n} \to \mathbb{R}^{n \times m}$$

Define:

$$\mathbf{B} = \mathbf{A}^{\mathsf{T}}$$

Then:

$$B_{ji} = A_{ij}, \qquad 1 \le i \le m, \quad 1 \le j \le n$$

where:

$$\mathbf{B} \in \mathbb{R}^{n \times m}$$

For example:

$$\begin{bmatrix} a & b & c \\ d & e & f \end{bmatrix}^{\mathsf{T}} = \begin{bmatrix} a & d \\ b & e \\ c & f \end{bmatrix}$$

Applying the transpose twice restores the original matrix:

$$\left(\mathbf{A}^{\mathsf{T}}\right)^{\mathsf{T}} = \mathbf{A}$$

For compatible matrices, transposition also reverses the order of matrix multiplication:

$$(\mathbf{AB})^{\mathsf{T}} = \mathbf{B}^{\mathsf{T}}\mathbf{A}^{\mathsf{T}}$$

Part 3 - Hints and Helper

In PyTorch, the transpose of a two-dimensional tensor can be obtained using `torch.transpose()` by exchanging dimensions 0 and 1. The `.T` property may also be used for a two-dimensional tensor.

The reader should verify that the input tensor has exactly two dimensions and should observe that the output shape reverses the row and column sizes. The transpose changes the arrangement of indices but does not change the stored values. Special attention should be paid to the difference between transposing a matrix and reshaping it, because reshaping does not generally exchange corresponding row and column indices.

Part 4 - Python code skeleton

```
import torch

def E05(A):
    A_transpose = torch...
    return A_transpose

def main():
    A = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.4.7 Exercise 06 - 2D Trace Law

Part 1 - Why this matters

In artificial intelligence systems, square matrices often represent linear transformations, covariance structures, similarity relations, or interactions between features. Analyzing every entry of such a matrix individually can be unnecessary when the goal is to obtain a compact summary of its diagonal behavior. The two-dimensional trace provides this summary by reducing the main diagonal of a square matrix to a single scalar value.

By applying the trace, artificial intelligence models and numerical algorithms can measure quantities such as the total variance stored in a covariance matrix, summarize the diagonal contribution of a transformation, and express matrix objectives in a concise and differentiable form. Trace expressions also appear in optimization, regularization, matrix calculus, and statistical learning, where they simplify operations involving sums of quadratic forms.

From a structural perspective, the trace is invariant under a change of basis and equals the sum of the eigenvalues of a square matrix, counted with algebraic multiplicity. In this sense, the two-dimensional trace is not merely a diagonal sum, but a fundamental scalar summary of a matrix transformation that remains meaningful across equivalent coordinate representations.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be a two-dimensional square matrix.

2D Trace Law defines the operation of summing all entries located on the main diagonal of a square matrix.

The trace operator is defined as:

$$\mathrm{tr} : \mathbb{R}^{n \times n} \to \mathbb{R}$$

Define:

$$t = \mathrm{tr}(\mathbf{A})$$

Then:

$$t = \sum_{i=1}^{n} A_{ii}$$

where:

$$t \in \mathbb{R}$$

For example:

$$\mathbf{A} = \begin{bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{bmatrix}$$

produces:

$$\operatorname{tr}(\mathbf{A}) = a + e + i$$

The trace is linear. For matrices $\mathbf{A}, \mathbf{B} \in \mathbb{R}^{n \times n}$ and scalar $\alpha \in \mathbb{R}$:

$$\operatorname{tr}(\mathbf{A} + \mathbf{B}) = \operatorname{tr}(\mathbf{A}) + \operatorname{tr}(\mathbf{B})$$

$$\operatorname{tr}(\alpha \mathbf{A}) = \alpha \operatorname{tr}(\mathbf{A})$$

For compatible matrices, the trace also satisfies the cyclic property:

$$\operatorname{tr}(\mathbf{AB}) = \operatorname{tr}(\mathbf{BA})$$

Part 3 - Hints and Helper

In PyTorch, the trace of a two-dimensional matrix is computed using `torch.trace()`. The function extracts the main diagonal and returns the sum of its entries as a scalar tensor.

The reader should verify that the input tensor has exactly two dimensions. For the mathematical law presented here, the matrix should also be square. Special attention should be paid to the main diagonal, whose entries satisfy identical row and column indices. The trace should not be confused with summing every entry in the matrix, because only entries of the form A_{ii} contribute to the result.

Part 4 - Python code skeleton

```
import torch

def E06(A):
    trace_value = torch...
    return trace_value

def main():
    A = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.4.8 Exercise 07 - 2D Cofactor Law

Part 1 - Why this matters

In artificial intelligence systems, matrix transformations are often analyzed through quantities such as determinants, inverses, and local sensitivities. The two-dimensional cofactor law

provides the structural components required to expand a determinant and construct the adjugate of a square matrix. Each cofactor measures how the determinant depends on the matrix entry located at a specific row and column.

By organizing these values into a cofactor matrix, mathematical and numerical methods can examine how individual entries contribute to the global behavior of a matrix transformation. Cofactors form a classical foundation for computing matrix inverses, differentiating determinants, and studying whether a transformation preserves or collapses information.

From a learning perspective, the cofactor law reveals the local structure hidden inside determinant-based operations. Although large artificial intelligence systems normally rely on efficient matrix factorizations instead of explicitly constructing cofactors, the law remains essential for understanding determinant gradients, inverse matrices, and the algebraic relationships behind differentiable linear transformations.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{n \times n}$ be a two-dimensional square matrix.

For each entry A_{ij}, let $\mathbf{M}_{ij} \in \mathbb{R}^{(n-1)\times(n-1)}$ denote the minor matrix formed by deleting row i and column j from $\mathbf{A}$.

2D Cofactor Law defines the signed determinant associated with each matrix entry.

The cofactor-matrix operator is defined as:

$$\mathrm{cof} : \mathbb{R}^{n \times n} \to \mathbb{R}^{n \times n}$$

Define:

$$\mathbf{C} = \mathrm{cof}(\mathbf{A})$$

Then each cofactor is:

$$C_{ij} = (-1)^{i+j} \det(\mathbf{M}_{ij}), \qquad 1 \le i, j \le n$$

where:

$$\mathbf{C} \in \mathbb{R}^{n \times n}$$

The signs of the cofactors follow the alternating pattern:

$$\begin{bmatrix} + & - & + & \cdots \\ - & + & - & \cdots \\ + & - & + & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

For example, if:

$$\mathbf{A} = \begin{bmatrix} a & b & c \\ d & e & f \\ g & h & i \end{bmatrix}$$

then the cofactor of A_{12} is:

$$C_{12} = (-1)^{1+2} \det \begin{bmatrix} d & f \\ g & i \end{bmatrix} = fg - di$$

The cofactor matrix is related to the adjugate by:

$$\text{adj}(\mathbf{A}) = \mathbf{C}^{\mathsf{T}}$$

and a determinant may be expanded along any fixed row i as:

$$\det(\mathbf{A}) = \sum_{j=1}^{n} A_{ij} C_{ij}$$

Part 3 - Hints and Helper

PyTorch does not provide a direct function that constructs the complete cofactor matrix. The reader can create each minor matrix by removing one row and one column, compute its determinant using `torch.linalg.det()`, and apply the alternating sign $(-1)^{i+j}$.

Python and PyTorch use zero-based indices, while the mathematical formula uses one-based indices. The alternating sign can therefore be generated carefully from the zero-based row and column positions. The input tensor must be two-dimensional and square, and it should use a supported floating-point or complex data type when its minors are passed to `torch.linalg.det()`.

Part 4 - Python code skeleton

```
import torch

def E07(A):
    C = torch...

    for i in range(...):
        for j in range(...):
            minor = A[...]
            sign = ...
            C[i, j] = sign * torch...

    return C

def main():
    A = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.4.9 Exercise 08 - 2D Adjugate Law

Part 1 - Why this matters

In artificial intelligence systems, square matrices describe transformations of features, parameters, and structured representations. Understanding how such transformations relate to

determinants and inverses requires a matrix that collects the signed minor information of every entry in the correct orientation. The two-dimensional adjugate provides this matrix by transposing the cofactor matrix.

The adjugate connects the local determinant contribution of each matrix entry to the global behavior of the complete transformation. It provides a direct algebraic relationship between a matrix, its determinant, and the identity matrix. When the determinant is nonzero, this relationship leads to the classical formula for the inverse matrix.

From a learning perspective, the adjugate law clarifies the structure behind inverse and determinant operations used in differentiable linear algebra. Although modern artificial intelligence systems normally use efficient matrix factorizations rather than explicitly constructing an adjugate, the law remains fundamental for understanding matrix sensitivity, determinant derivatives, and the algebraic conditions that make transformations reversible.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{n\times n}$ be a two-dimensional square matrix, and let $\mathbf{C} = \operatorname{cof}(\mathbf{A})$ be its cofactor matrix.

2D Adjugate Law defines the adjugate of a square matrix as the transpose of its cofactor matrix.

The adjugate operator is defined as:

$$\operatorname{adj} : \mathbb{R}^{n\times n} \to \mathbb{R}^{n\times n}$$

Define:

$$\mathbf{B} = \operatorname{adj}(\mathbf{A})$$

Then:

$$\mathbf{B} = \mathbf{C}^{\mathsf{T}} = \operatorname{cof}(\mathbf{A})^{\mathsf{T}}$$

Equivalently, each entry satisfies:

$$B_{ij} = C_{ji} = (-1)^{i+j} \det(\mathbf{M}_{ji})$$

where $\mathbf{M}_{ji}$ is formed by deleting row j and column i from $\mathbf{A}$, and:

$$\mathbf{B} \in \mathbb{R}^{n\times n}$$

For the special case:

$$\mathbf{A} = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$$

the adjugate is:

$$\operatorname{adj}(\mathbf{A}) = \begin{bmatrix} d & -b \\ -c & a \end{bmatrix}$$

The adjugate satisfies the fundamental identity:

$$\mathbf{A}\operatorname{adj}(\mathbf{A}) = \operatorname{adj}(\mathbf{A})\mathbf{A} = \det(\mathbf{A})\mathbf{I}_n$$

If $\det(\mathbf{A}) \neq 0$, then:

$$\mathbf{A}^{-1} = \frac{1}{\det(\mathbf{A})} \operatorname{adj}(\mathbf{A})$$

The adjugate remains defined even when $\mathbf{A}$ is singular, although the inverse formula cannot be used when $\det(\mathbf{A}) = 0$.

Part 3 - Hints and Helper

PyTorch does not provide a direct function for constructing the adjugate of a matrix. The reader can first construct the cofactor matrix using the method from the 2D Cofactor Law, then transpose it using `torch.transpose()` or the `.T` property.

The input tensor must be two-dimensional and square. Special attention should be paid to the order of operations: the adjugate is the transpose of the cofactor matrix, not the cofactor matrix itself. Computing $\det(\mathbf{A})\mathbf{A}^{-1}$ may reproduce the adjugate for a nonsingular matrix, but that approach is invalid for singular matrices even though their adjugates still exist.

Part 4 - Python code skeleton

```
import torch

def E08(A):
    cofactor_matrix = torch...
    adjugate_matrix = torch...
    return adjugate_matrix

def main():
    A = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.4.10 Exercise 09 - 2D Rank Law

Part 1 - Why this matters

In artificial intelligence systems, matrices store features, transformations, and relationships between variables. Not every row or column necessarily adds new information: some may be linear combinations of others. The two-dimensional rank measures the number of independent directions contained in a matrix and therefore reveals its effective dimensionality.

Rank is important when diagnosing redundant features, compressed representations, singular transformations, and low-rank approximations. A full- rank weight matrix preserves the maximum number of directions allowed by its shape, while a rank-deficient matrix collapses part of the represented space.

From a learning perspective, rank connects matrix structure to information capacity. It appears in dimensionality reduction, matrix factorization, attention analysis, parameter-efficient learning, and numerical stability.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix.

2D Rank Law defines the dimension of the vector space spanned by the columns of $\mathbf{A}$, equivalently by its rows.

The rank operator is defined as:

$$\text{rank} : \mathbb{R}^{m \times n} \to \{0, 1, \ldots, \min(m, n)\}$$

Define:

$$r = \text{rank}(\mathbf{A})$$

Then:

$$r = \dim(\text{Col}(\mathbf{A})) = \dim(\text{Row}(\mathbf{A}))$$

and:

$$0 \leq r \leq \min(m, n)$$

The matrix has full rank when:

$$r = \min(m, n)$$

For a square matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$:

$$\text{rank}(\mathbf{A}) = n \quad \iff \quad \det(\mathbf{A}) \neq 0$$

Part 3 - Hints and Helper

In PyTorch, matrix rank is computed using `torch.linalg.matrix_rank()`. The function estimates numerical rank by counting singular values that exceed a tolerance.

The reader should use a floating-point or complex tensor and remember that numerical rank can depend on tolerance. Values that are mathematically nonzero but extremely small may be treated as zero because of finite precision.

Part 4 - Python code skeleton

```
import torch

def E09(A):
    rank_value = torch...
    return rank_value

def main():
    A = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.4.11 Exercise 10 - 2D Row Sum Law

Part 1 - Why this matters

In artificial intelligence systems, each row of a matrix often represents one observation, token, sample, or spatial position, while its columns represent features. The two-dimensional row sum compresses every row into one scalar by aggregating all of its feature values.

Row sums are useful for computing per-sample totals, checking probability normalization, constructing masks, and summarizing activations. They preserve the row axis while reducing the feature axis, allowing an entire batch to be processed simultaneously.

From a structural perspective, the row sum is an axis-specific reduction. Its meaning depends on which axis represents features, so selecting the correct dimension is as important as performing the addition itself.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix.
2D Row Sum Law defines the sum of all entries in each row.
The row-sum operator is defined as:

$$\text{rowsum} : \mathbb{R}^{m \times n} \to \mathbb{R}^{m}$$

Define:

$$\mathbf{s} = \text{rowsum}(\mathbf{A})$$

Then:

$$s_i = \sum_{j=1}^{n} A_{ij}, \qquad 1 \le i \le m$$

where:

$$\mathbf{s} \in \mathbb{R}^{m}$$

For example:

$$\begin{bmatrix} a & b & c \\ d & e & f \end{bmatrix} \mapsto \begin{bmatrix} a+b+c \\ d+e+f \end{bmatrix}$$

Part 3 - Hints and Helper

In PyTorch, use `torch.sum()` with the dimension corresponding to the columns. For a tensor shaped (m, n), rows are retained by reducing `dim=1`.

The reader should distinguish the mathematical axis from Python's zero-based dimension number. Using `dim=0` would calculate column sums instead.

Part 4 - Python code skeleton

```
import torch

def E10(A):
    row_sums = torch...
    return row_sums
```

```
def main():
    A = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.4.12 Exercise 11 - 2D Column Sum Law

Part 1 - Why this matters

In artificial intelligence systems, matrix columns frequently represent features while rows represent samples, tokens, or observations. The two-dimensional column sum aggregates each feature across all rows, producing one total for every column.

Column sums can summarize feature activity across a batch, count activated conditions, accumulate statistics, and support normalization procedures. They reduce the observation axis while preserving the feature axis.

From a structural perspective, the column sum demonstrates that matrix reductions are axis-dependent. Reducing the wrong axis changes both the output shape and the meaning of the result.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix.
2D Column Sum Law defines the sum of all entries in each column.
The column-sum operator is defined as:

$$\text{colsum} : \mathbb{R}^{m \times n} \to \mathbb{R}^n$$

Define:

$$\mathbf{s} = \text{colsum}(\mathbf{A})$$

Then:

$$s_j = \sum_{i=1}^{m} A_{ij}, \qquad 1 \le j \le n$$

where:

$$\mathbf{s} \in \mathbb{R}^n$$

For example:

$$\begin{bmatrix} a & b & c \\ d & e & f \end{bmatrix} \mapsto \begin{bmatrix} a+d & b+e & c+f \end{bmatrix}$$

Part 3 - Hints and Helper

In PyTorch, use `torch.sum()` with the dimension corresponding to the rows. For a tensor shaped (m, n), columns are retained by reducing `dim=0`.

The reader should check the output shape carefully. Using `dim=1` would calculate row sums instead.

Part 4 - Python code skeleton

```
import torch

def E11(A):
    column_sums = torch...
    return column_sums

def main():
    A = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.4.13 Exercise 12 - 2D Row Mean Law

Part 1 - Why this matters

In artificial intelligence systems, rows commonly represent individual samples, tokens, or positions and columns represent their features. The two-dimensional row mean summarizes every row by its average feature value, producing a scale-aware representation that does not grow with the number of columns.

Row means appear in pooling, per-sample statistics, activation monitoring, and data analysis. Unlike a row sum, the mean divides by the number of features, which makes comparisons across equally interpreted rows more direct.

From a structural perspective, the row mean is a reduction over the column axis. It retains one result per row and therefore preserves the matrix's sample organization while compressing its feature dimension.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix with $n > 0$.

2D Row Mean Law defines the arithmetic mean of each row.

The row-mean operator is defined as:

$$\text{rowmean} : \mathbb{R}^{m \times n} \to \mathbb{R}^m$$

Define:

$$\boldsymbol{\mu} = \text{rowmean}(\mathbf{A})$$

Then:

$$\mu_i = \frac{1}{n} \sum_{j=1}^{n} A_{ij}, \qquad 1 \le i \le m$$

where:

$$\boldsymbol{\mu} \in \mathbb{R}^m$$

Equivalently:

$$\text{rowmean}(\mathbf{A}) = \frac{1}{n} \text{rowsum}(\mathbf{A})$$

Part 3 - Hints and Helper

In PyTorch, use `torch.mean()` and reduce the column dimension. For a tensor shaped (m, n), this corresponds to `dim=1`.

The input should use a floating-point or complex data type. The reader should not use `dim=0`, because that would produce column means.

Part 4 - Python code skeleton

```
import torch

def E12(A):
    row_means = torch...
    return row_means

def main():
    A = torch...
    print(E12(...))

if __name__ == "__main__":
    main()
```

1.4.14 Exercise 13 - 2D Column Mean Law

Part 1 - Why this matters

In artificial intelligence systems, matrix columns often correspond to features and rows correspond to samples or observations. The two-dimensional column mean calculates the average value of each feature across the complete set of rows.

Column means are fundamental to feature centering, dataset statistics, normalization, bias analysis, and activation monitoring. They provide one representative value per feature while removing the batch or observation axis.

From a structural perspective, the column mean is a reduction over rows. It preserves the feature axis and produces the mean vector commonly subtracted from every row when centering a dataset.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ be a two-dimensional matrix with $m > 0$.

2D Column Mean Law defines the arithmetic mean of each column.

The column-mean operator is defined as:

$$\text{colmean} : \mathbb{R}^{m \times n} \to \mathbb{R}^{n}$$

Define:

$$\boldsymbol{\mu} = \text{colmean}(\mathbf{A})$$

Then:

$$\mu_j = \frac{1}{m} \sum_{i=1}^{m} A_{ij}, \qquad 1 \leq j \leq n$$

where:

$$\boldsymbol{\mu} \in \mathbb{R}^n$$

Equivalently:

$$\text{colmean}(\mathbf{A}) = \frac{1}{m}\,\text{colsum}(\mathbf{A})$$

Part 3 - Hints and Helper

In PyTorch, use `torch.mean()` and reduce the row dimension. For a tensor shaped (m, n), this corresponds to `dim=0`.

The input should use a floating-point or complex data type. The reader should check that the output contains one mean for each original column.

Part 4 - Python code skeleton

```
import torch

def E13(A):
    column_means = torch...
    return column_means

def main():
    A = torch...
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.4.15 Exercise 14 - 2D Broadcasting Law

Part 1 - Why this matters

In artificial intelligence systems, matrix operations frequently combine a large collection of values with a smaller tensor such as a bias vector, scale vector, or normalization statistic. Explicitly copying the smaller tensor to match the larger shape would waste memory and obscure the intended operation. Two-dimensional broadcasting provides a rule for aligning compatible shapes and applying the operation as if the smaller tensor had been repeated.

Broadcasting allows one bias value to be applied to every row, one scale value to be applied to every column, or one scalar to interact with an entire matrix. It is therefore central to neural-network layers, feature normalization, attention masks, and element-wise transformations.

From a structural perspective, broadcasting is a shape-compatibility law. It does not define a new arithmetic operator; instead, it determines how existing element-wise operators act on tensors with different but compatible shapes.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^n$.

2D Broadcasting Law allows **b** to behave as if it were repeated across all m rows of **A** during an element-wise operation.

For broadcasted addition, define:

$$\mathbf{C} = \mathbf{A} + \mathbf{b}$$

Then:

$$C_{ij} = A_{ij} + b_j, \qquad 1 \leq i \leq m, \quad 1 \leq j \leq n$$

where:

$$\mathbf{C} \in \mathbb{R}^{m \times n}$$

For general tensor shapes, dimensions are compared from right to left. Two dimensions are compatible when they are equal or when at least one of them is 1. Missing leading dimensions are treated as dimensions of size 1.

For example:

$$(m, n) \text{ and } (n) \quad \longrightarrow \quad (m, n)$$

and:

$$(m, n) \text{ and } (m, 1) \quad \longrightarrow \quad (m, n)$$

Broadcasting is invalid when corresponding dimensions are unequal and neither dimension is 1.

Part 3 - Hints and Helper

PyTorch applies broadcasting automatically to compatible element-wise operations such as addition, subtraction, multiplication, and division. The reader may use `torch.broadcast_tensors()` to inspect the aligned shapes explicitly.

The reader should compare shapes from the final dimension toward the first. Special attention should be paid to the difference between shapes $(m,)$, $(m, 1)$, and $(1, m)$. Broadcasting conceptually expands singleton dimensions, but it does not normally create repeated copies of the underlying data.

Part 4 - Python code skeleton

```
import torch

def E14(A, b):
    C = A ... b
    return C

def main():
    A = torch...
    b = torch...
    print(E14(...))

if __name__ == "__main__":
    main()
```

1.5 T03 - Higher-Dimension Tensor Laws

Mathematics and Theory

1.5.1 Exercise 00 - 3D Tensor Multiplication Law

Part 1 - Why this matters

Three-dimensional tensors commonly represent batches of feature maps, sequences, or volumetric data. Element-wise multiplication allows two aligned representations to interact without mixing their positions. It is used in gating, masking, attention weighting, and feature modulation, where every value is controlled by the value at the same index in another tensor.

Unlike matrix multiplication, this law preserves the complete tensor shape. It therefore expresses local interaction rather than contraction between axes.

Part 2 - Mathematical form

Let $\mathcal{A}, \mathcal{B} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$.

3D Tensor Multiplication Law defines:

$$\odot : \mathbb{R}^{d_1 \times d_2 \times d_3} \times \mathbb{R}^{d_1 \times d_2 \times d_3} \to \mathbb{R}^{d_1 \times d_2 \times d_3}$$

$$\mathcal{C} = \mathcal{A} \odot \mathcal{B}, \qquad C_{ijk} = A_{ijk} B_{ijk}$$

for $1 \leq i \leq d_1$, $1 \leq j \leq d_2$, and $1 \leq k \leq d_3$.

Part 3 - Hints and Helper

In PyTorch, aligned element-wise multiplication may be written with `torch.mul()` or the `*` operator. Verify that the shapes are equal or broadcasting-compatible, and do not confuse this operation with `torch.matmul()`.

Part 4 - Python code skeleton

```
import torch

def E00(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.5.2 Exercise 01 - 3D Outer Product Law

Part 1 - Why this matters

The outer product constructs higher-order interactions from lower-dimensional representations. Given two vectors, it records every pairwise product in a matrix; extending the idea to three vectors produces a three-dimensional tensor containing every triple interaction. This is

useful for multilinear models, feature interaction analysis, and tensor factorization.

The operation increases dimensionality without summing over any index, thereby preserving every combination of input coordinates.

Part 2 - Mathematical form

Let $\mathbf{a} \in \mathbb{R}^m$, $\mathbf{b} \in \mathbb{R}^n$, and $\mathbf{c} \in \mathbb{R}^p$.
3D Outer Product Law defines:

$$\otimes : \mathbb{R}^m \times \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}^{m \times n \times p}$$

$$\mathcal{T} = \mathbf{a} \otimes \mathbf{b} \otimes \mathbf{c}, \qquad T_{ijk} = a_i b_j c_k$$

No axis is contracted, and the output contains mnp entries.

Part 3 - Hints and Helper

In PyTorch, `torch.einsum()` can express the complete operation directly. It may also be built by reshaping the vectors to singleton-aligned shapes and using broadcasting. Ensure that no index is repeated in the output equation.

Part 4 - Python code skeleton

```
import torch

def E01(a, b, c):
    T = torch...
    return T

def main():
    a = torch...
    b = torch...
    c = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.5.3 Exercise 02 - 3D Einstein Summation Law

Part 1 - Why this matters

Einstein summation provides a compact language for tensor operations. Repeated indices identify axes to multiply and sum, while unrepeated output indices are preserved. A single notation can express dot products, matrix multiplication, batch operations, transposes, reductions, and general contractions.

This makes complex neural-network transformations easier to describe and often allows PyTorch to select an efficient computational path.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{b\times m\times n}$ and $\mathcal{B} \in \mathbb{R}^{b\times n\times p}$.
Using Einstein notation, define:

$$C_{bij} = \sum_{k=1}^{n} A_{bik} B_{bkj}$$

or compactly:

$$C_{bij} = A_{bik} B_{bkj}$$

where the repeated index k is summed and b, i, j remain in the output. Thus $\mathcal{C} \in \mathbb{R}^{b\times m\times p}$.

Part 3 - Hints and Helper

In PyTorch, use `torch.einsum()` with an equation describing input and output indices. Every dimension sharing a label must have a compatible size. Carefully distinguish the batch index from the contracted index.

Part 4 - Python code skeleton

```
import torch

def E02(A, B):
    C = torch.einsum("...", A, B)
    return C

def main():
    A = torch...
    B = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.5.4 Exercise 03 - Batch Matrix Multiplication Law

Part 1 - Why this matters

Neural networks process many samples simultaneously. Batch matrix multiplication applies an independent matrix product to every batch element, allowing sequences, attention heads, and feature maps to be transformed in parallel without explicit Python loops.

The batch axis is preserved while the final two axes follow ordinary matrix multiplication.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{b\times m\times n}$ and $\mathcal{B} \in \mathbb{R}^{b\times n\times p}$.
Batch Matrix Multiplication Law defines:

$$\mathcal{C} = \mathcal{A} \mathbin{@} \mathcal{B} \in \mathbb{R}^{b\times m\times p}$$

$$C_{rij} = \sum_{k=1}^{n} A_{rik} B_{rkj}, \qquad 1 \le r \le b$$

Each batch slice satisfies $\mathbf{C}_r = \mathbf{A}_r\mathbf{B}_r$.

Part 3 - Hints and Helper

In PyTorch, `torch.bmm()` performs batch multiplication for two 3D tensors and does not broadcast the batch dimension. Check that batch sizes and inner matrix dimensions match. `torch.matmul()` supports broader broadcasting behavior.

Part 4 - Python code skeleton

```
import torch

def E03(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.5.5 Exercise 04 - Tensor Contraction Law

Part 1 - Why this matters

Tensor contraction combines tensors by multiplying along selected axes and summing those axes away. It generalizes dot products and matrix multiplication, forming the basis of attention, multilinear layers, tensor networks, and many scientific machine-learning computations.

The choice of contracted axes determines both the meaning and shape of the result.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{a\times b\times c}$ and $\mathcal{B} \in \mathbb{R}^{c\times d\times e}$.

Contracting the third axis of $\mathcal{A}$ with the first axis of $\mathcal{B}$ gives $\mathcal{C} \in \mathbb{R}^{a\times b\times d\times e}$:

$$C_{ij\ell q} = \sum_{k=1}^{c} A_{ijk}B_{k\ell q}$$

The contracted axes must have equal sizes and do not appear in the output.

Part 3 - Hints and Helper

In PyTorch, `torch.tensordot()` accepts the axes to contract. `torch.einsum()` can express the same operation with named index labels. Verify the axis order of the output after contraction.

Part 4 - Python code skeleton

```
import torch

def E04(A, B):
    C = torch.tensordot(A, B, dims=...)
    return C

def main():
    A = torch...
    B = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.5.6 Exercise 05 - Tensor Repetition Law

Part 1 - Why this matters

Tensor repetition duplicates values along selected dimensions. It is useful when constructing repeated patterns, matching explicit batch shapes, or generating structured training data. Unlike broadcasting, repetition creates a larger tensor whose data pattern is physically repeated.

Because it can increase memory use substantially, the repetition counts should be chosen deliberately.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and let $r_1, r_2, r_3 \in \mathbb{N}$.

The repeated tensor has shape:

$$\mathcal{R} \in \mathbb{R}^{(r_1 d_1) \times (r_2 d_2) \times (r_3 d_3)}$$

and entries:

$$R_{ijk} = A_{((i-1) \bmod d_1)+1,((j-1) \bmod d_2)+1,((k-1) \bmod d_3)+1}$$

Part 3 - Hints and Helper

In PyTorch, `Tensor.repeat()` accepts one repetition count per dimension. The number of counts must be at least the number of tensor dimensions. Do not confuse `repeat()` with a broadcasted view.

Part 4 - Python code skeleton

```
import torch

def E05(A, repeats):
    R = A.repeat(...)
    return R

def main():
    A = torch...
```

```
    repeats = (...)
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.5.7 Exercise 06 - Tensor Tiling Law

Part 1 - Why this matters

Tensor tiling repeats a complete tensor pattern across one or more axes. It can construct grids, repeated positional patterns, synthetic feature layouts, and explicitly expanded examples. Tiling resembles repetition conceptually but emphasizes placing copies of the full pattern in adjacent blocks.

Since the output stores all copies, its memory cost grows with the product of the repetition factors.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and $r_1, r_2, r_3 \in \mathbb{N}$.

Define:

$$\mathcal{T} = \text{tile}(\mathcal{A}; r_1, r_2, r_3) \in \mathbb{R}^{r_1 d_1 \times r_2 d_2 \times r_3 d_3}$$

with the periodic indexing rule:

$$T_{ijk} = A_{i \bmod d_1, j \bmod d_2, k \bmod d_3}$$

when zero-based indices are used.

Part 3 - Hints and Helper

In PyTorch, `torch.tile()` takes a tuple of repetition factors. If fewer factors than dimensions are supplied, leading factors of one are added. Check the resulting shape and distinguish tiling from singleton expansion.

Part 4 - Python code skeleton

```
import torch

def E06(A, dims):
    T = torch...
    return T

def main():
    A = torch...
    dims = (...)
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.5.8 Exercise 07 - Tensor Broadcasting Law

Part 1 - Why this matters

Higher-dimensional broadcasting allows tensors such as biases, masks, and normalization statistics to interact with batches, channels, and spatial axes without explicitly copying data. It is fundamental to vectorized neural- network computation and reduces both code complexity and memory use.

Broadcasting aligns shapes from the final dimension toward the first and conceptually expands singleton axes.

Part 2 - Mathematical form

Two dimensions are broadcasting-compatible when they are equal or at least one is 1. Missing leading dimensions are treated as 1.

For $\mathcal{A} \in \mathbb{R}^{b\times m\times n}$ and $\mathbf{v} \in \mathbb{R}^{n}$:

$$\mathcal{C} = \mathcal{A} + \mathbf{v} \in \mathbb{R}^{b\times m\times n}$$

$$C_{ijk} = A_{ijk} + v_k$$

The output size of each aligned axis is the larger compatible size.

Part 3 - Hints and Helper

PyTorch broadcasts compatible tensors automatically in element-wise operations. Use `torch.broadcast_shapes()` or `torch.broadcast_tensors()` to inspect compatibility. Pay attention to the difference between shapes (n), $(1, n)$, and $(n, 1)$.

Part 4 - Python code skeleton

```
import torch

def E07(A, v):
    C = A ... v
    return C

def main():
    A = torch...
    v = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.5.9 Exercise 08 - Tensor Indexing Law

Part 1 - Why this matters

Tensor indexing retrieves specific values or lower-dimensional sections from a higher-dimensional representation. Neural-network code uses indexing to select samples, tokens, channels, coordinates, and labels. Correct indexing preserves the semantic meaning of every axis and avoids

silently selecting the wrong data.

Selecting one integer index removes that axis from the output, while selecting a range can preserve it.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. Selecting indices (i, j, k) produces the scalar:

$$x = A_{ijk} \in \mathbb{R}$$

Selecting only the first index produces a matrix slice:

$$\mathbf{M} = \mathcal{A}_{i,:,:} \in \mathbb{R}^{d_2 \times d_3}$$

Valid mathematical indices satisfy $1 \leq i \leq d_1$, $1 \leq j \leq d_2$, and $1 \leq k \leq d_3$.

Part 3 - Hints and Helper

PyTorch uses zero-based indexing, so the first position has index 0. Negative indices count backward from the end. Verify the output dimension after every integer index and avoid indices outside the valid range.

Part 4 - Python code skeleton

```
import torch

def E08(A, i, j, k):
    value = A[...]
    return value

def main():
    A = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.5.10 Exercise 09 - Tensor Advanced Slicing Law

Part 1 - Why this matters

Advanced slicing extracts structured regions rather than single entries. It allows models and data pipelines to select time windows, spatial patches, channel intervals, reversed sequences, or regularly sampled positions without writing explicit loops.

Each axis may specify a start, stop, and step, making the resulting shape a direct consequence of the chosen index ranges.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$. A slice along each axis is described by index sets I, J, and K:

$$\mathcal{S} = \mathcal{A}_{I,J,K}$$

If $I = (s_1 : s_2 : q)$, it selects indices:

$$s_1,\ s_1 + q,\ s_1 + 2q, \ldots < s_2$$

for a positive step q. The output shape equals the number of selected indices on each preserved axis.

Part 3 - Hints and Helper

In PyTorch, use Python slice notation `start:stop:step`. The stop index is excluded. Use `:` to retain an entire axis and `...` to represent omitted intermediate axes. A negative step is not supported directly in ordinary PyTorch slicing; use `torch.flip()` when reversal is required.

Part 4 - Python code skeleton

```
import torch

def E09(A):
    S = A[..., ..., ...]
    return S

def main():
    A = torch...
    print(E09(A))

if __name__ == "__main__":
    main()
```

1.5.11 Exercise 10 - Tensor Padding Law

Part 1 - Why this matters

Padding adds values around tensor boundaries. Convolutional networks use it to control spatial output size, preserve edge information, align tensors, and make dimensions compatible with later operations. Padding may use constants, reflection, replication, or circular continuation.

The selected padding order and mode determine both the new shape and the values introduced at the boundary.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{c \times h \times w}$ and add $p_l, p_r, p_t, p_b \geq 0$ values to the left, right, top, and bottom.

The padded tensor satisfies:

$$\mathcal{P} \in \mathbb{R}^{c \times (h + p_t + p_b) \times (w + p_l + p_r)}$$

For constant padding value v, original entries are shifted by (p_t, p_l), while all newly created boundary positions equal v.

Part 3 - Hints and Helper

In PyTorch, use `torch.nn.functional.pad()`. Padding values are listed from the final dimension backward; for 2D spatial padding the order is left, right, top, bottom. Check which modes support the input dimensionality.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E10(A, padding, value=0):
    P = F.pad(A, ..., mode="...", value=value)
    return P

def main():
    A = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.5.12 Exercise 11 - Tensor Cropping Law

Part 1 - Why this matters

Cropping removes boundary regions or extracts a focused subregion from a tensor. It is used to align feature maps, remove padded areas, select image patches, and restrict computation to a region of interest. Cropping changes the shape without modifying values that remain inside the selected region.

Mathematically, cropping is a bounded slicing operation.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{c \times h \times w}$. Removing $r_t, r_b, r_l, r_r \geq 0$ positions from its boundaries gives:

$$\mathcal{C} = \mathcal{A}_{:, r_t:h-r_b, r_l:w-r_r}$$

$$\mathcal{C} \in \mathbb{R}^{c \times (h-r_t-r_b) \times (w-r_l-r_r)}$$

The retained dimensions must remain positive.

Part 3 - Hints and Helper

PyTorch implements cropping naturally with slicing. Remember that stop indices are excluded. Validate that the crop sizes do not remove more elements than an axis contains, and preserve the channel axis with `:`.

Part 4 - Python code skeleton

```
import torch

def E11(A, top, bottom, left, right):
    C = A[..., ..., ...]
    return C

def main():
    A = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.5.13 Exercise 12 - Tensor Stacking Law

Part 1 - Why this matters

Stacking combines equally shaped tensors by creating a new axis. It is used to assemble samples into batches, collect model outputs, organize time steps, and construct multi-view representations. Unlike concatenation, stacking does not extend an existing axis; it increases tensor dimensionality.

The position of the new axis determines the semantic organization of the result.

Part 2 - Mathematical form

Let $\mathcal{A}^{(1)}, \ldots, \mathcal{A}^{(q)} in \mathbb{R}^{d_1 \times d_2 \times d_3}$.

Stacking along a new leading axis defines:

$$\mathcal{S} = \text{stack}(\mathcal{A}^{(1)}, \ldots, \mathcal{A}^{(q)}) \in \mathbb{R}^{q \times d_1 \times d_2 \times d_3}$$

$$S_{rijk} = A^{(r)}_{ijk}$$

All input tensors must have identical shapes.

Part 3 - Hints and Helper

In PyTorch, use `torch.stack()` and specify `dim` for the new axis. Compare it with `torch.cat()`, which requires an existing axis and does not add a dimension.

Part 4 - Python code skeleton

```
import torch

def E12(tensors):
    S = torch.stack(tensors, dim=...)
    return S

def main():
    tensors = [torch..., torch...]
    print(E12(...))

if __name__ == "__main__":
    main()
```

1.5.14 Exercise 13 - Tensor Splitting Law

Part 1 - Why this matters

Tensor splitting divides one tensor into ordered sections along a chosen axis. It supports separating batches, partitioning features, distributing work, and recovering components that were previously concatenated. The original values and order are preserved across the output sections.

Split sizes may be equal or explicitly specified, subject to the size of the selected axis.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and split its second axis into sizes $s_1, \ldots, s_q$ satisfying:

$$\sum_{r=1}^{q} s_r = d_2$$

Then:

$$(\mathcal{A}^{(1)}, \ldots, \mathcal{A}^{(q)}) = \text{split}(\mathcal{A}; s_1, \ldots, s_q)$$

where $\mathcal{A}^{(r)} \in \mathbb{R}^{d_1 \times s_r \times d_3}$.

Part 3 - Hints and Helper

In PyTorch, `torch.split()` accepts either one section size or a list of sizes. When one size is supplied, the final section may be smaller. Select the axis with `dim` and verify that explicit sizes sum correctly.

Part 4 - Python code skeleton

```
import torch

def E13(A, sizes, dim):
    parts = torch.split(A, ..., dim=...)
    return parts

def main():
    A = torch...
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.5.15 Exercise 14 - Tensor Chunking Law

Part 1 - Why this matters

Chunking partitions a tensor into a requested number of approximately equal pieces along one axis. It is useful for minibatch processing, parallel work, memory-limited computation, and dividing feature groups without manually calculating every boundary.

When the axis size is not divisible by the requested number, the final chunk may be smaller, and PyTorch may return fewer chunks than requested.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ and request q chunks along an axis of size d. The tensor is partitioned into consecutive sections whose regular chunk size is determined from d and q, while the final returned section may contain fewer entries:

$$(\mathcal{A}^{(1)}, \ldots, \mathcal{A}^{(r)}) = \text{chunk}(\mathcal{A}; q)$$

where $r \leq q$ and concatenating the sections along the same axis reconstructs $\mathcal{A}$.

Part 3 - Hints and Helper

In PyTorch, use `torch.chunk()` with the requested number of chunks and the target `dim`. Do not assume that every chunk has the same size or that the number returned is always exactly the number requested; inspect the resulting tuple and shapes.

Part 4 - Python code skeleton

```
import torch

def E14(A, chunks, dim):
    parts = torch.chunk(A, ..., dim=...)
    return parts

def main():
    A = torch...
    print(E14(...))

if __name__ == "__main__":
    main()
```

1.6 T04 - Tensor shape Tranformation Laws

Mathematics and Theory

1.6.1 Exercise 00 - Tensor Reshape Law

Part 1 - Why this matters

Neural networks frequently reinterpret the same stored values under a new shape. Reshaping converts images into token sequences, separates attention heads, prepares activations for linear layers, and restores structured outputs. The values and their linear order remain unchanged; only their organization across dimensions changes.

Part 2 - Mathematical form

Let $\mathcal{A}$ have shape $(d_1, \ldots, d_k)$ and let the target shape be $(e_1, \ldots, e_r)$. Reshaping is valid when:

$$\prod_{i=1}^{k} d_i = \prod_{j=1}^{r} e_j$$

$$\mathcal{B} = \text{reshape}(\mathcal{A}; e_1, \ldots, e_r)$$

The flattened element order of $\mathcal{B}$ equals that of $\mathcal{A}$.

Part 3 - Hints and Helper

In PyTorch, use `torch.reshape()` or `Tensor.reshape()`. One target dimension may be `-1` so PyTorch infers its size. Reshape may return a view or a copy, so code should not rely on a particular storage result.

Part 4 - Python code skeleton

```
import torch

def E00(A, shape):
    B = torch...
    return B

def main():
    A = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.6.2 Exercise 01 - Tensor View Law

Part 1 - Why this matters

A tensor view presents existing storage with a different shape without copying its data. Views make shape transformations memory-efficient and are common when preparing activations for attention, convolution, and linear algebra. Because the tensors share storage, a permitted in-place change can be visible through both representations.

Part 2 - Mathematical form

For $\mathcal{A}$ with N elements, a view of shape $(e_1, \ldots, e_r)$ requires:

$$N = \prod_{j=1}^{r} e_j$$

$$\mathcal{B} = \text{view}(\mathcal{A}; e_1, \ldots, e_r)$$

and $\mathcal{A}$ and $\mathcal{B}$ reference the same underlying data while using different index-to-storage mappings.

Part 3 - Hints and Helper

Use `Tensor.view()` in PyTorch. The requested shape must be compatible with the tensor's size and strides. A non-contiguous tensor may need `contiguous()` first; alternatively, `reshape()` can handle more cases by copying when necessary.

Part 4 - Python code skeleton

```
import torch

def E01(A, shape):
    B = A.view(...)
    return B

def main():
    A = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.6.3 Exercise 02 - Tensor Permute Law

Part 1 - Why this matters

Permutation reorders every tensor axis. It converts between layouts such as channels-first and channels-last, rearranges batch and sequence axes, and aligns dimensions for later operations. No values are added or removed; only the meaning and position of axes change.

Part 2 - Mathematical form

Let $\mathcal{A}$ have shape $(d_0, \ldots, d_{k-1})$ and let π be a permutation of $(0, \ldots, k-1)$. Then:

$$\mathcal{B} = \text{permute}(\mathcal{A}; \pi)$$

has shape $(d_{\pi(0)}, \ldots, d_{\pi(k-1)})$, with:

$$B_{i_0 \ldots i_{k-1}} = A_{j_0 \ldots j_{k-1}}, \qquad i_r = j_{\pi(r)}$$

Part 3 - Hints and Helper

Use `Tensor.permute()` in PyTorch and provide every dimension exactly once. The result is usually a non-contiguous view; call `contiguous()` only when a later operation requires contiguous storage.

Part 4 - Python code skeleton

```
import torch

def E02(A, dims):
    B = A.permute(...)
    return B
```

```
def main():
    A = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.6.4 Exercise 03 - Tensor Transpose Law

Part 1 - Why this matters

Tensor transpose swaps two selected dimensions while leaving all other axes in place. It aligns matrices inside batches, exchanges spatial axes, and prepares query, key, or feature dimensions for multiplication. Transpose is therefore a special case of axis permutation.

Part 2 - Mathematical form

Let $\mathcal{A}$ have shape $(d_0, \ldots, d_{k-1})$. Swapping dimensions p and q gives:

$$\mathcal{B} = \text{transpose}(\mathcal{A}; p, q)$$

where the output shape equals the input shape with d_p and d_q exchanged. Applying the same transpose twice restores $\mathcal{A}$.

Part 3 - Hints and Helper

Use `torch.transpose()` or `Tensor.transpose()` with two dimension indices. Unlike `permute()`, transpose swaps only two axes. The result generally shares storage and may be non-contiguous.

Part 4 - Python code skeleton

```
import torch

def E03(A, dim0, dim1):
    B = torch.transpose(A, ..., ...)
    return B

def main():
    A = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.6.5 Exercise 04 - Tensor Expand Law

Part 1 - Why this matters

Expansion makes singleton dimensions behave as larger dimensions without copying their values. It efficiently prepares biases, masks, and shared features for operations across batches or spatial positions. Expanded entries can refer to the same storage, making the operation memory-efficient.

Part 2 - Mathematical form

If $\mathcal{A}$ has a dimension of size 1, that dimension may expand to size r. For $\mathcal{A} \in \mathbb{R}^{1\times n}$:

$$\mathcal{B} = \text{expand}(\mathcal{A}; m, n) \in \mathbb{R}^{m\times n}$$

$$B_{ij} = A_{1j}$$

Only singleton dimensions may grow; existing non-singleton sizes must remain unchanged.

Part 3 - Hints and Helper

Use `Tensor.expand()` in PyTorch. A size of `-1` preserves an existing dimension. Expansion creates a view with stride zero along expanded axes, so avoid unsafe in-place writes to the expanded result.

Part 4 - Python code skeleton

```
import torch

def E04(A, sizes):
    B = A.expand(...)
    return B

def main():
    A = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.6.6 Exercise 05 - Tensor Repeat Law

Part 1 - Why this matters

Repeat creates explicit copies of a tensor pattern along chosen dimensions. It is useful when independent stored copies are required, when constructing grids, or when producing repeated training examples. Unlike expand, repeat allocates a larger tensor and can consume substantially more memory.

Part 2 - Mathematical form

For $\mathcal{A}$ with shape $(d_1, \ldots, d_k)$ and repetition factors $(r_1, \ldots, r_k)$:

$$\mathcal{B} = \text{repeat}(\mathcal{A}; r_1, \ldots, r_k)$$

$$\text{shape}(\mathcal{B}) = (r_1 d_1, \ldots, r_k d_k)$$

The values follow a periodic pattern along every repeated axis.

Part 3 - Hints and Helper

Use `Tensor.repeat()` in PyTorch with one factor per dimension. Repeat copies data, whereas `expand()` creates a broadcast-like view. Verify the memory and shape consequences before repeating large tensors.

Part 4 - Python code skeleton

```
import torch

def E05(A, repeats):
    B = A.repeat(...)
    return B

def main():
    A = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.6.7 Exercise 06 - Tensor Flip Law

Part 1 - Why this matters

Flipping reverses the order of values along selected dimensions. It supports image augmentation, reversed sequences, symmetric processing, and orientation changes while preserving tensor shape. Multiple axes may be reversed in one operation.

Part 2 - Mathematical form

Let $\mathcal{A}$ have shape $(d_0, \ldots, d_{k-1})$. Flipping axis q gives:

$$\mathcal{B} = \text{flip}(\mathcal{A}; q)$$

$$B_{i_0 \ldots i_q \ldots i_{k-1}} = A_{i_0 \ldots (d_q - 1 - i_q) \ldots i_{k-1}}$$

using zero-based indices. The output shape is unchanged.

Part 3 - Hints and Helper

Use `torch.flip()` with a tuple or list of dimensions. Dimension order does not change; only the values along the selected axes are reversed. Confirm which axis represents width, height, sequence, or batch before flipping.

Part 4 - Python code skeleton

```
import torch

def E06(A, dims):
    B = torch.flip(A, dims=...)
    return B

def main():
    A = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.6.8 Exercise 07 - Tensor Rotate Law

Part 1 - Why this matters

Tensor rotation turns data by multiples of 90° within a plane defined by two dimensions. It is widely used for image and feature-map augmentation, orientation normalization, and testing rotational behavior. Dimensions outside the selected plane remain unchanged.

Part 2 - Mathematical form

Let $\mathcal{A}$ contain a plane along dimensions p and q. Define:

$$\mathcal{B} = \mathrm{rot90}(\mathcal{A}; k, p, q)$$

where $k \in \mathbb{Z}$ counts counterclockwise quarter-turns. Rotations satisfy:

$$\mathrm{rot90}(\mathcal{A}; k+4, p, q) = \mathrm{rot90}(\mathcal{A}; k, p, q)$$

For odd k, the sizes of the selected plane dimensions are exchanged.

Part 3 - Hints and Helper

Use `torch.rot90()` with `k` and a pair of dimensions. Positive `k` rotates from the first selected axis toward the second. Verify both orientation and output shape, especially for non-square planes.

Part 4 - Python code skeleton

```
import torch

def E07(A, k, dims):
    B = torch.rot90(A, k=..., dims=...)
    return B

def main():
    A = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.6.9 Exercise 08 - Tensor Squeeze Law

Part 1 - Why this matters

Squeeze removes dimensions whose size is one. Such singleton axes commonly appear after batching, indexing, reductions with preserved dimensions, or model outputs. Removing them can align shapes with downstream functions while leaving all stored values unchanged.

Part 2 - Mathematical form

If $\mathcal{A}$ has shape $(d_1, 1, d_3)$, squeezing the second axis gives:

$$\mathcal{B} = \text{squeeze}(\mathcal{A}; 2) \in \mathbb{R}^{d_1 \times d_3}$$

Only axes of size 1 may be removed. The total number and linear order of elements remain unchanged.

Part 3 - Hints and Helper

Use `torch.squeeze()`. Supplying `dim` removes only the intended singleton axis; omitting it removes every singleton dimension. Avoid accidentally removing a batch dimension when its current size happens to be one.

Part 4 - Python code skeleton

```
import torch

def E08(A, dim):
    B = torch.squeeze(A, dim=...)
    return B

def main():
    A = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.6.10 Exercise 09 - Tensor Unsqueeze Law

Part 1 - Why this matters

Unsqueeze inserts a dimension of size one. It prepares vectors for broadcasting, adds batch or channel axes, and aligns tensors with functions that expect a specific number of dimensions. The operation changes shape but not the number or order of stored values.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^n$, inserting a leading axis gives:

$$\mathbf{X} = \text{unsqueeze}(\mathbf{x}; 0) \in \mathbb{R}^{1 \times n}$$

Inserting a trailing axis gives a different shape:

$$\text{unsqueeze}(\mathbf{x}; 1) \in \mathbb{R}^{n \times 1}$$

Part 3 - Hints and Helper

Use `torch.unsqueeze()` or `Tensor.unsqueeze()`. The new axis may be inserted at any valid position from the beginning through the end. Choose its location according to the intended broadcasting semantics.

Part 4 - Python code skeleton

```
import torch

def E09(A, dim):
    B = torch.unsqueeze(A, dim=...)
    return B

def main():
    A = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.6.11 Exercise 10 - Tensor Flatten Law

Part 1 - Why this matters

Flatten merges a consecutive range of dimensions into one. Convolutional features are often flattened before a linear layer, and groups of structural axes may be combined for storage or processing. Dimensions outside the selected range remain unchanged.

Part 2 - Mathematical form

Let $\mathcal{A}$ have shape $(d_0, \ldots, d_{k-1})$. Flattening dimensions s through t gives an output dimension of size:

$$D = \prod_{i=s}^{t} d_i$$

and shape:

$$(d_0, \ldots, d_{s-1}, D, d_{t+1}, \ldots, d_{k-1})$$

The total number and linear order of elements are preserved.

Part 3 - Hints and Helper

Use `torch.flatten()` with `start_dim` and `end_dim`. The default flattens every dimension. To preserve the batch axis, a common choice is `start_dim=1`.

Part 4 - Python code skeleton

```
import torch

def E10(A, start_dim, end_dim):
    B = torch.flatten(A, start_dim=..., end_dim=...)
    return B

def main():
    A = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.6.12 Exercise 11 - Tensor Unflatten Law

Part 1 - Why this matters

Unflatten decomposes one dimension into several named or positional dimensions. It restores spatial structure, separates attention heads, and reconstructs multi-axis representations after a previous flattening operation. The product of the new sizes must equal the size of the original dimension.

Part 2 - Mathematical form

Let dimension q of $\mathcal{A}$ have size D, and choose $(e_1, \ldots, e_r)$ such that:

$$D = \prod_{j=1}^{r} e_j$$

Then:

$$\mathcal{B} = \text{unflatten}(\mathcal{A}; q, e_1, \ldots, e_r)$$

replaces dimension D by $(e_1, \ldots, e_r)$ while preserving all values and their linear order.

Part 3 - Hints and Helper

Use `torch.unflatten()` or `Tensor.unflatten()`. Specify the dimension to split and the new sizes. One size may be inferred with `-1` when the remaining sizes determine it uniquely.

Part 4 - Python code skeleton

```
import torch

def E11(A, dim, sizes):
    B = torch.unflatten(A, dim=..., sizes=...)
    return B

def main():
    A = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.7 T05 - Differential Calculus Laws

Mathematics and Theory

1.7.1 Exercise 00 - Gradient Law

Part 1 - Why this matters

Learning adjusts parameters in the direction that changes a scalar objective. The gradient collects every first-order partial derivative, identifying the direction of steepest increase; its negative guides gradient descent.

Part 2 - Mathematical form

For differentiable $f : \mathbb{R}^n \to \mathbb{R}$:

$$\nabla f(\mathbf{x}) = \begin{bmatrix} \frac{\partial f}{\partial x_1} & \cdots & \frac{\partial f}{\partial x_n} \end{bmatrix}^{\mathsf{T}} \in \mathbb{R}^n$$

For tensor input $\mathcal{X}$, $\nabla_{\mathcal{X}} f$ has the same shape as $\mathcal{X}$.

Part 3 - Hints and Helper

In PyTorch, set `requires_grad=True`, build a scalar output, and use `torch.autograd.grad()` or `backward()`. Gradients accumulate in `.grad`, so clear them between optimization steps.

Part 4 - Python code skeleton

```
import torch

def E00(x):
    y = ...
    gradient = torch.autograd.grad(y, x)[0]
    return gradient

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E00(x))

if __name__ == "__main__":
    main()
```

1.7.2 Exercise 01 - Jacobian Matrix Law

Part 1 - Why this matters

The Jacobian records how every component of a vector output responds to every input component. It describes local sensitivity, coordinate transformations, and the derivative propagated through vector-valued neural-network layers.

Part 2 - Mathematical form

For $\mathbf{f} : \mathbb{R}^n \to \mathbb{R}^m$:

$$\mathbf{J}_\mathbf{f}(\mathbf{x}) = \left[\frac{\partial f_i}{\partial x_j}\right] \in \mathbb{R}^{m \times n}$$

Its ith row is the transpose of ∇f_i.

Part 3 - Hints and Helper

Use `torch.autograd.functional.jacobian()` or `torch.func.jacrev()` in PyTorch. Check whether the function returns one tensor or a tuple, because that affects the Jacobian structure.

Part 4 - Python code skeleton

```
import torch

def E01(function, x):
    J = torch.autograd.functional.jacobian(...)
    return J

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.7.3 Exercise 02 - Hessian Matrix Law

Part 1 - Why this matters

The Hessian measures how a gradient changes, revealing local curvature of a scalar objective. It supports second-order optimization, stability analysis, and identifying flat or sharply curved directions in loss landscapes.

Part 2 - Mathematical form

For twice-differentiable $f : \mathbb{R}^n \to \mathbb{R}$:

$$\mathbf{H}_f(\mathbf{x}) = \left[\frac{\partial^2 f}{\partial x_i \partial x_j}\right] \in \mathbb{R}^{n \times n}$$

If mixed partials are continuous, $\mathbf{H}_f = \mathbf{H}_f^\mathsf{T}$.

Part 3 - Hints and Helper

Use `torch.autograd.functional.hessian()` or `torch.func.hessian()`. The target function must return a scalar. Explicit Hessians can be expensive for large parameter vectors.

Part 4 - Python code skeleton

```
import torch

def E02(function, x):
    H = torch.autograd.functional.hessian(...)
    return H

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.7.4 Exercise 03 - Divergence Law

Part 1 - Why this matters

Divergence measures the local net expansion of a vector field. It appears in continuous normalizing flows, physics-informed neural networks, conservation laws, and models that learn dynamical systems.

Part 2 - Mathematical form

For differentiable $\mathbf{F} : \mathbb{R}^n \to \mathbb{R}^n$:

$$\nabla \cdot \mathbf{F} = \sum_{i=1}^{n} \frac{\partial F_i}{\partial x_i} = \operatorname{tr}(\mathbf{J}_{\mathbf{F}}) \in \mathbb{R}$$

Positive values indicate local source-like expansion and negative values local sink-like contraction.

Part 3 - Hints and Helper

Compute the Jacobian with PyTorch autograd and sum its diagonal. Preserve the computational graph with `create_graph=True` if later derivatives are required.

Part 4 - Python code skeleton

```
import torch

def E03(function, x):
    J = torch.autograd.functional.jacobian(...)
    divergence = torch...
    return divergence

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.7.5 Exercise 04 - Curl Law

Part 1 - Why this matters

Curl measures local rotational tendency in a three-dimensional vector field. It is important in learned fluid dynamics, electromagnetic models, and physics-informed systems where rotational structure must be represented.

Part 2 - Mathematical form

For $\mathbf{F} = (F_1, F_2, F_3) : \mathbb{R}^3 \to \mathbb{R}^3$:

$$\nabla \times \mathbf{F} = \begin{bmatrix} \frac{\partial F_3}{\partial x_2} - \frac{\partial F_2}{\partial x_3} \\ \frac{\partial F_1}{\partial x_3} - \frac{\partial F_3}{\partial x_1} \\ \frac{\partial F_2}{\partial x_1} - \frac{\partial F_1}{\partial x_2} \end{bmatrix}$$

Part 3 - Hints and Helper

PyTorch has no general high-level curl function. Construct the Jacobian with autograd, then combine its off-diagonal entries with the correct signs and order.

Part 4 - Python code skeleton

```
import torch

def E04(function, x):
    J = torch.autograd.functional.jacobian(...)
    curl = torch.stack((..., ..., ...))
    return curl

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.7.6 Exercise 05 - Laplacian Law

Part 1 - Why this matters

The Laplacian summarizes second-order spatial variation. It appears in diffusion, heat equations, smoothing, regularization, and physics-informed neural networks that enforce partial differential equations.

Part 2 - Mathematical form

For twice-differentiable $f : \mathbb{R}^n \to \mathbb{R}$:

$$\Delta f = \nabla^2 f = \sum_{i=1}^{n} \frac{\partial^2 f}{\partial x_i^2} = \operatorname{tr}(\mathbf{H}_f)$$

Part 3 - Hints and Helper

Compute the Hessian using PyTorch autograd and take its trace. For large problems, forming the full Hessian may be expensive; this exercise focuses on the mathematical construction.

Part 4 - Python code skeleton

```
import torch

def E05(function, x):
    H = torch.autograd.functional.hessian(...)
    laplacian = torch...
    return laplacian

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.7.7 Exercise 06 - Partial Derivative Law

Part 1 - Why this matters

A partial derivative isolates how a multivariable function responds to one input while the others are held fixed. Neural-network gradients are assembled from these local sensitivities.

Part 2 - Mathematical form

For $f(x_1, \ldots, x_n)$, the partial derivative with respect to x_i is:

$$\frac{\partial f}{\partial x_i}(\mathbf{x}) = \lim_{h \to 0} \frac{f(\mathbf{x} + h\mathbf{e}_i) - f(\mathbf{x})}{h}$$

when the limit exists.

Part 3 - Hints and Helper

Use PyTorch autograd to compute the full gradient and select the component for the desired variable. Ensure the output is scalar or provide an appropriate gradient output.

Part 4 - Python code skeleton

```
import torch

def E06(function, x, index):
    y = function(x)
    gradient = torch.autograd.grad(...)[0]
    return gradient[...]
```

```
def main():
    x = torch.tensor(..., requires_grad=True)
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.7.8 Exercise 07 - Chain Rule Law

Part 1 - Why this matters

The chain rule is the foundation of backpropagation. It propagates derivatives through compositions of layers, allowing a final loss to influence every earlier parameter.

Part 2 - Mathematical form

For $y = f(u)$ and $u = g(x)$:

$$\frac{dy}{dx} = \frac{df}{du}\frac{dg}{dx}$$

For vector functions $\mathbf{f} \circ \mathbf{g}$:

$$\mathbf{J}_{\mathbf{f}\circ\mathbf{g}}(\mathbf{x}) = \mathbf{J}_{\mathbf{f}}(\mathbf{g}(\mathbf{x}))\mathbf{J}_{\mathbf{g}}(\mathbf{x})$$

Part 3 - Hints and Helper

PyTorch autograd applies the chain rule automatically. Build the composed expression from tracked tensors and differentiate the final scalar output with respect to the original input.

Part 4 - Python code skeleton

```
import torch

def E07(x):
    u = ...
    y = ...
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E07(x))

if __name__ == "__main__":
    main()
```

1.7.9 Exercise 08 - Product Rule Law

Part 1 - Why this matters

The product rule differentiates multiplicative interactions, including gates, attention weights, regularizers, and products between learned functions. Both factors contribute to the final

derivative.

Part 2 - Mathematical form

For differentiable scalar functions $u(x)$ and $v(x)$:

$$\frac{d}{dx}[u(x)v(x)] = u'(x)v(x) + u(x)v'(x)$$

For scalar fields, $\nabla(uv) = v\nabla u + u\nabla v$.

Part 3 - Hints and Helper

Construct both differentiable factors in PyTorch, multiply them, and use autograd. To verify the law, compute the two right-hand contributions separately without detaching either factor.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    u = ...
    v = ...
    y = u * v
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E08(x))

if __name__ == "__main__":
    main()
```

1.7.10 Exercise 09 - Quotient Rule Law

Part 1 - Why this matters

The quotient rule differentiates ratios, which occur in normalization, probability formulas, similarity measures, and scale-invariant objectives. The denominator must remain nonzero.

Part 2 - Mathematical form

For differentiable $u(x)$ and $v(x) \neq 0$:

$$\frac{d}{dx}\left[\frac{u(x)}{v(x)}\right] = \frac{u'(x)v(x) - u(x)v'(x)}{v(x)^2}$$

Part 3 - Hints and Helper

Use ordinary differentiable division in PyTorch and autograd. Choose test values away from a zero denominator to avoid undefined derivatives and numerical instability.

Part 4 - Python code skeleton

```
import torch

def E09(x):
    u = ...
    v = ...
    y = u / v
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E09(x))

if __name__ == "__main__":
    main()
```

1.7.11 Exercise 10 - Power Rule Law

Part 1 - Why this matters

The power rule differentiates polynomial terms used in losses, regularization, and nonlinear transformations. It is one of the basic laws from which more complex derivatives are assembled.

Part 2 - Mathematical form

For constant p and values where x^p is differentiable:

$$\frac{d}{dx}x^p = px^{p-1}$$

For a differentiable inner function $u(x)$:

$$\frac{d}{dx}u(x)^p = pu(x)^{p-1}u'(x)$$

Part 3 - Hints and Helper

Use `torch.pow()` or `**` and differentiate with autograd. Fractional or negative powers impose domain restrictions and may be undefined at some inputs.

Part 4 - Python code skeleton

```
import torch

def E10(x, p):
    y = torch...
```

```
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.7.12 Exercise 11 - Exponential Derivative Law

Part 1 - Why this matters

Exponential functions appear in probabilities, softmax, energy-based models, and continuous growth or decay. Their derivative preserves the exponential form, making them central to differentiable modeling.

Part 2 - Mathematical form

$$\frac{d}{dx}e^x = e^x$$

More generally, for differentiable $u(x)$:

$$\frac{d}{dx}e^{u(x)} = e^{u(x)}u'(x)$$

Part 3 - Hints and Helper

Use `torch.exp()` and autograd. Large positive inputs may overflow and large negative inputs may underflow, so stable formulations are important in probability computations.

Part 4 - Python code skeleton

```
import torch

def E11(x):
    y = torch...
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E11(x))

if __name__ == "__main__":
    main()
```

1.7.13 Exercise 12 - Logarithmic Derivative Law

Part 1 - Why this matters

Logarithms turn products into sums and appear in likelihoods, cross-entropy, information theory, and numerically stable probability calculations. Their derivative grows near zero, revealing an important stability boundary.

Part 2 - Mathematical form

For $x > 0$:

$$\frac{d}{dx} \ln x = \frac{1}{x}$$

For differentiable $u(x) > 0$:

$$\frac{d}{dx} \ln u(x) = \frac{u'(x)}{u(x)}$$

Part 3 - Hints and Helper

Use `torch.log()` and autograd. Inputs must be positive for real-valued logarithms. Values close to zero can produce very large gradients.

Part 4 - Python code skeleton

```
import torch

def E12(x):
    y = torch...
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E12(x))

if __name__ == "__main__":
    main()
```

1.7.14 Exercise 13 - Sigmoid Derivative Law

Part 1 - Why this matters

Sigmoid maps real values into $(0, 1)$ and is used for binary probabilities and gates. Its derivative can be written using its own output, which makes local gradient computation compact.

Part 2 - Mathematical form

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

$$\sigma'(x) = \sigma(x)[1 - \sigma(x)]$$

The derivative is positive and at most 1/4; it approaches zero for large positive or negative inputs.

Part 3 - Hints and Helper

Use `torch.sigmoid()` and autograd. Compare the automatic derivative with the analytical expression computed from the already obtained sigmoid output.

Part 4 - Python code skeleton

```
import torch

def E13(x):
    y = torch...
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E13(x))

if __name__ == "__main__":
    main()
```

1.7.15 Exercise 14 - Tanh Derivative Law

Part 1 - Why this matters

Hyperbolic tangent maps values into $(-1, 1)$ and provides zero-centered activations in recurrent and feed-forward networks. Its derivative also depends directly on its output.

Part 2 - Mathematical form

$$\tanh(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}}$$

$$\frac{d}{dx}\tanh(x) = 1 - \tanh^2(x)$$

The derivative is largest at zero and approaches zero as $|x|$ grows.

Part 3 - Hints and Helper

Use `torch.tanh()` and autograd. Compare the result with $1 - y^2$, where y is the tanh output.

Part 4 - Python code skeleton

```
import torch

def E14(x):
    y = torch...
    derivative = torch.autograd.grad(...)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E14(x))

if __name__ == "__main__":
    main()
```

1.7.16 Exercise 15 - ReLU Derivative Law

Part 1 - Why this matters

ReLU passes positive activations and suppresses negative ones. Its simple piecewise derivative supports efficient training, though negative inputs receive zero gradient.

Part 2 - Mathematical form

$$\mathrm{ReLU}(x) = \max(0, x)$$

$$\mathrm{ReLU}'(x) = \begin{cases} 0, & x < 0, \\ 1, & x > 0. \end{cases}$$

The classical derivative is undefined at $x = 0$; PyTorch uses the subgradient value 0 there.

Part 3 - Hints and Helper

Use `torch.relu()` or `torch.nn.functional.relu()` and autograd. Include negative, zero, and positive test values to observe the piecewise rule.

Part 4 - Python code skeleton

```
import torch

def E15(x):
    y = torch...
    derivative = torch.autograd.grad(y.sum(), x)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E15(x))

if __name__ == "__main__":
    main()
```

1.7.17 Exercise 16 - LeakyReLU Derivative Law

Part 1 - Why this matters

LeakyReLU retains a small nonzero slope for negative inputs, allowing gradients to continue flowing where ordinary ReLU would block them. The negative slope is a chosen constant.

Part 2 - Mathematical form

For $\alpha > 0$:

$$\mathrm{LReLU}_\alpha(x) = \begin{cases} x, & x \geq 0, \\ \alpha x, & x < 0, \end{cases}$$

$$\mathrm{LReLU}'_\alpha(x) = \begin{cases} 1, & x > 0, \\ \alpha, & x < 0. \end{cases}$$

At $x = 0$ the classical derivative is undefined when $\alpha \neq 1$; PyTorch uses the negative-slope branch value α.

Part 3 - Hints and Helper

Use `torch.nn.functional.leaky_relu()` with an explicit `negative_slope`. Sum vector outputs before calling autograd.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E16(x, alpha):
    y = F.leaky_relu(x, negative_slope=...)
    derivative = torch.autograd.grad(y.sum(), x)[0]
    return derivative

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E16(...))

if __name__ == "__main__":
    main()
```

1.7.18 Exercise 17 - Softmax Derivative Law

Part 1 - Why this matters

Softmax converts logits into a normalized probability vector. Because every output depends on every input, its derivative is a full Jacobian rather than an element-wise scalar derivative. This coupling is central to classification and attention.

Part 2 - Mathematical form

For $\mathbf{z} \in \mathbb{R}^n$:

$$s_i = \frac{e^{z_i}}{\sum_{k=1}^{n} e^{z_k}}$$

$$\frac{\partial s_i}{\partial z_j} = s_i(\delta_{ij} - s_j)$$

Equivalently:

$$\mathbf{J} = \operatorname{diag}(\mathbf{s}) - \mathbf{s}\mathbf{s}^{\mathsf{T}}$$

Part 3 - Hints and Helper

Use `torch.softmax()` with an explicit dimension, then compute the Jacobian with `torch.autograd.fu`
Do not treat the derivative as only $s_i(1 - s_i)$; off-diagonal terms are nonzero.

Part 4 - Python code skeleton

```
import torch

def E17(z):
    function = lambda value: torch.softmax(value, dim=...)
    J = torch.autograd.functional.jacobian(...)
    return J

def main():
    z = torch.tensor(..., requires_grad=True)
    print(E17(z))

if __name__ == "__main__":
    main()
```

1.7.19 Exercise 18 - Loss Gradient Law

Part 1 - Why this matters

The loss gradient connects prediction error to parameter updates. Backpropagation uses the chain rule to compute how a scalar loss changes with every model parameter, enabling optimization across the complete network.

Part 2 - Mathematical form

Let predictions be $\hat{\mathbf{y}} = f(\mathbf{x}; \boldsymbol{\theta})$ and let $L(\hat{\mathbf{y}}, \mathbf{y}) \in \mathbb{R}$. Then:

$$\nabla_{\boldsymbol{\theta}} L = \mathbf{J}_{f,\boldsymbol{\theta}}^{\mathsf{T}} \nabla_{\hat{\mathbf{y}}} L$$

A gradient-descent update is:

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \nabla_{\boldsymbol{\theta}} L$$

Part 3 - Hints and Helper

Build predictions and a scalar loss from parameters requiring gradients. Call `loss.backward()` or `torch.autograd.grad()`. Do not detach the prediction, and clear accumulated parameter gradients before a new step.

Part 4 - Python code skeleton

```
import torch

def E18(parameters, x, target):
    prediction = ...
    loss = ...
    gradients = torch.autograd.grad(loss, parameters)
    return loss, gradients

def main():
    parameters = (...)
    x = torch...
    target = torch...
    print(E18(...))

if __name__ == "__main__":
    main()
```

1.8 T06 - Optimization Laws

Mathematics and Theory

1.8.1 Exercise 00 - Gradient Descent Law

Part 1 - Why this matters

Gradient descent is the basic mechanism that turns a loss gradient into a parameter update. It repeatedly moves parameters opposite the direction of steepest local increase, seeking values that reduce the objective.

Part 2 - Mathematical form

For loss $L(\boldsymbol{\theta})$ and learning rate $\eta > 0$:

$$\mathbf{g}_t = \nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_t)$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \mathbf{g}_t$$

The learning rate controls the update magnitude.

Part 3 - Hints and Helper

In PyTorch, compute a scalar loss, call `backward()`, and update parameters inside `torch.no_grad()`. Clear gradients before the next iteration. `torch.optim.SGD()` with zero momentum implements this rule.

Part 4 - Python code skeleton

```
import torch

def E00(parameter, loss, learning_rate):
```

```
    loss.backward()
    with torch.no_grad():
        parameter -= ...
    parameter.grad = None
    return parameter

def main():
    parameter = torch.tensor(..., requires_grad=True)
    loss = ...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.8.2 Exercise 01 - Stochastic Gradient Descent Law

Part 1 - Why this matters

Stochastic gradient descent estimates the full-data gradient from one example or a mini-batch. Its updates are cheaper and noisier than full-batch gradient descent, enabling training on large datasets and often helping exploration of the loss landscape.

Part 2 - Mathematical form

For mini-batch $\mathcal{B}_t$ of size B:

$$\widehat{\mathbf{g}}_t = \frac{1}{B} \sum_{i \in \mathcal{B}_t} \nabla_{\boldsymbol{\theta}} \ell_i(\boldsymbol{\theta}_t)$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \widehat{\mathbf{g}}_t$$

Under uniform sampling, this is an unbiased full-gradient estimate.

Part 3 - Hints and Helper

Use `torch.optim.SGD()` and compute loss on one mini-batch per step. Call `zero_grad()`, `backward()`, then `step()` in that order.

Part 4 - Python code skeleton

```
import torch

def E01(model, batch_x, batch_y, optimizer, loss_function):
    optimizer.zero_grad()
    prediction = model(...)
    loss = loss_function(...)
    loss.backward()
    optimizer.step()
    return loss

def main():
    model = ...
```

```
    optimizer = torch.optim.SGD(...)
    print(E01(...))

if __name__ == "__main__":
    main()
```

1.8.3 Exercise 02 - Momentum Law

Part 1 - Why this matters

Momentum accumulates a velocity from previous gradients. It accelerates motion along consistent directions and reduces oscillation across steep directions, often converging faster than plain SGD.

Part 2 - Mathematical form

With momentum coefficient $0 \leq \mu < 1$ and $\mathbf{v}_0 = \mathbf{0}$:

$$\mathbf{g}_t = \nabla L(\boldsymbol{\theta}_t)$$

$$\mathbf{v}_t = \mu \mathbf{v}_{t-1} + \mathbf{g}_t$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \mathbf{v}_t$$

Part 3 - Hints and Helper

Use `torch.optim.SGD()` with a positive `momentum`. The velocity is persistent optimizer state and must not be reinitialized at every step.

Part 4 - Python code skeleton

```
import torch

def E02(parameter, gradient, velocity, learning_rate, momentum):
    velocity = ...
    parameter = ...
    return parameter, velocity

def main():
    parameter = torch...
    gradient = torch...
    velocity = torch.zeros_like(parameter)
    print(E02(...))

if __name__ == "__main__":
    main()
```

1.8.4 Exercise 03 - RMSProp Law

Part 1 - Why this matters

RMSProp adapts each parameter's step size using an exponential moving average of squared gradients. Coordinates with consistently large gradients receive smaller normalized updates, improving behavior on objectives with uneven scales.

Part 2 - Mathematical form

With decay $0 \leq \alpha < 1$, $\mathbf{s}_0 = \mathbf{0}$, and $\varepsilon > 0$:

$$\mathbf{s}_t = \alpha \mathbf{s}_{t-1} + (1 - \alpha)(\mathbf{g}_t \odot \mathbf{g}_t)$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \frac{\mathbf{g}_t}{\sqrt{\mathbf{s}_t} + \varepsilon}$$

All vector operations are element-wise.

Part 3 - Hints and Helper

Use `torch.optim.RMSprop()`. Preserve the running squared-gradient state between updates, and keep ε to prevent division by zero.

Part 4 - Python code skeleton

```
import torch

def E03(parameter, gradient, square_avg, lr, alpha, eps):
    square_avg = ...
    parameter = ...
    return parameter, square_avg

def main():
    parameter = torch...
    gradient = torch...
    square_avg = torch.zeros_like(parameter)
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.8.5 Exercise 04 - Adam Optimizer Law

Part 1 - Why this matters

Adam combines momentum-like first moments with RMSProp-like second moments. It adapts updates per parameter and uses bias correction to compensate for moment estimates initialized at zero.

Part 2 - Mathematical form

For step $t \geq 1$:

$$\mathbf{m}_t = \beta_1 \mathbf{m}_{t-1} + (1 - \beta_1)\mathbf{g}_t$$

$$\mathbf{v}_t = \beta_2 \mathbf{v}_{t-1} + (1 - \beta_2)\mathbf{g}_t^2$$

$$\widehat{\mathbf{m}}_t = \frac{\mathbf{m}_t}{1 - \beta_1^t}, \qquad \widehat{\mathbf{v}}_t = \frac{\mathbf{v}_t}{1 - \beta_2^t}$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \frac{\widehat{\mathbf{m}}_t}{\sqrt{\widehat{\mathbf{v}}_t} + \varepsilon}$$

Part 3 - Hints and Helper

Use `torch.optim.Adam()`. Preserve both moment tensors and the step counter. Squaring, division, and square roots are element-wise.

Part 4 - Python code skeleton

```
import torch

def E04(parameter, gradient, m, v, step, lr, betas, eps):
    m = ...
    v = ...
    m_hat = ...
    v_hat = ...
    parameter = ...
    return parameter, m, v

def main():
    parameter = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.8.6 Exercise 05 - AdamW Law

Part 1 - Why this matters

AdamW separates weight decay from Adam's adaptive gradient normalization. This decoupling makes shrinkage act directly on parameters instead of being rescaled as part of the adaptive gradient, yielding clearer regularization behavior.

Part 2 - Mathematical form

After computing Adam's bias-corrected moments, AdamW applies:

$$\boldsymbol{\theta}_{t+1} = (1 - \eta\lambda)\boldsymbol{\theta}_t - \eta \frac{\widehat{\mathbf{m}}_t}{\sqrt{\widehat{\mathbf{v}}_t} + \varepsilon}$$

where $\lambda \geq 0$ is the decoupled weight-decay coefficient.

Part 3 - Hints and Helper

Use `torch.optim.AdamW()`. Do not also add the same L_2 penalty to the loss unless intentionally applying two regularization effects. Bias and normalization parameters are often placed in groups with no decay.

Part 4 - Python code skeleton

```
import torch

def E05(model, loss):
    optimizer = torch.optim.AdamW(
        model.parameters(), lr=..., weight_decay=...
    )
    optimizer.zero_grad()
    loss.backward()
    optimizer.step()
    return model

def main():
    model = ...
    loss = ...
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.8.7 Exercise 06 - Nesterov Momentum Law

Part 1 - Why this matters

Nesterov momentum evaluates the gradient at a look-ahead position suggested by the existing velocity. This anticipatory correction can reduce overshooting and respond sooner when the objective changes direction.

Part 2 - Mathematical form

With $\mathbf{v}_0 = \mathbf{0}$:

$$\widetilde{\boldsymbol{\theta}}_t = \boldsymbol{\theta}_t - \eta\mu\mathbf{v}_{t-1}$$

$$\mathbf{v}_t = \mu\mathbf{v}_{t-1} + \nabla L(\widetilde{\boldsymbol{\theta}}_t)$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta\mathbf{v}_t$$

Part 3 - Hints and Helper

Use `torch.optim.SGD()` with `momentum` and `nesterov=True`. PyTorch uses an algebraically related implementation; do not reset its momentum buffer between steps.

Part 4 - Python code skeleton

```
import torch

def E06(model, learning_rate, momentum):
    optimizer = torch.optim.SGD(
        model.parameters(), lr=...,
        momentum=..., nesterov=True
    )
    return optimizer

def main():
    model = ...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.8.8 Exercise 07 - Learning Rate Decay Law

Part 1 - Why this matters

Learning-rate decay uses larger exploratory steps early in training and smaller refinement steps later. A schedule can improve stability near a solution and reduce persistent oscillation.

Part 2 - Mathematical form

An exponential schedule is:

$$\eta_t = \eta_0 \gamma^t, \qquad 0 < \gamma < 1$$

A step schedule updated every s epochs is:

$$\eta_t = \eta_0 \gamma^{\lfloor t/s \rfloor}$$

The optimizer update then uses η_t in place of a constant learning rate.

Part 3 - Hints and Helper

PyTorch provides schedulers such as `ExponentialLR` and `StepLR`. Call scheduler steps at the intended frequency and monitor the current optimizer learning rate to avoid accidental extra decay.

Part 4 - Python code skeleton

```
import torch

def E07(optimizer, gamma):
    scheduler = torch.optim.lr_scheduler.ExponentialLR(
        optimizer, gamma=...
    )
    return scheduler
```

```
def main():
    optimizer = ...
    scheduler = E07(...)
    scheduler.step()
    print(optimizer.param_groups[0]["lr"])

if __name__ == "__main__":
    main()
```

1.8.9 Exercise 08 - Weight Decay Law

Part 1 - Why this matters

Weight decay discourages large parameter magnitudes and can improve generalization. In its classical coupled form, it is equivalent to adding an L_2 penalty to the objective for ordinary gradient descent.

Part 2 - Mathematical form

Define the regularized loss:

$$L_{\text{reg}}(\boldsymbol{\theta}) = L(\boldsymbol{\theta}) + \frac{\lambda}{2}\|\boldsymbol{\theta}\|_2^2$$

Then:

$$\nabla L_{\text{reg}} = \nabla L + \lambda\boldsymbol{\theta}$$

and gradient descent gives:

$$\boldsymbol{\theta}_{t+1} = (1 - \eta\lambda)\boldsymbol{\theta}_t - \eta\nabla L$$

Part 3 - Hints and Helper

Use the `weight_decay` option in an appropriate PyTorch optimizer. Classical coupled L_2 regularization is not generally equivalent to decoupled decay under adaptive optimizers; AdamW handles the latter explicitly.

Part 4 - Python code skeleton

```
import torch

def E08(model, learning_rate, decay):
    optimizer = torch.optim.SGD(
        model.parameters(), lr=..., weight_decay=...
    )
    return optimizer

def main():
    model = ...
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.9 T07 - Statistics Probability Laws

Mathematics and Theory

1.9.1 Exercise 00 - Mean Law

Part 1 - Why this matters

The mean summarizes the central level of data and underlies centering, normalization, loss aggregation, and feature statistics in machine learning.

Part 2 - Mathematical form

For observations $x_1, \ldots, x_n$ with $n > 0$:

$$\bar{x} = \frac{1}{n} \sum_{i=1}^{n} x_i$$

For a random variable X, the population mean is $\mu = \mathbb{E}[X]$ when the expectation exists.

Part 3 - Hints and Helper

Use `torch.mean()` with a floating-point or complex tensor. Specify `dim` when reducing selected axes and use `keepdim=True` when the result must remain broadcasting-compatible.

Part 4 - Python code skeleton

```
import torch

def E00(x):
    mean = torch...
    return mean

def main():
    x = torch...
    print(E00(x))

if __name__ == "__main__":
    main()
```

1.9.2 Exercise 01 - Median Law

Part 1 - Why this matters

The median identifies the middle of ordered data and is more resistant to extreme values than the mean. It supports robust statistics, preprocessing, and outlier-resistant summaries.

Part 2 - Mathematical form

Let $x_{(1)} \leq \cdots \leq x_{(n)}$ be sorted observations:

$$\text{median}(x) = \begin{cases} x_{((n+1)/2)}, & n \text{ odd}, \\ \frac{x_{(n/2)} + x_{(n/2+1)}}{2}, & n \text{ even}. \end{cases}$$

Part 3 - Hints and Helper

Use `torch.median()` carefully: for an even number of elements it returns the lower of the two middle values, not their average. Use `torch.quantile(x, 0.5)` for the interpolated statistical median.

Part 4 - Python code skeleton

```
import torch

def E01(x):
    median = torch...
    return median

def main():
    x = torch...
    print(E01(x))

if __name__ == "__main__":
    main()
```

1.9.3 Exercise 02 - Mode Law

Part 1 - Why this matters

The mode is the most frequent observed value. It is especially meaningful for categorical or discrete data, label analysis, majority decisions, and detecting dominant outcomes.

Part 2 - Mathematical form

For dataset $D = \{x_1, \ldots, x_n\}$, define frequency $c(a) = |\{i : x_i = a\}|$. Then:

$$\text{Mode}(D) = \arg\max_a c(a)$$

The mode may be non-unique when several values share the maximum frequency.

Part 3 - Hints and Helper

Use `torch.mode()` along a dimension. It returns both values and indices and selects one value when ties exist. Use `torch.unique(..., return_counts=True)` when every tied mode must be identified.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    values, counts = torch.unique(...)
    modes = values[...]
    return modes

def main():
    x = torch...
    print(E02(x))

if __name__ == "__main__":
    main()
```

1.9.4 Exercise 03 - Variance Law

Part 1 - Why this matters

Variance measures dispersion around the mean. It is central to normalization, uncertainty estimation, initialization analysis, and statistical modeling.

Part 2 - Mathematical form

Population variance is:

$$\sigma^2 = \frac{1}{n}\sum_{i=1}^{n}(x_i - \mu)^2$$

The unbiased sample variance for $n > 1$ is:

$$s^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2$$

Part 3 - Hints and Helper

Use `torch.var()`. Set `correction=0` for population variance and `correction=1` for the usual unbiased sample estimate. State which definition the exercise uses.

Part 4 - Python code skeleton

```
import torch

def E03(x, correction):
    variance = torch.var(x, correction=...)
    return variance

def main():
    x = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.9.5 Exercise 04 - Standard Deviation Law

Part 1 - Why this matters

Standard deviation expresses spread in the same units as the original data. It supports standardization, uncertainty reporting, anomaly thresholds, and monitoring activation scale.

Part 2 - Mathematical form

Standard deviation is the nonnegative square root of variance:

$$\sigma = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i - \mu)^2}$$

For the unbiased sample-variance convention:

$$s = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2}$$

Part 3 - Hints and Helper

Use `torch.std()` and select the desired `correction`. Standard deviation is not the unbiased estimator of population standard deviation merely because its underlying variance uses Bessel's correction.

Part 4 - Python code skeleton

```
import torch

def E04(x, correction):
    standard_deviation = torch.std(x, correction=...)
    return standard_deviation

def main():
    x = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.9.6 Exercise 05 - Covariance Law

Part 1 - Why this matters

Covariance measures whether two variables vary together. Covariance matrices describe feature relationships and appear in PCA, Gaussian models, whitening, and uncertainty estimation.

Part 2 - Mathematical form

Population covariance is:

$$\mathrm{Cov}(X, Y) = \mathbb{E}[(X - \mu_X)(Y - \mu_Y)]$$

For paired samples, the unbiased estimate is:

$$s_{xy} = \frac{1}{n-1} \sum_{i=1}^{n} (x_i - \bar{x})(y_i - \bar{y})$$

Part 3 - Hints and Helper

Use `torch.cov()` with variables arranged in rows and observations in columns. Check tensor orientation and the correction convention before reading off diagonal covariances.

Part 4 - Python code skeleton

```
import torch

def E05(x, y):
    data = torch.stack((...))
    covariance = torch.cov(...)
    return covariance

def main():
    x = torch...
    y = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

1.9.7 Exercise 06 - Correlation Law

Part 1 - Why this matters

Correlation normalizes covariance into a unitless measure of linear association. It supports feature analysis, redundancy detection, and interpreting relationships across variables with different scales.

Part 2 - Mathematical form

For nonzero standard deviations:

$$\rho_{XY} = \frac{\mathrm{Cov}(X, Y)}{\sigma_X \sigma_Y}$$

and $-1 \leq \rho_{XY} \leq 1$. Correlation is undefined if either variable has zero variance.

Part 3 - Hints and Helper

Use `torch.corrcoef()` with variables in rows. Correlation measures linear association and does not by itself establish causation or independence.

Part 4 - Python code skeleton

```
import torch

def E06(x, y):
    data = torch.stack((...))
    correlation = torch.corrcoef(...)
    return correlation

def main():
    x = torch...
    y = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

1.9.8 Exercise 07 - Probability Density Function Law

Part 1 - Why this matters

A probability density function describes how probability is distributed over a continuous variable. Probabilistic models use densities for likelihoods, uncertainty, sampling, and expected values.

Part 2 - Mathematical form

A valid PDF f_X satisfies:

$$f_X(x) \geq 0, \qquad \int_{-\infty}^{\infty} f_X(x)\,dx = 1$$

and interval probability is:

$$\Pr(a \leq X \leq b) = \int_a^b f_X(x)\,dx$$

For a continuous variable, $\Pr(X = x) = 0$ even when $f_X(x) > 0$.

Part 3 - Hints and Helper

PyTorch distributions provide `log_prob()`, which returns log density for continuous distributions. Exponentiating gives density, not point probability.

Part 4 - Python code skeleton

```
import torch

def E07(distribution, x):
    log_density = distribution.log_prob(...)
    density = torch.exp(...)
    return density

def main():
```

```
    distribution = torch.distributions.Normal(...)
    x = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

1.9.9 Exercise 08 - Normal Distribution Law

Part 1 - Why this matters

The normal distribution models continuous variation and noise and underlies Gaussian likelihoods, initialization schemes, latent-variable models, and many statistical approximations.

Part 2 - Mathematical form

For $X \sim \mathcal{N}(\mu, \sigma^2)$ with $\sigma > 0$:

$$f_X(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{(x-\mu)^2}{2\sigma^2}\right]$$

$$\mathbb{E}[X] = \mu, \qquad \mathrm{Var}(X) = \sigma^2$$

Part 3 - Hints and Helper

Use `torch.distributions.Normal(loc, scale)`. The second argument is standard deviation, not variance. Use `sample()` or `rsample()` when a reparameterized differentiable sample is required.

Part 4 - Python code skeleton

```
import torch

def E08(mean, standard_deviation, x):
    distribution = torch.distributions.Normal(...)
    density = torch.exp(distribution.log_prob(...))
    return density

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.9.10 Exercise 09 - Uniform Distribution Law

Part 1 - Why this matters

The uniform distribution assigns equal density across an interval. It is used for random initialization, bounded exploration, simulation, and constructing simple prior distributions.

Part 2 - Mathematical form

For $X \sim \mathcal{U}(a, b)$ with $a < b$:

$$f_X(x) = \begin{cases} \frac{1}{b-a}, & a \le x \le b, \\ 0, & \text{otherwise} \end{cases}$$

$$\mathbb{E}[X] = \frac{a+b}{2}, \qquad \mathrm{Var}(X) = \frac{(b-a)^2}{12}$$

Part 3 - Hints and Helper

Use `torch.distributions.Uniform(low, high)` or `torch.rand()` followed by affine scaling. Ensure every lower bound is strictly smaller than its corresponding upper bound.

Part 4 - Python code skeleton

```
import torch

def E09(low, high, x):
    distribution = torch.distributions.Uniform(...)
    density = torch.exp(distribution.log_prob(...))
    return density

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.9.11 Exercise 10 - Bernoulli Law

Part 1 - Why this matters

The Bernoulli distribution models one binary outcome. It supports binary classification, dropout masks, binary latent variables, and repeated-trial probability models.

Part 2 - Mathematical form

For $X \sim \mathrm{Bernoulli}(p)$ with $0 \le p \le 1$:

$$\Pr(X = x) = p^x (1-p)^{1-x}, \qquad x \in \{0, 1\}$$

$$\mathbb{E}[X] = p, \qquad \mathrm{Var}(X) = p(1-p)$$

Part 3 - Hints and Helper

Use `torch.distributions.Bernoulli()` with either probabilities or logits, but not both. Logits are often numerically convenient in neural-network models.

Part 4 - Python code skeleton

```
import torch

def E10(probability):
    distribution = torch.distributions.Bernoulli(probs=...)
    sample = distribution.sample()
    return sample

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.9.12 Exercise 11 - Softmax Probability Law

Part 1 - Why this matters

Softmax converts arbitrary logits into a categorical probability vector. It is used for multi-class predictions and attention weights while preserving relative preference between alternatives.

Part 2 - Mathematical form

For logits $\mathbf{z} \in \mathbb{R}^K$:

$$p_i = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}}$$

$$p_i > 0, \qquad \sum_{i=1}^{K} p_i = 1$$

Adding the same constant to all logits leaves the probabilities unchanged.

Part 3 - Hints and Helper

Use `torch.softmax(logits, dim=...)`. PyTorch applies a stable implementation; specify the class axis correctly. Use `log_softmax` when log probabilities are required.

Part 4 - Python code skeleton

```
import torch

def E11(logits, dim):
    probabilities = torch.softmax(...)
    return probabilities

def main():
    logits = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.9.13 Exercise 12 - Entropy Law

Part 1 - Why this matters

Entropy measures uncertainty in a probability distribution. It appears in decision trees, reinforcement learning, information bottlenecks, uncertainty analysis, and regularization of predicted distributions.

Part 2 - Mathematical form

For a discrete distribution $\mathbf{p} = (p_1, \ldots, p_K)$:

$$H(\mathbf{p}) = -\sum_{i=1}^{K} p_i \log p_i$$

with $0 \log 0$ defined by continuity as 0. Natural logarithms measure entropy in nats; base-2 logarithms measure bits.

Part 3 - Hints and Helper

In PyTorch, compute entropy from probabilities and log probabilities, using `torch.special.xlogy()` or safe masking to handle zeros. Many `torch.distributions` objects also provide `entropy()`.

Part 4 - Python code skeleton

```
import torch

def E12(probabilities):
    entropy = -torch.sum(...)
    return entropy

def main():
    probabilities = torch...
    print(E12(probabilities))

if __name__ == "__main__":
    main()
```

1.9.14 Exercise 13 - KL Divergence Law

Part 1 - Why this matters

Kullback–Leibler divergence measures the information lost when distribution Q approximates distribution P. It is central to variational inference, knowledge distillation, distribution matching, and probabilistic regularization.

Part 2 - Mathematical form

For discrete distributions P and Q:

$$D_{\mathrm{KL}}(P \| Q) = \sum_i p_i \log \frac{p_i}{q_i}$$

assuming $q_i > 0$ whenever $p_i > 0$. It satisfies $D_{\mathrm{KL}}(P\|Q) \geq 0$ but is generally not symmetric and is not a distance metric.

Part 3 - Hints and Helper

Use `torch.nn.functional.kl_div()` carefully: by default its input is log probabilities and its target is probabilities. Choose an explicit reduction such as `batchmean` according to the intended definition.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E13(log_q, p):
    divergence = F.kl_div(..., reduction="...")
    return divergence

def main():
    log_q = torch...
    p = torch...
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.9.15 Exercise 14 - Jensen Inequality Law

Part 1 - Why this matters

Jensen's inequality connects convex functions with expectations. It underlies many bounds in optimization, information theory, variational inference, and the analysis of losses and estimators.

Part 2 - Mathematical form

If φ is convex and X is integrable:

$$\varphi(\mathbb{E}[X]) \leq \mathbb{E}[\varphi(X)]$$

For weights $w_i \geq 0$ with $\sum_i w_i = 1$:

$$\varphi\left(\sum_i w_i x_i\right) \leq \sum_i w_i \varphi(x_i)$$

The inequality reverses for concave φ. Equality holds, among other cases, when all positively weighted inputs are equal.

Part 3 - Hints and Helper

Use PyTorch to compute both sides for a chosen convex function such as $\varphi(x) = x^2$. Verify that weights are nonnegative and normalized before comparing the two scalar results.

Part 4 - Python code skeleton

```
import torch

def E14(x, weights):
    left = (... ) ** 2
    right = torch.sum(...)
    return left, right

def main():
    x = torch...
    weights = torch...
    print(E14(...))

if __name__ == "__main__":
    main()
```

1.10 T08 - Neural Network Transformatin Laws

Mathematics and Theory

1.10.1 Exercise 00 - Linear Transformation Law

Part 1 - Why this matters

Linear layers mix input features with learned weights and add a bias. They form the core transformation in multilayer perceptrons, attention projections, classifiers, and many neural-network blocks.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{W} \in \mathbb{R}^{m \times n}$, and $\mathbf{b} \in \mathbb{R}^m$:

$$\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{b} \in \mathbb{R}^m$$

For a batch $\mathbf{X} \in \mathbb{R}^{B \times n}$, PyTorch uses $\mathbf{Y} = \mathbf{X}\mathbf{W}^\mathsf{T} + \mathbf{b}$.

Part 3 - Hints and Helper

Use `torch.nn.Linear(in_features, out_features)`. Its stored weight has shape (m, n), and it transforms the final input dimension while preserving leading batch dimensions.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

def E00(x, in_features, out_features):
    layer = nn.Linear(...)
    y = layer(...)
    return y
```

```
def main():
    x = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

1.10.2 Exercise 01 - Convolution Law

Part 1 - Why this matters

Convolution extracts local patterns using shared kernels. Weight sharing makes it efficient for images, signals, and spatial feature maps while preserving translation-aware structure.

Part 2 - Mathematical form

For 2D input X, PyTorch's convolution layer computes cross-correlation:

$$Y_{oij} = b_o + \sum_{c=1}^{C_{in}} \sum_{u=0}^{K_h-1} \sum_{v=0}^{K_w-1} W_{ocuv} X_{c,\, iS_h+uD_h-P_h,\, jS_w+vD_w-P_w}$$

using valid padded indices. Kernels are not spatially reversed in this practical definition.

Part 3 - Hints and Helper

Use `torch.nn.Conv2d()`. Track channels, kernel size, stride, padding, dilation, and groups. Inputs normally have shape (N, C, H, W).

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

def E01(x):
    convolution = nn.Conv2d(...)
    y = convolution(...)
    return y

def main():
    x = torch...
    print(E01(x))

if __name__ == "__main__":
    main()
```

1.10.3 Exercise 02 - Transposed Convolution Law

Part 1 - Why this matters

Transposed convolution learns spatial upsampling for decoders, segmentation, and generative networks. It applies the transpose of the linear map represented by convolution with respect to suitable vectorizations; it is not generally the inverse of convolution.

Part 2 - Mathematical form

For one spatial dimension, the output size is:

$$L_{out} = (L_{in} - 1)S - 2P + D(K - 1) + O + 1$$

where S is stride, P padding, D dilation, K kernel size, and O output padding. The same rule applies independently to height and width.

Part 3 - Hints and Helper

Use `torch.nn.ConvTranspose2d()`. Choose `output_padding` only to resolve output-shape ambiguity; it does not add ordinary zero padding to the output.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

def E02(x):
    layer = nn.ConvTranspose2d(...)
    y = layer(...)
    return y

def main():
    x = torch...
    print(E02(x))

if __name__ == "__main__":
    main()
```

1.10.4 Exercise 03 - Depthwise Convolution Law

Part 1 - Why this matters

Depthwise convolution applies separate spatial filters to individual input channels. It greatly reduces parameters and computation and is commonly paired with a 1×1 pointwise convolution in efficient architectures.

Part 2 - Mathematical form

With depth multiplier M, each input channel c produces M outputs:

$$Y_{c,m,i,j} = b_{c,m} + \sum_{u,v} W_{c,m,u,v} X_{c,i+u,j+v}$$

There is no summation across input channels. The output channel count is $C_{out} = MC_{in}$.

Part 3 - Hints and Helper

Use `nn.Conv2d()` with `groups=in_channels` and `out_channels=M*in_channels`. Standard depthwise convolution requires the output channel count to be divisible by the input channel count.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

def E03(x, channels, multiplier):
    layer = nn.Conv2d(
        channels, ..., kernel_size=..., groups=...
    )
    return layer(x)

def main():
    x = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

1.10.5 Exercise 04 - Softmax Activation Law

Part 1 - Why this matters

Softmax converts logits into a normalized probability distribution and is used for multiclass prediction and attention weighting.

Part 2 - Mathematical form

For logits $\mathbf{z} \in \mathbb{R}^K$:

$$s_i = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}}, \qquad s_i > 0, \quad \sum_i s_i = 1$$

Subtracting $\max_j z_j$ before exponentiation leaves the result unchanged and improves numerical stability.

Part 3 - Hints and Helper

Use `torch.softmax()` with the correct class dimension. Do not apply softmax before `CrossEntropyLoss`, because that loss expects raw logits.

Part 4 - Python code skeleton

```
import torch

def E04(logits, dim):
    probabilities = torch.softmax(...)
```

```
    return probabilities

def main():
    logits = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

1.10.6 Exercise 05 - Sigmoid Activation Law

Part 1 - Why this matters

Sigmoid maps real inputs to $(0, 1)$, making it useful for binary probabilities, gates, and independent multi-label outputs. Large-magnitude inputs saturate and produce small gradients.

Part 2 - Mathematical form

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

$$0 < \sigma(x) < 1, \qquad \sigma'(x) = \sigma(x)[1 - \sigma(x)]$$

Part 3 - Hints and Helper

Use `torch.sigmoid()`. For binary loss from logits, prefer `BCEWithLogitsLoss` instead of applying sigmoid followed by ordinary BCE, because the combined implementation is more stable.

Part 4 - Python code skeleton

```
import torch

def E05(x):
    y = torch...
    return y

def main():
    x = torch...
    print(E05(x))

if __name__ == "__main__":
    main()
```

1.10.7 Exercise 06 - ReLU Activation Law

Part 1 - Why this matters

ReLU introduces nonlinearity while remaining computationally simple. It passes positive signals and sets negative signals to zero, but units can stop receiving gradients when they remain negative.

Part 2 - Mathematical form

$$\mathrm{ReLU}(x) = \max(0, x) = \begin{cases} 0, & x \leq 0, \\ x, & x > 0. \end{cases}$$

It is continuous but not classically differentiable at zero.

Part 3 - Hints and Helper

Use `torch.relu()`, `nn.ReLU()`, or the functional form. PyTorch uses derivative zero at $x = 0$. Avoid unsafe in-place activation when earlier values are needed by autograd.

Part 4 - Python code skeleton

```
import torch

def E06(x):
    y = torch...
    return y

def main():
    x = torch...
    print(E06(x))

if __name__ == "__main__":
    main()
```

1.10.8 Exercise 07 - GELU Activation Law

Part 1 - Why this matters

GELU smoothly weights inputs according to a Gaussian probability and is widely used in Transformer architectures. Unlike ReLU, it does not impose a hard zero threshold.

Part 2 - Mathematical form

$$\mathrm{GELU}(x) = x\Phi(x)$$

where Φ is the standard normal CDF. A common approximation is:

$$\frac{x}{2}\left[1 + \tanh\left(\sqrt{\frac{2}{\pi}}(x + 0.044715x^3)\right)\right]$$

Part 3 - Hints and Helper

Use `torch.nn.functional.gelu()` or `nn.GELU()`. The `approximate` option selects the exact or tanh approximation.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E07(x):
    y = F.gelu(x, approximate="...")
    return y

def main():
    x = torch...
    print(E07(x))

if __name__ == "__main__":
    main()
```

1.10.9 Exercise 08 - Swish Activation Law

Part 1 - Why this matters

Swish is a smooth, non-monotonic activation that gates an input by its sigmoid. It retains small negative outputs and can support smoother optimization than a hard threshold.

Part 2 - Mathematical form

For parameter $\beta > 0$:

$$\text{Swish}_\beta(x) = x\sigma(\beta x)$$

The common case $\beta = 1$ is also called SiLU:

$$\text{SiLU}(x) = x\sigma(x)$$

Part 3 - Hints and Helper

Use `torch.nn.functional.silu()` or `nn.SiLU()` for $\beta = 1$. For a different β, multiply the input explicitly by `torch.sigmoid(beta*x)`.

Part 4 - Python code skeleton

```
import torch

def E08(x, beta):
    y = x * torch.sigmoid(...)
    return y

def main():
    x = torch...
```

```
    print(E08(...))

if __name__ == "__main__":
    main()
```

1.10.10 Exercise 09 - Cross Entropy Loss Law

Part 1 - Why this matters

Cross entropy penalizes predicted class distributions that assign low probability to the correct class. It is the standard objective for multiclass classification and combines naturally with softmax logits.

Part 2 - Mathematical form

For logits $\mathbf{z}$ and correct class y:

$$L(\mathbf{z}, y) = -\log \frac{e^{z_y}}{\sum_{j=1}^{K} e^{z_j}} = -z_y + \log \sum_{j=1}^{K} e^{z_j}$$

For a target distribution $\mathbf{q}$:

$$L = -\sum_{i} q_i \log p_i$$

Part 3 - Hints and Helper

Use `nn.CrossEntropyLoss()` with raw logits. For class-index targets, use integer labels of dtype `torch.long`; do not apply softmax first.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

def E09(logits, targets):
    loss_function = nn.CrossEntropyLoss()
    loss = loss_function(...)
    return loss

def main():
    logits = torch...
    targets = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

1.10.11 Exercise 10 - MSE Loss Law

Part 1 - Why this matters

Mean squared error measures average squared prediction error. It strongly penalizes large deviations and is widely used in regression, reconstruction, and denoising.

Part 2 - Mathematical form

For predictions $\hat{y}_1, \ldots, \hat{y}_N$ and targets y_i:

$$L_{\text{MSE}} = \frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2$$

$$\frac{\partial L}{\partial \hat{y}_i} = \frac{2}{N}(\hat{y}_i - y_i)$$

Part 3 - Hints and Helper

Use `torch.nn.functional.mse_loss()` or `nn.MSELoss()`. Predictions and targets must have compatible shapes; choose reduction `mean`, `sum`, or `none` intentionally.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E10(prediction, target):
    loss = F.mse_loss(...)
    return loss

def main():
    prediction = torch...
    target = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

1.10.12 Exercise 11 - L1 Loss Law

Part 1 - Why this matters

L1 loss measures average absolute error. It is less sensitive to extreme errors than MSE and is used in robust regression, reconstruction, and sparse-error settings.

Part 2 - Mathematical form

$$L_1 = \frac{1}{N}\sum_{i=1}^{N}|\hat{y}_i - y_i|$$

For nonzero error:

$$\frac{\partial L_1}{\partial \hat{y}_i} = \frac{1}{N}\,\mathrm{sign}(\hat{y}_i - y_i)$$

At zero error, PyTorch uses subgradient zero.

Part 3 - Hints and Helper

Use `torch.nn.functional.l1_loss()` or `nn.L1Loss()` and select the intended reduction.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E11(prediction, target):
    loss = F.l1_loss(...)
    return loss

def main():
    prediction = torch...
    target = torch...
    print(E11(...))

if __name__ == "__main__":
    main()
```

1.10.13 Exercise 12 - Binary Cross Entropy Loss Law

Part 1 - Why this matters

Binary cross entropy evaluates probabilities for binary or independent multi-label outcomes. It penalizes confident incorrect predictions strongly and corresponds to the negative Bernoulli log-likelihood.

Part 2 - Mathematical form

For target $y \in \{0, 1\}$ and probability $p \in (0, 1)$:

$$L_{\mathrm{BCE}}(p, y) = -[y \log p + (1 - y) \log(1 - p)]$$

The dataset loss is commonly the mean over all elements.

Part 3 - Hints and Helper

Use `binary_cross_entropy()` only with probabilities. For raw logits, prefer `binary_cross_entropy_w` or `BCEWithLogitsLoss` for numerical stability.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E12(logits, targets):
    loss = F.binary_cross_entropy_with_logits(...)
    return loss

def main():
    logits = torch...
    targets = torch...
    print(E12(...))

if __name__ == "__main__":
    main()
```

1.10.14 Exercise 13 - LogSoftmax Law

Part 1 - Why this matters

LogSoftmax produces normalized log probabilities directly. It avoids separately computing potentially tiny probabilities before taking logarithms and is used with negative log-likelihood objectives.

Part 2 - Mathematical form

For logits $\mathbf{z} \in \mathbb{R}^K$:

$$\ell_i = \log \frac{e^{z_i}}{\sum_j e^{z_j}} = z_i - \log \sum_{j=1}^{K} e^{z_j}$$

and e^{ℓ_i} forms a probability distribution.

Part 3 - Hints and Helper

Use `torch.log_softmax()` or `nn.LogSoftmax()` with the class dimension. Do not reproduce it as `log(softmax(x))`, which is less numerically stable.

Part 4 - Python code skeleton

```
import torch

def E13(logits, dim):
    log_probabilities = torch.log_softmax(...)
    return log_probabilities

def main():
    logits = torch...
    print(E13(...))

if __name__ == "__main__":
    main()
```

1.10.15 Exercise 14 - LogSoftmax Gradient Law

Part 1 - Why this matters

The LogSoftmax gradient shows how each log probability depends on every logit. This coupling is central to stable classification gradients and the behavior of negative log-likelihood losses.

Part 2 - Mathematical form

Let $\ell_i = \text{LogSoftmax}(\mathbf{z})_i$ and $s_i = \text{Softmax}(\mathbf{z})_i$. Then:

$$\frac{\partial \ell_i}{\partial z_j} = \delta_{ij} - s_j$$

For upstream gradient $g_i = \partial L / \partial \ell_i$:

$$\frac{\partial L}{\partial z_j} = g_j - s_j \sum_i g_i$$

Part 3 - Hints and Helper

Use `torch.autograd.functional.jacobian()` to inspect the full Jacobian, or supply an upstream gradient to `torch.autograd.grad()`. Differentiate `log_softmax` directly rather than detaching its output.

Part 4 - Python code skeleton

```
import torch

def E14(logits):
    function = lambda value: torch.log_softmax(value, dim=...)
    jacobian = torch.autograd.functional.jacobian(...)
    return jacobian

def main():
    logits = torch.tensor(..., requires_grad=True)
    print(E14(logits))

if __name__ == "__main__":
    main()
```

Book 2

Applied Linear Algebra in Code

2.1 Introduction

2.1.1 What will the book teach you

After building the mathematical foundations of tensors and neural networks, you must learn how to translate linear algebra into clear, correct, and efficient code. This book will teach you how to apply the most important linear algebra concepts using PyTorch, beginning with basic tensor construction and progressing through vector operations, matrix multiplication, broadcasting, shape reasoning, and projection onto vector spaces.

You will not study these concepts as isolated formulas. Instead, you will learn how tensor shapes, data types, devices, dimensions, and numerical precision affect real implementations. You will also practise identifying shape errors, debugging invalid operations, comparing different computational methods, and designing functions that remain safe when tensor dimensions change.

The book consists of practical exercises and coding challenges. Each exercise will introduce a problem and provide guidance for finding a solution, but the complete solution will not be provided. You must reason about the mathematics, predict the tensor shapes, write the PyTorch code, test the result, and correct your own mistakes. This process will develop the problem-solving skills needed to build reliable artificial intelligence systems rather than simply copy existing code.

Before moving to the next book, make sure that you can explain every operation, predict its output shape, and implement it without depending on a prepared solution. The objective is not only to make the code run, but to understand why it works, when it fails, and how it can be improved.

2.1.2 The Chapters (ALA00 - ALA06) included in this book

- ALA00 - Tensor Operations in Code
- ALA01 - Vector Dot & Norm Computation
- ALA02 - Matrix Multiplication (matmul / mm)
- ALA03 - Outer vs Inner Product

- ALA04 - Broadcasting Rules & Mechanics
- ALA05 - Shape Reasoning & Dimension Flow
- ALA06 - Basis, Span & Projection (Applied)

2.2 ALA00 - Tensor Operations in Code

Mathematics and Theory

2.2.1 Exercise 00 - Basic Tensor Creation

Part 1 - Why this matters

Every PyTorch program begins by representing data as tensors. Images, text embeddings, model parameters, labels, and numerical measurements all become tensors before a neural network can process them. Creating a tensor correctly determines its initial values, dimensions, and numerical behaviour.

Tensor creation is also the first point where implementation mistakes can enter a pipeline. An incorrect shape, data type, or value pattern may remain hidden until a later operation fails. Learning several creation methods helps you choose between fixed data, initialized storage, random samples, and structured sequences.

Part 2 - Mathematical form

A tensor of order k with shape $(d_1, \ldots, d_k)$ is an element of:

$$\mathcal{X} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$$

Its number of elements is:

$$N = \prod_{i=1}^{k} d_i$$

Tensor creation assigns one value to every valid index of this shape.

Part 3 - Hints and Helper

Use `torch.tensor()` for explicit data, `torch.zeros()` and `torch.ones()` for constant initialization, `torch.arange()` for sequences, and `torch.rand()` for uniform random values. Specify `dtype` and `device` when defaults are unsuitable.

Part 4 - Python code skeleton

```
import torch

def E00():
    A = torch...
    B = torch...
    C = torch...
    return A, B, C
```

```
def main():
    tensors = E00()
    print(...)

if __name__ == "__main__":
    main()
```

2.2.2 Exercise 01 - Tensor Shape Inspection

Part 1 - Why this matters

Tensor shape describes how values are organized across dimensions. In a neural network, these dimensions may represent batches, channels, sequence positions, height, width, or features. Inspecting shape is therefore essential before combining tensors or passing them into a layer.

Shape inspection also supports debugging and documentation. A tensor can contain the expected values but still be unusable because its axes are ordered incorrectly. Understanding rank, dimension sizes, and element count allows you to predict whether an operation is mathematically valid.

Part 2 - Mathematical form

For $\mathcal{X} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$:

$$\text{shape}(\mathcal{X}) = (d_1, \ldots, d_k)$$

$$\text{ndim}(\mathcal{X}) = k, qquad \text{numel}(\mathcal{X}) = \prod_{i=1}^{k} d_i$$

Part 3 - Hints and Helper

Inspect `tensor.shape`, `tensor.ndim`, `tensor.size()`, and `tensor.numel()`. Use `size(dim)` to read one axis. Do not confuse the number of dimensions with the total number of values.

Part 4 - Python code skeleton

```
import torch

def E01(A):
    shape = ...
    dimensions = ...
    elements = ...
    return shape, dimensions, elements

def main():
    A = torch...
    print(E01(A))

if __name__ == "__main__":
    main()
```

2.2.3 Exercise 02 - Tensor Type Conversion

Part 1 - Why this matters

Tensor data type controls how values are stored and which operations are available. Floating-point types support gradients and neural-network training, integer types represent indices and class labels, and Boolean tensors represent logical conditions and masks.

Type conversion affects precision, memory use, and compatibility. Converting a floating-point tensor to an integer removes its fractional information, while using a lower-precision floating type may introduce rounding error. A correct program converts types intentionally rather than relying on accidental defaults.

Part 2 - Mathematical form

A conversion maps stored values from one numerical set to another:

$$\text{cast}_{\tau_1 \to \tau_2} : \mathbb{T}_{\tau_1}^{d_1 \times \cdots \times d_k} \to \mathbb{T}_{\tau_2}^{d_1 \times \cdots \times d_k}$$

The shape is preserved, but values may be rounded, truncated, or represented with different precision.

Part 3 - Hints and Helper

Use `tensor.to(dtype=...)`, `tensor.float()`, `tensor.long()`, or `tensor.bool()`. Inspect `tensor.dtype` before and after conversion. Class indices for many PyTorch losses require `torch.long`.

Part 4 - Python code skeleton

```
import torch

def E02(A):
    float_tensor = A...
    integer_tensor = A...
    boolean_tensor = A...
    return float_tensor, integer_tensor, boolean_tensor

def main():
    A = torch...
    print(E02(A))

if __name__ == "__main__":
    main()
```

2.2.4 Exercise 03 - Tensor Device Assignment

Part 1 - Why this matters

PyTorch tensors perform computation on a device such as the CPU or a CUDA GPU. Moving tensors to a GPU can accelerate large parallel operations, while the CPU remains useful for

data loading, control logic, and workloads that are too small to benefit from transfer overhead.

All tensors participating in most operations must be on the same device. Device mismatch errors commonly occur when a model is moved to the GPU but its inputs or newly created helper tensors remain on the CPU. Device-aware code must work correctly even when CUDA is unavailable.

Part 2 - Mathematical form

Device assignment changes the storage location without changing mathematical content:

$$\mathcal{X}_{\text{CPU}} \longmapsto \mathcal{X}_{\text{device}}$$

$$\text{shape}(\mathcal{X}_{\text{CPU}}) = \text{shape}(\mathcal{X}_{\text{device}})$$

Part 3 - Hints and Helper

Choose a device with `torch.cuda.is_available()`, create `torch.device(...)`, and move tensors with `tensor.to(device)`. Inspect `tensor.device`. Moving data returns a tensor and does not always modify the original variable in place.

Part 4 - Python code skeleton

```
import torch

def E03(A):
    device = torch.device(...)
    A_device = A.to(...)
    return A_device

def main():
    A = torch...
    print(E03(A).device)

if __name__ == "__main__":
    main()
```

2.2.5 Exercise 04 - Element-wise Addition

Part 1 - Why this matters

Element-wise addition combines aligned tensor values without mixing positions. Neural networks use it to add biases, residual connections, learned updates, masks, and accumulated features. The operation is simple, but its validity depends on tensor shapes.

When shapes differ, PyTorch may apply broadcasting rather than reject the operation. This can be intentional, such as adding one bias per feature, or an unnoticed bug that produces a valid but incorrectly interpreted output.

Part 2 - Mathematical form

For aligned tensors $\mathcal{A}, \mathcal{B} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$:

$$\mathcal{C} = \mathcal{A} + \mathcal{B}, \qquad C_{i_1 \ldots i_k} = A_{i_1 \ldots i_k} + B_{i_1 \ldots i_k}$$

The output has the common or broadcasted shape.

Part 3 - Hints and Helper

Use the `+` operator or `torch.add()`. Inspect both input shapes and the output shape. Use `torch.broadcast_shapes()` when you need to check compatibility before addition.

Part 4 - Python code skeleton

```
import torch

def E04(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

2.2.6 Exercise 05 - Element-wise Multiplication

Part 1 - Why this matters

Element-wise multiplication lets one tensor scale, gate, or mask another at corresponding positions. It appears in attention weights, activation gates, feature modulation, dropout masks, and many loss calculations.

This operation is different from a dot product or matrix multiplication because it performs no summation and normally preserves the aligned shape. Confusing these operations changes both the mathematics and the output dimensions.

Part 2 - Mathematical form

For aligned tensors $\mathcal{A}$ and $\mathcal{B}$:

$$\mathcal{C} = \mathcal{A} \odot \mathcal{B}$$

$$C_{i_1 \ldots i_k} = A_{i_1 \ldots i_k} B_{i_1 \ldots i_k}$$

No index is contracted or reduced.

Part 3 - Hints and Helper

Use the `*` operator or `torch.mul()`. Verify shape compatibility and do not use `torch.matmul()` for this law. Broadcasting may apply when singleton dimensions are present.

Part 4 - Python code skeleton

```
import torch

def E05(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

2.2.7 Exercise 06 - Scalar-Tensor Operations

Part 1 - Why this matters

Scalar-tensor operations apply one value to every element of a tensor. They are used to scale features, shift activations, normalize measurements, adjust thresholds, and implement learning formulas without constructing a second full tensor.

PyTorch handles the scalar through broadcasting, so the tensor shape is usually preserved. The selected operator still matters: multiplication changes scale, addition changes location, and division may create undefined or unstable values when the scalar is zero or extremely small.

Part 2 - Mathematical form

For scalar $\alpha \in \mathbb{R}$ and tensor $\mathcal{A} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$:

$$(\alpha\mathcal{A})_{i_1 \ldots i_k} = \alpha A_{i_1 \ldots i_k}$$

$$(\mathcal{A} + \alpha)_{i_1 \ldots i_k} = A_{i_1 \ldots i_k} + \alpha$$

The output shape equals the input shape.

Part 3 - Hints and Helper

Use standard operators such as `+`, `-`, `*`, and `/`. Observe PyTorch type promotion when a scalar and tensor use different numerical types. Avoid division by zero.

Part 4 - Python code skeleton

```
import torch

def E06(A, scalar):
    scaled = ...
    shifted = ...
    divided = ...
    return scaled, shifted, divided

def main():
```

```
    A = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

2.2.8 Exercise 07 - Tensor Comparison Operations

Part 1 - Why this matters

Tensor comparisons test relationships between aligned values and return Boolean results. They identify thresholds, classification decisions, valid ranges, matching labels, and conditions used to control later tensor operations.

Comparison output is not a single Boolean unless the tensor contains one element or the result is reduced. Each position produces its own truth value, and broadcasting rules may apply between differently shaped operands.

Part 2 - Mathematical form

For aligned tensors $\mathcal{A}$ and $\mathcal{B}$, equality defines:

$$C_{i_1 \ldots i_k} = \begin{cases} \text{True}, & A_{i_1 \ldots i_k} = B_{i_1 \ldots i_k}, \\ \text{False}, & \text{otherwise.} \end{cases}$$

Other relations replace equality with $\neq, <, \leq, >, \geq$.

Part 3 - Hints and Helper

Use operators such as `==`, `!=`, `>`, and `<=`, or PyTorch comparison functions. Use `torch.all()` or `torch.any()` only when a reduced Boolean conclusion is required.

Part 4 - Python code skeleton

```
import torch

def E07(A, B):
    equal = ...
    greater = ...
    less_or_equal = ...
    return equal, greater, less_or_equal

def main():
    A = torch...
    B = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

2.2.9 Exercise 08 - Boolean Masking Challenge

Part 1 - Why this matters

Boolean masking selects or modifies tensor values according to logical conditions. It is used to remove invalid data, isolate classes, apply thresholds, ignore padded tokens, and restrict loss calculations to relevant positions.

Masking can either extract matching values into a one-dimensional result or preserve shape by replacing values conditionally. Understanding this difference is essential because direct Boolean indexing and `torch.where()` produce different output structures.

Part 2 - Mathematical form

For condition mask $\mathcal{M}$ with the same shape as $\mathcal{A}$:

$$\mathcal{S} = \{A_{i_1 \ldots i_k} : M_{i_1 \ldots i_k} = \text{True}\}$$

A shape-preserving conditional tensor is:

$$C_i = \begin{cases} A_i, & M_i = \text{True}, \\ B_i, & M_i = \text{False}. \end{cases}$$

Part 3 - Hints and Helper

Build masks with comparisons and combine conditions using `&`, `|`, and `~`, adding parentheses around each comparison. Use `A[mask]` for extraction and `torch.where()` for shape-preserving selection.

Part 4 - Python code skeleton

```
import torch

def E08(A, lower, upper):
    mask = (... ) & (... )
    selected = A[...]
    replaced = torch.where(...)
    return selected, replaced

def main():
    A = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

2.2.10 Exercise 09 - Tensor Operation Chain Challenge

Part 1 - Why this matters

Real machine-learning programs rarely perform only one tensor operation. Data usually passes through a chain of scaling, shifting, masking, reduction, and shape transformations. Every stage must receive the shape and type produced by the stage before it.

Chained operations test whether you understand data flow rather than isolated syntax. A mathematically correct individual step can still break the full pipeline through unintended broadcasting, type conversion, device mismatch, or loss of dimensions.

Part 2 - Mathematical form

Let the transformation chain be:

$$\mathcal{B} = \alpha\mathcal{A} + \beta$$

$$\mathcal{M} = \mathcal{B} > \tau$$

$$\mathbf{s} = \sum_{j} \text{where}(\mathcal{M}, \mathcal{B}, 0)$$

Each output becomes the next operation's input.

Part 3 - Hints and Helper

Implement one step at a time and inspect shape, dtype, and device after every stage. Avoid unnecessary intermediate copies, but keep meaningful variable names while debugging. Confirm which axis the final reduction uses.

Part 4 - Python code skeleton

```
import torch

def E09(A, alpha, beta, threshold):
    B = ...
    mask = ...
    filtered = torch.where(...)
    result = torch.sum(...)
    return result

def main():
    A = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

2.2.11 Exercise 10 - Debugging Tensor Type Errors

Part 1 - Why this matters

Tensor type errors occur when an operation receives a dtype that does not match its mathematical or API requirements. Examples include supplying floating-point class labels where integer indices are expected or requesting gradients from an integer tensor.

Debugging these errors requires understanding the data's role, not merely forcing every tensor to the same type. Features, parameters, labels, masks, and indices often require different dtypes, and an incorrect conversion can hide an error while changing the meaning of the computation.

Part 2 - Mathematical form

An operation F has a type domain:

$$F : \mathbb{T}_{\tau_1} \times \mathbb{T}_{\tau_2} o \mathbb{T}_{\tau_3}$$

A call is valid only when each input belongs to an accepted dtype domain or a defined promotion rule converts it safely.

Part 3 - Hints and Helper

Print `dtype`, `shape`, and `device` for every input near the failing operation. Read the API requirement, then convert only the tensor whose semantic role demands conversion. Remember that only floating-point and complex tensors can require gradients.

Part 4 - Python code skeleton

```
import torch

def E10(features, labels):
    print(features.dtype, labels.dtype)
    fixed_features = features...
    fixed_labels = labels...
    result = ...
    return result

def main():
    features = torch...
    labels = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

2.2.12 Exercise 11 - Tensor Operation Optimization Challenge

Part 1 - Why this matters

Efficient tensor code expresses work as vectorized operations that PyTorch can execute in optimized native kernels and parallelize on accelerators. Replacing Python loops with tensor operations often improves speed, readability, and GPU utilization.

Optimization is not simply shortening code. A faster implementation must preserve numerical results, shape semantics, gradient flow, and reasonable memory use. Temporary tensors, repeated device transfers, explicit copies, and unnecessary synchronization can make otherwise vectorized code inefficient.

Part 2 - Mathematical form

An element-wise loop:

$$C_i = f(A_i), \qquad i = 1, \ldots, N$$

can be represented as the vectorized transformation:

$$\mathcal{C} = f(\mathcal{A})$$

when f acts independently on tensor elements. Correct optimization requires the vectorized and reference outputs to agree within an appropriate tolerance.

Part 3 - Hints and Helper

Identify Python loops, repeated allocations, and transfers inside the hot path. Use broadcasting, reductions, and fused PyTorch expressions where appropriate. Validate with `torch.allclose()` and benchmark after CUDA synchronization when measuring GPU execution.

Part 4 - Python code skeleton

```
import torch

def E11(A):
    optimized = ...
    return optimized

def main():
    A = torch...
    result = E11(A)
    reference = ...
    print(torch.allclose(result, reference))

if __name__ == "__main__":
    main()
```

2.3 ALA01 - Vector Dot & Norm Computation

Mathematics and Theory

2.3.1 Exercise 00 - Manual Dot Product Implementation

Part 1 - Why this matters

Implementing a dot product manually reveals how two vectors are combined: each pair of aligned components is multiplied, then every product is accumulated into one scalar. This pattern appears inside matrix multiplication, linear layers, attention scores, and similarity measures.

The manual version is not intended to outperform PyTorch. Its purpose is to connect loop logic with the mathematical summation and to practise validating length, dtype, and device compatibility before using optimized library operations.

Part 2 - Mathematical form

For $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$:

$$\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^{n} x_i y_i \in \mathbb{R}$$

Both vectors must have the same number of components.

Part 3 - Hints and Helper

Initialize an accumulator without converting tensor values into Python numbers, then iterate over valid indices and add one product at a time. Do not call `torch.dot()`, `torch.sum()`, or matrix multiplication in the manual implementation.

Part 4 - Python code skeleton

```
import torch

def E00(x, y):
    result = ...
    for i in range(...):
        result = result + ...
    return result

def main():
    x = torch...
    y = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

2.3.2 Exercise 01 - Dot Product Using PyTorch

Part 1 - Why this matters

PyTorch provides an optimized dot-product operation that executes the same mathematics as the manual implementation while using efficient native kernels. This is the appropriate form for real models and large numerical workloads.

Using the library operation also makes the intended mathematics explicit. However, it still requires compatible one-dimensional tensors, so understanding the shape rule remains necessary even when the computation is automated.

Part 2 - Mathematical form

For $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$:

$$d = \mathbf{x}^\mathsf{T}\mathbf{y} = \sum_{i=1}^{n} x_i y_i$$

The output d is a scalar tensor.

Part 3 - Hints and Helper

Use `torch.dot()` for two 1D tensors. Inspect both tensors' shapes, dtypes, and devices first. Compare its result with the manual implementation using `torch.allclose()`.

Part 4 - Python code skeleton

```
import torch

def E01(x, y):
    result = torch...
    return result

def main():
    x = torch...
    y = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

2.3.3 Exercise 02 - L2 Norm Calculation

Part 1 - Why this matters

The L2 norm measures Euclidean vector length. It is used to normalize embeddings, calculate distances, constrain parameters, and measure gradient or activation magnitude in neural networks.

Because the norm squares and sums all components, every coordinate contributes to the final magnitude. Large components receive greater influence, and the result is always nonnegative and equals zero only for the zero vector.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^n$:

$$\|\mathbf{x}\|_2 = \sqrt{\sum_{i=1}^{n} x_i^2}$$

It satisfies homogeneity:

$$\|\alpha\mathbf{x}\|_2 = |\alpha|\|\mathbf{x}\|_2$$

Part 3 - Hints and Helper

Use `torch.linalg.vector_norm(x, ord=2)` or `torch.norm()`. Specify a dimension for batched vectors. Use a floating-point tensor when calculating norms.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    norm = torch.linalg.vector_norm(...)
```

```
    return norm

def main():
    x = torch...
    print(E02(x))

if __name__ == "__main__":
    main()
```

2.3.4 Exercise 03 - L1 Norm Calculation

Part 1 - Why this matters

The L1 norm sums absolute component magnitudes. It appears in sparse regularization, robust error measures, feature selection, and comparisons where linear rather than squared magnitude is desired.

Unlike the L2 norm, the L1 norm does not increase the influence of large values through squaring. Its geometry can encourage solutions with exactly zero components when used as an optimization penalty.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^n$:

$$\|\mathbf{x}\|_1 = \sum_{i=1}^{n} |x_i|$$

The result is nonnegative and equals zero exactly when $\mathbf{x} = \mathbf{0}$.

Part 3 - Hints and Helper

Use `torch.linalg.vector_norm(x, ord=1)` or explicitly combine `torch.abs()` and `torch.sum()`. Specify the vector dimension for batched input.

Part 4 - Python code skeleton

```
import torch

def E03(x):
    norm = torch.linalg.vector_norm(...)
    return norm

def main():
    x = torch...
    print(E03(x))

if __name__ == "__main__":
    main()
```

2.3.5 Exercise 04 - Vector Normalization

Part 1 - Why this matters

Vector normalization removes magnitude while preserving direction. It allows embeddings and features to be compared on a common scale and is a required step in cosine similarity and many geometric algorithms.

The zero vector has no direction and cannot be divided by its norm. Practical implementations must therefore define safe behaviour for zero or nearly zero norms rather than allowing division to generate invalid values.

Part 2 - Mathematical form

For nonzero $\mathbf{x} \in \mathbb{R}^n$:

$$\widehat{\mathbf{x}} = \frac{\mathbf{x}}{\|\mathbf{x}\|_2}$$

$$\|\widehat{\mathbf{x}}\|_2 = 1$$

Part 3 - Hints and Helper

Use `torch.nn.functional.normalize()` with `p=2` and the correct dimension, or divide by a safely clamped norm. Choose a small epsilon that protects zero norms without unnecessarily changing ordinary vectors.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E04(x):
    normalized = F.normalize(x, p=..., dim=..., eps=...)
    return normalized

def main():
    x = torch...
    print(E04(x))

if __name__ == "__main__":
    main()
```

2.3.6 Exercise 05 - Cosine Similarity Implementation

Part 1 - Why this matters

Cosine similarity compares vector direction independently of magnitude. It is widely used for embeddings, document retrieval, recommendation, clustering, and measuring similarity between learned representations.

The measure ranges from -1 to 1 for real nonzero vectors. Positive values indicate similar direction, zero indicates orthogonality, and negative values indicate opposing direction. Zero norms require numerical protection.

Part 2 - Mathematical form

For nonzero $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$:

$$\text{cos_sim}(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x} \cdot \mathbf{y}}{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2}$$

Part 3 - Hints and Helper

Implement the formula using dot products and norms, or use `torch.nn.functional.cosine_similari` Specify the feature dimension and an epsilon. Test with identical, orthogonal, and opposite vectors.

Part 4 - Python code skeleton

```
import torch

def E05(x, y, eps):
    numerator = ...
    denominator = ...
    similarity = numerator / ...
    return similarity

def main():
    x = torch...
    y = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

2.3.7 Exercise 06 - Angle Between Two Vectors

Part 1 - Why this matters

The angle between vectors gives an interpretable geometric measure of directional difference. It is used in orientation analysis, embedding geometry, robotics, and algorithms that compare directions rather than raw distances.

The inverse cosine is sensitive when numerical rounding moves cosine similarity slightly outside $[-1, 1]$. A stable implementation clamps the computed cosine before applying the inverse trigonometric function.

Part 2 - Mathematical form

For nonzero vectors:

$$\theta = \arccos\left(\frac{\mathbf{x} \cdot \mathbf{y}}{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2}\right), \qquad 0 \le \theta \le \pi$$

Part 3 - Hints and Helper

Compute cosine similarity, clamp it to $[-1, 1]$, then use `torch.acos()`. The output is in radians. Convert to degrees only if the exercise explicitly requires it.

Part 4 - Python code skeleton

```
import torch

def E06(x, y):
    cosine = ...
    safe_cosine = torch.clamp(...)
    angle = torch.acos(...)
    return angle

def main():
    x = torch...
    y = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

2.3.8 Exercise 07 - Batched Dot Product

Part 1 - Why this matters

Machine-learning systems process many vector pairs at once. A batched dot product computes one scalar interaction for every pair without a Python loop, supporting attention scores, batch similarity, and parallel feature comparison.

The batch dimension must be preserved while the feature dimension is reduced. Choosing the wrong reduction axis can collapse samples together or produce an output whose shape looks valid but has the wrong meaning.

Part 2 - Mathematical form

For $\mathbf{X}, \mathbf{Y} \in \mathbb{R}^{B \times n}$:

$$d_b = \sum_{i=1}^{n} X_{bi} Y_{bi}, \qquad b = 1, \ldots, B$$

$$\mathbf{d} \in \mathbb{R}^{B}$$

Part 3 - Hints and Helper

Multiply aligned batches element-wise and sum across the feature dimension, or use `torch.einsum()`. Confirm that the result has exactly one value per batch item.

Part 4 - Python code skeleton

```
import torch

def E07(X, Y):
    products = ...
    dots = torch.sum(..., dim=...)
    return dots

def main():
    X = torch...
    Y = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

2.3.9 Exercise 08 - Stability Issues in Norm Computation

Part 1 - Why this matters

Directly squaring very large components can overflow, while squaring extremely small components can underflow. These problems can turn a mathematically finite norm into infinity or zero and corrupt later normalization or similarity calculations.

Numerical stability depends on dtype as well as formula. Higher precision offers a wider and more accurate numerical range, while stable norm algorithms can rescale intermediate values. Adding epsilon protects division but does not fix every overflow problem in the original norm computation.

Part 2 - Mathematical form

A scaled L2 norm may use $s = \max_i |x_i|$:

$$\|\mathbf{x}\|_2 = s\sqrt{\sum_i \left(\frac{x_i}{s}\right)^2}$$

for $s > 0$. This avoids directly squaring the largest original magnitude.

Part 3 - Hints and Helper

Compare a naive square-sum-square-root calculation with `torch.linalg.vector_norm()`. Test large and small magnitudes and compare `float32` with `float64`. Handle the zero vector separately in a manual scaled implementation.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    naive = torch.sqrt(torch.sum(...))
    stable = torch.linalg.vector_norm(...)
    return naive, stable
```

```
def main():
    x = torch.tensor(..., dtype=torch.float32)
    print(E08(x))

if __name__ == "__main__":
    main()
```

2.3.10 Exercise 09 - Gradient-safe Dot Product Challenge

Part 1 - Why this matters

A differentiable dot product must remain connected to PyTorch's computation graph. This allows a loss built from the result to propagate gradients back to both input vectors and, ultimately, to the parameters that produced them.

Seemingly harmless actions can break this connection. Extracting values with `.item()`, converting through NumPy, wrapping an existing tensor with `torch.tensor()`, or detaching intermediate results prevents autograd from tracing the intended computation.

Part 2 - Mathematical form

For $d = \mathbf{x} \cdot \mathbf{y}$:

$$\nabla_{\mathbf{x}} d = \mathbf{y}, \qquad \nabla_{\mathbf{y}} d = \mathbf{x}$$

The implementation should produce these gradients through automatic differentiation.

Part 3 - Hints and Helper

Use only differentiable PyTorch operations on tensors requiring gradients. Call `torch.autograd.grad()` for both inputs and compare the returned gradients with the analytical expressions. Avoid in-place modification of tracked leaf tensors.

Part 4 - Python code skeleton

```
import torch

def E09(x, y):
    dot = ...
    gradients = torch.autograd.grad(dot, (..., ...))
    return dot, gradients

def main():
    x = torch.tensor(..., requires_grad=True)
    y = torch.tensor(..., requires_grad=True)
    print(E09(...))

if __name__ == "__main__":
    main()
```

2.3.11 Exercise 10 - Custom Similarity Metric Design

Part 1 - Why this matters

Different applications define similarity differently. Direction may matter more than magnitude for text embeddings, while scale or component importance may be essential in another dataset. Designing a custom metric requires translating the application's meaning into a precise mathematical rule.

A useful metric should also have understood range, symmetry, numerical behaviour, and differentiability. Combining several terms without controlling their scales can make one component dominate even when the formula appears balanced.

Part 2 - Mathematical form

One possible design combines cosine similarity with normalized distance:

$$S(\mathbf{x}, \mathbf{y}) = \alpha \cos_\text{sim}(\mathbf{x}, \mathbf{y}) + (1 - \alpha)\frac{1}{1 + \|\mathbf{x} - \mathbf{y}\|_2}$$

where $0 \leq \alpha \leq 1$. Other defensible formulas may be designed if their properties are explained.

Part 3 - Hints and Helper

Choose the desired invariances and output range before coding. Protect zero norms, keep operations differentiable, and test identical, opposite, orthogonal, scaled, and zero vectors. Explain what a high and low score mean.

Part 4 - Python code skeleton

```
import torch

def E10(x, y, alpha, eps):
    directional_score = ...
    distance_score = ...
    similarity = ...
    return similarity

def main():
    x = torch...
    y = torch...
    print(E10(...))

if __name__ == "__main__":
    main()
```

2.4 ALA02 - Matrix Multiplication (matmul / mm)

Mathematics and Theory

2.4.1 Exercise 00 - Basic Matrix Multiplication

Part 1 - Why this matters

Matrix multiplication combines input features through weighted sums. It is the central operation behind linear layers, coordinate transformations, attention, and many numerical algorithms used in artificial intelligence.

Unlike element-wise multiplication, each output entry depends on an entire row of the first matrix and an entire column of the second. Understanding this rule allows you to predict both shape compatibility and the meaning of every output dimension.

Part 2 - Mathematical form

For $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{n \times p}$:

$$\mathbf{C} = \mathbf{AB} \in \mathbb{R}^{m \times p}$$

$$C_{ij} = \sum_{k=1}^{n} A_{ik} B_{kj}$$

Part 3 - Hints and Helper

Use `torch.matmul()` or the `@` operator. Check that the columns of $\mathbf{A}$ equal the rows of $\mathbf{B}$. Do not replace matrix multiplication with the element-wise `*` operator.

Part 4 - Python code skeleton

```
import torch

def E00(A, B):
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

2.4.2 Exercise 01 - matmul vs mm Comparison

Part 1 - Why this matters

PyTorch offers both `matmul` and `mm`, but their accepted inputs are different. Choosing the correct function makes the intended dimensional behaviour clear and prevents code from silently relying on broadcasting.

The functions agree for ordinary 2D matrix multiplication. Outside that case, `matmul` supports vectors and higher-dimensional batches, whereas `mm` is restricted to two matrices and does not broadcast batch axes.

Part 2 - Mathematical form

For 2D matrices:

$$\text{mm}(\mathbf{A}, \mathbf{B}) = \text{matmul}(\mathbf{A}, \mathbf{B}) = \mathbf{AB}$$

For batch shapes, `matmul` treats the final two axes as matrices and broadcasts compatible leading axes.

Part 3 - Hints and Helper

Test 1D, 2D, and 3D inputs with both functions. Record output shapes and errors. Use `torch.allclose()` when both functions accept the same inputs; do not catch an error without explaining why it occurred.

Part 4 - Python code skeleton

```
import torch

def E01(A, B):
    matmul_result = torch.matmul(...)
    mm_result = torch.mm(...)
    return matmul_result, mm_result

def main():
    A = torch...
    B = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

2.4.3 Exercise 02 - Manual Matrix Multiplication

Part 1 - Why this matters

Manual matrix multiplication exposes the three-index structure hidden inside an optimized library call. Two loops choose an output position, while a third loop accumulates products across the shared inner dimension.

This implementation is educational rather than performant. It helps you reason about row-column interaction, output initialization, and index boundaries before using the optimized operation in real models.

Part 2 - Mathematical form

For compatible $\mathbf{A}$ and $\mathbf{B}$:

$$C_{ij} = \sum_{k=1}^{n} A_{ik} B_{kj}, \quad i = 1, \ldots, m, \quad j = 1, \ldots, p$$

The output must be initialized with shape (m, p).

Part 3 - Hints and Helper

Validate the inner dimensions, allocate an output on the same dtype and device, then use three loops. Do not call `matmul`, `mm`, `einsum`, or `@`. Compare the result with PyTorch afterward.

Part 4 - Python code skeleton

```
import torch

def E02(A, B):
    C = torch.zeros(..., dtype=A.dtype, device=A.device)
    for i in range(...):
        for j in range(...):
            for k in range(...):
                C[i, j] = C[i, j] + ...
    return C

def main():
    A = torch...
    B = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

2.4.4 Exercise 03 - Shape Compatibility Check

Part 1 - Why this matters

Matrix multiplication is valid only when its inner dimensions match. Checking this condition before computation produces clearer errors and prevents confusion between matrix, batch, and feature dimensions.

A robust compatibility function should also predict the result shape. This turns shape reasoning into an explicit contract that can be reused in data pipelines and custom neural-network layers.

Part 2 - Mathematical form

For shapes (m, n) and (q, p):

$$\mathbf{AB} \text{ is defined} \quad \Longleftrightarrow \quad n = q$$

When defined:

$$\text{shape}(\mathbf{AB}) = (m, p)$$

Part 3 - Hints and Helper

Inspect `shape[-1]` of the first matrix and `shape[-2]` of the second. Raise an informative `ValueError` that reports both shapes. Require two dimensions for this exercise before adding batch support later.

Part 4 - Python code skeleton

```
import torch

def E03(A, B):
    if A.ndim != ... or B.ndim != ...:
        raise ValueError(...)
    if ... != ...:
        raise ValueError(...)
    output_shape = (..., ...)
    return output_shape

def main():
    A = torch...
    B = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

2.4.5 Exercise 04 - Batched Matrix Multiplication

Part 1 - Why this matters

Batched matrix multiplication performs many independent matrix products in one vectorized operation. It is used for sequences, attention heads, batches of transformations, and any workload where corresponding matrix pairs must be multiplied in parallel.

The batch axis is preserved rather than contracted. PyTorch's `bmm` requires both inputs to be 3D and requires equal batch sizes; it does not broadcast the batch dimension.

Part 2 - Mathematical form

For $\mathcal{A} \in \mathbb{R}^{B\times m\times n}$ and $\mathcal{B} \in \mathbb{R}^{B\times n\times p}$:

$$C_{bij} = \sum_{k=1}^{n} A_{bik} B_{bkj}$$

$$\mathcal{C} \in \mathbb{R}^{B\times m\times p}$$

Part 3 - Hints and Helper

Use `torch.bmm()` and verify rank, batch size, and inner dimensions. Compare one output slice with an ordinary matrix multiplication of the corresponding input slices.

Part 4 - Python code skeleton

```
import torch

def E04(A, B):
    C = torch.bmm(...)
    return C
```

```
def main():
    A = torch...
    B = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

2.4.6 Exercise 05 - High-Dimensional matmul Challenge

Part 1 - Why this matters

High-dimensional matrix multiplication treats the final two dimensions as matrices and the earlier dimensions as batch structure. This behaviour supports multi-head attention, ensembles, time-dependent transformations, and nested batches without manual loops.

The leading dimensions follow broadcasting rules, while the final inner matrix dimensions must still match exactly. Predicting the result therefore requires combining broadcast reasoning with ordinary matrix shape reasoning.

Part 2 - Mathematical form

For shapes:

$$\mathcal{A} : (a_1, \ldots, a_r, m, n), \qquad \mathcal{B} : (b_1, \ldots, b_s, n, p)$$

the leading shapes are broadcast to $\boldsymbol{\beta}$, producing:

$$\text{shape}(\text{matmul}(\mathcal{A}, \mathcal{B})) = (\boldsymbol{\beta}, m, p)$$

Part 3 - Hints and Helper

Compare leading shapes from right to left, then check the final inner dimensions separately. Use `torch.broadcast_shapes()` to inspect batch compatibility and `torch.matmul()` for the final operation.

Part 4 - Python code skeleton

```
import torch

def E05(A, B):
    batch_shape = torch.broadcast_shapes(...)
    predicted_shape = (...)
    result = torch.matmul(...)
    return predicted_shape, result

def main():
    A = torch...
    B = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

2.4.7 Exercise 06 - Performance Comparison Challenge

Part 1 - Why this matters

Optimized matrix multiplication uses highly tuned kernels and parallel hardware, while Python loops introduce interpreter overhead and prevent efficient use of the GPU. Measuring this difference demonstrates why vectorized linear algebra is essential for artificial intelligence workloads.

Reliable benchmarking requires more than reading the clock once. Startup costs, GPU asynchrony, caching, matrix size, dtype, warm-up, and repeated trials can all distort a result if the experiment is not designed carefully.

Part 2 - Mathematical form

If T_{manual} and $T_{optimized}$ are measured execution times, speedup is:

$$S = \frac{T_{manual}}{T_{optimized}}$$

Both implementations must compute equivalent outputs before performance is compared.

Part 3 - Hints and Helper

Warm up each method, repeat measurements, and compare a robust statistic such as the median. Synchronize CUDA before timing boundaries. Validate outputs with `torch.allclose()` and avoid including tensor creation in only one method.

Part 4 - Python code skeleton

```
import time
import torch

def E06(A, B):
    if A.is_cuda:
        torch.cuda.synchronize()
    start = time.perf_counter()
    optimized = ...
    if A.is_cuda:
        torch.cuda.synchronize()
    optimized_time = ...
    return optimized, optimized_time

def main():
    A = torch...
    B = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

2.4.8 Exercise 07 - Matrix Multiplication Debugging

Part 1 - Why this matters

Matrix multiplication failures often originate from incorrect shape, axis order, dtype, or device rather than the multiplication function itself. A clear debugging process isolates these conditions before changing the mathematics.

Some bugs do not raise exceptions. Accidentally transposing the wrong matrix or broadcasting an unintended batch axis can produce a valid result with incorrect meaning, so debugging must include expected output shape and numerical tests.

Part 2 - Mathematical form

For $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{q \times p}$, the diagnostic condition is:

$$n = q$$

If a transpose is intended, its shape effect must be written explicitly before checking compatibility.

Part 3 - Hints and Helper

Print shape, ndim, dtype, and device immediately before multiplication. State the expected mathematical shapes, identify which axis is wrong, then make the smallest justified correction. Do not apply random transposes until the code runs.

Part 4 - Python code skeleton

```
import torch

def E07(A, B):
    print(A.shape, A.dtype, A.device)
    print(B.shape, B.dtype, B.device)
    fixed_A = ...
    fixed_B = ...
    result = torch.matmul(...)
    return result

def main():
    A = torch...
    B = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

2.4.9 Exercise 08 - Numerical Precision Challenge

Part 1 - Why this matters

Matrix multiplication accumulates many products, so rounding error can grow with matrix size and value scale. Different dtypes balance precision, memory, speed, and hardware support, and may produce slightly different results.

Lower precision can accelerate neural-network training but is more vulnerable to overflow, underflow, and loss of small contributions. Comparing results requires tolerances rather than exact equality and a higher-precision reference when practical.

Part 2 - Mathematical form

For approximate result $\widehat{\mathbf{C}}$ and reference $\mathbf{C}$:

$$E_{abs} = \|\widehat{\mathbf{C}} - \mathbf{C}\|_\infty$$

$$E_{rel} = \frac{\|\widehat{\mathbf{C}} - \mathbf{C}\|_\infty}{\|\mathbf{C}\|_\infty + \varepsilon}$$

Part 3 - Hints and Helper

Compute the same product in multiple floating dtypes and compare against a `float64` reference where supported. Use `torch.allclose()` with explicit tolerances and report absolute and relative error, not only pass or fail.

Part 4 - Python code skeleton

```
import torch

def E08(A, B):
    reference = torch.matmul(A.to(...), B.to(...))
    lower_precision = torch.matmul(A.to(...), B.to(...))
    absolute_error = ...
    relative_error = ...
    return absolute_error, relative_error

def main():
    A = torch...
    B = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

2.4.10 Exercise 09 - Custom Linear Layer Implementation

Part 1 - Why this matters

A linear neural-network layer is matrix multiplication combined with a broadcasted bias. Implementing one manually connects matrix-shape rules to model parameters, batching, initialization, and automatic differentiation.

A correct custom layer must register its weights and bias as parameters so optimizers can discover them. It must also transform the final feature axis and preserve any leading batch dimensions.

Part 2 - Mathematical form

For input $\mathbf{X} \in \mathbb{R}^{B \times n}$, weight $\mathbf{W} \in \mathbb{R}^{m \times n}$, and bias $\mathbf{b} \in \mathbb{R}^{m}$:

$$\mathbf{Y} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b} \in \mathbb{R}^{B \times m}$$

Part 3 - Hints and Helper

Subclass `torch.nn.Module`, store trainable tensors with `nn.Parameter`, and define `forward`. Initialize parameters with a scale appropriate to input width. Compare output and gradients with `nn.Linear` configured with identical parameters.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn

class CustomLinear(nn.Module):
    def __init__(self, in_features, out_features):
        super().__init__()
        self.weight = nn.Parameter(...)
        self.bias = nn.Parameter(...)

    def forward(self, x):
        return ...

def E09(x, in_features, out_features):
    layer = CustomLinear(...)
    return layer(...)

def main():
    x = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

2.5 ALA03 - Outer vs Inner Product

Mathematics and Theory

2.5.1 Exercise 00 - Inner Product Coding Challenge

Part 1 - Why this matters

The inner product compresses two aligned vectors into one scalar that measures their weighted alignment. It appears in similarity scores, linear models, attention, projections, and the calculation of angles between vectors.

Coding the operation requires more than multiplying values. The vectors must share a compatible dimension, dtype, and device, and the implementation should preserve automatic differentiation when the inputs participate in a neural network.

Part 2 - Mathematical form

For $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$:

$$\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{i=1}^{n} x_i y_i = \mathbf{x}^\mathsf{T} \mathbf{y} \in \mathbb{R}$$

Part 3 - Hints and Helper

Implement the calculation using aligned multiplication and reduction, then compare it with `torch.dot()`. Check that the result is scalar and that gradients can flow to both vectors.

Part 4 - Python code skeleton

```
import torch

def E00(x, y):
    products = ...
    inner_product = torch.sum(...)
    return inner_product

def main():
    x = torch...
    y = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

2.5.2 Exercise 01 - Outer Product Coding Challenge

Part 1 - Why this matters

The outer product records every pairwise interaction between two vectors. It creates a matrix rather than a scalar and is useful for feature interactions, rank-one updates, covariance-like constructions, and tensor factorization.

Because its output contains one entry for every pair of input components, its memory cost grows as the product of vector lengths. The operation preserves all pairwise information instead of summing it away.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^m$ and $\mathbf{y} \in \mathbb{R}^n$:

$$\mathbf{M} = \mathbf{x}\mathbf{y}^\mathsf{T} \in \mathbb{R}^{m \times n}$$

$$M_{ij} = x_i y_j$$

Part 3 - Hints and Helper

Use `torch.outer()` or reshape the vectors to $(m, 1)$ and $(1, n)$ before broadcasted multiplication. Verify that the output axes correspond to the first and second vectors in that order.

Part 4 - Python code skeleton

```
import torch

def E01(x, y):
    outer_product = torch...
    return outer_product

def main():
    x = torch...
    y = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

2.5.3 Exercise 02 - Shape Interpretation Challenge

Part 1 - Why this matters

Inner and outer products use the same two vectors but produce fundamentally different shapes. Correct shape interpretation prevents a scalar similarity operation from being confused with a matrix of pairwise interactions.

Shape also reveals what information an operation preserves. The inner product contracts the shared coordinate axis, while the outer product introduces two independent axes and performs no reduction.

Part 2 - Mathematical form

For $\mathbf{x} \in \mathbb{R}^m$ and $\mathbf{y} \in \mathbb{R}^n$:

$$\text{shape}(\mathbf{x}\mathbf{y}^\mathsf{T}) = (m, n)$$

The inner product is defined only when $m = n$ and has scalar shape:

$$\text{shape}(\mathbf{x}^\mathsf{T}\mathbf{y}) = ()$$

Part 3 - Hints and Helper

Write a function that predicts validity and output shape before computing either product. Then compare the prediction with PyTorch. Remember that a scalar tensor has zero dimensions even though it contains one element.

Part 4 - Python code skeleton

```
import torch

def E02(x, y):
    inner_valid = ...
    inner_shape = ...
    outer_shape = (..., ...)
    return inner_valid, inner_shape, outer_shape

def main():
    x = torch...
    y = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

2.5.4 Exercise 03 - Rank Analysis Challenge

Part 1 - Why this matters

An outer product creates a structured matrix whose columns are scaled versions of one vector. This means the matrix carries pairwise values but only one independent column direction when both vectors are nonzero.

Rank analysis connects a coding operation to linear dependence and low-rank models. It explains why sums of a small number of outer products can represent compressed matrices and why one outer product cannot describe an arbitrary full-rank matrix.

Part 2 - Mathematical form

For $\mathbf{M} = \mathbf{x}\mathbf{y}^\mathsf{T}$:

$$\operatorname{rank}(\mathbf{M}) \leq 1$$

More precisely:

$$\operatorname{rank}(\mathbf{M}) = \begin{cases} 0, & \mathbf{x} = \mathbf{0} \text{ or } \mathbf{y} = \mathbf{0}, \\ 1, & \text{otherwise.} \end{cases}$$

Part 3 - Hints and Helper

Construct outer products for nonzero and zero vectors, then use `torch.linalg.matrix_rank()`. Use floating-point tensors and remember that numerical rank depends on tolerance for nearly zero values.

Part 4 - Python code skeleton

```
import torch

def E03(x, y):
    matrix = torch.outer(...)
    rank = torch.linalg.matrix_rank(...)
```

```
    return matrix, rank

def main():
    x = torch...
    y = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

2.5.5 Exercise 04 - Feature Interaction Matrix Design

Part 1 - Why this matters

A feature interaction matrix represents how every component of one feature vector combines with every component of another. Such matrices can expose cross-feature patterns that a single inner-product score would hide.

Designing the matrix requires deciding whether interactions should be computed per sample, averaged across a batch, normalized, or weighted. These choices change the interpretation even when the underlying operation remains an outer product.

Part 2 - Mathematical form

For one sample:

$$\mathbf{I} = \mathbf{x}\mathbf{y}^{\mathsf{T}}, \qquad I_{ij} = x_i y_j$$

For batches $\mathbf{X} \in \mathbb{R}^{B\times m}$ and $\mathbf{Y} \in \mathbb{R}^{B\times n}$, a mean interaction matrix is:

$$\bar{\mathbf{I}} = \frac{1}{B}\sum_{b=1}^{B} \mathbf{x}_b \mathbf{y}_b^{\mathsf{T}}$$

Part 3 - Hints and Helper

Use broadcasting, `torch.einsum()`, or batched matrix multiplication. Keep the batch axis until the final aggregation and verify whether the desired output is (B, m, n) or (m, n).

Part 4 - Python code skeleton

```
import torch

def E04(X, Y):
    batch_interactions = ...
    mean_interaction = torch.mean(..., dim=...)
    return mean_interaction

def main():
    X = torch...
    Y = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

2.5.6 Exercise 05 - Memory Cost Comparison Challenge

Part 1 - Why this matters

An inner product stores one output value, while an outer product stores every pairwise interaction. For long vectors or large batches, this difference can turn a small computation into a major memory allocation.

Memory reasoning must include dtype size as well as element count. A matrix with the same shape consumes different bytes in `float16`, `float32`, and `float64`, and intermediate tensors may increase peak memory beyond the final output size.

Part 2 - Mathematical form

For lengths m and n and b bytes per element:

$$M_{inner} = b$$

$$M_{outer} = mnb$$

For batch size B, explicit batched outer products require $Bmnb$ bytes.

Part 3 - Hints and Helper

Use `tensor.numel() * tensor.element_size()` to calculate storage bytes. Compare predicted and actual output storage for several sizes and dtypes. Do not confuse storage size with the complete runtime's peak memory use.

Part 4 - Python code skeleton

```
import torch

def E05(x, y):
    inner = ...
    outer = ...
    inner_bytes = ...
    outer_bytes = ...
    return inner_bytes, outer_bytes

def main():
    x = torch...
    y = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

2.5.7 Exercise 06 - Use-Case Driven Product Selection

Part 1 - Why this matters

Selecting an inner or outer product should follow the information required by the application. A similarity score, projection coefficient, or attention logit normally needs contraction

to a scalar, while a complete interaction map or rank-one matrix construction needs an outer product.

The wrong choice may still produce valid code but an unusable shape or excessive memory cost. A disciplined design process predicts the desired output, explains which indices should remain, and only then selects the PyTorch operation.

Part 2 - Mathematical form

Choose the inner product when the required output is:

$$s = \sum_i x_i y_i$$

Choose the outer product when the required output is:

$$M_{ij} = x_i y_j$$

The first contracts an aligned index; the second preserves both indices.

Part 3 - Hints and Helper

Write a function that accepts a use-case label and validates the input shapes before selecting `torch.dot()` or `torch.outer()`. Return both the result and a short reason for the selected operation.

Part 4 - Python code skeleton

```
import torch

def E06(x, y, use_case):
    if use_case == "similarity":
        result = ...
        reason = ...
    elif use_case == "interaction_matrix":
        result = ...
        reason = ...
    else:
        raise ValueError(...)
    return result, reason

def main():
    x = torch...
    y = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

2.6 ALA04 - Broadcasting Rules & Mechanics

Mathematics and Theory

2.6.1 Exercise 00 - Simple Broadcasting Addition

Part 1 - Why this matters

Artificial intelligence programs frequently add information stored at different levels of detail. A matrix may contain a batch of feature vectors, while a single vector may contain a bias or offset shared by every example. Broadcasting makes this addition concise by matching the shared vector to every compatible row.

Understanding this mechanism is important because the short expression hides a precise shape transformation. Predicting the resulting dimensions before running the code helps prevent silent semantic mistakes and prepares the reader for bias addition in linear layers and other neural network operations.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{b} \in \mathbb{R}^{n}$. Broadcasting treats $\mathbf{b}$ as if its row were available for every row of $\mathbf{A}$.

Define:

$$\mathbf{C} = \mathbf{A} + \mathbf{b}, \qquad \mathbf{C} \in \mathbb{R}^{m \times n}.$$

Element-wise:

$$C_{ij} = A_{ij} + b_j, \qquad 1 \leq i \leq m,\ 1 \leq j \leq n.$$

The dimension n matches directly, and the missing leading dimension of $\mathbf{b}$ is treated as a broadcastable dimension of size one.

Part 3 - Hints and Helper

In PyTorch, the addition operator and `torch.add()` both apply broadcasting automatically. Inspect `A.shape`, `b.shape`, and the expected output shape before performing the operation. Do not use `repeat()` merely to copy the vector into multiple rows; broadcasting can represent the same computation without explicitly constructing those copies.

Part 4 - Python code skeleton

```
import torch

def E00(A, b):
    C = torch...
    return C

def main():
    A = torch...
    b = torch...
    print(E00(A, b))

if __name__ == "__main__":
    main()
```

2.6.2 Exercise 01 - Broadcasting Multiplication

Part 1 - Why this matters

Feature maps often require a different scale for every channel while sharing that scale across all samples and spatial positions. Broadcasting multiplication expresses this operation directly, avoiding the need to manually construct a full-sized tensor of repeated channel values.

This pattern appears in normalization, attention, calibration, and learned gating mechanisms. Correctly positioning singleton dimensions is essential: the same numbers can produce a valid but conceptually incorrect result when their axes do not represent the intended batch, channel, height, and width roles.

Part 2 - Mathematical form

Let $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$ and let $\mathbf{s} \in \mathbb{R}^{C}$. Reshape the scale conceptually as $\tilde{\mathbf{s}} \in \mathbb{R}^{1\times C\times 1\times 1}$.

Define:

$$\mathcal{Y} = \mathcal{X} \odot \tilde{\mathbf{s}}, \qquad \mathcal{Y} \in \mathbb{R}^{B\times C\times H\times W}.$$

Element-wise:

$$Y_{bchw} = X_{bchw} s_c.$$

The singleton axes of $\tilde{\mathbf{s}}$ broadcast across the batch and spatial dimensions, while its channel axis matches C.

Part 3 - Hints and Helper

Use `unsqueeze()` or indexing with `None` to place the channel dimension correctly, then apply `torch.mul()` or `*`. Verify that the scale has conceptual shape `(1, C, 1, 1)` rather than relying only on the fact that an operation happens to run.

Part 4 - Python code skeleton

```
import torch

def E01(X, scale):
    scale = scale...
    Y = torch...
    return Y

def main():
    X = torch...
    scale = torch...
    print(E01(X, scale))

if __name__ == "__main__":
    main()
```

2.6.3 Exercise 02 - Broadcasting with Scalars

Part 1 - Why this matters

Scalar values are used throughout numerical computing to shift, scale, clip, or normalize every entry of a tensor consistently. Broadcasting allows a single number to interact with a tensor of any shape, making mathematical expressions both compact and close to their theoretical notation.

Although scalar broadcasting is the simplest broadcasting case, it establishes an important mental model: an operand does not need to be physically copied to match the other tensor. This becomes especially useful when interpreting learning rates, temperature parameters, regularization coefficients, and normalization constants in machine learning code.

Part 2 - Mathematical form

Let $\mathcal{X} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$ and let $\alpha \in \mathbb{R}$ be a scalar.
Define a scaled and shifted tensor:

$$\mathcal{Y} = \alpha\mathcal{X} + \alpha.$$

For every valid multi-index $(i_1, \ldots, i_k)$:

$$Y_{i_1 \ldots i_k} = \alpha X_{i_1 \ldots i_k} + \alpha.$$

The output retains the shape of $\mathcal{X}$ because the scalar is compatible with every tensor dimension.

Part 3 - Hints and Helper

Create a tensor with two or more dimensions and a Python scalar or zero-dimensional PyTorch tensor. Apply ordinary arithmetic operators, then compare the input and output shapes. If the scalar is stored as a tensor, also consider whether its `dtype` and `device` are compatible with the input.

Part 4 - Python code skeleton

```
import torch

def E02(X, alpha):
    Y = ...
    return Y

def main():
    X = torch...
    alpha = ...
    print(E02(X, alpha))

if __name__ == "__main__":
    main()
```

2.6.4 Exercise 03 - Broadcasting Across Dimensions

Part 1 - Why this matters

Real tensor programs commonly combine operands with several independent roles, such as batches, channels, rows, and columns. Broadcasting across multiple axes allows each operand to vary only along the dimensions it represents while being shared across the remaining dimensions.

Mastering this operation reduces unnecessary data duplication and makes complex shape flows easier to express. It also requires disciplined dimension reasoning, because broadcasting compares sizes from the trailing dimension toward the leading dimension rather than matching axes according to their names.

Part 2 - Mathematical form

Let $\mathcal{A} \in \mathbb{R}^{B\times 1\times H\times W}$ and $\mathcal{B} \in \mathbb{R}^{1\times C\times 1\times 1}$.

Define:

$$\mathcal{C} = \mathcal{A} + \mathcal{B}, \qquad \mathcal{C} \in \mathbb{R}^{B\times C\times H\times W}.$$

Element-wise:

$$C_{bchw} = A_{b1hw} + B_{1c11}.$$

In general, two axes are compatible when their sizes are equal or when at least one size is 1. Missing leading axes are treated as axes of size 1.

Part 3 - Hints and Helper

Write both shapes with their trailing dimensions aligned. Compare each pair from right to left, selecting the non-singleton size for the output. Use `torch.broadcast_shapes()` to check your predicted shape, then perform the arithmetic operation and verify the result.

Part 4 - Python code skeleton

```
import torch

def E03(A, B):
    expected_shape = torch...
    C = ...
    return expected_shape, C

def main():
    A = torch...
    B = torch...
    print(E03(A, B))

if __name__ == "__main__":
    main()
```

2.6.5 Exercise 04 - Invalid Broadcasting Detection

Part 1 - Why this matters

Not every pair of tensor shapes can be combined through broadcasting. Detecting an incompatible axis before performing an operation produces clearer diagnostics than allowing a low-level runtime error to appear deep inside a data pipeline or neural network.

A compatibility checker also strengthens shape reasoning by separating the rule from the computation itself. The reader must align dimensions, account for missing leading axes, and identify the exact axis where two non-singleton sizes conflict.

Part 2 - Mathematical form

Let the aligned shapes of two tensors be $(a_1, \ldots, a_k)$ and $(b_1, \ldots, b_k)$, after padding the shorter shape with leading ones.

Broadcasting is valid if and only if:

$$\forall r \in \{1, \ldots, k\}, \qquad a_r = b_r \ \vee \ a_r = 1 \ \vee \ b_r = 1.$$

When valid, the output size along axis r is:

$$c_r = \max(a_r, b_r).$$

If any aligned axis fails the compatibility condition, the complete operation is invalid.

Part 3 - Hints and Helper

Read the two shape tuples and left-pad the shorter one with ones. Examine the paired sizes without carrying out tensor arithmetic. Return both a Boolean result and useful information about the conflicting axis. You may compare your custom logic with `torch.broadcast_shapes()`, which raises an error for incompatible shapes.

Part 4 - Python code skeleton

```
import torch

def E04(shape_a, shape_b):
    aligned_a = ...
    aligned_b = ...
    is_valid = ...
    return is_valid

def main():
    shape_a = (...)
    shape_b = (...)
    print(E04(shape_a, shape_b))

if __name__ == "__main__":
    main()
```

2.6.6 Exercise 05 - Broadcasting Debugging Challenge

Part 1 - Why this matters

Broadcasting errors often originate from a tensor whose values are correct but whose dimensions are arranged incorrectly. A feature vector intended for the channel axis may accidentally align with width, or an omitted singleton dimension may cause an otherwise meaningful operation to fail.

Effective debugging therefore requires more than changing shapes until the code runs. The programmer must identify the semantic role of every axis, predict the desired output, and introduce singleton dimensions only where the data is meant to be shared.

Part 2 - Mathematical form

Suppose $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$ and a bias $\mathbf{b} \in \mathbb{R}^{C}$ must be added along the channel axis.

The direct shapes

$$(B, C, H, W) \quad \text{and} \quad (C)$$

compare C with W at the trailing axis and may be invalid or semantically wrong. The intended bias shape is:

$$\widetilde{\mathbf{b}} \in \mathbb{R}^{1\times C\times 1\times 1}.$$

Then:

$$Y_{bchw} = X_{bchw} + b_c.$$

Part 3 - Hints and Helper

Print the input shapes and label their conceptual axes. Align them from the right, locate the first conflicting or misplaced dimension, and use `unsqueeze()`, `reshape()`, or indexed `None` dimensions to express the intended sharing. Avoid solving the error with arbitrary `repeat()` calls.

Part 4 - Python code skeleton

```
import torch

def E05(X, bias):
    print("X shape:", ...)
    print("bias shape:", ...)
    corrected_bias = bias...
    Y = ...
    return Y

def main():
    X = torch...
    bias = torch...
    print(E05(X, bias))

if __name__ == "__main__":
    main()
```

2.6.7 Exercise 06 - Memory-efficient Broadcasting

Part 1 - Why this matters

Large tensors can make explicit repetition expensive in both memory and execution time. Broadcasting and expanded views allow one set of values to participate in a larger computation without first allocating storage for every repeated copy.

This distinction becomes significant in high-resolution feature maps and large batches. Learning when to rely on implicit broadcasting or `expand()`, and when actual independent copies from `repeat()` are necessary, helps produce scalable and predictable tensor programs.

Part 2 - Mathematical form

Let $\mathbf{b} \in \mathbb{R}^C$ and suppose it is shared across a batch of size B. The logical expanded matrix $\mathbf{B} \in \mathbb{R}^{B \times C}$ satisfies:

$$B_{ij} = b_j.$$

Explicit repetition stores BC values, while a broadcasted or expanded view can reference the original C values through its stride information. For $\mathbf{X} \in \mathbb{R}^{B \times C}$:

$$Y_{ij} = X_{ij} + b_j$$

can therefore be computed without materializing B copies of $\mathbf{b}$.

Part 3 - Hints and Helper

Construct equivalent operands using `expand()` and `repeat()`. Compare their shapes, element counts, storage relationships, and strides. Remember that an expanded view can contain zero strides and should not be modified in place when multiple logical entries refer to the same stored value.

Part 4 - Python code skeleton

```
import torch

def E06(X, bias):
    expanded = bias...
    repeated = bias...
    Y = ...
    return Y, expanded, repeated

def main():
    X = torch...
    bias = torch...
    result = E06(X, bias)
    print(result)

if __name__ == "__main__":
    main()
```

2.6.8 Exercise 07 - Broadcasting in Neural Layers

Part 1 - Why this matters

Neural layers routinely apply one learned parameter across many observations. After a linear transformation, a bias vector is added to every item in a batch; in convolutional networks, one bias value may be shared across all spatial locations of its channel. Broadcasting expresses this parameter sharing directly.

Implementing the pattern manually reveals how a layer's algebra maps to tensor shapes. It also makes clear why the bias contains one value per output feature rather than one value per sample, helping the reader distinguish learned model parameters from temporary expanded views.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{B \times d_{\text{in}}}$, $\mathbf{W} \in \mathbb{R}^{d_{\text{out}} \times d_{\text{in}}}$, and $\mathbf{b} \in \mathbb{R}^{d_{\text{out}}}$.
A linear layer is defined as:

$$\mathbf{Y} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}, \qquad \mathbf{Y} \in \mathbb{R}^{B \times d_{\text{out}}}.$$

Element-wise:

$$Y_{ij} = \sum_{k=1}^{d_{\text{in}}} X_{ik} W_{jk} + b_j.$$

Broadcasting shares b_j across the batch axis while preserving a distinct bias for every output feature.

Part 3 - Hints and Helper

First compute the matrix multiplication with `torch.matmul()` or the `@` operator. Confirm that its final dimension equals the length of the bias vector, then add the bias directly and let PyTorch broadcast it across the batch. Compare the result shape with the prediction from the mathematical form.

Part 4 - Python code skeleton

```
import torch

def E07(X, W, bias):
    linear_output = torch...
    Y = ...
    return Y

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E07(X, W, bias))

if __name__ == "__main__":
    main()
```

2.7 ALA05 - Shape Reasoning & Dimension Flow

Mathematics and Theory

2.7.1 Exercise 00 - Shape Tracking Basics

Part 1 - Why this matters

Tensor values cannot be interpreted correctly without knowing how their axes are organized. A shape describes the number of dimensions and the size of every dimension, allowing the programmer to distinguish batches, features, channels, rows, columns, and other structural roles.

Shape tracking is therefore a basic debugging and design skill in artificial intelligence programming. Predicting the shape before and after each operation helps expose incorrect assumptions early and makes tensor code easier to explain, test, and extend.

Part 2 - Mathematical form

Let $\mathcal{X}$ be a tensor with shape:

$$\text{shape}(\mathcal{X}) = (d_1, d_2, \ldots, d_k).$$

The number of dimensions is:

$$\dim(\mathcal{X}) = k,$$

and the total number of elements is:

$$\text{numel}(\mathcal{X}) = \prod_{i=1}^{k} d_i.$$

If $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$, its axes may represent batch, channel, height, and width respectively.

Part 3 - Hints and Helper

In PyTorch, inspect `tensor.shape`, `tensor.dim()`, and `tensor.numel()`. Record the meaning of each axis rather than reporting only its numeric size. Verify manually that multiplying all shape dimensions produces the same element count returned by PyTorch.

Part 4 - Python code skeleton

```
import torch

def E00(X):
    shape = X...
    dimensions = X...
    elements = X...
    return shape, dimensions, elements

def main():
    X = torch...
    print(E00(X))

if __name__ == "__main__":
    main()
```

2.7.2 Exercise 01 - Multi-step Shape Prediction

Part 1 - Why this matters

Neural network programs transform tensor shapes through several consecutive operations. A tensor may be transposed, reshaped, reduced, and expanded before it reaches the next layer, so understanding only one operation at a time is not enough to guarantee that the complete pipeline is valid.

Multi-step prediction trains the reader to follow dimension flow without relying on trial and error. It also reveals which transformations preserve the number of elements, which remove axes, and which change the logical interpretation of the same stored values.

Part 2 - Mathematical form

Let $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$. Consider the sequence:

$$\mathcal{X}_1 = \text{permute}(\mathcal{X}, 0, 2, 3, 1),$$

$$\mathcal{X}_2 = \text{reshape}(\mathcal{X}_1, B, HW, C),$$

$$\mathcal{X}_3 = \text{mean}(\mathcal{X}_2, \text{dim} = 1).$$

The corresponding shape flow is:

$$(B, C, H, W) \to (B, H, W, C) \to (B, HW, C) \to (B, C).$$

The reshape is valid because both intermediate tensors contain $BCHW$ elements.

Part 3 - Hints and Helper

Write the expected shape after every line before running the code. Track axis meaning as well as axis size, and check the element count before each reshape. Remember that a reduction removes its selected dimension unless `keepdim=True` is used.

Part 4 - Python code skeleton

```
import torch

def E01(X):
    X1 = X...
    X2 = X1...
    X3 = X2...
    return X1.shape, X2.shape, X3.shape

def main():
    X = torch...
    print(E01(X))

if __name__ == "__main__":
    main()
```

2.7.3 Exercise 02 - Shape Mismatch Debugging

Part 1 - Why this matters

Many tensor failures are caused by incompatible dimensions rather than incorrect numerical formulas. Matrix multiplication, concatenation, broadcasting, and neural layers each impose different shape requirements, and an error message may identify sizes without explaining their intended meanings.

Systematic shape debugging replaces random reshaping with evidence. By examining the operation's mathematical contract and tracing the origin of each axis, the programmer can correct the actual structural mistake without silently changing the data interpretation.

Part 2 - Mathematical form

Let $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{q \times p}$. The product $\mathbf{AB}$ is defined only when:

$$n = q.$$

When the condition holds:

$$\mathbf{C} = \mathbf{AB} \in \mathbb{R}^{m \times p}, \qquad C_{ij} = \sum_{k=1}^{n} A_{ik} B_{kj}.$$

If $n \neq q$, the mismatch must be corrected at the source or through a mathematically justified transformation such as transposition.

Part 3 - Hints and Helper

Print both shapes and state which dimensions the operation expects to match. Create a compatibility check before calling `torch.matmul()`. Do not use `reshape()` merely to force matching sizes; first determine whether the second tensor has been constructed or oriented incorrectly.

Part 4 - Python code skeleton

```
import torch

def E02(A, B):
    compatible = ...
    if not compatible:
        return ...
    C = torch...
    return C

def main():
    A = torch...
    B = torch...
    print(E02(A, B))

if __name__ == "__main__":
    main()
```

2.7.4 Exercise 03 - Dynamic Shape Handling

Part 1 - Why this matters

Production models often receive batches whose size changes between calls, and image or sequence dimensions may also vary. Code that assumes fixed numeric sizes can work for one example yet fail on the final smaller batch or on data from a different source.

Dynamic shape handling makes tensor functions reusable across valid inputs. The key is to derive new dimensions from the current tensor while preserving required relationships, rather than embedding constants that describe only the original test case.

Part 2 - Mathematical form

Let $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$, where B, H, and W may vary between calls. Flatten the non-batch dimensions:

$$\mathbf{Y} = \text{reshape}(\mathcal{X}, B, CHW), \qquad \mathbf{Y} \in \mathbb{R}^{B\times CHW}.$$

Equivalently, the second dimension can be inferred from the invariant element count:

$$\text{numel}(\mathbf{Y}) = \text{numel}(\mathcal{X}) = BCHW.$$

The batch dimension remains independent for every valid positive value of B.

Part 3 - Hints and Helper

Read the batch size from `X.shape[0]` and let PyTorch infer one reshape dimension using `-1`. Test the function with several batch and spatial sizes. Confirm that the output always retains the original batch size and that its element count remains unchanged.

Part 4 - Python code skeleton

```
import torch

def E03(X):
    batch_size = X.shape[...]
    Y = X...
    return Y

def main():
    X1 = torch...
    X2 = torch...
    print(E03(X1).shape)
    print(E03(X2).shape)

if __name__ == "__main__":
    main()
```

2.7.5 Exercise 04 - Shape-safe Function Design

Part 1 - Why this matters

A tensor function should communicate and enforce the shapes it accepts. Without clear checks, an invalid input may fail much later or, more dangerously, produce a valid output whose axes carry the wrong meaning through accidental broadcasting or an unintended reduction.

Shape-safe design turns structural expectations into explicit contracts. Helpful validation messages make functions easier to reuse, while preservation checks ensure that an operation does not lose or mix information unexpectedly.

Part 2 - Mathematical form

Suppose a function normalizes a batch of feature vectors $\mathbf{X} \in \mathbb{R}^{B \times F}$. Its domain requires:

$$\dim(\mathbf{X}) = 2, \qquad B > 0, \qquad F > 0.$$

For each row, define:

$$Y_{ij} = \frac{X_{ij}}{\sqrt{\sum_{k=1}^{F} X_{ik}^2 + \varepsilon}}, \qquad \varepsilon > 0.$$

The function must preserve the shape:

$$\text{shape}(\mathbf{Y}) = (B, F).$$

Part 3 - Hints and Helper

Validate the tensor rank and feature size before computing the result. Use an informative `ValueError` or an assertion that describes the expected and received shapes. During norm calculation, preserve the reduced axis with `keepdim=True` so division broadcasts along the intended feature axis.

Part 4 - Python code skeleton

```
import torch

def E04(X, epsilon=1e-8):
    if X.dim() ...:
        raise ValueError(...)
    norms = torch...
    Y = ...
    return Y

def main():
    X = torch...
    print(E04(X))

if __name__ == "__main__":
    main()
```

2.7.6 Exercise 05 - Model Shape Pipeline Validation

Part 1 - Why this matters

A model is a sequence of shape contracts. The output of preprocessing becomes the input of a layer, the layer output feeds an activation or reduction, and a final representation must match the prediction head. One incorrect transition can invalidate every later stage.

Pipeline validation records these transitions and checks them at meaningful boundaries. This provides faster debugging than inspecting only the final error and creates a compact structural description that remains useful when batch sizes or model parameters change.

Part 2 - Mathematical form

Let a batch of images be $\mathcal{X} \in \mathbb{R}^{B\times C\times H\times W}$. Consider a pipeline that flattens each image and applies two linear transformations:

$$\mathbf{X}_1 = \text{flatten}(\mathcal{X}, 1) \in \mathbb{R}^{B\times CHW},$$
$$\mathbf{X}_2 = \mathbf{X}_1\mathbf{W}_1^\mathsf{T} + \mathbf{b}_1 \in \mathbb{R}^{B\times D},$$
$$\mathbf{Y} = \mathbf{X}_2\mathbf{W}_2^\mathsf{T} + \mathbf{b}_2 \in \mathbb{R}^{B\times K}.$$

Therefore $\mathbf{W}_1 \in \mathbb{R}^{D\times CHW}$ and $\mathbf{W}_2 \in \mathbb{R}^{K\times D}$ are required.

Part 3 - Hints and Helper

Store the shape after every pipeline stage and compare it with the expected contract. Validate the input feature dimension of each weight matrix before performing multiplication. Test with more than one batch size to confirm that only the batch axis changes while all learned feature dimensions remain fixed.

Part 4 - Python code skeleton

```
import torch

def E05(X, W1, b1, W2, b2):
    shapes = [X.shape]
    X1 = X...
    shapes.append(X1.shape)
    X2 = ...
    shapes.append(X2.shape)
    Y = ...
    shapes.append(Y.shape)
    return Y, shapes

def main():
    X = torch...
    W1, b1 = torch..., torch...
    W2, b2 = torch..., torch...
    print(E05(X, W1, b1, W2, b2))

if __name__ == "__main__":
    main()
```

2.8 ALA06 - Basis, Span & Projection (Applied)

Mathematics and Theory

2.8.1 Exercise 00 - Vector Projection Implementation

Part 1 - Why this matters

Vector projection extracts the part of one vector that points in the direction of another. In artificial intelligence and data analysis, this operation helps measure directional agreement, isolate a chosen component, and express data in terms of meaningful reference directions.

Implementing projection directly connects the geometric idea with tensor code. It also highlights an important numerical requirement: the direction vector must not have zero length, because the projection formula divides by its squared norm.

Part 2 - Mathematical form

Let $\mathbf{x}, \mathbf{v} \in \mathbb{R}^n$, where $\mathbf{v} \neq \mathbf{0}$. The projection of $\mathbf{x}$ onto $\mathbf{v}$ is:

$$\text{proj}_{\mathbf{v}}(\mathbf{x}) = \frac{\mathbf{x}^\mathsf{T}\mathbf{v}}{\mathbf{v}^\mathsf{T}\mathbf{v}}\mathbf{v}.$$

The scalar projection coefficient is:

$$\alpha = \frac{\mathbf{x}^\mathsf{T}\mathbf{v}}{\|\mathbf{v}\|_2^2},$$

so the projected vector is $\alpha\mathbf{v} \in \mathbb{R}^n$.

Part 3 - Hints and Helper

Use `torch.dot()` for the numerator and denominator. Check that both inputs are one-dimensional, have equal lengths, and that the denominator is not zero. Compute the scalar coefficient first, then multiply it by the direction vector while preserving its shape.

Part 4 - Python code skeleton

```
import torch

def E00(x, v):
    numerator = torch...
    denominator = torch...
    projection = ...
    return projection

def main():
    x = torch...
    v = torch...
    print(E00(x, v))

if __name__ == "__main__":
    main()
```

2.8.2 Exercise 01 - Orthogonal Projection

Part 1 - Why this matters

An orthogonal projection separates a vector into a component inside a target direction and a residual perpendicular to that direction. This decomposition is useful for removing unwanted components, analyzing errors, and understanding how data relates to a chosen axis.

The perpendicularity condition provides a strong correctness test that goes beyond comparing expected numbers. If the implementation is correct, the dot product between the residual and the projection direction should be zero, apart from small floating-point error.

Part 2 - Mathematical form

Let $\mathbf{x}, \mathbf{u} \in \mathbb{R}^n$ and assume that $\|\mathbf{u}\|_2 = 1$. Define:

$$\mathbf{p} = (\mathbf{x}^\mathsf{T}\mathbf{u})\mathbf{u},$$

where $\mathbf{p}$ is the orthogonal projection of $\mathbf{x}$ onto the line spanned by $\mathbf{u}$.

The residual is:

$$\mathbf{r} = \mathbf{x} - \mathbf{p}.$$

Orthogonality requires:

$$\mathbf{u}^\mathsf{T}\mathbf{r} = 0.$$

Part 3 - Hints and Helper

Normalize the direction vector with `torch.linalg.vector_norm()` before computing the projection. Return both the projected component and the residual. Use `torch.dot()` and `torch.isclose()` to test whether the residual is orthogonal within a reasonable tolerance.

Part 4 - Python code skeleton

```
import torch

def E01(x, direction):
    unit_direction = direction / torch...
    projection = ...
    residual = ...
    orthogonality = torch...
    return projection, residual, orthogonality

def main():
    x = torch...
    direction = torch...
    print(E01(x, direction))

if __name__ == "__main__":
    main()
```

2.8.3 Exercise 02 - Projection Error Measurement

Part 1 - Why this matters

A projection is an approximation whenever the original vector does not lie entirely in the selected direction or subspace. Measuring the remaining error quantifies how much information the projection fails to represent and allows different approximation choices to be compared objectively.

Projection error appears in dimensionality reduction, least-squares fitting, signal reconstruction, and model compression. Both the residual vector and its norm are useful: one shows the direction of the missing information, while the other summarizes its magnitude as a single value.

Part 2 - Mathematical form

Let $\mathbf{x} \in \mathbb{R}^n$ and let $\hat{\mathbf{x}}$ be its projection. Define the residual:

$$\mathbf{e} = \mathbf{x} - \hat{\mathbf{x}}.$$

The absolute projection error is:

$$E = \|\mathbf{e}\|_2.$$

When $\|\mathbf{x}\|_2 \neq 0$, the relative error is:

$$E_{\text{rel}} = \frac{\|\mathbf{x} - \hat{\mathbf{x}}\|_2}{\|\mathbf{x}\|_2}.$$

Smaller values indicate that the projection preserves more of the original vector.

Part 3 - Hints and Helper

Compute the residual before calling `torch.linalg.vector_norm()`. Validate that the original and projected vectors have the same shape. Handle the zero-vector case explicitly when computing relative error, because its norm cannot be used as a denominator.

Part 4 - Python code skeleton

```
import torch

def E02(x, projected_x):
    residual = ...
    absolute_error = torch...
    relative_error = ...
    return residual, absolute_error, relative_error

def main():
    x = torch...
    projected_x = torch...
    print(E02(x, projected_x))

if __name__ == "__main__":
    main()
```

2.8.4 Exercise 03 - Subspace Projection Challenge

Part 1 - Why this matters

Projecting onto a subspace extends vector projection from one direction to several directions. It allows a high-dimensional observation to be represented using a smaller collection of basis vectors, retaining only the components that the chosen subspace can explain.

This operation is central to least-squares approximation and many representation methods. The implementation depends on whether the basis is orthonormal; using the simpler orthonormal formula on a general basis produces an incorrect result even when all tensor shapes are valid.

Part 2 - Mathematical form

Let $\mathbf{x} \in \mathbb{R}^n$ and let the columns of $\mathbf{A} \in \mathbb{R}^{n \times k}$ be linearly independent basis vectors. The projection matrix onto $\text{span}(\mathbf{A})$ is:

$$\mathbf{P} = \mathbf{A}(\mathbf{A}^\mathsf{T}\mathbf{A})^{-1}\mathbf{A}^\mathsf{T}.$$

The projected vector is:

$$\hat{\mathbf{x}} = \mathbf{P}\mathbf{x}.$$

If $\mathbf{Q}^\mathsf{T}\mathbf{Q} = \mathbf{I}$, then the orthonormal case simplifies to:

$$\hat{\mathbf{x}} = \mathbf{Q}\mathbf{Q}^\mathsf{T}\mathbf{x}.$$

Part 3 - Hints and Helper

Prefer solving the coefficient system with `torch.linalg.solve()` instead of explicitly computing an inverse. Check that the basis matrix has shape `(n, k)` and full column rank. Verify that the residual is orthogonal to every basis column by examining `A.T @ residual`.

Part 4 - Python code skeleton

```
import torch

def E03(x, A):
    gram_matrix = A.T @ ...
    right_side = A.T @ ...
    coefficients = torch.linalg...
    projected_x = ...
    return projected_x

def main():
    x = torch...
    A = torch...
    print(E03(x, A))

if __name__ == "__main__":
    main()
```

2.8.5 Exercise 04 - Feature Space Reduction

Part 1 - Why this matters

Feature vectors may contain many dimensions even when most useful variation lies inside a much smaller subspace. Projecting data onto a reduced basis replaces the original coordinates with fewer coefficients, decreasing storage and computation while preserving the information represented by that basis.

The reduced coordinates and reconstructed features serve different purposes. The coordinates are the compact representation used by later computations, whereas reconstruction maps those coordinates back to the original feature space so that information loss can be inspected.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{B \times D}$ contain B observations and let $\mathbf{Q} \in \mathbb{R}^{D \times K}$ contain K orthonormal basis vectors, where $K < D$ and $\mathbf{Q}^\mathsf{T}\mathbf{Q} = \mathbf{I}_K$.

The reduced feature representation is:

$$\mathbf{Z} = \mathbf{X}\mathbf{Q} \in \mathbb{R}^{B \times K}.$$

The reconstruction is:

$$\widehat{\mathbf{X}} = \mathbf{Z}\mathbf{Q}^\mathsf{T} \in \mathbb{R}^{B \times D}.$$

Thus each observation changes from D features to K coordinates.

Part 3 - Hints and Helper

Use matrix multiplication for both reduction and reconstruction. Check the basis with `Q.T @ Q` and compare it with an identity matrix using `torch.allclose()`. Print all intermediate shapes and measure the reconstruction error without assuming that it must be zero.

Part 4 - Python code skeleton

```
import torch

def E04(X, Q):
    reduced = torch...
    reconstructed = torch...
    error = ...
    return reduced, reconstructed, error

def main():
    X = torch...
    Q = torch...
    print(E04(X, Q))

if __name__ == "__main__":
    main()
```

2.8.6 Exercise 05 - Projection-based Optimization Insight

Part 1 - Why this matters

Optimization steps sometimes need to satisfy a linear constraint. An ordinary gradient may point partly outside the set of allowed directions, so applying it directly can violate the constraint even when it reduces the objective function. Projection removes the forbidden component before the parameters are updated.

This idea provides a practical link between linear algebra and constrained learning. By decomposing a gradient into admissible and inadmissible parts, the reader can see how geometric structure changes an optimization direction without changing the original loss calculation.

Part 2 - Mathematical form

Let $\mathbf{g} \in \mathbb{R}^n$ be a gradient and let the feasible directions satisfy:

$$\mathbf{a}^\mathsf{T}\mathbf{d} = 0, \qquad \mathbf{a} \neq \mathbf{0}.$$

Remove the component of $\mathbf{g}$ parallel to $\mathbf{a}$:

$$\mathbf{g}_\perp = \mathbf{g} - \frac{\mathbf{g}^\mathsf{T}\mathbf{a}}{\mathbf{a}^\mathsf{T}\mathbf{a}}\mathbf{a}.$$

For learning rate $\eta > 0$, a projected update is:

$$\boldsymbol{\theta}_{\text{new}} = \boldsymbol{\theta} - \eta\mathbf{g}_\perp.$$

The projected direction satisfies $\mathbf{a}^\mathsf{T}\mathbf{g}_\perp = 0$.

Part 3 - Hints and Helper

Compute the forbidden gradient component using the vector projection law, then subtract it from the original gradient. Verify the constraint numerically before updating the parameters. Compare the ordinary and projected update directions to observe exactly what the projection removed.

Part 4 - Python code skeleton

```
import torch

def E05(theta, gradient, constraint, learning_rate):
    forbidden_component = ...
    projected_gradient = ...
    new_theta = ...
    constraint_check = torch...
    return new_theta, projected_gradient, constraint_check

def main():
    theta = torch...
    gradient = torch...
    constraint = torch...
    learning_rate = ...
```

```
    print(E05(theta, gradient, constraint, learning_rate))

if __name__ == "__main__":
    main()
```

Book 3

Autograd & Backprop Mechanics

3.1 Introduction

3.1.1 What will the book teach you

Before building and training advanced artificial intelligence models, you must understand how gradients move through tensor operations. This book teaches the mechanics of automatic differentiation and backpropagation using PyTorch. You will begin by constructing computational graphs and distinguishing leaf tensors from non-leaf tensors, then progress toward tracing gradient flow through complete neural network operations.

The book connects mathematical differentiation with practical code. You will calculate gradients manually, verify them with Autograd, apply the chain rule, and study how gradients are accumulated, retained, blocked, or detached. These skills will help you understand what PyTorch performs during training instead of treating the backward pass as an invisible process.

Each chapter contains exercises that combine mathematical reasoning, tensor shape analysis, implementation, observation, and debugging. Complete the challenges without copying a finished solution. The objective is to predict values and gradients, test your reasoning in code, diagnose failures, and gradually develop the ability to inspect an entire backpropagation pipeline independently.

3.1.2 The Chapters (ABM00 - ABM06) included in this book

- ABM00 - Computational Graph Construction
- ABM01 - Forward vs Backward Pass
- ABM02 - Manual Gradient Calculation
- ABM03 - Chain Rule in Code
- ABM04 - Autograd Engine in PyTorch
- ABM05 - Backprop Through Linear Layers
- ABM06 - Gradient Flow Debugging

3.2 ABM00 - Computational Graph Construction

Mathematics and Theory

3.2.1 Exercise 00 - Tensor with requires_grad Setup

Part 1 - Why this matters

Training begins by identifying which tensors need derivatives. In PyTorch, `requires_grad=True` tells Autograd to record operations involving a tensor so that a later backward pass can compute its gradient.

This setting should normally be enabled for trainable floating-point parameters, not every tensor in a program. Understanding it prevents unnecessary graph construction and clarifies why some tensors receive a value in `.grad` while others do not.

Part 2 - Mathematical form

Let $\mathbf{x} \in \mathbb{R}^n$ be a trainable tensor and define:

$$y = f(\mathbf{x}).$$

Enabling gradient tracking requests the derivative:

$$\nabla_{\mathbf{x}} y = \left[\frac{\partial y}{\partial x_1}, \ldots, \frac{\partial y}{\partial x_n} \right].$$

The tensor $\mathbf{x}$ is a leaf when it is created directly rather than as the result of a tracked operation.

Part 3 - Hints and Helper

Create a floating-point tensor using the `requires_grad` argument. Inspect `requires_grad`, `is_leaf`, and `grad_fn` before performing any operation. Integer tensors cannot require gradients.

Part 4 - Python code skeleton

```
import torch

def E00(values):
    x = torch.tensor(..., requires_grad=...)
    return x, x.requires_grad, x.is_leaf, x.grad_fn

def main():
    print(E00([...]))

if __name__ == "__main__":
    main()
```

3.2.2 Exercise 01 - Simple Operation Graph Creation

Part 1 - Why this matters

Every differentiable operation applied to a tracked tensor becomes a node in a computational graph. The graph records how an output was produced, allowing Autograd to follow the dependencies in reverse during backpropagation.

A small graph makes this mechanism visible without the complexity of a neural network. Inspecting its tensors builds the habit of connecting each Python expression with a mathematical operation and a local derivative.

Part 2 - Mathematical form

Let $x \in \mathbb{R}$ require gradients and define:

$$y = 3x + 2.$$

The graph contains multiplication followed by addition, and its derivative is:

$$\frac{dy}{dx} = 3.$$

Although the constant 2 affects the forward value, its derivative contribution with respect to x is zero.

Part 3 - Hints and Helper

Create the expression in two separate operations and inspect `grad_fn` after each one. Do not call `backward()` yet; the goal is to construct and observe the graph created during the forward computation.

Part 4 - Python code skeleton

```
import torch

def E01(x):
    multiplied = x * ...
    y = multiplied + ...
    return multiplied, y, multiplied.grad_fn, y.grad_fn

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E01(x))

if __name__ == "__main__":
    main()
```

3.2.3 Exercise 02 - Multi-Operation Graph Building

Part 1 - Why this matters

Real models combine many operations before producing a loss. Autograd links these operations into one graph, preserving every dependency needed to apply the chain rule across the complete forward computation.

Building a multi-operation graph develops the ability to trace intermediate values and predict gradient paths. This is essential when an output depends on the same input through nonlinear transformations.

Part 2 - Mathematical form

Let $x \in \mathbb{R}$ and define:

$$a = x^2, \qquad b = 3a, \qquad y = b + \sin(x).$$

Therefore:

$$y = 3x^2 + \sin(x), \qquad \frac{dy}{dx} = 6x + \cos(x).$$

The final gradient combines contributions from both paths leading from x to y.

Part 3 - Hints and Helper

Store every intermediate tensor instead of writing one long expression. Inspect its value, `requires_grad`, and `grad_fn`. Sketch the operations and arrows before using the graph for backpropagation.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    a = ...
    b = ...
    c = torch...
    y = ...
    return a, b, c, y

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(x))

if __name__ == "__main__":
    main()
```

3.2.4 Exercise 03 - Leaf vs Non-Leaf Tensor Detection

Part 1 - Why this matters

Leaf tensors are the starting points of a computational graph and usually represent model parameters or direct inputs. Non-leaf tensors are intermediate results created by tracked operations and carry information about the operation that produced them.

The distinction determines where PyTorch stores gradients by default. Leaf tensors with gradient tracking populate `.grad` after backpropagation, whereas a non-leaf tensor requires `retain_grad()` if its intermediate gradient must be inspected.

Part 2 - Mathematical form

Let x be created directly with gradient tracking and define:

$$y = 2x, \qquad z = y^2.$$

Then x is a leaf, while y and z are non-leaf tensors. Their dependencies are represented as:

$$x \longrightarrow y \longrightarrow z.$$

For scalar x, $dz/dx = 8x$ and $dz/dy = 2y$.

Part 3 - Hints and Helper

Inspect `is_leaf` and `grad_fn` for all three tensors. Call `retain_grad()` on an intermediate only if you want its gradient stored. Compare the `.grad` fields after a scalar backward pass.

Part 4 - Python code skeleton

```
import torch

def E03(x):
    y = ...
    z = ...
    y.retain_grad()
    z.backward()
    return (...)

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E03(x))

if __name__ == "__main__":
    main()
```

3.2.5 Exercise 04 - Graph Retention After Backward

Part 1 - Why this matters

During a backward pass, PyTorch normally releases saved intermediate values once they are no longer needed. This memory-saving behavior means that the same graph cannot usually be traversed backward a second time.

Graph retention is useful when several gradient calculations genuinely depend on the same forward graph, but it increases memory use. Knowing when retention is necessary prevents both graph-reuse errors and unnecessary memory consumption.

Part 2 - Mathematical form

Let:

$$y = x^3.$$

A backward traversal computes:

$$\frac{dy}{dx} = 3x^2.$$

Repeated backward calls on the same y also accumulate gradients in $x.grad$. After two valid traversals without clearing the gradient, the stored value is:

$$x.grad = 2(3x^2).$$

Part 3 - Hints and Helper

Use `retain_graph=True` on the backward call that must preserve the graph for another traversal. Observe both graph lifetime and gradient accumulation. Retention does not automatically reset `x.grad`.

Part 4 - Python code skeleton

```
import torch

def E04(x):
    y = ...
    y.backward(retain_graph=...)
    first_gradient = x.grad...
    y.backward()
    second_gradient = x.grad...
    return first_gradient, second_gradient

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E04(x))

if __name__ == "__main__":
    main()
```

3.2.6 Exercise 05 - Detaching Tensor from Graph

Part 1 - Why this matters

Some computations need a tensor's current value without allowing later operations to send gradients back through its history. Detaching creates a tensor that shares data with the original tensor but is disconnected from the recorded computational graph.

This mechanism is useful for fixed targets, logging, selected model branches, and algorithms with intentionally blocked gradients. Because storage may be shared, detaching should not be confused with making an independent copy.

Part 2 - Mathematical form

Let $y = f(x)$ and define a detached value:

$$\widetilde{y} = \text{stopgrad}(y).$$

The forward values satisfy $\widetilde{y} = y$, but Autograd treats:

$$\frac{\partial \widetilde{y}}{\partial x} = 0.$$

If $z = g(\widetilde{y})$, the path from z through $\widetilde{y}$ to x does not contribute to the gradient.

Part 3 - Hints and Helper

Create an intermediate result, call `detach()`, and compare the original and detached tensors using `requires_grad`, `is_leaf`, and `grad_fn`. Use `detach().clone()` when independent storage is also required.

Part 4 - Python code skeleton

```
import torch

def E05(x):
    y = ...
    detached_y = y...
    return y, detached_y, (...)

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E05(x))

if __name__ == "__main__":
    main()
```

3.2.7 Exercise 06 - Stop-Gradient Simulation Challenge

Part 1 - Why this matters

A branching graph may require learning through one path while treating another path as a fixed signal. Stop-gradient behavior makes this distinction explicit, allowing both branches to affect the forward result but only selected branches to influence parameter updates.

This pattern appears in target networks, contrastive objectives, and staged training strategies. Reasoning about each path separately prevents the mistaken assumption that equal forward values imply equal gradient behavior.

Part 2 - Mathematical form

Let:

$$a = x^2, \qquad b = \text{stopgrad}(x^2), \qquad y = a + b.$$

The forward value is:

$$y = 2x^2,$$

but only a contributes to the derivative:

$$\frac{dy}{dx} = 2x.$$

Without stop-gradient, the derivative would instead be $4x$.

Part 3 - Hints and Helper

Build the two branches separately and detach only the branch intended to remain constant during differentiation. Predict the gradient before calling `backward()`, then compare it with an equivalent graph in which neither branch is detached.

Part 4 - Python code skeleton

```
import torch

def E06(x):
    trainable_branch = ...
    blocked_branch = (...).detach()
    y = ...
    y.backward()
    return y, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E06(x))

if __name__ == "__main__":
    main()
```

3.2.8 Exercise 07 - Graph Reuse Error Debugging

Part 1 - Why this matters

Calling backward twice on a graph whose saved values were released produces a common Autograd error. The message can be confusing until the programmer distinguishes reusing output values from reusing the recorded graph itself.

Correct debugging depends on the intended algorithm. A graph may need explicit retention, or the forward computation may be safely performed again to create a fresh graph. Choosing between these options affects memory and program structure.

Part 2 - Mathematical form

For a forward computation:

$$y = f(x),$$

one graph represents the operations used to produce this particular y. After a normal backward traversal:

$$\nabla_x y = \frac{\partial f}{\partial x},$$

saved intermediates may be freed. Recomputing $y = f(x)$ constructs a new graph with the same mathematical derivative but a separate lifetime.

Part 3 - Hints and Helper

Reproduce the error with two backward calls, then repair it in two ways: retain the first graph when required, or recompute the forward output before the second call. Reset gradients when comparing results so accumulation does not hide the behavior being studied.

Part 4 - Python code skeleton

```
import torch

def E07(x):
    y = ...
    y.backward(...)
    first_gradient = x.grad...
    x.grad = ...
    second_output = ...
    second_output.backward()
    return first_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E07(x))

if __name__ == "__main__":
    main()
```

3.2.9 Exercise 08 - In-place Operation Graph Failure

Part 1 - Why this matters

An in-place operation changes an existing tensor instead of producing a separate output. This can reduce allocations, but it may overwrite a value that Autograd saved for computing a derivative, making the backward calculation invalid.

PyTorch also protects leaf tensors requiring gradients from many in-place changes. Learning to recognize operations whose names end with an underscore helps prevent subtle graph corruption and version-counter errors.

Part 2 - Mathematical form

Suppose:

$$y = x^2.$$

Backward requires the original x because:

$$\frac{dy}{dx} = 2x.$$

If an in-place operation changes x after the forward computation, the stored forward value and current value no longer describe the same graph. An out-of-place operation instead creates x_{new} while preserving x.

Part 3 - Hints and Helper

Construct a small failing example and read the complete error message. Identify which tensor was modified and replace the in-place expression with an out-of-place equivalent. Do not hide the problem using `.data`, because that bypasses Autograd's safety checks.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    y = ...
    modified_x = x ...
    loss = ...
    loss.backward()
    return modified_x, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E08(x))

if __name__ == "__main__":
    main()
```

3.2.10 Exercise 09 - Manual Graph Reasoning Challenge

Part 1 - Why this matters

Autograd is most useful when its results can be predicted and explained. Manual graph reasoning breaks a complicated expression into nodes, identifies every path from an input to the output, and applies local derivatives in reverse order.

This final challenge combines branching, shared intermediates, and the chain rule. It prepares the reader to diagnose real models by reasoning about graph structure before relying on printed gradient values.

Part 2 - Mathematical form

Let:

$$a = x^2, \qquad b = 3a, \qquad c = \sin(a), \qquad y = b + c.$$

Both branches depend on the shared node a. The local derivatives are:

$$\frac{da}{dx} = 2x, \quad \frac{db}{da} = 3, \quad \frac{dc}{da} = \cos(a).$$

Therefore:

$$\frac{dy}{dx} = \left(3 + \cos(x^2)\right) 2x.$$

Part 3 - Hints and Helper

Draw the graph and label each edge with its local derivative. Begin at y and move backward, adding contributions where branches meet. Compute the manual gradient first, then use Autograd only to verify the prediction.

Part 4 - Python code skeleton

```
import torch

def E09(x):
    a = ...
    b = ...
    c = torch...
    y = ...
    manual_gradient = ...
    y.backward()
    return manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E09(x))

if __name__ == "__main__":
    main()
```

3.3 ABM01 - Forward vs Backward Pass

Mathematics and Theory

3.3.1 Exercise 00 - Forward Pass Value Tracking

Part 1 - Why this matters

The forward pass transforms inputs through a sequence of operations and produces intermediate values and a final output. Recording these values makes it possible to verify the numerical behavior of a model before studying its gradients.

Forward tracking also reveals which quantities Autograd may need later during backpropagation. Separating forward values from backward gradients prevents the two stages from being treated as one unexplained process.

Part 2 - Mathematical form

Let $x \in \mathbb{R}$ and define:

$$a = 2x + 1, \qquad b = a^2, \qquad y = \tanh(b).$$

The forward pass evaluates the graph in dependency order:

$$x \longrightarrow a \longrightarrow b \longrightarrow y.$$

Each value is computed from values already available to its left.

Part 3 - Hints and Helper

Store every intermediate tensor and print its value, shape, and `grad_fn`. Do not call `backward()` in this exercise. Predict all values manually for a simple input before comparing them with PyTorch.

Part 4 - Python code skeleton

```
import torch

def E00(x):
    a = ...
    b = ...
    y = torch...
    return a, b, y

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E00(x))

if __name__ == "__main__":
    main()
```

3.3.2 Exercise 01 - Backward Call on Scalar Loss

Part 1 - Why this matters

Model training normally reduces many predictions to one scalar loss. Calling `backward()` on that scalar starts reverse-mode differentiation and computes how the loss changes with respect to every required leaf tensor.

A scalar output supplies an implicit starting derivative of one. Understanding this seed explains why backward can be called without an explicit argument on a scalar but requires additional gradient information for a non-scalar output.

Part 2 - Mathematical form

Let $\mathbf{x} \in \mathbb{R}^n$ and define:

$$L = \sum_{i=1}^{n} (x_i - t_i)^2.$$

Since $L \in \mathbb{R}$, backpropagation begins with:

$$\frac{\partial L}{\partial L} = 1,$$

and produces:

$$\frac{\partial L}{\partial x_i} = 2(x_i - t_i).$$

Part 3 - Hints and Helper

Compute element-wise errors, square them, and reduce them with `torch.sum()` before calling `backward()`. Confirm that the loss has zero dimensions and compare `x.grad` with the manual derivative.

Part 4 - Python code skeleton

```
import torch

def E01(x, target):
    error = ...
    loss = torch...
    loss.backward()
    return loss, x.grad

def main():
    x = torch.tensor([...], requires_grad=True)
    target = torch.tensor([...])
    print(E01(x, target))

if __name__ == "__main__":
    main()
```

3.3.3 Exercise 02 - Gradient Accumulation Observation

Part 1 - Why this matters

PyTorch adds newly computed gradients to the existing `.grad` field of a leaf tensor. This supports algorithms that combine contributions from several losses or smaller batches, but it can also cause incorrect updates when the previous gradient is forgotten.

Observing accumulation directly establishes an important training-loop rule: gradient buffers persist independently of the graph that produced them. Repeated backward calls therefore change stored gradients even when each graph is new.

Part 2 - Mathematical form

For $L = x^2$:

$$\frac{dL}{dx} = 2x.$$

If two backward passes contribute gradients g_1 and g_2 without clearing the buffer, PyTorch stores:

$$x.grad = g_1 + g_2.$$

For two identical passes, this becomes $x.grad = 4x$.

Part 3 - Hints and Helper

Construct a fresh scalar loss before each backward pass so graph reuse is not the variable being tested. Clone the gradient after the first pass, run the second pass, and compare both stored values without zeroing in between.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    loss1 = ...
    loss1.backward()
    first = x.grad...
    loss2 = ...
    loss2.backward()
    second = x.grad...
    return first, second

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(x))

if __name__ == "__main__":
    main()
```

3.3.4 Exercise 03 - Zeroing Gradients Correctly

Part 1 - Why this matters

Independent optimization steps should not normally inherit gradients from the previous step. Clearing gradient buffers before a new backward pass ensures that the parameter update reflects the current loss rather than an unintended sum of old and new derivatives.

PyTorch allows a gradient to be set to zero or reset to `None`. Both can prevent unwanted accumulation, but setting it to `None` can avoid a fill operation and clearly indicates that no gradient has yet been computed.

Part 2 - Mathematical form

At training step t, let:

$$g_t = \nabla_\theta L_t(\theta).$$

The desired buffer before backward is empty, producing:

$$\theta.grad = g_t.$$

Without clearing a previous gradient g_{t-1}, the stored result becomes:

$$\theta.grad = g_{t-1} + g_t.$$

Part 3 - Hints and Helper

Run two separate losses and clear `x.grad` between them. Try both `x.grad.zero_()` and assigning `None`, taking care not to call `zero_()` before a gradient tensor exists.

Part 4 - Python code skeleton

```
import torch

def E03(x):
    first_loss = ...
    first_loss.backward()
    first_gradient = x.grad...
    x.grad = ...
    second_loss = ...
    second_loss.backward()
    return first_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E03(x))

if __name__ == "__main__":
    main()
```

3.3.5 Exercise 04 - Multiple Backward Calls Challenge

Part 1 - Why this matters

Several objectives may depend on the same trainable tensor. Their gradient contributions can be computed through separate backward calls or through one combined loss, provided graph lifetimes and accumulation are handled correctly.

Comparing these approaches demonstrates the linearity of differentiation. It also separates the mathematical addition of loss gradients from PyTorch's mechanical accumulation inside the parameter gradient buffer.

Part 2 - Mathematical form

Let:

$$L_1 = x^2, \qquad L_2 = 3x, \qquad L = L_1 + L_2.$$

Then:

$$\frac{dL}{dx} = \frac{dL_1}{dx} + \frac{dL_2}{dx} = 2x + 3.$$

Separate backward calls accumulate the same total when both graphs are valid.

Part 3 - Hints and Helper

Compute two losses from the same leaf and call backward on each. Then reset the gradient, reconstruct the forward computation, sum the losses, and use one backward call. Compare the final gradients with `torch.allclose()`.

Part 4 - Python code skeleton

```
import torch

def E04(x):
```

```
    loss1 = ...
    loss2 = ...
    loss1.backward(...)
    loss2.backward()
    separate_gradient = x.grad...
    return separate_gradient

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E04(x))

if __name__ == "__main__":
    main()
```

3.3.6 Exercise 05 - retain_graph Usage Challenge

Part 1 - Why this matters

A backward pass normally frees saved intermediates to reduce memory use. `retain_graph=True` preserves them when another backward traversal must use the same forward graph, but careless retention can keep unnecessary memory alive.

The challenge is to use retention only when the algorithm requires graph reuse. Recomputing a forward pass is often clearer, while retention is appropriate when multiple derivatives must be obtained from exactly the same recorded graph.

Part 2 - Mathematical form

Let a shared intermediate be:

$$h = x^2, qquadL_1 = 2h, qquadL_2 = h^2.$$

The losses share the path $x \to h$. Their derivatives are:

$$\frac{dL_1}{dx} = 4x, \qquad \frac{dL_2}{dx} = 4x^3.$$

Traversing both from one forward graph requires preserving shared saved data until the final traversal.

Part 3 - Hints and Helper

Call backward on the first loss with graph retention, then call backward on the second normally. Observe accumulated gradients and compare them with the manual sum. Explain why retaining the graph on the final call is unnecessary.

Part 4 - Python code skeleton

```
import torch

def E05(x):
    shared = ...
```

```
    loss1 = ...
    loss2 = ...
    loss1.backward(retain_graph=...)
    loss2.backward()
    return x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E05(x))

if __name__ == "__main__":
    main()
```

3.3.7 Exercise 06 - Backward Through Branching Graph

Part 1 - Why this matters

Computational graphs branch when one tensor feeds several later operations. During backpropagation, every path contributes to the gradient of the shared ancestor, so ignoring one branch produces an incomplete derivative.

Branching is common in residual connections, multi-head models, and objectives with several terms. Manual path analysis makes the addition of gradient contributions visible before Autograd performs it automatically.

Part 2 - Mathematical form

Let:

$$a = x^2, \qquad b = 3x, \qquad y = a + b.$$

There are two paths from x to y, therefore:

$$\frac{dy}{dx} = \frac{\partial y}{\partial a}\frac{da}{dx} + \frac{\partial y}{\partial b}\frac{db}{dx} = 2x + 3.$$

Part 3 - Hints and Helper

Build each branch separately and retain the intermediate tensors for inspection. Draw both gradient paths, compute their contributions manually, and compare their sum with the leaf gradient after one backward call.

Part 4 - Python code skeleton

```
import torch

def E06(x):
    branch_a = ...
    branch_b = ...
    y = ...
    y.backward()
    manual_gradient = ...
```

```
    return manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E06(x))

if __name__ == "__main__":
    main()
```

3.3.8 Exercise 07 - Gradient Flow Order Reasoning

Part 1 - Why this matters

The forward pass follows dependencies from inputs to outputs, whereas the backward pass propagates derivatives from the loss toward earlier tensors. This reverse order is required because each upstream gradient depends on gradients already obtained from downstream operations.

Understanding the order helps interpret hooks and debug deep graphs. The engine may schedule independent branches internally, but it must respect the dependency relationships defined by the chain rule.

Part 2 - Mathematical form

For:

$$a = f(x), \qquad b = g(a), \qquad L = h(b),$$

the forward order is $x \to a \to b \to L$. The backward calculation is:

$$\frac{dL}{db} \longrightarrow \frac{dL}{da} = \frac{dL}{db}\frac{db}{da} \longrightarrow \frac{dL}{dx} = \frac{dL}{da}\frac{da}{dx}.$$

Part 3 - Hints and Helper

Call `retain_grad()` on non-leaf intermediates and register simple hooks that report when their gradients arrive. Compare the observed trace with the reverse dependency order predicted on paper.

Part 4 - Python code skeleton

```
import torch

def E07(x):
    a = ...
    b = ...
    loss = ...
    a.retain_grad()
    b.retain_grad()
    loss.backward()
    return x.grad, a.grad, b.grad
```

```
def main():
    x = torch.tensor(..., requires_grad=True)
    print(E07(x))

if __name__ == "__main__":
    main()
```

3.3.9 Exercise 08 - Backward Error Debugging

Part 1 - Why this matters

Backward failures often result from a non-scalar output, a detached graph, a reused graph, or a tensor that never required gradients. Reading the tensor properties before changing code is more reliable than applying unrelated fixes.

A systematic diagnosis identifies whether the graph exists, whether the output has the expected shape, and whether the requested leaf participates in a valid path to the loss. This method turns runtime errors into structural evidence.

Part 2 - Mathematical form

For a vector output $\mathbf{y} = f(\mathbf{x}) \in \mathbb{R}^m$, a backward seed $\mathbf{v} \in \mathbb{R}^m$ computes a vector–Jacobian product:

$$\mathbf{v}^\top \frac{\partial \mathbf{y}}{\partial \mathbf{x}}.$$

Alternatively, reducing the output to a scalar loss:

$$L = \sum_{i=1}^{m} y_i$$

permits an implicit seed of one.

Part 3 - Hints and Helper

Inspect the output's shape, `requires_grad`, and `grad_fn`, then inspect the leaf tensor. For a vector output, either define a meaningful scalar reduction or provide a matching gradient argument to `backward()`.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    output = ...
    print(output.shape, output.requires_grad, output.grad_fn)
    scalar_loss = torch...
    scalar_loss.backward()
    return x.grad

def main():
    x = torch.tensor([...], requires_grad=True)
```

```
    print(E08(x))

if __name__ == "__main__":
    main()
```

3.3.10 Exercise 09 - Custom Forward–Backward Trace

Part 1 - Why this matters

A complete trace records both the numerical forward path and the derivative path through the same graph. Pairing these stages produces an auditable explanation of how a final loss value leads to a particular input gradient.

This challenge combines intermediate tracking, retained gradients, local derivatives, and reverse-order reasoning. It prepares the reader to analyze a small model as a structured computation rather than a single formula.

Part 2 - Mathematical form

Let:

$$a = 2x, qquadb = a + 1, qquadc = b^2, qquadL = \frac{1}{2}c.$$

The backward trace is:

$$\frac{dL}{dc} = \frac{1}{2}, \qquad \frac{dL}{db} = b, qquad\frac{dL}{da} = b, \qquad \frac{dL}{dx} = 2b.$$

The trace should connect each stored forward value to its corresponding gradient.

Part 3 - Hints and Helper

Retain gradients for all non-leaf intermediates, store their forward values, and call backward once on the scalar loss. Return an ordered structure containing each node name, value, and gradient, then compare it with the manual trace.

Part 4 - Python code skeleton

```
import torch

def E09(x):
    a = ...
    b = ...
    c = ...
    loss = ...
    for tensor in (...):
        tensor.retain_grad()
    loss.backward()
    trace = ...
    return trace

def main():
    x = torch.tensor(..., requires_grad=True)
```

```
    print(E09(x))

if __name__ == "__main__":
    main()
```

3.4 ABM02 - Manual Gradient Calculation

Mathematics and Theory

3.4.1 Exercise 00 - Derivative of Linear Function

Part 1 - Why this matters

Linear functions provide the simplest setting for connecting a forward value to its derivative. Their constant slope shows how one small input change produces a proportional output change everywhere in the domain.

Manually deriving this gradient establishes the notation and verification process used throughout backpropagation. It also clarifies that the bias changes the forward output but does not change the derivative with respect to the input.

Part 2 - Mathematical form

Let:

$$y = ax + b, \qquad a, b, x \in \mathbb{R}.$$

The derivative with respect to x is:

$$\frac{dy}{dx} = a.$$

If a and b are also trainable, then:

$$\frac{\partial y}{\partial a} = x, \qquad \frac{\partial y}{\partial b} = 1.$$

Part 3 - Hints and Helper

Calculate the three derivatives on paper before writing code. Create floating-point tensors for x, a, and b, then compare the manual results with their `.grad` values after a scalar backward pass.

Part 4 - Python code skeleton

```
import torch

def E00(x, a, b):
    y = ...
    manual_dx = ...
    y.backward()
    return y, manual_dx, x.grad
```

```
def main():
    x = torch.tensor(..., requires_grad=True)
    a = torch.tensor(..., requires_grad=True)
    b = torch.tensor(..., requires_grad=True)
    print(E00(x, a, b))

if __name__ == "__main__":
    main()
```

3.4.2 Exercise 01 - Manual Gradient vs Autograd Check

Part 1 - Why this matters

Autograd is trustworthy only when the programmer understands what its result represents. Comparing an automatic gradient with a manually derived expression provides a direct correctness check for both the mathematics and implementation.

This comparison is especially useful while developing custom losses or unfamiliar tensor formulas. A mismatch becomes evidence that an operation, reduction, graph connection, or manual derivative has been interpreted incorrectly.

Part 2 - Mathematical form

Let:

$$f(x) = x^3 + 2x^2 - 5x + 1.$$

Its manual derivative is:

$$f'(x) = 3x^2 + 4x - 5.$$

For a selected value $x = x_0$, correctness requires:

$$g_{manual} = f'(x_0) \approx g_{autograd}.$$

Part 3 - Hints and Helper

Evaluate the polynomial using tracked PyTorch operations, derive the gradient independently, and call `backward()` once. Compare floating-point values with `torch.allclose()` rather than exact equality.

Part 4 - Python code skeleton

```
import torch

def E01(x):
    y = ...
    manual_gradient = ...
    y.backward()
    matches = torch...
    return manual_gradient, x.grad, matches

def main():
```

```
    x = torch.tensor(..., requires_grad=True)
    print(E01(x))

if __name__ == "__main__":
    main()
```

3.4.3 Exercise 02 - Gradient of Quadratic Function

Part 1 - Why this matters

Quadratic functions introduce gradients that depend on the current input rather than remaining constant. They are fundamental to squared-error losses, distance measures, regularization, and many optimization examples.

Their derivative also provides an intuitive view of optimization: the gradient is zero at the vertex and grows in magnitude farther away. Its sign identifies the direction in which the function increases.

Part 2 - Mathematical form

Let:

$$f(x) = ax^2 + bx + c.$$

The first derivative is:

$$\frac{df}{dx} = 2ax + b,$$

and the second derivative is:

$$\frac{d^2 f}{dx^2} = 2a.$$

When $a > 0$, the stationary point is a minimum at $x = -b/(2a)$.

Part 3 - Hints and Helper

Choose coefficients and evaluate both the function and manual derivative at several input values. Use a separate tracked tensor for each test or clear its gradient before constructing a new forward computation.

Part 4 - Python code skeleton

```
import torch

def E02(x, a, b, c):
    y = ...
    manual_gradient = ...
    y.backward()
    return y, manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(x, ..., ..., ...))

if __name__ == "__main__":
    main()
```

3.4.4 Exercise 03 - Chain Rule Manual Verification

Part 1 - Why this matters

Most model outputs depend on parameters through several intermediate operations. The chain rule connects the local derivative of every operation so that a final loss gradient can reach the earliest input.

Manual verification makes the multiplication of local derivatives explicit. This prepares the reader to reason about deep graphs where Autograd applies the same principle repeatedly in reverse order.

Part 2 - Mathematical form

Let:

$$u = x^2 + 1, \qquad y = \sin(u).$$

The local derivatives are:

$$\frac{dy}{du} = \cos(u), \qquad \frac{du}{dx} = 2x.$$

Therefore:

$$\frac{dy}{dx} = \cos(x^2 + 1)\, 2x.$$

Part 3 - Hints and Helper

Store u and y separately. Calculate both local derivatives and multiply them before calling backward. Retain the intermediate gradient if you also want to compare Autograd's value for dy/du.

Part 4 - Python code skeleton

```
import torch

def E03(x):
    u = ...
    y = torch...
    local_dy_du = ...
    local_du_dx = ...
    manual_gradient = ...
    y.backward()
    return manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E03(x))

if __name__ == "__main__":
    main()
```

3.4.5 Exercise 04 - Vector Gradient Computation

Part 1 - Why this matters

Machine learning losses usually depend on vectors of parameters or predictions. The gradient collects one partial derivative for every input component, producing a vector that has the same shape as the differentiated vector.

Computing this result manually demonstrates how a scalar reduction combines independent element-wise contributions. It also builds the shape reasoning needed to distinguish a gradient from a full Jacobian.

Part 2 - Mathematical form

Let $\mathbf{x} \in \mathbb{R}^n$ and define:

$$L(\mathbf{x}) = \sum_{i=1}^{n} x_i^2.$$

For each component:

$$\frac{\partial L}{\partial x_i} = 2x_i.$$

Therefore:

$$\nabla_{\mathbf{x}} L = 2\mathbf{x} \in \mathbb{R}^n.$$

Part 3 - Hints and Helper

Build the scalar loss with an element-wise square followed by a sum. Derive the complete gradient tensor without a Python loop, then verify its values and shape against `x.grad`.

Part 4 - Python code skeleton

```
import torch

def E04(x):
    loss = torch...
    manual_gradient = ...
    loss.backward()
    return manual_gradient, x.grad, x.grad.shape

def main():
    x = torch.tensor([...], requires_grad=True)
    print(E04(x))

if __name__ == "__main__":
    main()
```

3.4.6 Exercise 05 - Matrix Gradient Reasoning

Part 1 - Why this matters

Weights in linear layers are matrices, so their gradients must preserve both row and column roles. Matrix gradient reasoning connects the compact notation of a linear transformation to

the contribution made by every input-output pair.

Understanding this structure helps detect accidental transposes and incompatible shapes. It also reveals why a batch produces a sum of outer-product contributions to the weight gradient.

Part 2 - Mathematical form

Let $\mathbf{W} \in \mathbb{R}^{m \times n}$, $\mathbf{x} \in \mathbb{R}^n$, and $\mathbf{y} = \mathbf{W}\mathbf{x}$. Define:

$$L = \sum_{i=1}^{m} y_i.$$

Since $y_i = \sum_j W_{ij} x_j$:

$$\frac{\partial L}{\partial W_{ij}} = x_j.$$

Thus every row of $\nabla_{\mathbf{W}} L$ equals $\mathbf{x}^\mathsf{T}$.

Part 3 - Hints and Helper

Calculate the output with matrix-vector multiplication and reduce it to a scalar. Construct the expected matrix gradient using shape-aware tensor operations, then compare its values and orientation with `W.grad`.

Part 4 - Python code skeleton

```
import torch

def E05(W, x):
    y = torch...
    loss = torch...
    manual_gradient = ...
    loss.backward()
    return manual_gradient, W.grad

def main():
    W = torch.tensor(..., requires_grad=True)
    x = torch.tensor(...)
    print(E05(W, x))

if __name__ == "__main__":
    main()
```

3.4.7 Exercise 06 - Broadcasting Gradient Challenge

Part 1 - Why this matters

Broadcasting allows one parameter to affect many output elements without storing explicit copies. During backpropagation, all gradient contributions created by those logical copies must be reduced back to the parameter's original shape.

This reduction is easy to overlook because the forward expression appears as a simple addition. Understanding it is essential for bias gradients and any shared parameter applied across batches or spatial dimensions.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{B \times F}$ and $\mathbf{b} \in \mathbb{R}^{F}$. Define:

$$Y_{ij} = X_{ij} + b_j, \qquad L = \sum_{i=1}^{B} \sum_{j=1}^{F} Y_{ij}.$$

The broadcasted bias appears once per batch item, so:

$$\frac{\partial L}{\partial b_j} = B.$$

Part 3 - Hints and Helper

Predict the bias gradient from the batch size before running the code. Confirm that Autograd reduces the expanded gradient along the broadcasted axis and returns a tensor with the original bias shape.

Part 4 - Python code skeleton

```
import torch

def E06(X, bias):
    Y = ...
    loss = torch...
    manual_bias_gradient = ...
    loss.backward()
    return manual_bias_gradient, bias.grad

def main():
    X = torch...
    bias = torch.tensor(..., requires_grad=True)
    print(E06(X, bias))

if __name__ == "__main__":
    main()
```

3.4.8 Exercise 07 - Gradient Shape Validation

Part 1 - Why this matters

A gradient with respect to a tensor must match that tensor's shape. Shape validation catches incomplete reductions, unintended broadcasting, and incorrect manual formulas even when some numerical values appear reasonable.

This rule is a practical invariant throughout neural network training. Parameters can be updated element by element only when the parameter tensor and its gradient have corresponding dimensions.

Part 2 - Mathematical form

For a scalar loss L and tensor $\mathcal{X} \in \mathbb{R}^{d_1 \times \cdots \times d_k}$:

$$\nabla_{\mathcal{X}} L = \left[\frac{\partial L}{\partial X_{i_1 \ldots i_k}} \right] \in \mathbb{R}^{d_1 \times \cdots \times d_k}.$$

Therefore:

$$\text{shape}(\nabla_{\mathcal{X}} L) = \text{shape}(\mathcal{X}).$$

Part 3 - Hints and Helper

Choose a multidimensional tensor and a scalar loss involving a reduction. Check the expected gradient shape before backward, then validate rank and every axis. Report a useful mismatch message rather than only returning `False`.

Part 4 - Python code skeleton

```
import torch

def E07(X):
    loss = ...
    manual_gradient = ...
    loss.backward()
    shape_valid = ...
    values_valid = torch...
    return shape_valid, values_valid

def main():
    X = torch.tensor(..., requires_grad=True)
    print(E07(X))

if __name__ == "__main__":
    main()
```

3.4.9 Exercise 08 - Numerical Gradient Approximation

Part 1 - Why this matters

A numerical gradient estimates a derivative using nearby function values rather than symbolic rules or Autograd. It provides an independent diagnostic when checking a manually implemented gradient or custom backward method.

The estimate is approximate because the step size introduces a tradeoff. A large step creates truncation error, while an extremely small step can magnify floating-point rounding error.

Part 2 - Mathematical form

For a scalar function f and small $h > 0$, the central-difference approximation is:

$$f'(x) \approx \frac{f(x+h) - f(x-h)}{2h}.$$

Its absolute comparison error is:

$$E = \left| g_{numerical} - g_{autograd} \right| .$$

Central differences generally provide better accuracy than a one-sided estimate for the same moderate step size.

Part 3 - Hints and Helper

Use double precision and evaluate the perturbed inputs without building an unnecessary gradient graph. Test several step sizes and compare the numerical estimate with both the analytical derivative and Autograd.

Part 4 - Python code skeleton

```
import torch

def function(x):
    return ...

def E08(x, h):
    forward_value = function(x + ...)
    backward_value = function(x - ...)
    numerical_gradient = ...
    return numerical_gradient

def main():
    x = torch.tensor(..., dtype=torch.float64)
    print(E08(x, ...))

if __name__ == "__main__":
    main()
```

3.4.10 Exercise 09 - Gradient Mismatch Debugging

Part 1 - Why this matters

Manual, numerical, and automatic gradients may disagree because of an incorrect derivative, a missing reduction, a detached path, accumulated gradients, poor numerical precision, or evaluation at different inputs. Random changes rarely identify which cause is responsible.

A structured comparison isolates the failure by checking the forward function, gradient shapes, graph connectivity, buffer state, and numerical tolerance in a fixed order. This method scales to debugging larger models.

Part 2 - Mathematical form

Let g_m, g_a, and g_n denote manual, Autograd, and numerical gradients. Define pairwise errors:

$$E_{ma} = \|g_m - g_a\|, \qquad E_{na} = \|g_n - g_a\|.$$

A relative error can be measured by:

$$E_{rel} = \frac{\|g_1 - g_2\|}{\max(\|g_1\|, \|g_2\|, \varepsilon)}.$$

Part 3 - Hints and Helper

Evaluate all methods at the same input and dtype. Clear old gradients, verify matching shapes, and print absolute and relative errors. Test simple input values to determine whether the mismatch is mathematical, structural, or numerical.

Part 4 - Python code skeleton

```
import torch

def E09(x, step_size, tolerance):
    manual_gradient = ...
    autograd_gradient = ...
    numerical_gradient = ...
    absolute_error = ...
    relative_error = ...
    matches = ...
    return (...)

def main():
    x = torch.tensor(..., dtype=torch.float64, requires_grad=True)
    print(E09(x, ..., ...))

if __name__ == "__main__":
    main()
```

3.5 ABM03 - Chain Rule in Code

Mathematics and Theory

3.5.1 Exercise 00 - Single-Chain Gradient Flow

Part 1 - Why this matters

A single chain shows the basic mechanism of backpropagation: every output depends on one previous intermediate until the original input is reached. The gradient is transported backward by multiplying local derivatives.

Studying a short chain makes forward and backward directions easy to separate. It provides the foundation for deeper graphs, where the same rule is repeated across many layers.

Part 2 - Mathematical form

Let $u = 2x + 1$ and $y = u^2$. The chain rule gives:

$$\frac{dy}{dx} = \frac{dy}{du}\frac{du}{dx} = (2u)(2) = 4(2x + 1).$$

The forward path is $x \to u \to y$, while gradient flow follows the reverse direction.

Part 3 - Hints and Helper

Store the intermediate tensor and retain its gradient. Calculate both local derivatives manually, multiply them, and compare the result with `x.grad` after one scalar backward call.

Part 4 - Python code skeleton

```
import torch

def E00(x):
    u = ...
    y = ...
    u.retain_grad()
    manual_gradient = ...
    y.backward()
    return manual_gradient, x.grad, u.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E00(x))

if __name__ == "__main__":
    main()
```

3.5.2 Exercise 01 - Multi-Operation Chain Rule

Part 1 - Why this matters

Real tensor expressions combine several different operations, each contributing its own local derivative. The complete input gradient is the product of these derivatives along the dependency chain.

Writing every intermediate prevents skipped factors and makes errors easier to locate. This discipline is directly applicable to tracing gradients through multiple neural network layers.

Part 2 - Mathematical form

Let $a = x^2$, $b = 3a + 1$, and $y = \log(b)$. Then:

$$\frac{dy}{dx} = \frac{dy}{db}\frac{db}{da}\frac{da}{dx} = \frac{1}{b} \cdot 3 \cdot 2x = \frac{6x}{3x^2 + 1}.$$

Part 3 - Hints and Helper

Implement the three operations separately and ensure the logarithm receives a positive input. Compute each local derivative at its correct forward value before comparing the product with Autograd.

Part 4 - Python code skeleton

```
import torch

def E01(x):
    a = ...
    b = ...
    y = torch...
    manual_gradient = ...
    y.backward()
    return manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E01(x))

if __name__ == "__main__":
    main()
```

3.5.3 Exercise 02 - Nested Function Gradient Flow

Part 1 - Why this matters

Nested functions express one transformation inside another, matching the layered structure of many artificial intelligence models. Differentiating the outer function alone is insufficient because its input also changes with the original variable.

Expanding a nested expression into named stages exposes the exact chain Autograd records. It also clarifies where each derivative must be evaluated during the backward pass.

Part 2 - Mathematical form

Let:

$$y = f(g(h(x))), \qquad h(x) = x^2, \quad g(h) = \sin(h), \quad f(g) = e^g.$$

Then:

$$\frac{dy}{dx} = e^{\sin(x^2)} \cos(x^2)\, 2x.$$

Part 3 - Hints and Helper

Create one tensor for each nested stage. Predict all forward values first, then calculate the derivative from the outside toward the inside and verify it using `backward()`.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    h = ...
    g = torch...
    y = torch...
    manual_gradient = ...
    y.backward()
    return manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(x))

if __name__ == "__main__":
    main()
```

3.5.4 Exercise 03 - Chain Rule with Activation

Part 1 - Why this matters

Activation functions insert nonlinear derivatives into a model's gradient path. Their local slope can preserve, reduce, or completely block an upstream gradient depending on the forward input.

Combining a linear transformation with an activation demonstrates how layer parameters and activation behavior interact. This is the smallest useful model of gradient flow through a neural unit.

Part 2 - Mathematical form

Let $z = wx + b$ and $y = \sigma(z)$, where:

$$\sigma(z) = \frac{1}{1 + e^{-z}}.$$

Since $\sigma'(z) = \sigma(z)(1 - \sigma(z))$:

$$\frac{dy}{dx} = y(1 - y)w.$$

Part 3 - Hints and Helper

Compute the pre-activation and activation separately. Use the already computed activation value in the manual sigmoid derivative, then compare gradients for several inputs including values where sigmoid saturates.

Part 4 - Python code skeleton

```
import torch

def E03(x, w, b):
```

```
    z = ...
    y = torch...
    manual_gradient = ...
    y.backward()
    return y, manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    w = torch.tensor(...)
    b = torch.tensor(...)
    print(E03(x, w, b))

if __name__ == "__main__":
    main()
```

3.5.5 Exercise 04 - Branching Chain Rule Challenge

Part 1 - Why this matters

A graph branches when one intermediate feeds more than one later operation. During backpropagation, every route from that intermediate to the loss contributes to its total gradient.

Branching appears in residual connections and multi-objective models. Correct reasoning requires multiplying derivatives along each path and then adding the path contributions where they meet.

Part 2 - Mathematical form

Let $a = x^2$, $b = 3a$, $c = \sin(a)$, and $y = b + c$. Then:

$$\frac{dy}{dx} = \left(\frac{db}{da} + \frac{dc}{da}\right)\frac{da}{dx} = \left(3 + \cos(x^2)\right)2x.$$

Part 3 - Hints and Helper

Draw both paths from a to y. Calculate their contributions separately, add them at the shared node, and only then multiply by the derivative from a to x.

Part 4 - Python code skeleton

```
import torch

def E04(x):
    a = ...
    branch_b = ...
    branch_c = torch...
    y = ...
    path_b = ...
    path_c = ...
    manual_gradient = ...
```

```
    y.backward()
    return path_b, path_c, manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E04(x))

if __name__ == "__main__":
    main()
```

3.5.6 Exercise 05 - Gradient Path Contribution Analysis

Part 1 - Why this matters

A total gradient can hide which branch dominates learning. Measuring each path contribution reveals whether several objectives reinforce one another, cancel one another, or differ greatly in scale.

This analysis is useful for debugging multi-loss systems and skip connections. It turns a single final gradient into an explanation of how individual computational routes affected the parameter.

Part 2 - Mathematical form

Let $L = L_1 + L_2$, where $L_1 = x^2$ and $L_2 = -3x$. The path contributions are:

$$g_1 = \frac{dL_1}{dx} = 2x, \qquad g_2 = \frac{dL_2}{dx} = -3.$$

Therefore:

$$\frac{dL}{dx} = g_1 + g_2 = 2x - 3.$$

Part 3 - Hints and Helper

Calculate each derivative manually and also obtain separate Autograd gradients with `torch.autograd.g` while retaining the shared graph when necessary. Verify that their sum equals the combined-loss gradient.

Part 4 - Python code skeleton

```
import torch

def E05(x):
    loss1 = ...
    loss2 = ...
    contribution1 = torch.autograd...
    contribution2 = torch.autograd...
    total = ...
    return contribution1, contribution2, total

def main():
```

```
    x = torch.tensor(..., requires_grad=True)
    print(E05(x))

if __name__ == "__main__":
    main()
```

3.5.7 Exercise 06 - Partial Gradient Blocking

Part 1 - Why this matters

Sometimes only one branch of a larger computation should update an earlier parameter. Partial blocking keeps every branch active in the forward calculation while preventing selected paths from contributing during backpropagation.

This mechanism is useful in multi-stage learning and fixed-target methods. The challenge is to block exactly the intended path without disconnecting other gradient routes that must remain trainable.

Part 2 - Mathematical form

Let:

$$a = x^2, \qquad b = 3x, \qquad y = a + \text{stopgrad}(b).$$

The forward value is $x^2 + 3x$, but:

$$\frac{dy}{dx} = 2x,$$

because the derivative contribution from b is blocked.

Part 3 - Hints and Helper

Build both branches and detach only the blocked branch before combining them. Compare forward values with an unblocked version and compare their gradients to identify the removed contribution.

Part 4 - Python code skeleton

```
import torch

def E06(x):
    active_branch = ...
    blocked_branch = (...).detach()
    y = ...
    y.backward()
    return y, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E06(x))

if __name__ == "__main__":
    main()
```

3.5.8 Exercise 07 - Detach Effect on Chain Rule

Part 1 - Why this matters

Detaching an intermediate breaks the chain rule at a precise boundary. Operations after that boundary can still form a new graph, but no derivative crosses backward into the history that produced the detached value.

Understanding this effect prevents accidental loss of learning signals. Equal tensor values do not imply equal gradient behavior when one value remains connected and the other has been detached.

Part 2 - Mathematical form

Let $u = x^2$ and $\widetilde{u} = \text{stopgrad}(u)$. If $y = 3\widetilde{u}$, then:

$$\frac{\partial y}{\partial \widetilde{u}} = 3, \qquad \frac{\partial \widetilde{u}}{\partial x} = 0,$$

so:

$$\frac{dy}{dx} = 0.$$

Part 3 - Hints and Helper

Inspect `requires_grad` and `grad_fn` before and after detaching. If later operations need their own gradient tracking, create an appropriate new leaf without reconnecting the original history.

Part 4 - Python code skeleton

```
import torch

def E07(x):
    u = ...
    detached_u = u.detach()
    new_leaf = detached_u...
    y = ...
    y.backward()
    return x.grad, new_leaf.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E07(x))

if __name__ == "__main__":
    main()
```

3.5.9 Exercise 08 - Chain Rule Failure Debugging

Part 1 - Why this matters

A missing gradient may result from detaching, converting to a Python value, using a non-differentiable operation, or inspecting a non-leaf gradient without retaining it. The mathematical formula can be correct while the implemented graph is broken.

Effective debugging follows the graph from the loss back toward the expected leaf. At each stage, tensor properties reveal where gradient tracking stopped or where the wrong object entered the computation.

Part 2 - Mathematical form

For a valid chain $x \to u \to L$:

$$\frac{dL}{dx} = \frac{dL}{du}\frac{du}{dx}.$$

If implementation replaces u with $\text{stopgrad}(u)$, then:

$$\frac{d\ \text{stopgrad}(u)}{dx} = 0,$$

and the chain contribution disappears.

Part 3 - Hints and Helper

Print `requires_grad`, `is_leaf`, and `grad_fn` for every node. Locate the first tensor that unexpectedly lacks history and repair the graph construction rather than assigning a gradient manually.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    u = ...
    suspicious_value = ...
    loss = ...
    print(...)
    loss.backward()
    return x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E08(x))

if __name__ == "__main__":
    main()
```

3.5.10 Exercise 09 - Full Graph Gradient Trace

Part 1 - Why this matters

A full trace combines forward values, graph structure, local derivatives, path contributions, and final gradients. This produces a complete explanation of how a scalar loss responds to its

earliest inputs.

The exercise integrates chains and branches into one debugging method. It prepares the reader to inspect larger models where an unexpected gradient must be traced across several dependent operations.

Part 2 - Mathematical form

Let $a = 2x$, $b = a^2$, $c = \sin(a)$, and $L = b + c$. Then:

$$\frac{dL}{da} = 2a + \cos(a), \qquad \frac{da}{dx} = 2,$$

and:

$$\frac{dL}{dx} = 2\left(2a + \cos(a)\right).$$

Part 3 - Hints and Helper

Retain gradients for all non-leaf nodes and record forward values before backward. Construct an ordered trace containing each node, its local derivative, retained gradient, and relationship to the manual result.

Part 4 - Python code skeleton

```
import torch

def E09(x):
    a = ...
    b = ...
    c = torch...
    loss = ...
    for tensor in (...):
        tensor.retain_grad()
    manual_gradient = ...
    loss.backward()
    trace = ...
    return manual_gradient, trace

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E09(x))

if __name__ == "__main__":
    main()
```

3.6 ABM04 - Autograd Engine in PyTorch

Mathematics and Theory

3.6.1 Exercise 00 - Autograd Basic Usage

Part 1 - Why this matters

Autograd automatically records differentiable operations involving tensors that require gradients. A scalar backward call then applies reverse-mode differentiation and stores results in the appropriate leaf tensors.

This basic workflow connects a forward formula, its computational graph, and parameter gradients. Mastering it provides the operational foundation for every later training exercise.

Part 2 - Mathematical form

Let $x \in \mathbb{R}$ and $L = (x-3)^2$. Then:

$$\frac{dL}{dx} = 2(x-3).$$

The forward pass computes L, and the backward pass evaluates this derivative at the current x.

Part 3 - Hints and Helper

Create a floating-point leaf with gradient tracking, calculate a scalar loss, and inspect its graph information. Call `backward()` once and compare `x.grad` with the manual derivative.

Part 4 - Python code skeleton

```
import torch

def E00(x):
    loss = ...
    loss.backward()
    manual_gradient = ...
    return loss, manual_gradient, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E00(x))

if __name__ == "__main__":
    main()
```

3.6.2 Exercise 01 - grad_fn Inspection

Part 1 - Why this matters

Every non-leaf output of a tracked operation contains a `grad_fn` describing the backward operation associated with its creation. Following these objects reveals the structure Autograd will traverse.

Graph inspection helps explain why a tensor is connected, detached, or unable to propagate a gradient. It is especially valuable when a long expression does not produce the expected leaf gradient.

Part 2 - Mathematical form

For:

$$a = x^2, \qquad b = 3a, \qquad L = b + 1,$$

the dependency chain is:

$$x \longrightarrow a \longrightarrow b \longrightarrow L.$$

The leaf x has no producing operation, while each non-leaf node has backward history.

Part 3 - Hints and Helper

Inspect `is_leaf`, `requires_grad`, and `grad_fn` at every stage. Explore `next_functions` carefully to identify predecessor nodes without modifying the graph.

Part 4 - Python code skeleton

```
import torch

def E01(x):
    a = ...
    b = ...
    loss = ...
    inspection = ...
    return inspection

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E01(x))

if __name__ == "__main__":
    main()
```

3.6.3 Exercise 02 - Gradient Accumulation Behavior

Part 1 - Why this matters

Leaf gradient buffers accumulate contributions instead of being overwritten automatically. This allows several backward computations to contribute to one update, but it also makes stale gradients a common training error.

Observing the buffer across multiple passes separates graph lifetime from gradient lifetime. A graph may be new for each forward pass while the same leaf's `.grad` continues to retain earlier values.

Part 2 - Mathematical form

For losses $L_1 = x^2$ and $L_2 = 3x$:

$$\nabla_x L_1 = 2x, \qquad \nabla_x L_2 = 3.$$

Without clearing the buffer, two backward passes store:

$$x.grad = 2x + 3.$$

Part 3 - Hints and Helper

Construct each loss through a valid forward graph and clone the gradient after each backward call. Then reset the buffer and show that a new backward result begins without the earlier contribution.

Part 4 - Python code skeleton

```
import torch

def E02(x):
    loss1 = ...
    loss1.backward()
    first = x.grad...
    loss2 = ...
    loss2.backward()
    accumulated = x.grad...
    return first, accumulated

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E02(x))

if __name__ == "__main__":
    main()
```

3.6.4 Exercise 03 - No-Grad Context Manager

Part 1 - Why this matters

Evaluation and parameter updates often need tensor calculations without constructing a backward graph. The `torch.no_grad()` context temporarily disables gradient recording even when its inputs normally require gradients.

Avoiding unnecessary graphs reduces memory use and execution overhead. The context is temporary, so operations performed after leaving it can resume gradient tracking according to their inputs.

Part 2 - Mathematical form

If x requires gradients and:

$$y = f(x)$$

is evaluated inside a no-gradient region, the forward value remains correct but no derivative path is recorded:

$$\frac{\partial y}{\partial x} \quad \text{is not tracked by Autograd.}$$

Part 3 - Hints and Helper

Compute the same expression inside and outside `torch.no_grad()`. Compare values, `requires_grad`, and `grad_fn`, then verify that tracking resumes after the context ends.

Part 4 - Python code skeleton

```
import torch

def E03(x):
    tracked = ...
    with torch.no_grad():
        untracked = ...
    tracked_again = ...
    return (...)

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E03(x))

if __name__ == "__main__":
    main()
```

3.6.5 Exercise 04 - Inference vs Training Mode Gradient

Part 1 - Why this matters

Module training mode and gradient recording control different behaviors. `model.train()` or `model.eval()` changes layers such as dropout and batch normalization, while gradient contexts determine whether Autograd records operations.

Inference normally combines evaluation mode with disabled gradient tracking, but neither setting automatically guarantees the other. Understanding the separation prevents unexpected stochastic outputs or unnecessary graph memory.

Part 2 - Mathematical form

For a model f_θ:

$$\widehat{\mathbf{y}} = f_\theta(\mathbf{x}).$$

Training requires derivatives such as $\nabla_\theta L$, whereas inference generally requires only the forward value $\widehat{\mathbf{y}}$. Evaluation mode may also change the definition of selected layer operations.

Part 3 - Hints and Helper

Run a small module once in training mode with gradients enabled and once in evaluation mode inside an inference or no-gradient context. Compare output properties and parameter gradient availability.

Part 4 - Python code skeleton

```
import torch

def E04(model, X):
    model...
    training_output = ...
    model...
    with torch.no_grad():
        inference_output = ...
    return (...)

def main():
    model = torch.nn...
    X = torch...
    print(E04(model, X))

if __name__ == "__main__":
    main()
```

3.6.6 Exercise 05 - Custom Autograd Function (Forward)

Part 1 - Why this matters

A custom Autograd function defines how a specialized tensor operation participates in PyTorch's graph. Its forward method computes the output and saves only the information that the matching backward calculation will require.

Separating forward logic from saved context encourages careful derivative design. The operation should use tensor expressions, preserve expected shapes, and avoid saving unnecessary data that increases graph memory.

Part 2 - Mathematical form

Define a custom operation:

$$y = x^3.$$

The forward method returns x^3 and saves x because the backward formula will require:

$$\frac{dy}{dx} = 3x^2.$$

Part 3 - Hints and Helper

Subclass `torch.autograd.Function` and implement a static `forward(ctx, input)` method. Save required tensors with `ctx.save_for_backward()` and invoke the operation using `apply()`.

Part 4 - Python code skeleton

```
import torch

class CubeFunction(torch.autograd.Function):
    @staticmethod
```

```
    def forward(ctx, input_tensor):
        ctx.save_for_backward(...)
        output = ...
        return output

def E05(x):
    return CubeFunction.apply(...)

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E05(x))

if __name__ == "__main__":
    main()
```

3.6.7 Exercise 06 - Custom Autograd Function (Backward)

Part 1 - Why this matters

The backward method receives the gradient arriving from later graph nodes and must return one gradient for every forward input. It combines that upstream value with the custom operation's local derivative.

An incorrect backward implementation can run without an obvious forward error yet train a model incorrectly. Manual analysis and numerical gradient checking are therefore essential parts of custom function development.

Part 2 - Mathematical form

For $y = x^3$ and scalar loss $L(y)$:

$$\frac{dL}{dx} = \frac{dL}{dy}\frac{dy}{dx} = \text{grad_output} \cdot 3x^2.$$

The returned gradient must have the same shape as x.

Part 3 - Hints and Helper

Retrieve saved tensors with `ctx.saved_tensors`. Multiply `grad_output` by the local derivative and return the result. Verify the custom operation against ordinary PyTorch operations and `gradcheck`.

Part 4 - Python code skeleton

```
import torch

class CubeFunction(torch.autograd.Function):
    @staticmethod
    def forward(ctx, input_tensor):
        ctx.save_for_backward(...)
        return ...
```

```
    @staticmethod
    def backward(ctx, grad_output):
        input_tensor, = ctx.saved_tensors
        grad_input = ...
        return grad_input

def E06(x):
    y = CubeFunction.apply(x)
    y.backward(...)
    return x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E06(x))

if __name__ == "__main__":
    main()
```

3.6.8 Exercise 07 - Autograd Graph Memory Analysis

Part 1 - Why this matters

Backward formulas may save forward tensors until gradient computation finishes. Large intermediates, retained graphs, and unnecessary tracking can therefore consume substantial memory even when the final output is small.

Memory analysis connects graph design with practical model capacity. Identifying which tensors remain reachable helps choose between graph retention, forward recomputation, checkpointing, and no-gradient execution.

Part 2 - Mathematical form

If a graph saves intermediates $\mathcal{S} = \{T_1, \ldots, T_k\}$, an approximate stored-data cost is:

$$M \approx \sum_{i=1}^{k} \text{numel}(T_i)\ \text{element_size}(T_i).$$

This excludes additional graph and allocator overhead.

Part 3 - Hints and Helper

Compare memory behavior for a tracked forward pass, a no-gradient pass, and a retained graph. On CUDA, synchronize appropriately and use PyTorch memory statistics; on CPU, focus on saved tensor sizes and graph references.

Part 4 - Python code skeleton

```
import torch

def E07(x):
```

```
    before = ...
    output = ...
    after_forward = ...
    loss = ...
    loss.backward(...)
    after_backward = ...
    return before, after_forward, after_backward

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E07(x))

if __name__ == "__main__":
    main()
```

3.6.9 Exercise 08 - Gradient Hook Implementation

Part 1 - Why this matters

A gradient hook executes when a tensor's gradient is produced during backpropagation. Hooks can observe, log, validate, or transform gradients without rewriting the forward expression.

Hooks are useful for debugging vanishing or exploding values and for specialized gradient transformations. Because a hook can change training behavior, observational hooks should return the original gradient or no replacement.

Part 2 - Mathematical form

Let an arriving gradient be $\mathbf{g}$. A monitoring hook computes a statistic such as:

$$s = \|\mathbf{g}\|_2.$$

A transforming hook instead returns:

$$\widetilde{\mathbf{g}} = H(\mathbf{g}),$$

which replaces the gradient passed farther backward.

Part 3 - Hints and Helper

Register a hook on a leaf or intermediate tensor, record its gradient norm, and run one backward pass. Store the returned handle and remove it afterward to prevent the hook from remaining active unexpectedly.

Part 4 - Python code skeleton

```
import torch

def E08(x):
    records = []
    def hook_function(gradient):
        records.append(...)
```

```
        return ...

    handle = x.register_hook(...)
    loss = ...
    loss.backward()
    handle.remove()
    return records, x.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E08(x))

if __name__ == "__main__":
    main()
```

3.6.10 Exercise 09 - Autograd Failure Debugging

Part 1 - Why this matters

Autograd failures can arise from disabled tracking, detached values, non-scalar outputs, in-place changes, graph reuse, dtype errors, or inspection of non-leaf gradients. Similar symptoms may therefore have different structural causes.

A disciplined diagnosis starts at the loss and follows the graph toward the expected parameter. Tensor metadata, shapes, error messages, and minimal reproductions identify the first point where assumptions and actual graph behavior diverge.

Part 2 - Mathematical form

For a valid scalar loss L and parameter θ:

$$\nabla_\theta L$$

exists in Autograd only when a differentiable recorded path connects θ to L. If every path is cut, the requested gradient is absent rather than mathematically propagated as an ordinary connected value.

Part 3 - Hints and Helper

Inspect dtype, shape, `requires_grad`, `is_leaf`, and `grad_fn`. Check for no-gradient regions, `detach()`, conversions, in-place operations, and reused graphs before applying a fix.

Part 4 - Python code skeleton

```
import torch

def E09(parameter):
    intermediate = ...
    loss = ...
    diagnostics = {
        "loss_shape": ...,
```

```
        "requires_grad": ...,
        "grad_fn": ...,
        "parameter_is_leaf": ...
    }
    loss.backward(...)
    return diagnostics, parameter.grad

def main():
    x = torch.tensor(..., requires_grad=True)
    print(E09(x))

if __name__ == "__main__":
    main()
```

3.7 ABM05 - Backprop Through Linear Layers

Mathematics and Theory

3.7.1 Exercise 00 - Single Linear Layer Backprop

Part 1 - Why this matters

A linear layer combines input features with trainable weights and bias before any activation is applied. Backpropagation must distribute an upstream gradient to the input, weight matrix, and bias vector.

Deriving all three gradients reveals the structure hidden inside a standard PyTorch layer. It also establishes the matrix orientation used throughout deeper neural networks.

Part 2 - Mathematical form

Let $\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{b}$ and let $\mathbf{g} = \nabla_{\mathbf{y}} L$. Then:

$$\nabla_{\mathbf{x}} L = \mathbf{W}^{\mathsf{T}}\mathbf{g}, \quad \nabla_{\mathbf{W}} L = \mathbf{g}\mathbf{x}^{\mathsf{T}}, \quad \nabla_{\mathbf{b}} L = \mathbf{g}.$$

Part 3 - Hints and Helper

Create leaf tensors for input, weight, and bias. Produce a scalar loss from the layer output, calculate the three manual gradients, and compare their shapes and values with Autograd.

Part 4 - Python code skeleton

```
import torch

def E00(x, W, bias):
    y = ...
    loss = torch...
    manual_gradients = ...
    loss.backward()
```

```
    return manual_gradients, x.grad, W.grad, bias.grad

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

3.7.2 Exercise 01 - Weight Gradient Verification

Part 1 - Why this matters

Each weight connects one input feature to one output feature. Its gradient is the product of the input activation and the upstream gradient reaching the corresponding output.

Weight-gradient verification exposes the outer-product structure used by linear-layer training. Incorrect transposes become visible because they change both axis meaning and gradient shape.

Part 2 - Mathematical form

For $\mathbf{y} = \mathbf{W}\mathbf{x}$ and upstream gradient $\mathbf{g}$:

$$\frac{\partial L}{\partial W_{ij}} = g_i x_j.$$

Therefore:

$$\nabla_{\mathbf{W}} L = \mathbf{g}\mathbf{x}^{\mathsf{T}}.$$

Part 3 - Hints and Helper

Supply an explicit upstream gradient to `y.backward(gradient)` or define an equivalent scalar loss. Construct the manual outer product and compare it with `W.grad`.

Part 4 - Python code skeleton

```
import torch

def E01(x, W, upstream):
    y = ...
    manual_weight_gradient = ...
    y.backward(...)
    return manual_weight_gradient, W.grad

def main():
    X = torch...
    W = torch...
    bias = torch...
```

```
    print(E01(...))

if __name__ == "__main__":
    main()
```

3.7.3 Exercise 02 - Bias Gradient Verification

Part 1 - Why this matters

A bias value is added directly to its output feature, so its local derivative is one. The bias gradient therefore equals the upstream gradient, summed across any axes where the bias was broadcast.

This simple rule becomes important with batches, where one bias parameter influences many examples. Verifying it prepares the reader to reason about broadcast reduction during backward.

Part 2 - Mathematical form

For one sample:

$$\mathbf{y} = \mathbf{W}\mathbf{x} + \mathbf{b} \quad \Rightarrow \quad \nabla_{\mathbf{b}} L = \mathbf{g}.$$

For a batch with upstream matrix $\mathbf{G}$:

$$\nabla_{\mathbf{b}} L = \sum_{i=1}^{B} \mathbf{G}_{i:}.$$

Part 3 - Hints and Helper

Use a batch so the bias is broadcast across rows. Provide or derive an upstream gradient matrix, sum it along the batch axis manually, and compare the result with `bias.grad`.

Part 4 - Python code skeleton

```
import torch

def E02(X, W, bias, upstream):
    Y = ...
    manual_bias_gradient = ...
    Y.backward(...)
    return manual_bias_gradient, bias.grad

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

3.7.4 Exercise 03 - Batch Linear Layer Backprop

Part 1 - Why this matters

Batch processing applies the same linear transformation to several samples simultaneously. Parameter gradients must aggregate contributions from every row while input gradients remain separate for each sample.

Matrix notation makes this aggregation efficient and explains how batch size enters gradient computation. It also clarifies the different shapes of input, weight, and bias gradients.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{B \times D}$ and:

$$\mathbf{Y} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}.$$

For $\mathbf{G} = \nabla_{\mathbf{Y}} L$:

$$\nabla_{\mathbf{X}} L = \mathbf{G}\mathbf{W}, \quad \nabla_{\mathbf{W}} L = \mathbf{G}^{\mathsf{T}}\mathbf{X}, \quad \nabla_{\mathbf{b}} L = \sum_{i=1}^{B} \mathbf{G}_{i:}.$$

Part 3 - Hints and Helper

Write all expected shapes before implementing the formulas. Use matrix multiplication and a batch-axis sum, then verify every manual gradient against a single backward pass.

Part 4 - Python code skeleton

```
import torch

def E03(X, W, bias, upstream):
    Y = ...
    manual_dX = ...
    manual_dW = ...
    manual_db = ...
    Y.backward(...)
    return (...)

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

3.7.5 Exercise 04 - Manual vs Autograd Linear Backprop

Part 1 - Why this matters

Manual and automatic backpropagation should produce the same gradients when they use the same forward values, loss reduction, and tensor orientation. Comparing them validates

both the algebra and code.

A mismatch often identifies a forgotten batch sum, incorrect transpose, or confusion between mean and sum loss. The comparison is therefore a focused debugging method rather than only a mathematical exercise.

Part 2 - Mathematical form

For mean squared error:

$$L = \frac{1}{N}\|\mathbf{Y} - \mathbf{T}\|_F^2, \quad \mathbf{G} = \frac{2}{N}(\mathbf{Y} - \mathbf{T}).$$

The linear-layer gradients follow from $\mathbf{G}$ using the batch formulas.

Part 3 - Hints and Helper

Compute the forward output and scalar loss once. Derive the upstream loss gradient with the exact same reduction, calculate all manual layer gradients, and compare them using `torch.allclose()`.

Part 4 - Python code skeleton

```
import torch

def E04(X, W, bias, target):
    Y = ...
    loss = ...
    upstream = ...
    manual_gradients = ...
    loss.backward()
    checks = ...
    return manual_gradients, checks

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

3.7.6 Exercise 05 - Gradient Scaling with Batch Size

Part 1 - Why this matters

The choice between summing and averaging per-sample losses changes how gradient magnitude depends on batch size. A summed loss generally grows with the number of examples, while a mean loss normalizes this effect.

Understanding this scaling is important when changing batch size or learning rate. Two mathematically related reductions can produce very different update magnitudes even on repeated data.

Part 2 - Mathematical form

For per-sample losses ℓ_i:

$$L_{\text{sum}} = \sum_{i=1}^{B} \ell_i, \qquad L_{\text{mean}} = \frac{1}{B} \sum_{i=1}^{B} \ell_i.$$

Therefore:

$$\nabla L_{\text{mean}} = \frac{1}{B} \nabla L_{\text{sum}}.$$

Part 3 - Hints and Helper

Use identical repeated samples and compute parameter gradients once with a sum and once with a mean. Clear gradient buffers and rebuild the forward graph between experiments, then compare their norm ratio.

Part 4 - Python code skeleton

```
import torch

def E05(X, W, bias, target):
    sum_loss = ...
    sum_loss.backward()
    sum_gradient = W.grad...
    W.grad = ...
    mean_loss = ...
    mean_loss.backward()
    mean_gradient = W.grad...
    return (...)

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

3.7.7 Exercise 06 - Frozen Layer Gradient Check

Part 1 - Why this matters

Freezing a layer prevents its parameters from receiving gradients and being updated while still allowing its forward output to feed later trainable layers. This is central to transfer learning and staged training.

A frozen parameter is different from a detached activation. Correct freezing leaves gradient flow available for later components and, when needed, for earlier inputs connected through the fixed operation.

Part 2 - Mathematical form

For $\mathbf{h} = \mathbf{W}_f\mathbf{x}$ with frozen $\mathbf{W}_f$:

$$\nabla_{\mathbf{W}_f} L \text{ is not requested,}$$

while a downstream trainable layer may still receive:

$$\nabla_{\mathbf{W}_t} L \neq 0.$$

Part 3 - Hints and Helper

Set `requires_grad_(False)` on only the intended parameters. Run forward and backward, then inspect frozen and trainable parameter gradients without wrapping the whole forward pass in `no_grad()`.

Part 4 - Python code skeleton

```
import torch

def E06(X, frozen_layer, trainable_layer):
    frozen_layer...
    hidden = ...
    output = ...
    loss = ...
    loss.backward()
    return (...)

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

3.7.8 Exercise 07 - Linear Stack Gradient Flow

Part 1 - Why this matters

Stacking linear layers causes gradients to be repeatedly multiplied by transposed weight matrices. The result explains how early-layer updates depend on every later layer in the chain.

Although a stack without activations is forward-equivalent to one linear transformation, its parameterization creates separate gradient tensors. Their magnitudes reveal how weight scales affect deep gradient flow.

Part 2 - Mathematical form

Let:

$$\mathbf{h} = \mathbf{W}_1\mathbf{x} + \mathbf{b}_1, \qquad \mathbf{y} = \mathbf{W}_2\mathbf{h} + \mathbf{b}_2.$$

For upstream $\mathbf{g}$:

$$\nabla_{\mathbf{h}} L = \mathbf{W}_2^{\mathsf{T}}\mathbf{g}, \qquad \nabla_{\mathbf{x}} L = \mathbf{W}_1^{\mathsf{T}}\nabla_{\mathbf{h}} L.$$

Part 3 - Hints and Helper

Retain the hidden tensor gradient and perform one backward pass. Calculate the manual reverse flow from output to hidden to input, then compare values and gradient norms at each stage.

Part 4 - Python code skeleton

```
import torch

def E07(x, W1, b1, W2, b2):
    hidden = ...
    hidden.retain_grad()
    output = ...
    loss = ...
    manual_flow = ...
    loss.backward()
    return manual_flow, hidden.grad, x.grad

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

3.7.9 Exercise 08 - Numerical Stability in Backprop

Part 1 - Why this matters

Large inputs or weights can create extremely large forward values and gradients, while small repeated factors can drive gradients toward zero. Limited floating-point range can then produce overflow, underflow, or loss of precision.

Monitoring finite values and gradient norms is essential before applying a parameter update. Higher precision, normalization, careful initialization, and gradient clipping address different sources of instability.

Part 2 - Mathematical form

For a depth-K scalar linear stack:

$$y = \left(\prod_{k=1}^{K} w_k \right) x.$$

The input derivative is:

$$\frac{dy}{dx} = \prod_{k=1}^{K} w_k.$$

Thus repeated $|w_k| > 1$ can amplify gradients, while repeated $|w_k| < 1$ can shrink them.

Part 3 - Hints and Helper

Build a controllable linear stack and test several depths and scales. Inspect `torch.isfinite()` and gradient norms, and compare float32 with float64 without using clipping to hide the original behavior.

Part 4 - Python code skeleton

```
import torch

def E08(x, weights):
    value = x
    for weight in weights:
        value = ...
    loss = ...
    loss.backward()
    diagnostics = ...
    return value, diagnostics

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

3.7.10 Exercise 09 - End-to-End Linear Backprop Challenge

Part 1 - Why this matters

An end-to-end exercise combines batched input, multiple linear layers, a scalar loss, manual gradient propagation, and Autograd verification. It tests whether every earlier rule remains consistent in one pipeline.

The goal is not merely to obtain gradients, but to explain their shapes and trace them from the loss through every parameter and intermediate. This mirrors the analysis required in a small trainable model.

Part 2 - Mathematical form

Let:

$$\mathbf{H} = \mathbf{X}\mathbf{W}_1^\top + \mathbf{b}_1, \quad \mathbf{Y} = \mathbf{H}\mathbf{W}_2^\top + \mathbf{b}_2,$$

and $L = \frac{1}{N}\|\mathbf{Y} - \mathbf{T}\|_F^2$. Starting with $\nabla_{\mathbf{Y}} L$, apply the batch linear formulas backward through layer two and then layer one.

Part 3 - Hints and Helper

Record every forward shape, derive the loss gradient with the correct reduction, and compute all manual gradients in reverse order. Compare each result separately with Autograd and report the largest error.

Part 4 - Python code skeleton

```
import torch

def E09(X, W1, b1, W2, b2, target):
    hidden = ...
    output = ...
    loss = ...
    manual_gradients = ...
    loss.backward()
    comparisons = ...
    return loss, manual_gradients, comparisons

def main():
    X = torch...
    W = torch...
    bias = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

3.8 ABM06 - Gradient Flow Debugging

Mathematics and Theory

3.8.1 Exercise 00 - Detecting Vanishing Gradients

Part 1 - Why this matters

Vanishing gradients occur when derivatives become extremely small as they pass through many layers. Early parameters then receive almost no learning signal, so their values change slowly even while later layers continue to train.

Detection requires comparing gradients across depth and over multiple steps. A small loss change alone does not identify vanishing flow; the parameter-gradient magnitudes provide direct evidence.

Part 2 - Mathematical form

For a chain with local derivatives $d_1, \ldots, d_K$:

$$\frac{\partial L}{\partial h_0} = \frac{\partial L}{\partial h_K} \prod_{k=1}^{K} d_k.$$

If $|d_k| < 1$ repeatedly, the product may approach zero as K grows.

Part 3 - Hints and Helper

Build a deep scalar or linear chain with controlled weight values. After backward, record every retained intermediate or parameter gradient norm and flag values below a chosen threshold without assuming one universal threshold.

Part 4 - Python code skeleton

```
import torch

def E00(model, X, target, threshold):
    output = ...
    loss = ...
    loss.backward()
    gradient_norms = ...
    vanishing_flags = ...
    return loss, gradient_norms, vanishing_flags

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E00(...))

if __name__ == "__main__":
    main()
```

3.8.2 Exercise 01 - Detecting Exploding Gradients

Part 1 - Why this matters

Exploding gradients arise when repeated derivative multiplication creates very large values. Parameter updates can become unstable, the loss may oscillate, and floating-point values may eventually become infinite or NaN.

Early detection should occur before the optimizer step corrupts parameters. Monitoring both magnitude and finiteness distinguishes rapid growth from a gradient that has already become numerically invalid.

Part 2 - Mathematical form

For a depth-K chain:

$$\left\| \frac{\partial L}{\partial h_0} \right\| \leq \left\| \frac{\partial L}{\partial h_K} \right\| \prod_{k=1}^{K} \|J_k\|.$$

Repeated Jacobian norms greater than one can amplify the gradient exponentially.

Part 3 - Hints and Helper

Create a controlled deep chain and inspect gradient norms after backward but before updating parameters. Check `torch.isfinite()` and compare each norm with a selected alert threshold.

Part 4 - Python code skeleton

```
import torch

def E01(model, X, target, threshold):
    loss = ...
    loss.backward()
    norms = ...
    finite_checks = ...
    exploding_flags = ...
    return norms, finite_checks, exploding_flags

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E01(...))

if __name__ == "__main__":
    main()
```

3.8.3 Exercise 02 - Gradient Norm Monitoring

Part 1 - Why this matters

A gradient tensor may contain many values, so its norm provides a compact measure of update magnitude. Recording norms across steps reveals trends that individual gradient prints cannot show clearly.

Norm monitoring supports diagnosis but does not replace inspecting shapes, signs, or distributions. A healthy range depends on the model, layer scale, loss reduction, and precision, so history and layer comparisons matter.

Part 2 - Mathematical form

For parameter gradient $\mathbf{g}$, the L_2 norm is:

$$\|\mathbf{g}\|_2 = \sqrt{\sum_i g_i^2}.$$

A global norm across parameters is:

$$G = \sqrt{\sum_p \|\nabla_p L\|_2^2}.$$

Part 3 - Hints and Helper

After backward, iterate over named parameters and skip entries whose gradient is `None`. Record per-parameter norms and compute a global norm without changing the gradients.

Part 4 - Python code skeleton

```
import torch

def E02(model):
    records = {}
    squared_total = ...
    for name, parameter in model.named_parameters():
        if parameter.grad is not None:
            norm = ...
            records[name] = norm
            squared_total = ...
    global_norm = ...
    return records, global_norm

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E02(...))

if __name__ == "__main__":
    main()
```

3.8.4 Exercise 03 - Layer-wise Gradient Inspection

Part 1 - Why this matters

A single global norm can hide which layer causes a problem. Layer-wise inspection compares gradient magnitude, finiteness, and parameter scale throughout the network to locate where useful flow disappears or instability begins.

The resulting profile should be interpreted in network order. A sudden change between neighboring layers often provides more useful evidence than declaring every small or large value independently abnormal.

Part 2 - Mathematical form

For layer ℓ with parameters θ_ℓ, define:

$$G_\ell = \|\nabla_{\theta_\ell} L\|_2.$$

A scale-aware ratio can be:

$$R_\ell = \frac{G_\ell}{\|\theta_\ell\|_2 + \varepsilon}.$$

Both quantities should be reported rather than relying on one alone.

Part 3 - Hints and Helper

Group named parameters by layer, then record parameter norms, gradient norms, ratios, and finite checks after one backward pass. Preserve network order so adjacent layers can be compared.

Part 4 - Python code skeleton

```
import torch

def E03(model, epsilon=1e-12):
    report = {}
    for name, parameter in model.named_parameters():
        gradient_norm = ...
        parameter_norm = ...
        ratio = ...
        report[name] = (...)
    return report

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

3.8.5 Exercise 04 - Broken Graph Debugging

Part 1 - Why this matters

A broken graph prevents the loss from reaching an expected parameter. Common causes include `detach()`, no-gradient contexts, tensor reconstruction, conversion to Python or NumPy, and using an unrelated tensor in the loss.

The key symptom is often a missing gradient rather than a wrong numeric value. Debugging should follow the dependency path backward and locate the first tensor whose history differs from the intended graph.

Part 2 - Mathematical form

For a required path:

$$\theta \longrightarrow h_1 \longrightarrow \cdots \longrightarrow L,$$

Autograd can compute $\nabla_\theta L$ only if every edge is recorded and differentiable. If one intermediate becomes stopgrad(h_j), the earlier path is disconnected.

Part 3 - Hints and Helper

Print `requires_grad`, `is_leaf`, and `grad_fn` for each intermediate. Find the earliest unexpected loss of graph history and correct that operation rather than assigning a gradient manually.

Part 4 - Python code skeleton

```
import torch

def E04(parameter, X):
    first = ...
    suspicious = ...
    output = ...
    loss = ...
    diagnostics = ...
    loss.backward(...)
    return diagnostics, parameter.grad

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E04(...))

if __name__ == "__main__":
    main()
```

3.8.6 Exercise 05 - requires_grad Misuse Debugging

Part 1 - Why this matters

Incorrect `requires_grad` settings can track constant data unnecessarily or prevent trainable parameters from receiving gradients. Enabling the flag after a disconnected computation does not recreate the history that was already lost.

Correct configuration begins by classifying tensors as trainable parameters, differentiable inputs, constants, or temporary intermediates. Only the intended leaves normally need explicit setup.

Part 2 - Mathematical form

If $y = f(x)$ is computed while x does not require gradients, later changing a disconnected tensor's flag cannot reconstruct:

$$x \longrightarrow y.$$

Gradient tracking must be enabled on the appropriate leaf before the forward operations whose derivatives are needed.

Part 3 - Hints and Helper

List every relevant tensor with its role and metadata before the forward pass. Check dtype and leaf status, then repair the original tensor creation or parameter configuration and rebuild the graph.

Part 4 - Python code skeleton

```
import torch

def E05(tensors):
    diagnostics = {}
    for name, tensor in tensors.items():
        diagnostics[name] = (...)
    corrected_tensors = ...
    return diagnostics, corrected_tensors

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E05(...))

if __name__ == "__main__":
    main()
```

3.8.7 Exercise 06 - Gradient Blocking Detection

Part 1 - Why this matters

Gradient blocking may be intentional, as with frozen targets, or accidental, as with detachments and saturated activations. A zero or missing gradient must therefore be traced to determine whether the behavior matches the design.

Comparing forward activity with backward flow helps locate the boundary. An intermediate can have a meaningful nonzero forward value while allowing little or no derivative to pass to its ancestors.

Part 2 - Mathematical form

For $h = f(x)$ and $y = g(h)$:

$$\frac{dy}{dx} = \frac{dy}{dh}\frac{dh}{dx}.$$

Flow is blocked if a factor is exactly zero, if h is detached, or if the implemented operation is not differentiable along the selected path.

Part 3 - Hints and Helper

Retain gradients on intermediate tensors and compare their norms from output toward input. Inspect activation ranges and graph metadata, and distinguish a zero tensor from `None`, since they indicate different situations.

Part 4 - Python code skeleton

```
import torch

def E06(model, X, target):
    intermediates = ...
    for tensor in intermediates:
```

```
        tensor.retain_grad()
    loss = ...
    loss.backward()
    flow_report = ...
    return flow_report

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

3.8.8 Exercise 07 - Hook-based Gradient Debugging

Part 1 - Why this matters

Hooks observe gradients at the moment they pass through selected tensors or parameters. They allow a model to collect a backward trace without adding gradient-printing logic to every training operation.

A diagnostic hook should record compact statistics and avoid unintended gradient modification. Hook handles must be removed after the experiment so repeated registrations do not duplicate logs or affect later runs.

Part 2 - Mathematical form

For a gradient $\mathbf{g}$, a hook may record:

$$\min(\mathbf{g}), \quad \max(\mathbf{g}), \quad \text{mean}(\mathbf{g}), \quad \|\mathbf{g}\|_2.$$

Returning $\mathbf{g}$ unchanged preserves the original backward computation.

Part 3 - Hints and Helper

Register hooks on selected named parameters, store detached statistics, run one backward pass, and remove every handle. Include shape and finite-value checks in the report.

Part 4 - Python code skeleton

```
import torch

def E07(model, loss):
    records = {}
    handles = []
    for name, parameter in model.named_parameters():
        handle = parameter.register_hook(...)
        handles.append(handle)
    loss.backward()
```

```
    for handle in handles:
        handle.remove()
    return records

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E07(...))

if __name__ == "__main__":
    main()
```

3.8.9 Exercise 08 - Training Collapse Diagnosis

Part 1 - Why this matters

Training collapse may appear as constant predictions, NaN loss, zero gradients, extreme updates, or failure to improve. These symptoms can originate from data, forward activations, loss configuration, gradients, optimizer settings, or parameter corruption.

Diagnosis should inspect the pipeline in order rather than immediately changing the model. A reproducible batch and measurements taken before and after each stage make it possible to identify when valid values first become abnormal.

Part 2 - Mathematical form

For update:

$$\theta_{t+1} = \theta_t - \eta g_t,$$

collapse may occur when $g_t \approx 0$, when $\|\eta g_t\|$ is excessive, or when either θ_t, L_t, or g_t is non-finite. Relative update size can be monitored as:

$$U_t = \frac{\|\eta g_t\|}{\|\theta_t\| + \varepsilon}.$$

Part 3 - Hints and Helper

Check input and target statistics, forward activation ranges, loss finiteness, gradient norms, learning rate, and parameter values in that order. Do not perform an optimizer step until all pre-update diagnostics are recorded.

Part 4 - Python code skeleton

```
import torch

def E08(model, X, target, learning_rate):
    diagnostics = {}
    output = ...
    loss = ...
    diagnostics["forward"] = ...
```

```
    loss.backward()
    diagnostics["gradients"] = ...
    diagnostics["relative_updates"] = ...
    return diagnostics

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E08(...))

if __name__ == "__main__":
    main()
```

3.8.10 Exercise 09 - Full Backprop Debugging Scenario

Part 1 - Why this matters

A complete debugging scenario combines shape validation, graph connectivity, activation inspection, gradient monitoring, and update analysis. The objective is to locate a fault using evidence rather than replacing several components at once.

The final report should identify the first abnormal stage, explain its downstream effects, and propose one targeted correction. Repeating the same controlled batch after that correction verifies whether the diagnosis was accurate.

Part 2 - Mathematical form

For a pipeline:

$$\mathbf{X} \to h_1 \to \cdots \to \widehat{\mathbf{Y}} \to L \to \nabla_\theta L \to \theta',$$

validate each transition. Useful invariants include compatible shapes, finite values, a recorded path to trainable parameters, and an update magnitude appropriate to parameter scale.

Part 3 - Hints and Helper

Create one deliberately faulty small model or training step. Capture input, forward, loss, graph, gradient, and proposed-update diagnostics; name the earliest failing check and change only its direct cause before rerunning.

Part 4 - Python code skeleton

```
import torch

def E09(model, X, target, optimizer):
    report = {}
    report["input"] = ...
    output = ...
    report["forward"] = ...
    loss = ...
    report["loss"] = ...
```

```
    optimizer.zero_grad(...)
    loss.backward()
    report["gradients"] = ...
    report["diagnosis"] = ...
    return report

def main():
    model = torch.nn...
    X = torch...
    target = torch...
    print(E09(...))

if __name__ == "__main__":
    main()
```

Book 4

Optimization in Code

4.1 Introduction

4.1.1 What will the book teach you

Training an artificial intelligence model is not completed by calculating a gradient. A gradient only describes how a loss changes locally with respect to the model parameters. Optimization is the process that converts this information into a sequence of controlled parameter updates, with the objective of moving the model toward better solutions while preserving numerical and training stability. This book teaches how that process works mathematically and how it is implemented directly in PyTorch code.

You will begin with the fundamental gradient descent update and construct a training loop without hiding its individual steps. For a parameter vector $\boldsymbol{\theta}$, a loss function $L(\boldsymbol{\theta})$, and a learning rate η, the basic update is:

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \nabla_{\boldsymbol{\theta}} L(\boldsymbol{\theta}_t).$$

Although this equation is short, its behavior depends on the scale and direction of the gradient, the geometry of the loss surface, the learning rate, the parameter initialization, the noise in the data, and the history of previous updates. The exercises will separate these factors so that you can observe how each one changes the optimization path.

The learning rate will be studied as more than a number selected by trial and error. You will examine how a small rate can make useful progress impractically slow, while a large rate can overshoot a minimum, oscillate, or cause divergence. You will implement learning-rate sweeps, schedules, warm-up strategies, and adaptive logic, then use recorded loss values and update behavior to distinguish slow convergence from instability. The objective is to develop evidence-based tuning skills instead of changing hyperparameters without a diagnosis.

After mastering vanilla gradient descent, you will study optimizers that maintain an internal state. Momentum stores a velocity that combines current and previous gradients, helping an update preserve useful direction and reduce oscillation. RMSProp stores a running average of squared gradients to adapt the update scale for each parameter. Adam combines estimates of the first and second moments and corrects their initialization bias. You will implement these equations manually before using or reproducing optimizer classes, so variables such as velocity, decay rate, moment estimates, bias correction, and numerical epsilon have clear mathematical

meanings.

This book also treats convergence as a measurable process rather than the simple completion of a fixed number of epochs. You will track loss curves, gradient norms, parameter changes, plateaus, oscillations, non-finite values, and long-run behavior. You will implement early stopping and stability checks, compare optimizers under controlled conditions, and investigate noisy gradients, vanishing gradients, exploding gradients, and training collapse. These exercises will teach you to determine whether training is improving, stalled, unstable, or only appearing successful because the chosen metric is incomplete.

Weight initialization is included because optimization begins before the first parameter update. Initial values determine the scale of forward activations and backward gradients, influence symmetry between units, and can make a model easy or difficult to optimize. You will compare zero, uniform, normal, Xavier, and He initialization, then connect their assumptions to activation behavior and gradient flow. The goal is not to memorize initialization function names, but to understand why different network structures require different starting scales.

4.1.2 How to approach the exercises

Every exercise should be treated as a controlled experiment. Begin by writing the mathematical update, predicting the expected behavior, and identifying which values must be recorded. Then implement the incomplete code, run it with a simple reproducible example, and compare the observation with the prediction. When two optimizers or hyperparameters are compared, keep the data, model, initialization, loss function, and random seed consistent so that the comparison measures the intended variable.

Do not judge an optimizer from one final loss value. Record the complete loss history, gradient statistics, parameter updates, convergence speed, and signs of instability. When training fails, locate the earliest abnormal stage before applying a correction. This method will prepare you to design and debug real training systems in which several optimization choices interact simultaneously.

4.1.3 The Chapters (OC00 - OC06) included in this book

- OC00 - Gradient Descent Implementation
- OC01 - Learning Rate Effects & Tuning
- OC02 - Momentum Update Rule
- OC03 - RMSProp Logic & Behavior
- OC04 - Adam Optimizer Math + Code
- OC05 - Convergence & Stability
- OC06 - Weight Initialization Impact

4.2 OC00 - Gradient Descent Implementation

Mathematics and Theory

4.2.1 Exercise 00 - Simple Gradient Descent Step

Part 1 - Why this matters

Gradient descent changes a parameter in the direction opposite to the local loss gradient. A single update is the smallest unit of optimization and makes the roles of the gradient and learning rate completely visible.

Studying one step before building a loop prevents parameter updates from becoming hidden optimizer behavior. It also establishes the rule that gradients are computed from the old parameter value before the new value is created.

Part 2 - Mathematical form

For parameter θ_t, gradient $g_t = \nabla_\theta L(\theta_t)$, and learning rate $\eta > 0$:

$$\theta_{t+1} = \theta_t - \eta g_t.$$

If $g_t > 0$, the update decreases θ; if $g_t < 0$, it increases θ.

Part 3 - Hints and Helper

Accept a parameter, its gradient, and a learning rate. Compute a new parameter without modifying the original tensor in place, then report the update displacement and verify its direction.

Part 4 - Python code skeleton

```
import torch

def E00(parameter, gradient, learning_rate):
    update = ...
    new_parameter = ...
    return new_parameter, update

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.2.2 Exercise 01 - Gradient Descent on Scalar Loss

Part 1 - Why this matters

A scalar objective allows the complete optimization path to be observed one value at a time. The derivative identifies the local downhill direction, while repeated updates reveal whether the chosen step size approaches the minimum.

This controlled example connects calculus, Autograd, and optimization without model complexity. It also shows that a decreasing loss is an observed result of appropriate updates, not a guarantee of every gradient descent configuration.

Part 2 - Mathematical form

Let:

$$L(\theta) = (\theta - a)^2, \qquad \frac{dL}{d\theta} = 2(\theta - a).$$

Gradient descent applies:

$$\theta_{t+1} = \theta_t - 2\eta(\theta_t - a),$$

whose minimum is at $\theta = a$.

Part 3 - Hints and Helper

Create a scalar leaf parameter and compute the loss and gradient. Apply the update inside `torch.no_grad()`, clear the gradient afterward, and record both old and new loss values.

Part 4 - Python code skeleton

```
import torch

def E01(parameter, target, learning_rate):
    loss = ...
    loss.backward()
    gradient = parameter.grad...
    with torch.no_grad():
        parameter ...
    parameter.grad = ...
    return loss, gradient, parameter

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.2.3 Exercise 02 - Gradient Descent on Vector Parameters

Part 1 - Why this matters

Models contain vectors and tensors of parameters rather than one scalar. Gradient descent applies the same update element by element, with a gradient tensor whose shape matches the parameter tensor.

Vector optimization introduces directional geometry. The negative gradient is the direction of steepest local decrease under the Euclidean norm, while its magnitude controls how far the learning-rate-scaled update moves.

Part 2 - Mathematical form

For $\boldsymbol{\theta} \in \mathbb{R}^n$ and:

$$L(\boldsymbol{\theta}) = \|\boldsymbol{\theta} - \mathbf{a}\|_2^2,$$

the gradient is:

$$\nabla_{\boldsymbol{\theta}} L = 2(\boldsymbol{\theta} - \mathbf{a}),$$

and $\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \nabla L$.

Part 3 - Hints and Helper

Check that the parameter, target, and gradient shapes match. Compute the vector loss with a reduction, call backward, update every component without tracking the update, and clear the gradient buffer.

Part 4 - Python code skeleton

```
import torch

def E02(parameters, target, learning_rate):
    loss = torch...
    loss.backward()
    gradient = parameters.grad...
    with torch.no_grad():
        parameters ...
    parameters.grad = ...
    return loss, gradient, parameters

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.2.4 Exercise 03 - Learning Rate Effect Observation

Part 1 - Why this matters

The learning rate scales every gradient step and strongly affects the optimization trajectory. A very small value can make progress slow, while a large value can overshoot the minimum or move the loss into an unstable region.

A fair learning-rate experiment must begin each run from the same parameter value and use the same number of steps. Tracking the complete history reveals speed, oscillation, and divergence that a final value may hide.

Part 2 - Mathematical form

For $L(\theta) = \frac{1}{2} c \theta^2$:

$$\theta_{t+1} = (1 - \eta c)\theta_t.$$

Convergence to zero requires:

$$|1 - \eta c| < 1,$$

showing that an acceptable learning rate depends on the curvature c.

Part 3 - Hints and Helper

Run several learning rates from identical initial conditions. Store parameter and loss histories separately for every run, and compare early progress, oscillation, and final distance from the minimum.

Part 4 - Python code skeleton

```
import torch

def E03(initial_value, learning_rates, steps):
    histories = {}
    for learning_rate in learning_rates:
        parameter = ...
        history = []
        for step in range(steps):
            loss = ...
            ...
        histories[learning_rate] = history
    return histories

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.2.5 Exercise 04 - Convergence vs Divergence Test

Part 1 - Why this matters

An optimization loop needs measurable criteria for deciding whether it is approaching a solution or becoming unstable. Loss decrease alone may be noisy, so parameter changes, gradient norms, and finite-value checks provide additional evidence.

Automatic detection helps stop harmful runs early and makes hyperparameter experiments comparable. The classification should be based on a defined observation window rather than one isolated fluctuation.

Part 2 - Mathematical form

Possible convergence indicators include:

$$|L_t - L_{t-1}| < \varepsilon_L, \qquad \|\nabla L_t\| < \varepsilon_g.$$

Divergence indicators may include non-finite values or sustained growth such as:

$$L_t > \rho L_{t-k}, \qquad \rho > 1.$$

Part 3 - Hints and Helper

Track loss, gradient norm, and parameter displacement at every step. Define tolerances and a patience window, then classify the run as converging, diverging, or inconclusive without relying on exact equality.

Part 4 - Python code skeleton

```
import torch

def E04(loss_history, gradient_history, tolerance, patience):
    finite = ...
    plateau = ...
    sustained_growth = ...
    status = ...
    return status

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.2.6 Exercise 05 - Manual Parameter Update Loop

Part 1 - Why this matters

A complete gradient descent loop repeatedly performs forward computation, loss calculation, gradient clearing, backpropagation, and parameter update. The order matters because stale gradients or tracked update operations change later behavior.

Implementing the loop manually exposes every state transition that high-level optimizers normally manage. This makes it easier to debug a model before introducing momentum or adaptive optimizer state.

Part 2 - Mathematical form

At each iteration t:

$$L_t = L(\theta_t), \quad g_t = \nabla_\theta L_t, \quad \theta_{t+1} = \theta_t - \eta g_t.$$

The gradient buffer must represent g_t alone unless deliberate accumulation is intended.

Part 3 - Hints and Helper

Write the loop without `torch.optim`. Clear gradients before or after each iteration consistently, update parameters under `torch.no_grad()`, and append detached scalar values to history.

Part 4 - Python code skeleton

```
import torch

def E05(parameter, target, learning_rate, steps):
    history = []
    for step in range(steps):
        loss = ...
        ...
        history.append(...)
    return parameter, history

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.2.7 Exercise 06 - Gradient Descent without Autograd

Part 1 - Why this matters

Manual differentiation separates the optimizer from PyTorch's automatic gradient engine. It tests whether the analytical gradient and update rule are understood independently of graph construction.

This method is practical for simple objectives and useful for verification. It becomes difficult for large models, which explains why Autograd automates derivatives while the mathematical optimizer rule remains unchanged.

Part 2 - Mathematical form

For:

$$L(\theta) = (\theta - a)^4,$$

the analytical gradient is:

$$\frac{dL}{d\theta} = 4(\theta - a)^3.$$

Thus:

$$\theta_{t+1} = \theta_t - 4\eta(\theta_t - a)^3.$$

Part 3 - Hints and Helper

Use ordinary tensors or Python numeric values without `requires_grad`. Implement the analytical gradient directly, record the loss before each update, and compare the path with an Autograd version.

Part 4 - Python code skeleton

```
import torch

def E06(parameter, target, learning_rate, steps):
```

```
    history = []
    for step in range(steps):
        loss = ...
        gradient = ...
        parameter = ...
        history.append(...)
    return parameter, history

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.2.8 Exercise 07 - Loss Curve Tracking Challenge

Part 1 - Why this matters

A loss curve records optimization behavior across time. Its shape can reveal smooth convergence, plateaus, oscillation, sudden instability, or noisy progress that one initial and final value cannot communicate.

Reliable tracking requires storing detached numeric values without preserving every computational graph. The history should also include step numbers and relevant experimental settings so different runs can be interpreted correctly.

Part 2 - Mathematical form

For iterations $t = 0, \ldots, T-1$, define the history:

$$\mathcal{H} = \{(t, L_t)\}_{t=0}^{T-1}.$$

A simple improvement measure is:

$$\Delta_t = L_{t-1} - L_t,$$

where positive Δ_t indicates a one-step decrease.

Part 3 - Hints and Helper

Record `loss.item()` after each forward pass and avoid storing live loss tensors. Return the history and summary statistics such as best loss, best step, final loss, and number of increases.

Part 4 - Python code skeleton

```
import torch

def E07(parameter, loss_function, learning_rate, steps):
    history = []
    for step in range(steps):
        loss = loss_function(...)
        history.append(...)
```

```
        ...
    summary = ...
    return history, summary

def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.2.9 Exercise 08 - Gradient Clipping Integration

Part 1 - Why this matters

Gradient clipping limits an update-driving gradient before it reaches the parameter update. It can reduce damage from occasional extreme gradients, but it does not correct the underlying source of instability.

Integrating clipping in the correct order is essential: gradients must first be computed, then measured and clipped, and only afterward used for the update. Monitoring pre- and post-clipping norms shows whether clipping is frequently active.

Part 2 - Mathematical form

For gradient $\mathbf{g}$ and maximum norm $c > 0$:

$$\widetilde{\mathbf{g}} = \mathbf{g} \min\left(1, \frac{c}{\|\mathbf{g}\|_2 + \varepsilon}\right).$$

The update becomes:

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \widetilde{\mathbf{g}}.$$

Part 3 - Hints and Helper

After backward, record the original norm, apply `torch.nn.utils.clip_grad_norm_()`, record the clipped norm, and update parameters. Do not clip before gradients exist.

Part 4 - Python code skeleton

```
import torch

def E08(parameters, loss, learning_rate, max_norm):
    loss.backward()
    before_norm = ...
    torch.nn.utils...
    after_norm = ...
    with torch.no_grad():
        for parameter in parameters:
            parameter ...
    return before_norm, after_norm
```

```
def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.2.10 Exercise 09 - End-to-End Gradient Descent Challenge

Part 1 - Why this matters

An end-to-end optimization task combines model prediction, scalar loss, Autograd, gradient diagnostics, parameter updates, and stopping logic. Every stage must cooperate for learning to occur correctly.

The final challenge should produce more than trained parameters. It should return evidence describing the optimization path, including loss history, gradient norms, stopping reason, and checks for non-finite or divergent behavior.

Part 2 - Mathematical form

For linear regression:

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b, \qquad L = \frac{1}{N}\|\hat{\mathbf{y}} - \mathbf{y}\|_2^2.$$

Gradient descent updates both parameters:

$$\mathbf{w}_{t+1} = \mathbf{w}_t - \eta \nabla_{\mathbf{w}} L, \quad b_{t+1} = b_t - \eta \frac{\partial L}{\partial b}.$$

Part 3 - Hints and Helper

Initialize trainable weight and bias tensors, implement the full loop without `torch.optim`, monitor loss and gradient norms, and stop safely on convergence or non-finite values. Preserve no live graphs in the returned history.

Part 4 - Python code skeleton

```
import torch

def E09(X, target, weight, bias, learning_rate, max_steps):
    history = []
    status = ...
    for step in range(max_steps):
        prediction = ...
        loss = ...
        ...
        history.append(...)
        if ...:
            break
    return weight, bias, history, status
```

```
def main():
    parameter = torch.tensor(..., requires_grad=True)
    print(E09(...))

if __name__ == "__main__":
    main()
```

4.3 OC01 - Learning Rate Effects & Tuning

Mathematics and Theory

4.3.1 Exercise 00 - Fixed Learning Rate Experiment

Part 1 - Why this matters

A fixed learning rate keeps the update scale constant throughout training. It provides a stable baseline for observing how one selected value interacts with the objective's curvature and gradient magnitude.

Because no schedule or adaptive logic changes the rate, every difference across steps comes from the evolving loss surface. This makes the experiment useful for learning how a simple optimizer behaves.

Part 2 - Mathematical form

For fixed $\eta > 0$:

$$\theta_{t+1} = \theta_t - \eta \nabla L(\theta_t), \qquad t = 0, \ldots, T-1.$$

The same η is used at every iteration even though the gradient changes.

Part 3 - Hints and Helper

Choose a simple objective and record the step, learning rate, parameter, loss, gradient, and update size. Verify that the learning rate remains constant and avoid storing live graphs in history.

Part 4 - Python code skeleton

```
import torch

def E00(parameter, learning_rate, steps):
    history = []
    for step in range(steps):
        loss = ...
        ...
        history.append(...)
    return parameter, history

def main():
    print(E00(...))
```

```
if __name__ == "__main__":
    main()
```

4.3.2 Exercise 01 - Too-Small Learning Rate Scenario

Part 1 - Why this matters

A learning rate can be stable yet too small to make useful progress. The loss may decrease at every step while the parameter remains far from the minimum after the available training budget.

This scenario must be distinguished from a plateau caused by a vanishing gradient. Measuring the raw gradient and the learning-rate-scaled update shows whether the optimizer is receiving a signal but moving too cautiously.

Part 2 - Mathematical form

For update:

$$\Delta\theta_t = -\eta g_t.$$

Even when $\|g_t\|$ is meaningful, a very small η gives:

$$\|\Delta\theta_t\| = \eta\|g_t\| \approx 0.$$

Part 3 - Hints and Helper

Run a small and a reference learning rate from identical initial values. Compare loss improvement, gradient norm, update norm, and distance from the optimum after the same number of steps.

Part 4 - Python code skeleton

```
import torch

def E01(initial_value, small_rate, reference_rate, steps):
    small_history = ...
    reference_history = ...
    comparison = ...
    return small_history, reference_history, comparison

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.3.3 Exercise 02 - Too-Large Learning Rate Scenario

Part 1 - Why this matters

An excessive learning rate can move parameters past a minimum and repeatedly reverse their position. With stronger instability, both parameters and loss can grow until they become non-finite.

Large-rate failure is not identical to an exploding gradient: an ordinary gradient multiplied by an excessive learning rate can already create a destructive update. Both quantities should therefore be monitored separately.

Part 2 - Mathematical form

For $L(\theta) = \frac{1}{2}c\theta^2$:

$$\theta_{t+1} = (1 - \eta c)\theta_t.$$

If:

$$|1 - \eta c| > 1,$$

the distance from the minimum grows and the iteration diverges.

Part 3 - Hints and Helper

Use a quadratic with known curvature and choose a rate outside its stable interval. Record signs, magnitudes, loss ratios, and finite checks, then stop safely if a limit or non-finite value is reached.

Part 4 - Python code skeleton

```
import torch

def E02(parameter, learning_rate, steps, safety_limit):
    history = []
    status = ...
    for step in range(steps):
        ...
        if ...:
            status = ...
            break
    return history, status

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.3.4 Exercise 03 - Learning Rate Sweep Experiment

Part 1 - Why this matters

A learning-rate sweep evaluates several candidate scales under the same controlled conditions. It reveals ranges that are too slow, productive, oscillatory, or immediately unstable before committing to a long training run.

Fair comparison requires resetting the model and optimizer state for every candidate. Otherwise later rates inherit parameters from earlier runs and the experiment no longer isolates the learning rate.

Part 2 - Mathematical form

For candidates:

$$\mathcal{E} = \{\eta_1, \eta_2, \ldots, \eta_K\},$$

run:

$$\theta_{t+1}^{(k)} = \theta_t^{(k)} - \eta_k \nabla L(\theta_t^{(k)}).$$

Each run must start from the same θ_0.

Part 3 - Hints and Helper

Use logarithmically spaced candidate rates, clone the same initialization, and collect identical metrics for a fixed budget. Rank rates by a defined score while rejecting non-finite runs.

Part 4 - Python code skeleton

```
import torch

def E03(initial_parameter, learning_rates, steps):
    results = {}
    for rate in learning_rates:
        parameter = initial_parameter...
        history = ...
        results[rate] = ...
    return results

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.3.5 Exercise 04 - Loss Oscillation Detection

Part 1 - Why this matters

Oscillation occurs when optimization repeatedly crosses a valley or minimum instead of settling smoothly. The loss may alternate, and parameter updates or gradients often reverse direction across successive steps.

Some oscillation can coexist with overall progress, so detection should use a window and quantify frequency or amplitude. One isolated loss increase is not enough to classify the complete run.

Part 2 - Mathematical form

Let:

$$\Delta_t = L_t - L_{t-1}.$$

A simple oscillation indicator counts sign changes:

$$S = \sum_{t=2}^{T-1} \mathbf{1}[\Delta_t \Delta_{t-1} < 0] \,.$$

Amplitude can be measured from the loss range inside a recent window.

Part 3 - Hints and Helper

Calculate loss differences over a selected window and count direction reversals. Combine this with parameter or gradient sign changes and return evidence rather than only a Boolean label.

Part 4 - Python code skeleton

```
import torch

def E04(loss_history, parameter_history, window):
    recent_losses = ...
    differences = ...
    sign_changes = ...
    amplitude = ...
    oscillating = ...
    return (...)

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.3.6 Exercise 05 - Adaptive Learning Rate Logic

Part 1 - Why this matters

Simple adaptive logic changes the learning rate in response to observed progress. It can reduce the rate after repeated non-improvement or cautiously increase it when training remains stable.

Any rule must define its metric, patience, bounds, and update timing. Reacting to every noisy step can make the learning rate itself oscillate and obscure the behavior it is intended to improve.

Part 2 - Mathematical form

One plateau-based rule is:

$$\eta_{t+1} = \begin{cases} \gamma \eta_t, & \text{if no improvement for } p \text{ steps,} \\ \eta_t, & \text{otherwise,} \end{cases}$$

where $0 < \gamma < 1$, with $\eta_{\min} \leq \eta_t \leq \eta_{\max}$.

Part 3 - Hints and Helper

Track the best loss and a non-improvement counter. Change the rate only after the patience condition, clamp it to defined bounds, and record every change with its triggering evidence.

Part 4 - Python code skeleton

```
import torch

def E05(loss_history, current_rate, factor, patience, min_rate):
    best_loss = ...
    wait = ...
    if ...:
        new_rate = ...
    else:
        new_rate = ...
    return new_rate

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.3.7 Exercise 06 - Learning Rate Scheduling Basics

Part 1 - Why this matters

A schedule changes the learning rate according to training progress rather than immediate gradient values. Larger early steps can accelerate exploration, while smaller later steps can refine parameters near a solution.

Schedules make the effective update rule time-dependent. Their units must be clear: a schedule may advance per optimizer step or per epoch, and calling it at the wrong frequency changes the intended curve.

Part 2 - Mathematical form

A step-decay schedule can be written:

$$\eta_t = \eta_0 \gamma^{\lfloor t/s \rfloor},$$

where s is the decay interval and $0 < \gamma < 1$. An exponential schedule uses:

$$\eta_t = \eta_0 \gamma^t.$$

Part 3 - Hints and Helper

Implement at least one schedule manually and print the rate for every step before using it in updates. Compare the generated sequence with a PyTorch scheduler and verify when the scheduler advances.

Part 4 - Python code skeleton

```
import torch

def E06(initial_rate, decay_factor, interval, total_steps):
    rates = []
    for step in range(total_steps):
        rate = ...
        rates.append(rate)
    return rates

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.3.8 Exercise 07 - Warm-up Learning Rate Strategy

Part 1 - Why this matters

Warm-up begins training with a reduced learning rate and increases it gradually to a target value. It can protect unstable early steps when parameters, activations, or optimizer statistics have not yet reached useful scales.

Warm-up is a temporary phase rather than a complete long-run schedule. The transition at its boundary should be continuous and followed by a defined constant or decay strategy.

Part 2 - Mathematical form

For linear warm-up over T_w steps:

$$\eta_t = \eta_{\max} \frac{t+1}{T_w}, \qquad 0 \le t < T_w.$$

Afterward:

$$\eta_t = \eta_{\max}$$

or another schedule begins from that value.

Part 3 - Hints and Helper

Generate and inspect the complete rate sequence before training. Check the first value, target value, warm-up length, and boundary transition, then compare early update norms with and without warm-up.

Part 4 - Python code skeleton

```
import torch

def E07(max_rate, warmup_steps, total_steps):
    rates = []
    for step in range(total_steps):
        if step < warmup_steps:
            rate = ...
        else:
            rate = ...
        rates.append(rate)
    return rates

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.3.9 Exercise 08 - Learning Rate Debugging Challenge

Part 1 - Why this matters

Poor learning-rate behavior can resemble other failures: slow progress may come from tiny gradients, while instability may come from non-finite data or incorrect loss scaling. Diagnosing the rate requires comparing gradients with actual update magnitudes.

A useful report separates the base rate, scheduled rate, gradient norm, update norm, loss trend, and parameter scale. This identifies whether the selected rate is wrong or merely receiving misleading inputs.

Part 2 - Mathematical form

The effective relative update is:

$$R_t = \frac{\eta_t \|g_t\|}{\|\theta_t\| + \varepsilon}.$$

A problematic R_t may result from η_t, g_t, or an unusually small parameter norm, so all components must be inspected.

Part 3 - Hints and Helper

Construct a run with one intentional rate-related fault. Record rate history and gradient/update statistics, check scheduler call order and loss reduction, then name the earliest inconsistent quantity.

Part 4 - Python code skeleton

```
import torch

def E08(parameter, loss_history, rate_history, gradient_history):
    diagnostics = {
```

```
        "loss_trend": ...,
        "rate_changes": ...,
        "relative_updates": ...,
        "finite": ...
    }
    diagnosis = ...
    return diagnostics, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.3.10 Exercise 09 - Optimal Learning Rate Search

Part 1 - Why this matters

There is no universally optimal learning rate; the useful value depends on the model, initialization, data, optimizer, batch size, and training budget. A search must therefore define what optimal means for the current experiment.

Selecting only the lowest training loss can favor unstable or overfitting runs. A robust score can include validation performance, convergence speed, stability, and repeatability across random seeds.

Part 2 - Mathematical form

For candidate η_k, define a score such as:

$$S_k = L_{\text{val},k} + \lambda_1 P_{\text{instability},k} + \lambda_2 T_k,$$

where penalties and time terms are normalized consistently. The selected rate is:

$$\eta^* = \arg\min_{\eta_k} S_k.$$

Part 3 - Hints and Helper

Use a coarse logarithmic sweep followed by a finer search around promising rates. Reinitialize every run, evaluate more than one seed, reject divergent trials, and return the full ranked results with the chosen criterion.

Part 4 - Python code skeleton

```
import torch

def E09(train_function, learning_rates, seeds):
    results = []
    for rate in learning_rates:
        trials = []
```

```
        for seed in seeds:
            trial = train_function(...)
            trials.append(trial)
        score = ...
        results.append(...)
    best_rate = ...
    return best_rate, results

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

4.4 OC02 - Momentum Update Rule

Mathematics and Theory

4.4.1 Exercise 00 - Momentum Concept Implementation

Part 1 - Why this matters

Momentum extends gradient descent with a state variable that remembers recent update direction. Consistent gradients build velocity, while conflicting gradients partially cancel, creating smoother and often faster motion.

Implementing the rule manually shows that the optimizer state is separate from both parameters and gradients. The velocity must persist across steps and match each parameter's shape.

Part 2 - Mathematical form

Using the convention in this chapter:

$$\mathbf{v}_t = \beta \mathbf{v}_{t-1} + \mathbf{g}_t, \qquad \boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \mathbf{v}_t,$$

where $0 \leq \beta < 1$ and $\mathbf{v}_0 = \mathbf{0}$.

Part 3 - Hints and Helper

Initialize velocity with `torch.zeros_like(parameter)` and update it before updating the parameter. Keep both updates outside Autograd's graph and return the new state explicitly.

Part 4 - Python code skeleton

```
import torch

def E00(parameter, gradient, velocity, learning_rate, momentum):
    new_velocity = ...
    new_parameter = ...
```

```
    return new_parameter, new_velocity

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.4.2 Exercise 01 - Velocity Term Tracking

Part 1 - Why this matters

The velocity contains historical information that cannot be reconstructed from the current gradient alone. Tracking it across steps reveals how earlier gradients continue to influence later parameter movement.

A velocity history also helps debug accidental reinitialization and excessive momentum. Recording gradient, velocity, and update norms makes the optimizer's memory observable.

Part 2 - Mathematical form

Expanding the recurrence gives:

$$\mathbf{v}_t = \mathbf{g}_t + \beta \mathbf{g}_{t-1} + \beta^2 \mathbf{g}_{t-2} + \cdots .$$

Older gradients receive exponentially decreasing weights.

Part 3 - Hints and Helper

Use a predefined gradient sequence and record velocity at each step without a loss function. Compare the computed state with a manual recurrence and verify that it is not reset inside the loop.

Part 4 - Python code skeleton

```
import torch

def E01(gradients, momentum):
    velocity = torch...
    history = []
    for gradient in gradients:
        velocity = ...
        history.append(velocity...)
    return history

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.4.3 Exercise 02 - Momentum vs Vanilla GD

Part 1 - Why this matters

Vanilla gradient descent uses only the current gradient, whereas momentum combines it with accumulated direction. Comparing both methods on the same objective reveals when history accelerates movement or changes oscillation.

A valid comparison must share initialization, learning rate, loss, and step budget. Separate parameter and optimizer states are required so one method does not influence the other.

Part 2 - Mathematical form

Vanilla gradient descent:

$$\theta_{t+1}^{GD} = \theta_t^{GD} - \eta g_t^{GD}.$$

Momentum:

$$v_t = \beta v_{t-1} + g_t^M, \qquad \theta_{t+1}^M = \theta_t^M - \eta v_t.$$

Part 3 - Hints and Helper

Run both optimizers from cloned initial parameters and record equal metrics. Compare loss, distance to the optimum, update size, and oscillation rather than only the final loss.

Part 4 - Python code skeleton

```
import torch

def E02(initial_parameter, learning_rate, momentum, steps):
    gd_parameter = ...
    momentum_parameter = ...
    velocity = ...
    gd_history, momentum_history = [], []
    for step in range(steps):
        ...
    return gd_history, momentum_history

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.4.4 Exercise 03 - Momentum Acceleration Effect

Part 1 - Why this matters

When gradients point consistently in one direction, momentum accumulates them and increases the effective step. This can move parameters rapidly through long, gently sloped regions where vanilla gradient descent progresses slowly.

Acceleration is not free: the stored velocity can carry an update past a minimum. Observing both benefits and overshoot builds a balanced understanding of momentum behavior.

Part 2 - Mathematical form

For an approximately constant gradient g:

$$v_t = g \sum_{k=0}^{t} \beta^k = g \frac{1 - \beta^{t+1}}{1 - \beta}.$$

As t grows:

$$v_t \to \frac{g}{1 - \beta}.$$

Part 3 - Hints and Helper

Use a region with nearly consistent gradient direction and compare velocity growth with vanilla update magnitude. Track when acceleration begins, when the gradient changes sign, and how long velocity persists.

Part 4 - Python code skeleton

```
import torch

def E03(parameter, learning_rate, momentum, steps):
    velocity = torch...
    history = []
    for step in range(steps):
        gradient = ...
        velocity = ...
        parameter = ...
        history.append(...)
    return history

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.4.5 Exercise 04 - Damped Oscillation Observation

Part 1 - Why this matters

On narrow valleys, vanilla updates can alternate sharply across the steep direction. Momentum can smooth changing gradients, but an aggressive coefficient or learning rate can also sustain oscillation.

Damping should be measured through amplitude over time. A trajectory is damped when successive excursions decrease, not merely because the parameter crosses the minimum several times.

Part 2 - Mathematical form

For a quadratic objective and momentum:

$$v_t = \beta v_{t-1} + c\theta_t, \qquad \theta_{t+1} = \theta_t - \eta v_t.$$

The pair (η, β) determines whether oscillations decay, persist, or grow.

Part 3 - Hints and Helper

Record parameter sign changes and peak absolute distances from the minimum. Compare early and late amplitudes over equal windows and classify the motion using defined tolerances.

Part 4 - Python code skeleton

```
import torch

def E04(parameter, learning_rate, momentum, steps):
    velocity = torch...
    trajectory = []
    for step in range(steps):
        ...
    peaks = ...
    damping_ratio = ...
    return trajectory, peaks, damping_ratio

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.4.6 Exercise 05 - Momentum Coefficient Tuning

Part 1 - Why this matters

The momentum coefficient controls how strongly past gradients influence the current velocity. Low values behave closer to vanilla gradient descent, while values near one preserve history for longer.

The best coefficient depends on learning rate, curvature, noise, and training budget. Tuning momentum independently while allowing other conditions to change produces misleading conclusions.

Part 2 - Mathematical form

The contribution of a gradient k steps old is:

$$\beta^k \mathbf{g}_{t-k}.$$

A rough memory timescale increases as β approaches one, while $\beta = 0$ reduces the rule to vanilla gradient descent.

Part 3 - Hints and Helper

Sweep several coefficients from the same initialization with a fixed learning rate. Record convergence speed, maximum overshoot, oscillation, and final loss, and reject non-finite runs.

Part 4 - Python code skeleton

```
import torch

def E05(initial_parameter, coefficients, learning_rate, steps):
    results = {}
    for coefficient in coefficients:
        velocity = ...
        parameter = ...
        history = ...
        results[coefficient] = ...
    return results

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.4.7 Exercise 06 - Momentum on Noisy Gradients

Part 1 - Why this matters

Mini-batch gradients contain sampling noise that changes from step to step. Momentum averages recent directions through its state, often reducing high-frequency variation while preserving a repeated underlying trend.

Excessive momentum can also retain outdated direction after the true gradient changes. The experiment should compare noise reduction with responsiveness rather than assuming more smoothing is always better.

Part 2 - Mathematical form

Let:

$$g_t = \mu_t + \varepsilon_t, \qquad v_t = \beta v_{t-1} + g_t,$$

where ε_t is zero-mean noise. The recurrence combines several noisy observations, but it also delays response when μ_t changes.

Part 3 - Hints and Helper

Generate a reproducible noisy gradient sequence and compare raw gradients with normalized or scaled velocity direction. Measure variance and response after an intentional change in the underlying trend.

Part 4 - Python code skeleton

```
import torch

def E06(true_gradients, noise_scale, momentum, seed):
    generator = torch...
    velocity = torch...
    records = []
    for true_gradient in true_gradients:
        noisy_gradient = ...
        velocity = ...
        records.append(...)
    return records

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.4.8 Exercise 07 - Custom Momentum Optimizer

Part 1 - Why this matters

A custom optimizer packages parameter updates and persistent velocity states into a reusable object. It must create one state tensor per parameter, skip missing gradients, update without graph tracking, and support clearing gradients.

Building the class exposes responsibilities normally handled by `torch.optim`. Correct state ownership is essential when parameters have different shapes, devices, or dtypes.

Part 2 - Mathematical form

For every parameter $\theta^{(i)}$:

$$v_t^{(i)} = \beta v_{t-1}^{(i)} + g_t^{(i)}, \qquad \theta_{t+1}^{(i)} = \theta_t^{(i)} - \eta v_t^{(i)}.$$

Each parameter requires an independent velocity state.

Part 3 - Hints and Helper

Store a parameter list and shape-matched velocities. Implement `step()` under `torch.no_grad()`, ignore parameters with `grad is None`, and provide an explicit gradient-reset method.

Part 4 - Python code skeleton

```
import torch

class CustomMomentum:
    def __init__(self, parameters, learning_rate, momentum):
        self.parameters = ...
        self.velocities = ...
```

```
    @torch.no_grad()
    def step(self):
        for parameter, velocity in zip(...):
            if parameter.grad is None:
                continue
            ...

    def zero_grad(self):
        ...

def E07(...):
    optimizer = CustomMomentum(...)
    return optimizer

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.4.9 Exercise 08 - Momentum Failure Debugging

Part 1 - Why this matters

Momentum can fail because velocity is reset each step, signs are inconsistent, gradients accumulate unintentionally, states use wrong shapes or devices, or hyperparameters create unstable dynamics.

Debugging must inspect both gradient and optimizer state. A correct gradient does not guarantee a correct update if velocity is stale, missing, or applied twice.

Part 2 - Mathematical form

For the chosen convention, the required invariants are:

$$\text{shape}(v_t) = \text{shape}(\theta_t) = \text{shape}(g_t),$$

and:

$$\Delta\theta_t = -\eta v_t.$$

Violating either relationship identifies an implementation error.

Part 3 - Hints and Helper

Log parameter, gradient, old velocity, new velocity, and actual displacement for a few deterministic steps. Verify update order, sign, state persistence, finite values, and gradient clearing.

Part 4 - Python code skeleton

```
import torch

def E08(parameter, gradients, learning_rate, momentum):
```

```
    velocity = torch...
    diagnostics = []
    for gradient in gradients:
        old_parameter = parameter...
        old_velocity = velocity...
        ...
        diagnostics.append(...)
    diagnosis = ...
    return diagnostics, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.4.10 Exercise 09 - Momentum Convergence Challenge

Part 1 - Why this matters

The final challenge combines a scalar or vector objective, Autograd, persistent velocity, convergence tests, loss tracking, and comparison with vanilla gradient descent. It measures whether momentum improves the complete optimization process.

A successful run should report its trajectory and stopping reason, not only the final parameter. The comparison must use identical starting conditions and an explicit definition of convergence.

Part 2 - Mathematical form

At every step:

$$g_t = \nabla_\theta L(\theta_t), \quad v_t = \beta v_{t-1} + g_t, \quad \theta_{t+1} = \theta_t - \eta v_t.$$

Possible stopping criteria include:

$$\|g_t\| < \varepsilon_g \quad \text{or} \quad |L_t - L_{t-1}| < \varepsilon_L$$

for a defined patience window.

Part 3 - Hints and Helper

Implement momentum without `torch.optim`, record all relevant states, and stop on convergence, divergence, or the step limit. Run a vanilla baseline and compare steps, best loss, overshoot, and stability.

Part 4 - Python code skeleton

```
import torch

def E09(parameter, loss_function, learning_rate, momentum,
        max_steps, tolerance):
    velocity = torch.zeros_like(parameter)
```

```
    history = []
    status = ...
    for step in range(max_steps):
        loss = loss_function(parameter)
        ...
        history.append(...)
        if ...:
            break
    return parameter, history, status

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

4.5 OC03 - RMSProp Logic & Behavior

Mathematics and Theory

4.5.1 Exercise 00 - RMSProp Accumulator Initialization

Part 1 - Why this matters

RMSProp stores a separate running estimate of squared gradients for every parameter element. This state begins at zero and gradually learns the recent scale of the gradients.

Correct initialization preserves parameter shape, dtype, and device. A shared scalar or incorrectly shaped accumulator would destroy RMSProp's element-wise adaptation.

Part 2 - Mathematical form

For parameter $\boldsymbol{\theta} \in \mathbb{R}^n$, initialize:

$$\mathbf{s}_0 = \mathbf{0} \in \mathbb{R}^n.$$

The state invariant is:

$$\text{shape}(\mathbf{s}_t) = \text{shape}(\boldsymbol{\theta}_t).$$

Part 3 - Hints and Helper

Use `torch.zeros_like(parameter)` and inspect shape, dtype, device, and gradient requirements. The accumulator is optimizer state and should not require gradients.

Part 4 - Python code skeleton

```
import torch

def E00(parameter):
    accumulator = torch...
    checks = ...
```

```
    return accumulator, checks

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.5.2 Exercise 01 - Running Average of Squared Gradients

Part 1 - Why this matters

Squaring gradients removes their sign and measures magnitude. RMSProp combines the new squared gradient with an exponentially decayed history, producing a local scale estimate for each parameter.

The running average smooths short-term variation without storing every past gradient. Its decay rate controls how quickly old information is forgotten.

Part 2 - Mathematical form

For gradient $\mathbf{g}_t$ and decay rate ρ:

$$\mathbf{s}_t = \rho \mathbf{s}_{t-1} + (1-\rho)\mathbf{g}_t \odot \mathbf{g}_t, \qquad 0 \leq \rho < 1.$$

Part 3 - Hints and Helper

Process a known gradient sequence and record the accumulator after every step. Verify element-wise squaring and ensure the state persists instead of being reinitialized inside the loop.

Part 4 - Python code skeleton

```
import torch

def E01(gradients, decay_rate):
    accumulator = torch...
    history = []
    for gradient in gradients:
        accumulator = ...
        history.append(accumulator...)
    return history

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.5.3 Exercise 02 - RMSProp Update Step Implementation

Part 1 - Why this matters

RMSProp divides each gradient by the square root of its recent squared-gradient average. Coordinates with persistently large gradients receive smaller effective steps, while smaller-scale coordinates are reduced less.

A positive epsilon protects division when the accumulator is zero or extremely small. Its placement must remain consistent with the selected RMSProp definition.

Part 2 - Mathematical form

Using the convention in this chapter:

$$\mathbf{s}_t = \rho \mathbf{s}_{t-1} + (1-\rho)\mathbf{g}_t^2,$$

$$\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta \frac{\mathbf{g}_t}{\sqrt{\mathbf{s}_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Update the accumulator before computing the normalized gradient. Perform state and parameter updates without graph tracking, and record the effective element-wise learning rates.

Part 4 - Python code skeleton

```
import torch

def E02(parameter, gradient, accumulator,
        learning_rate, decay_rate, epsilon):
    new_accumulator = ...
    normalized_gradient = ...
    new_parameter = ...
    return new_parameter, new_accumulator, normalized_gradient

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.5.4 Exercise 03 - Effect of Decay Rate

Part 1 - Why this matters

The decay rate determines the memory length of RMSProp's squared-gradient estimate. A high value changes slowly and emphasizes longer history, while a lower value reacts quickly to recent scale changes.

Neither behavior is always superior. Slow adaptation may lag after a regime change, while rapid adaptation may follow noisy spikes too closely.

Part 2 - Mathematical form

A gradient from k steps earlier contributes a weight proportional to:

$$(1-\rho)\rho^k.$$

Thus larger ρ preserves old squared gradients for more steps.

Part 3 - Hints and Helper

Run identical gradient sequences with several decay rates. Include a sudden magnitude change and compare response time, smoothness, and normalized update sizes.

Part 4 - Python code skeleton

```
import torch

def E03(gradients, decay_rates, epsilon):
    results = {}
    for decay_rate in decay_rates:
        accumulator = ...
        history = ...
        results[decay_rate] = history
    return results

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.5.5 Exercise 04 - RMSProp vs Momentum Comparison

Part 1 - Why this matters

Momentum adapts direction using a running first-order state, while RMSProp adapts coordinate scale using squared gradients. Their states answer different optimization problems and should not be treated as interchangeable.

A fair comparison uses identical initialization, data, learning budget, and evaluation metrics. State trajectories help explain differences that a final loss alone cannot reveal.

Part 2 - Mathematical form

Momentum:

$$\mathbf{v}_t = \beta \mathbf{v}_{t-1} + \mathbf{g}_t.$$

RMSProp:

$$\mathbf{s}_t = \rho \mathbf{s}_{t-1} + (1-\rho)\mathbf{g}_t^2, \quad \Delta\theta_t = -\eta \frac{\mathbf{g}_t}{\sqrt{\mathbf{s}_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Run both methods from cloned parameters on an objective with different curvature across dimensions. Compare loss, path, update norms, oscillation, and optimizer states.

Part 4 - Python code skeleton

```
import torch

def E04(initial_parameter, loss_function, steps, settings):
    momentum_history = ...
    rmsprop_history = ...
    comparison = ...
    return momentum_history, rmsprop_history, comparison

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.5.6 Exercise 05 - Stability under High Gradient Variance

Part 1 - Why this matters

When gradient magnitudes vary greatly between steps or coordinates, one global learning rate can create uneven updates. RMSProp's scale estimate can reduce the effect of repeatedly large-gradient coordinates.

The accumulator responds to squared magnitude, so extreme outliers can also suppress later updates until their influence decays. Stability must be evaluated together with recovery speed.

Part 2 - Mathematical form

For noisy gradient:

$$\mathbf{g}_t = \boldsymbol{\mu}_t + \boldsymbol{\varepsilon}_t,$$

RMSProp uses:

$$\mathbf{s}_t = \rho \mathbf{s}_{t-1} + (1-\rho)\mathbf{g}_t^2.$$

The normalized magnitude is $\mathbf{g}_t/(\sqrt{\mathbf{s}_t} + \varepsilon)$.

Part 3 - Hints and Helper

Generate reproducible gradients with different variances and occasional spikes. Compare raw and normalized update distributions, finite values, and recovery after a spike.

Part 4 - Python code skeleton

```
import torch

def E05(gradients, decay_rate, epsilon):
    accumulator = torch...
    records = []
```

```
    for gradient in gradients:
        accumulator = ...
        normalized = ...
        records.append(...)
    return records

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.5.7 Exercise 06 - RMSProp without Autograd

Part 1 - Why this matters

Manual gradients allow RMSProp to be studied independently of computational graphs. This separates analytical differentiation from the optimizer state and parameter update rule.

The exercise confirms that RMSProp does not require Autograd conceptually; Autograd only provides gradients for complex objectives. State persistence and update ordering remain unchanged.

Part 2 - Mathematical form

For $L(\theta) = (\theta - a)^2$:

$$g_t = 2(\theta_t - a),$$

then:

$$s_t = \rho s_{t-1} + (1-\rho) g_t^2, \qquad \theta_{t+1} = \theta_t - \eta \frac{g_t}{\sqrt{s_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Use ordinary tensors without `requires_grad`. Implement the analytical gradient and RMSProp recurrence, recording loss, gradient, accumulator, and update at every step.

Part 4 - Python code skeleton

```
import torch

def E06(parameter, target, learning_rate,
        decay_rate, epsilon, steps):
    accumulator = torch.zeros_like(parameter)
    history = []
    for step in range(steps):
        gradient = ...
        accumulator = ...
        parameter = ...
        history.append(...)
    return parameter, history
```

```
def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.5.8 Exercise 07 - Custom RMSProp Optimizer

Part 1 - Why this matters

A custom optimizer stores one squared-gradient accumulator for each parameter and applies the RMSProp rule whenever gradients are available. It must also manage gradient clearing and preserve device and dtype compatibility.

Packaging the algorithm exposes the distinction between model parameters, temporary gradients, and persistent optimizer state. Missing gradients must be skipped without shifting state-to-parameter alignment.

Part 2 - Mathematical form

For each parameter $\theta^{(i)}$:

$$s_t^{(i)} = \rho s_{t-1}^{(i)} + (1-\rho)(g_t^{(i)})^2,$$

$$\theta_{t+1}^{(i)} = \theta_t^{(i)} - \eta \frac{g_t^{(i)}}{\sqrt{s_t^{(i)}} + \varepsilon}.$$

Part 3 - Hints and Helper

Store parameters and `zeros_like` accumulators in matching order. Implement `step()` under `torch.no_grad()`, skip `None` gradients, and add `zero_grad()`.

Part 4 - Python code skeleton

```
import torch

class CustomRMSProp:
    def __init__(self, parameters, learning_rate,
                 decay_rate, epsilon):
        self.parameters = ...
        self.accumulators = ...

    @torch.no_grad()
    def step(self):
        for parameter, accumulator in zip(...):
            if parameter.grad is None:
                continue
            ...

    def zero_grad(self):
```

```
        ...

def E07(...):
    return CustomRMSProp(...)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.5.9 Exercise 08 - RMSProp Debugging Challenge

Part 1 - Why this matters

RMSProp failures can result from resetting the accumulator, using the gradient instead of its square, reversing decay weights, omitting epsilon, or applying the update before refreshing state.

Debugging requires inspecting optimizer state alongside gradients and parameters. A correct loss gradient can still produce an incorrect training path when the accumulator recurrence is wrong.

Part 2 - Mathematical form

The required checks include:

$$s_t \geq 0, \qquad \text{shape}(s_t) = \text{shape}(g_t),$$

and:

$$s_t = \rho s_{t-1} + (1-\rho) g_t^2.$$

The actual displacement must equal the chosen normalized update rule.

Part 3 - Hints and Helper

Use a deterministic short gradient sequence and log old state, squared gradient, new state, denominator, and displacement. Compare each line with a manual calculation.

Part 4 - Python code skeleton

```
import torch

def E08(parameter, gradients, learning_rate,
        decay_rate, epsilon):
    accumulator = torch.zeros_like(parameter)
    diagnostics = []
    for gradient in gradients:
        old_accumulator = accumulator...
        ...
        diagnostics.append(...)
    diagnosis = ...
```

```
    return diagnostics, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.5.10 Exercise 09 - RMSProp Convergence Evaluation

Part 1 - Why this matters

Convergence evaluation measures whether RMSProp reaches a useful solution efficiently and stably. It should include trajectory evidence, stopping reason, gradient behavior, and comparison with a baseline.

One final loss cannot reveal oscillation, stalled normalized updates, or sensitivity to decay and epsilon. Controlled repeated trials provide stronger conclusions.

Part 2 - Mathematical form

At each step:

$$g_t = \nabla L(\theta_t), \quad s_t = \rho s_{t-1} + (1-\rho) g_t^2,$$
$$\theta_{t+1} = \theta_t - \eta \frac{g_t}{\sqrt{s_t} + \varepsilon}.$$

Stop using defined gradient, loss-change, divergence, or step-limit criteria.

Part 3 - Hints and Helper

Implement RMSProp without `torch.optim`, record all state summaries, and compare it with vanilla gradient descent from the same initialization. Report steps, best loss, final loss, stability, and stopping reason.

Part 4 - Python code skeleton

```
import torch

def E09(parameter, loss_function, learning_rate,
        decay_rate, epsilon, max_steps, tolerance):
    accumulator = torch.zeros_like(parameter)
    history = []
    status = ...
    for step in range(max_steps):
        ...
        if ...:
            break
    return parameter, history, status

def main():
    print(E09(...))
```

```
if __name__ == "__main__":
    main()
```

4.6 OC04 - Adam Optimizer Math + Code

Mathematics and Theory

4.6.1 Exercise 00 - Adam First Moment Initialization

Part 1 - Why this matters

Adam's first moment is an exponential moving average of gradients. It represents a smoothed direction and must be initialized separately for every parameter tensor.

Initializing the state with matching zeros preserves shape, dtype, and device while introducing no artificial direction before the first gradient arrives.

Part 2 - Mathematical form

For parameter $\boldsymbol{\theta}$, initialize:

$$\mathbf{m}_0 = \mathbf{0}.$$

The recurrence used later is:

$$\mathbf{m}_t = \beta_1 \mathbf{m}_{t-1} + (1 - \beta_1)\mathbf{g}_t.$$

Part 3 - Hints and Helper

Use `torch.zeros_like(parameter)` and verify that the state does not require gradients. Record the invariant that its shape and device match the parameter.

Part 4 - Python code skeleton

```
import torch

def E00(parameter):
    first_moment = torch...
    checks = ...
    return first_moment, checks

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.6.2 Exercise 01 - Adam Second Moment Initialization

Part 1 - Why this matters

Adam's second moment tracks an exponential average of squared gradients. It provides an element-wise estimate of gradient scale used to normalize the first moment.

This state is nonnegative and independent from the first moment. Keeping two correctly aligned states is essential because they represent direction and scale separately.

Part 2 - Mathematical form

Initialize:

$$\mathbf{v}_0 = \mathbf{0}.$$

Then:

$$\mathbf{v}_t = \beta_2 \mathbf{v}_{t-1} + (1 - \beta_2)\mathbf{g}_t \odot \mathbf{g}_t.$$

Part 3 - Hints and Helper

Create a zero state matching the parameter and verify shape, dtype, device, and nonnegativity. Do not reuse the same tensor object for first and second moments.

Part 4 - Python code skeleton

```
import torch

def E01(parameter):
    second_moment = torch...
    checks = ...
    return second_moment, checks

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.6.3 Exercise 02 - Bias Correction Implementation

Part 1 - Why this matters

Because Adam's moment estimates start at zero, their early values are biased toward zero. Bias correction divides by the remaining initialization weight, producing estimates with the intended scale.

The correction depends on a one-based update counter. Starting at zero causes division by zero, while incrementing the counter at the wrong point shifts every correction factor.

Part 2 - Mathematical form

At update $t \geq 1$:

$$\widehat{\mathbf{m}}_t = \frac{\mathbf{m}_t}{1-\beta_1^t}, \qquad \widehat{\mathbf{v}}_t = \frac{\mathbf{v}_t}{1-\beta_2^t}.$$

Part 3 - Hints and Helper

Update raw moments first, increment or define the step consistently, and then apply correction. Test the first step with a constant gradient, where corrected moments have an easy expected value.

Part 4 - Python code skeleton

```
import torch

def E02(first_moment, second_moment,
        beta1, beta2, step):
    corrected_first = ...
    corrected_second = ...
    return corrected_first, corrected_second

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.6.4 Exercise 03 - Adam Update Rule from Scratch

Part 1 - Why this matters

Adam combines a smoothed gradient direction with an adaptive scale estimate. The complete update requires both moment recurrences, both bias corrections, epsilon, and a persistent step counter.

Implementing the rule from scratch reveals the exact ordering hidden inside a library optimizer. A small error in state or counter handling changes all later parameter updates.

Part 2 - Mathematical form

For $t \geq 1$:

$$m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t, \quad v_t = \beta_2 v_{t-1} + (1-\beta_2) g_t^2,$$

$$\theta_{t+1} = \theta_t - \eta \frac{\widehat{m}_t}{\sqrt{\widehat{v}_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Increment the step once per optimizer update, refresh raw moments, correct them, and update parameters outside the graph. Return all new states so the caller can preserve them.

Part 4 - Python code skeleton

```
import torch

def E03(parameter, gradient, first_moment, second_moment,
        step, learning_rate, beta1, beta2, epsilon):
    step = ...
    new_first = ...
    new_second = ...
    corrected_first = ...
    corrected_second = ...
    new_parameter = ...
    return (...)

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.6.5 Exercise 04 - Adam vs RMSProp Comparison

Part 1 - Why this matters

RMSProp normalizes the current gradient using a squared-gradient average, whereas Adam also smooths gradient direction and corrects both moments during early steps.

Their similar adaptive denominators can hide important behavioral differences. A controlled comparison should inspect states and trajectories, not only final loss.

Part 2 - Mathematical form

RMSProp uses:

$$s_t = \rho s_{t-1} + (1-\rho) g_t^2.$$

Adam uses:

$$m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t, \quad v_t = \beta_2 v_{t-1} + (1-\beta_2) g_t^2,$$

with bias-corrected m_t and v_t.

Part 3 - Hints and Helper

Clone identical initial parameters and run equal training budgets. Compare loss, updates, stability, and state response to direction changes while documenting each method's hyperparameters.

Part 4 - Python code skeleton

```
import torch

def E04(initial_parameter, loss_function, settings, steps):
    rmsprop_history = ...
    adam_history = ...
    comparison = ...
```

```
    return rmsprop_history, adam_history, comparison

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.6.6 Exercise 05 - Adam Hyperparameter Sensitivity

Part 1 - Why this matters

Adam behavior depends on learning rate, first-moment decay, second-moment decay, and epsilon. Each controls a different part of the update, so tuning several at once makes the cause of a change difficult to identify.

Sensitivity experiments reveal whether performance is robust or depends on a narrow configuration. Every candidate must start with fresh parameters, moments, and step counter.

Part 2 - Mathematical form

Adam is controlled by:

$$\eta, \quad \beta_1, \quad \beta_2, \quad \varepsilon.$$

The effective update is:

$$\Delta\theta_t = -\eta \frac{\widehat{m}_t}{\sqrt{\widehat{v}_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Vary one hyperparameter at a time around a baseline and reinitialize all state. Record convergence speed, loss, update norms, and finite checks before attempting a combined search.

Part 4 - Python code skeleton

```
import torch

def E05(initial_parameter, configurations, loss_function, steps):
    results = {}
    for configuration in configurations:
        parameter = ...
        first_moment = ...
        second_moment = ...
        history = ...
        results[...] = ...
    return results

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.6.7 Exercise 06 - Adam on Sparse Gradients

Part 1 - Why this matters

Sparse gradients update only a small subset of parameter coordinates at each step. Adam stores moment states per coordinate, so active and inactive entries can carry different histories.

Zero gradients still interact with exponential decay in a dense implementation. The reader must distinguish truly absent sparse entries from explicit zeros and understand the optimizer support of the chosen representation.

Part 2 - Mathematical form

For coordinate i:

$$m_{t,i} = \beta_1 m_{t-1,i} + (1 - \beta_1) g_{t,i},$$
$$v_{t,i} = \beta_2 v_{t-1,i} + (1 - \beta_2) g_{t,i}^2.$$

When $g_{t,i} = 0$, stored moments decay but may remain nonzero.

Part 3 - Hints and Helper

Use a small gradient sequence with changing active indices. Track every coordinate's raw and corrected moments and compare active updates with the residual influence on inactive entries.

Part 4 - Python code skeleton

```
import torch

def E06(parameter, sparse_gradients, settings):
    first_moment = torch.zeros_like(parameter)
    second_moment = torch.zeros_like(parameter)
    history = []
    for step, gradient in enumerate(sparse_gradients, start=1):
        ...
        history.append(...)
    return history

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.6.8 Exercise 07 - Custom Adam Optimizer Class

Part 1 - Why this matters

A custom Adam class must own parameter references, two moment tensors per parameter, a consistent update counter, hyperparameters, and gradient-reset behavior.

Correct state alignment is critical across parameters with different shapes and missing gradients. The class should make update ordering explicit and avoid recording optimizer operations in Autograd.

Part 2 - Mathematical form

For each parameter $\theta^{(i)}$, store:

$$m^{(i)}, \quad v^{(i)}.$$

At global step t, update both states, compute bias-corrected estimates, and apply:

$$\theta^{(i)} \leftarrow \theta^{(i)} - \eta \frac{\widehat{m}^{(i)}}{\sqrt{\widehat{v}^{(i)}} + \varepsilon}.$$

Part 3 - Hints and Helper

Initialize states with `zeros_like`, implement `step()` under `torch.no_grad()`, handle `None` gradients, and test against `torch.optim.Adam` on a deterministic sequence.

Part 4 - Python code skeleton

```
import torch

class CustomAdam:
    def __init__(self, parameters, learning_rate,
                 beta1, beta2, epsilon):
        self.parameters = ...
        self.first_moments = ...
        self.second_moments = ...
        self.step_count = ...

    @torch.no_grad()
    def step(self):
        self.step_count += ...
        for parameter, first, second in zip(...):
            if parameter.grad is None:
                continue
            ...

    def zero_grad(self):
        ...

def E07(...):
    return CustomAdam(...)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.6.9 Exercise 08 - Adam Failure Case Debugging

Part 1 - Why this matters

Adam can fail through an off-by-one step counter, missing bias correction, moment reinitialization, unsquared second moment, misplaced epsilon, stale gradients, or mismatched state tensors.

Debugging requires a deterministic short sequence and full state visibility. Checking only the parameter output cannot identify which internal recurrence first became incorrect.

Part 2 - Mathematical form

Required invariants include:

$$v_t \geq 0, \quad t \geq 1,$$

$$\widehat{m}_t = \frac{m_t}{1-\beta_1^t}, \qquad \widehat{v}_t = \frac{v_t}{1-\beta_2^t}.$$

The actual displacement must match the normalized corrected update.

Part 3 - Hints and Helper

Log old states, gradient, new raw states, correction denominators, corrected states, denominator, and displacement. Compare the first incorrect quantity with a manual reference.

Part 4 - Python code skeleton

```
import torch

def E08(parameter, gradients, settings):
    first = torch.zeros_like(parameter)
    second = torch.zeros_like(parameter)
    diagnostics = []
    for step, gradient in enumerate(gradients, start=1):
        ...
        diagnostics.append(...)
    diagnosis = ...
    return diagnostics, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.6.10 Exercise 09 - Adam End-to-End Training Challenge

Part 1 - Why this matters

The final Adam challenge combines a model, scalar loss, Autograd gradients, two moment states, bias correction, parameter updates, convergence monitoring, and stability checks.

A complete result includes training history and diagnostic evidence. The implementation should be compared with PyTorch Adam under identical initialization to validate both mathematics and state handling.

Part 2 - Mathematical form

For each step t:

$$g_t = \nabla_\theta L, \quad m_t = \beta_1 m_{t-1} + (1-\beta_1) g_t,$$

$$v_t = \beta_2 v_{t-1} + (1-\beta_2) g_t^2, \quad \theta_{t+1} = \theta_t - \eta \frac{\widehat{m}_t}{\sqrt{\widehat{v}_t} + \varepsilon}.$$

Part 3 - Hints and Helper

Implement training without `torch.optim`, record loss and state norms, and stop on convergence, divergence, or step limit. Compare parameters and histories with a library optimizer using the same settings.

Part 4 - Python code skeleton

```
import torch

def E09(model, X, target, settings, max_steps):
    parameters = list(model.parameters())
    first_moments = ...
    second_moments = ...
    history = []
    status = ...
    for step in range(1, max_steps + 1):
        ...
        history.append(...)
        if ...:
            break
    return model, history, status

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

4.7 OC05 - Convergence & Stability

Mathematics and Theory

4.7.1 Exercise 00 - Convergence Criteria Detection

Part 1 - Why this matters

Optimization needs explicit evidence for deciding when useful progress has become sufficiently small. A fixed epoch count alone cannot distinguish an unfinished run from one that

has already stabilized.

Combining loss change, gradient norm, and parameter displacement produces a stronger decision than any single signal. Criteria should hold for a patience window to resist noise.

Part 2 - Mathematical form

Possible conditions are:

$$|L_t - L_{t-1}| < \varepsilon_L, \quad \|g_t\| < \varepsilon_g, \quad \|\theta_t - \theta_{t-1}\| < \varepsilon_\theta.$$

Convergence may be declared when selected conditions persist for p steps.

Part 3 - Hints and Helper

Implement configurable tolerances and patience. Reject non-finite values before checking convergence and return the evidence and exact stopping reason.

Part 4 - Python code skeleton

```
import torch

def E00(losses, gradient_norms, update_norms,
        tolerances, patience):
    checks = ...
    converged = ...
    reason = ...
    return converged, reason, checks

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.7.2 Exercise 01 - Loss Plateau Detection

Part 1 - Why this matters

A plateau is a period in which the monitored loss shows little meaningful improvement. It may indicate convergence, an inadequate learning rate, vanishing gradients, or a region that the current optimizer cannot escape.

Plateau detection should compare improvement over a window rather than exact equality between adjacent floating-point values. Validation loss is often more useful than training loss for stopping decisions.

Part 2 - Mathematical form

For window length w, define:

$$I_t = \min(L_{t-w:t}) - L_t.$$

A plateau can be reported when:

$$I_t < \delta$$

for a specified patience interval, using a consistent minimum-improvement rule.

Part 3 - Hints and Helper

Track the best loss, minimum required improvement, and waiting counter. Handle noisy temporary increases without resetting the best value incorrectly.

Part 4 - Python code skeleton

```
import torch

def E01(loss_history, min_improvement, patience):
    best = ...
    wait = ...
    plateau_start = ...
    for step, loss in enumerate(loss_history):
        ...
    return plateau_start, wait

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.7.3 Exercise 02 - Divergence Pattern Identification

Part 1 - Why this matters

Divergence may appear as sustained loss growth, growing parameter or gradient norms, repeated oscillations with increasing amplitude, or non-finite values. Detecting it early prevents corrupted updates and wasted computation.

One loss increase is not sufficient because stochastic training is noisy. Pattern identification combines trend, ratios, windows, and safety limits.

Part 2 - Mathematical form

Possible evidence includes:

$$L_t > \rho L_{t-k}, \qquad \|g_t\| > \tau_g,$$

or:

$$L_t \notin \mathbb{R}_{finite}.$$

A sustained-growth rule requires the condition across several observations.

Part 3 - Hints and Helper

Inspect loss, gradient norm, update norm, and finiteness. Classify non-finite failure immediately, but use a patience window for ordinary growth or oscillation.

Part 4 - Python code skeleton

```
import torch

def E02(losses, gradient_norms, update_norms,
        growth_factor, patience):
    finite = ...
    growth_pattern = ...
    oscillation_growth = ...
    status = ...
    return status

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.7.4 Exercise 03 - Early Stopping Logic

Part 1 - Why this matters

Early stopping ends training when validation performance no longer improves, limiting unnecessary computation and reducing the chance of continued overfitting.

A correct implementation preserves the best model state rather than the final state. Minimum improvement, patience, evaluation frequency, and metric direction must all be explicit.

Part 2 - Mathematical form

For validation metric M_t to be minimized, improvement occurs when:

$$M_t < M_{best} - \delta.$$

Otherwise a counter increases, and training stops when:

$$\text{wait} \geq p.$$

Part 3 - Hints and Helper

Track best metric, best step, waiting count, and a cloned model state. Restore the best state after stopping and test the logic on a predefined metric sequence.

Part 4 - Python code skeleton

```
import torch

def E03(model, validation_metric, state):
    improved = ...
    if improved:
        state["best"] = ...
        state["weights"] = ...
        state["wait"] = ...
```

```
    else:
        state["wait"] = ...
    stop = ...
    return stop, state

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.7.5 Exercise 04 - Gradient Explosion Mitigation

Part 1 - Why this matters

Exploding gradients create excessive update magnitudes and can make parameters or losses non-finite. Mitigation must occur after diagnosis and before the optimizer applies a harmful step.

Gradient clipping limits immediate damage, while initialization, normalization, architecture, loss scaling, and learning-rate changes address different root causes. Clipping should therefore be monitored rather than applied invisibly.

Part 2 - Mathematical form

Global norm clipping with threshold c uses:

$$\tilde{\mathbf{g}} = \mathbf{g} \min\left(1, \frac{c}{\|\mathbf{g}\| + \varepsilon}\right).$$

The clipped gradient satisfies $\|\tilde{\mathbf{g}}\| \leq c$.

Part 3 - Hints and Helper

Record pre-clipping norms and finite checks, apply clipping after backward, record post-clipping norms, and update only if values remain valid. Count how often clipping activates.

Part 4 - Python code skeleton

```
import torch

def E04(model, loss, max_norm):
    loss.backward()
    before = ...
    clipping_result = torch.nn.utils...
    after = ...
    safe = ...
    return before, after, safe

def main():
    print(E04(...))
```

```
if __name__ == "__main__":
    main()
```

4.7.6 Exercise 05 - Gradient Vanishing Mitigation

Part 1 - Why this matters

Vanishing gradients prevent early layers from receiving enough signal to learn. Mitigation may involve activation choice, initialization, normalization, residual paths, or architectural depth.

There is no meaningful way to clip a vanished gradient upward without changing the optimization problem. The appropriate response is to identify where attenuation begins and address its mechanism.

Part 2 - Mathematical form

For chained Jacobians:

$$\nabla_{h_0} L = \nabla_{h_K} L \prod_{k=1}^{K} J_k.$$

Repeated operator norms below one can make:

$$\|\nabla_{h_0} L\| \to 0.$$

Part 3 - Hints and Helper

Measure gradients layer by layer before changing the model. Compare a saturating activation or poor initialization with a suitable activation, initialization, or residual connection under identical data.

Part 4 - Python code skeleton

```
import torch

def E05(model_variants, X, target):
    reports = {}
    for name, model in model_variants.items():
        output = ...
        loss = ...
        loss.backward()
        reports[name] = ...
    return reports

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.7.7 Exercise 06 - Stability under Noisy Data

Part 1 - Why this matters

Noisy samples and mini-batches create fluctuating losses and gradients even when the expected optimization direction is useful. Stability means maintaining bounded, finite progress without overreacting to every observation.

Experiments should use repeated seeds and summarize distributions rather than one trajectory. Batch size, optimizer state, clipping, and learning-rate schedules influence the noise response.

Part 2 - Mathematical form

Let stochastic gradient be:

$$g_t = \nabla L(\theta_t) + \varepsilon_t, \qquad \mathbb{E}[\varepsilon_t] = 0.$$

Stability can be described using the mean and variance of loss, gradient norm, and parameter displacement over a window.

Part 3 - Hints and Helper

Add controlled noise with a seeded generator and run several trials. Report mean, variance, worst finite loss, and divergence frequency for each configuration.

Part 4 - Python code skeleton

```
import torch

def E06(train_function, noise_levels, seeds):
    results = {}
    for noise in noise_levels:
        trials = []
        for seed in seeds:
            trials.append(train_function(...))
        results[noise] = ...
    return results

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.7.8 Exercise 07 - Optimizer Comparison Experiment

Part 1 - Why this matters

Optimizer comparison determines how different update rules behave under the same task and computational budget. A fair experiment controls initialization, data order, model, loss,

batch size, and stopping rules.

The lowest final training loss is not enough. Speed, validation performance, stability, memory state, and sensitivity across seeds should also be considered.

Part 2 - Mathematical form

For optimizer o, define measurements:

$$\mathcal{M}_o = (L_{best}, L_{final}, T_{target}, G_{max}, D_o),$$

where T_{target} is time or steps to a target and D_o indicates divergence frequency.

Part 3 - Hints and Helper

Clone the same initial state for every optimizer and repeat across seeds. Store full histories and aggregate metrics with identical evaluation frequency.

Part 4 - Python code skeleton

```
import torch

def E07(model_factory, optimizer_factories, data, seeds):
    results = {}
    for name, optimizer_factory in optimizer_factories.items():
        trials = []
        for seed in seeds:
            model = model_factory(...)
            ...
            trials.append(...)
        results[name] = ...
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.7.9 Exercise 08 - Stability Debugging Scenario

Part 1 - Why this matters

Stability failures often involve interacting causes such as an excessive rate, poor initialization, incorrect loss reduction, stale gradients, non-finite data, or optimizer state errors.

A disciplined scenario captures evidence before changing anything. The first abnormal stage should determine one targeted correction, followed by a repeat of the same controlled run.

Part 2 - Mathematical form

For update:

$$\theta_{t+1} = \theta_t + \Delta\theta_t,$$

monitor relative size:

$$R_t = \frac{\|\Delta\theta_t\|}{\|\theta_t\| + \varepsilon}.$$

Also require finite inputs, activations, loss, gradients, optimizer states, and parameters.

Part 3 - Hints and Helper

Create one faulty training step and record diagnostics in pipeline order. Identify the earliest failed invariant, apply only its direct fix, and compare before-and-after histories.

Part 4 - Python code skeleton

```
import torch

def E08(model, optimizer, X, target):
    report = {}
    report["data"] = ...
    output = ...
    report["forward"] = ...
    loss = ...
    report["loss"] = ...
    loss.backward()
    report["gradients"] = ...
    report["diagnosis"] = ...
    return report

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.7.10 Exercise 09 - Long-Run Training Stability Test

Part 1 - Why this matters

A configuration that survives a few steps may fail after optimizer states grow, schedules change, rare batches occur, or numerical errors accumulate. Long-run testing exposes delayed instability.

The test must use periodic summaries and checkpoints rather than retaining every graph or printing every tensor. Reproducibility and recovery information are part of stability engineering.

Part 2 - Mathematical form

Across T steps, track:

$$L_t, \quad \|g_t\|, \quad \|\Delta\theta_t\|, \quad \|\theta_t\|.$$

A stable run requires finite bounded behavior and defined progress criteria throughout the horizon.

Part 3 - Hints and Helper

Run many steps with scheduled diagnostic intervals, finite checks, validation evaluation, and recoverable checkpoints. Report worst values, trend summaries, stopping reason, and the last valid step.

Part 4 - Python code skeleton

```
import torch

def E09(model, optimizer, train_loader,
        validation_function, max_steps, check_interval):
    summaries = []
    status = ...
    last_valid_step = ...
    for step in range(max_steps):
        ...
        if step % check_interval == 0:
            summary = ...
            summaries.append(summary)
        if ...:
            break
    return summaries, status, last_valid_step

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

4.8 OC06 - Weight Initialization Impact

Mathematics and Theory

4.8.1 Exercise 00 - Zero Initialization Experiment

Part 1 - Why this matters

Zero initialization provides a controlled demonstration of symmetry. When hidden units begin with identical weights, they receive identical signals and remain unable to learn distinct features.

Zero weights are not universally invalid: some biases and final parameters may safely begin at zero. The experiment should identify which tensors suffer from symmetry rather than applying one rule to every parameter.

Part 2 - Mathematical form

If two hidden units have:

$$\mathbf{w}_1 = \mathbf{w}_2 = \mathbf{0},$$

then they produce equal activations and, under symmetric conditions:

$$\nabla_{\mathbf{w}_1} L = \nabla_{\mathbf{w}_2} L.$$

Their updates remain identical.

Part 3 - Hints and Helper

Initialize all weights to zero, run one forward and backward pass, and compare unit activations and gradient rows. Repeat with zero biases but nonzero random weights to isolate the cause.

Part 4 - Python code skeleton

```
import torch

def E00(model, X, target):
    with torch.no_grad():
        for parameter in model.parameters():
            parameter...
    output = ...
    loss = ...
    loss.backward()
    diagnostics = ...
    return loss, diagnostics

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

4.8.2 Exercise 01 - Random Uniform Initialization

Part 1 - Why this matters

Uniform initialization samples weights from a bounded interval, breaking symmetry between units. The interval width determines the initial variance and therefore affects activation and gradient scale.

A reproducible experiment should use a seeded generator and report observed statistics. Choosing bounds without considering layer fan size can make deep signals grow or shrink.

Part 2 - Mathematical form

For:

$$W_{ij} \sim \mathcal{U}(-a, a),$$

the expectation and variance are:

$$\mathbb{E}[W_{ij}] = 0, \qquad \mathrm{Var}(W_{ij}) = \frac{a^2}{3}.$$

Part 3 - Hints and Helper

Initialize a weight tensor uniformly under `torch.no_grad()`. Record min, max, mean, variance, and reproducibility under a fixed seed, then inspect one forward pass.

Part 4 - Python code skeleton

```
import torch

def E01(shape, lower, upper, seed):
    generator = torch...
    weights = torch.empty(...)
    weights.uniform_(..., generator=generator)
    statistics = ...
    return weights, statistics

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

4.8.3 Exercise 02 - Random Normal Initialization

Part 1 - Why this matters

Normal initialization samples most weights near the mean while allowing occasional larger magnitudes. Its standard deviation directly controls the initial variance of linear combinations.

Using the same standard deviation for layers with different fan-in can produce inconsistent activation scales. Measuring empirical and predicted variance connects distribution choice with network structure.

Part 2 - Mathematical form

For:

$$W_{ij} \sim \mathcal{N}(\mu, \sigma^2),$$

usually $\mu = 0$. If independent inputs have variance q, a linear pre-activation approximately satisfies:

$$\mathrm{Var}(z) \approx fan_{in}\sigma^2 q.$$

Part 3 - Hints and Helper

Generate weights with a seeded normal distribution and compare empirical mean and variance with targets. Pass random inputs through the layer and record output variance.

Part 4 - Python code skeleton

```
import torch

def E02(shape, mean, standard_deviation, seed):
    generator = torch...
    weights = torch.empty(...)
    weights.normal_(..., generator=generator)
    statistics = ...
    return weights, statistics

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

4.8.4 Exercise 03 - Xavier Initialization Implementation

Part 1 - Why this matters

Xavier initialization chooses weight scale using both fan-in and fan-out. It is designed to preserve signal variance approximately through layers with symmetric activations such as tanh.

Implementing the formula requires correct interpretation of weight orientation. For a linear weight shaped `(out_features, in_features)`, fan-in and fan-out correspond to its second and first dimensions.

Part 2 - Mathematical form

Xavier normal uses:

$$\mathrm{Var}(W) = \frac{2}{fan_{in} + fan_{out}}.$$

Xavier uniform uses:

$$W_{ij} \sim \mathcal{U}(-a, a), \qquad a = \sqrt{\frac{6}{fan_{in} + fan_{out}}}.$$

Part 3 - Hints and Helper

Calculate fans from the layer shape and implement one Xavier variant manually. Compare observed statistics with `torch.nn.init.xavier_uniform_()` or its normal counterpart.

Part 4 - Python code skeleton

```
import torch

def E03(weight, seed):
    fan_in = ...
    fan_out = ...
    bound = ...
    with torch.no_grad():
        weight.uniform_(...)
```

```
    return weight, (...)

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

4.8.5 Exercise 04 - He Initialization Implementation

Part 1 - Why this matters

He initialization accounts for the variance reduction introduced by ReLU-like activations. It uses fan-in to maintain useful forward signal scale through deep rectified networks.

The formula is connected to the intended nonlinearity and propagation direction. Applying it mechanically to every activation can create a mismatch between its assumptions and actual network behavior.

Part 2 - Mathematical form

He normal for ReLU uses:

$$W_{ij} \sim \mathcal{N}\left(0, \frac{2}{fan_{in}}\right),$$

so:

$$\sigma = \sqrt{\frac{2}{fan_{in}}}.$$

A corresponding uniform bound is $a = \sqrt{6/fan_{in}}$.

Part 3 - Hints and Helper

Compute fan-in correctly and implement He normal under no-gradient mode. Compare empirical variance and activation variance with PyTorch Kaiming initialization.

Part 4 - Python code skeleton

```
import torch

def E04(weight, seed):
    fan_in = ...
    standard_deviation = ...
    with torch.no_grad():
        weight.normal_(...)
    return weight, (...)

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

4.8.6 Exercise 05 - Initialization Effect on Gradient Flow

Part 1 - Why this matters

Initialization determines the scales of forward activations and backward gradients before learning has a chance to correct them. Poor scales can saturate activations, create dead units, or amplify and attenuate gradients across depth.

A useful analysis measures every layer rather than only the final loss. Comparing activation and gradient norms shows where signal quality first changes.

Part 2 - Mathematical form

For a deep chain:

$$h_\ell = \phi(W_\ell h_{\ell-1}),$$

backward flow contains:

$$\nabla_{h_{\ell-1}} L = W_\ell^\top \operatorname{diag}(\phi'(z_\ell))\nabla_{h_\ell} L.$$

The initial W_ℓ scales both directions.

Part 3 - Hints and Helper

Create identical architectures with several initialization schemes and the same input. Retain activation gradients, then record per-layer activation variance, saturation or zero rate, and gradient norm.

Part 4 - Python code skeleton

```
import torch

def E05(model_factories, X, target, seed):
    reports = {}
    for name, factory in model_factories.items():
        model = factory(...)
        activations = ...
        loss = ...
        loss.backward()
        reports[name] = ...
    return reports

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

4.8.7 Exercise 06 - Initialization vs Convergence Speed

Part 1 - Why this matters

A suitable initialization can reduce the number of optimization steps required to reach a target loss. It starts the model in a region where activations and gradients support effective

learning.

Convergence comparison must control optimizer, learning rate, data order, model architecture, and random seeds. One lucky run is not sufficient to judge an initialization method.

Part 2 - Mathematical form

For initialization method i, define:

$$T_i(\tau) = \min\{t : L_t^{(i)} \leq \tau\}.$$

If the target is never reached, report $T_i(\tau)$ as censored rather than assigning an artificial successful time.

Part 3 - Hints and Helper

Train each initialization under identical settings across multiple seeds. Report time or steps to target, best and final loss, divergence frequency, and variability.

Part 4 - Python code skeleton

```
import torch

def E06(model_factory, initialization_methods,
        train_function, seeds, target_loss):
    results = {}
    for method in initialization_methods:
        trials = []
        for seed in seeds:
            model = model_factory(...)
            method(...)
            trials.append(train_function(...))
        results[...] = ...
    return results

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

4.8.8 Exercise 07 - Bad Initialization Failure Case

Part 1 - Why this matters

Bad initialization can make weights too small, too large, identical, or incorrectly scaled for the activation. Symptoms include constant activations, saturation, dead ReLUs, vanished gradients, exploding gradients, and non-finite loss.

Constructing a controlled failure teaches how to connect observable symptoms to the starting parameter distribution. The correction should target the initialization rather than hide its effect with unrelated changes.

Part 2 - Mathematical form

If linear inputs are independent with variance q:

$$\mathrm{Var}(z) \approx fan_{in}\,\mathrm{Var}(W)q.$$

An excessively large $\mathrm{Var}(W)$ amplifies signals, while an excessively small value suppresses them.

Part 3 - Hints and Helper

Choose one intentionally poor scale and record weight statistics, layer activations, gradient norms, and finite checks before any optimizer step. Then apply one appropriate initialization and repeat.

Part 4 - Python code skeleton

```
import torch

def E07(model, bad_scale, X, target):
    initialize_badly = ...
    output = ...
    loss = ...
    loss.backward()
    failure_report = ...
    return failure_report

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

4.8.9 Exercise 08 - Initialization Debugging Challenge

Part 1 - Why this matters

Initialization bugs include wrong fan calculation, transposed shape assumptions, accidental reinitialization, mixed schemes, ignored bias policy, missing no-gradient context, and lost reproducibility.

Debugging should inspect the actual initialized tensors rather than trust the function name. Empirical statistics and first-pass signal measurements reveal whether the implementation matches the intended formula.

Part 2 - Mathematical form

For intended variance σ^2_{target}, compare:

$$r = \frac{\mathrm{Var}(W)_{observed}}{\sigma^2_{target}}.$$

Large deviation, incorrect mean, or identical rows can identify formula, sampling, or symmetry errors.

Part 3 - Hints and Helper

Record shape, fans, expected and observed statistics, duplicate-row checks, seed, activation variance, and gradient norm. Name the earliest inconsistency and change only its cause.

Part 4 - Python code skeleton

```
import torch

def E08(model, initialization_name, seed, X, target):
    report = {}
    report["parameter_statistics"] = ...
    output = ...
    report["activation_statistics"] = ...
    loss = ...
    loss.backward()
    report["gradient_statistics"] = ...
    report["diagnosis"] = ...
    return report

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

4.8.10 Exercise 09 - End-to-End Initialization Comparison

Part 1 - Why this matters

The final comparison evaluates initialization as part of a complete training system. It combines statistical validation, first-pass activation and gradient analysis, convergence speed, stability, and final performance.

A fair conclusion must aggregate multiple random seeds and keep all non-initialization settings fixed. The best method is the one that matches the architecture and activation under the chosen criteria, not a universal winner.

Part 2 - Mathematical form

For method i, collect:

$$\mathcal{M}_i = (V_W, V_h, G_1, T_\tau, L_{best}, D),$$

representing weight variance, activation variance, early gradient scale, time to target, best loss, and divergence. Aggregate these measurements across seeds.

Part 3 - Hints and Helper

Compare zero, uniform, normal, Xavier, and He methods on the same model family. Reset model and optimizer for every trial, store full histories, and rank methods with a stated criterion.

Part 4 - Python code skeleton

```
import torch

def E09(model_factory, initialization_methods,
        train_function, seeds):
    results = {}
    for method in initialization_methods:
        trials = []
        for seed in seeds:
            model = model_factory(...)
            method(model, seed)
            diagnostics = ...
            training_result = train_function(...)
            trials.append((diagnostics, training_result))
        results[method.__name__] = ...
    return results

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

Book 5

Loss Functions & Training Loop

5.1 Introduction

5.1.1 What will the book teach you

An artificial intelligence model does not learn merely because it produces an output. Learning begins when the output is compared with a desired target and that comparison is translated into a mathematical signal that the optimization process can use. A loss function performs this translation. It converts the difference between prediction and target into a scalar objective whose gradient describes how the model parameters should change. This book teaches how to design, implement, inspect, and use that signal inside a complete training system.

The choice of loss defines what the model is rewarded for improving. Two losses can evaluate the same predictions yet assign very different importance to large errors, outliers, class imbalance, uncertainty, and incorrect confidence. A loss is therefore not only a technical requirement for calling `backward()`; it is a mathematical statement about the behavior the model should learn. You will study how per-example errors become vector losses, how reduction converts them into a scalar, and how `sum` and `mean` change gradient scale as batch size changes.

For regression, you will implement mean squared error manually and through PyTorch. Given predictions $\widehat{y}_i$ and targets y_i, the standard mean squared error is:

$$L_{MSE} = \frac{1}{N}\sum_{i=1}^{N}(\widehat{y}_i - y_i)^2.$$

You will inspect its gradient, sensitivity to outliers, numerical behavior with large values, weighted variants, and differences from mean absolute error. The objective is to understand not only how to compute MSE, but why squaring errors changes the optimization signal and when that behavior is appropriate.

For classification, you will study cross-entropy from probabilities, one-hot targets, class indices, logits, LogSoftmax, and negative log-likelihood. You will derive the relationship:

$$\text{CrossEntropy}(\mathbf{z}, y) = -\log\left(\frac{e^{z_y}}{\sum_{c=1}^{C} e^{z_c}}\right),$$

while also learning why direct exponentiation can be numerically unstable. The exercises will connect the mathematical formula with PyTorch's expectation that `CrossEntropyLoss` normally receives raw logits and class-index targets, not already normalized probabilities. You

will debug incorrect shapes, class imbalance, unstable logarithms, and common cases where mathematically meaningful data is passed to the wrong interface.

After the loss functions are understood, the book builds the training loop from its individual state transitions. A complete training step follows a deliberate order: read a batch, calculate predictions, calculate a scalar loss, clear old gradients, perform backpropagation, update parameters, and record detached diagnostics. You will implement this process manually and with a PyTorch optimizer, then investigate bugs caused by misplaced gradient clearing, accumulated graphs, missing parameter updates, non-finite gradients, and incorrect logging.

Training on a dataset introduces batching and epochs. A mini-batch provides a stochastic estimate of the full-dataset gradient, while an epoch represents one complete traversal of the training data. You will construct batch and epoch loops, shuffle data correctly, handle the final incomplete batch, compare batch sizes, and deliberately accumulate gradients across several batches. Particular attention will be given to loss reduction and accumulation scaling, because the meaning of an update can change when the number of samples contributing to it is not accounted for.

A falling training loss does not prove that a model has learned a general rule. The model may instead memorize patterns specific to its training examples. You will therefore separate training and validation data, use `train()` and `eval()` modes correctly, disable gradient tracking during evaluation, and compute validation metrics without updating model parameters. You will learn to identify overfitting from the relationship between training and validation histories and to select a model from validation evidence rather than its final training loss.

The final part of the book treats overfitting prevention as a collection of controlled interventions. You will study weight decay, dropout, data augmentation, and early stopping, then connect them to the bias–variance tradeoff. Each method changes a different part of the learning system: the objective, the network behavior, the data distribution, or the training duration. The exercises will teach you to diagnose underfitting and overfitting before choosing a method, instead of adding every regularization technique at once.

5.1.2 How to approach the exercises

Treat every exercise as a small scientific experiment. Begin by identifying the prediction shape, target representation, unreduced loss shape, scalar reduction, and expected gradient scale. Predict the behavior before running the program, then compare the prediction with recorded values. When two losses, batch sizes, or regularization methods are compared, preserve the model initialization, data, optimizer settings, random seed, and training budget so that the intended factor is the only meaningful difference.

Do not evaluate a training pipeline using one number. Record training loss, validation loss, task metrics, gradient norms, learning rate, batch size, and the reason training stopped. Keep logging tensors detached from their computational graphs, and never allow validation data to influence parameter updates or hyperparameter decisions indirectly through data leakage. The goal is to produce training code that is not only functional, but explainable, reproducible, and safe to debug.

5.1.3 The Chapters (LFTL00 - LFTL06) included in this book

- LFTL00 - What is Loss and Why
- LFTL01 - MSE Loss Implementation
- LFTL02 - Cross-Entropy Logic
- LFTL03 - Building Training Loop Manually
- LFTL04 - Batching + Epochs
- LFTL05 - Evaluation & Validation Split
- LFTL06 - Overfitting Prevention Methods

5.2 LFTL00 - What is Loss and Why

Mathematics and Theory

5.2.1 Exercise 00 - Define Loss for Simple Regression

Part 1 - Why this matters

A regression model produces continuous predictions, but optimization requires a scalar objective describing their disagreement with targets. A loss function turns prediction error into a quantity that can be minimized.

Defining the loss makes the task objective explicit. Different transformations of the same error create different gradients and therefore different learning behavior.

Part 2 - Mathematical form

For prediction $\widehat{y}$ and target y, a simple squared loss is:

$$L(\widehat{y}, y) = (\widehat{y} - y)^2.$$

It is nonnegative and equals zero exactly when $\widehat{y} = y$.

Part 3 - Hints and Helper

Accept scalar floating-point tensors with compatible shapes. Compute the residual first and then the loss, returning both so their relationship can be inspected.

Part 4 - Python code skeleton

```
import torch

def E00(prediction, target):
    error = ...
    loss = ...
    return error, loss
```

```
def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.2.2 Exercise 01 - Compare Prediction vs Target

Part 1 - Why this matters

Loss calculation begins with a valid comparison between prediction and target. Their shapes, units, ordering, and semantic meaning must agree before a numerical difference can represent model error.

Broadcasting can make an incorrectly shaped comparison run without an exception. Shape validation protects the loss from silently comparing the wrong values.

Part 2 - Mathematical form

For vectors $\widehat{\mathbf{y}}, \mathbf{y} \in \mathbb{R}^N$, define residuals:

$$\mathbf{e} = \widehat{\mathbf{y}} - \mathbf{y}, \qquad e_i = \widehat{y}_i - y_i.$$

Useful raw comparisons include signed error e_i and absolute error $|e_i|$.

Part 3 - Hints and Helper

Check exact shape agreement before subtraction unless broadcasting is intentionally part of the task. Return signed errors, absolute errors, and a validity check.

Part 4 - Python code skeleton

```
import torch

def E01(predictions, targets):
    if ...:
        raise ValueError(...)
    signed_errors = ...
    absolute_errors = torch...
    return signed_errors, absolute_errors

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.2.3 Exercise 02 - Scalar Loss Computation

Part 1 - Why this matters

Backpropagation commonly begins from one scalar loss. When several errors exist, a reduction defines how they contribute to this single optimization objective.

A scalar loss is not merely required by software convenience. Its reduction determines the relative scale of gradients and the meaning of reported training values.

Part 2 - Mathematical form

Given per-element losses ℓ_i:

$$L = \frac{1}{N}\sum_{i=1}^{N} \ell_i$$

is a scalar mean reduction. For squared error:

$$\ell_i = (\widehat{y}_i - y_i)^2.$$

Part 3 - Hints and Helper

Compute an unreduced loss tensor first, inspect its shape, and then reduce it explicitly. Verify that the final tensor has zero dimensions before calling backward.

Part 4 - Python code skeleton

```
import torch

def E02(predictions, targets):
    element_losses = ...
    scalar_loss = torch...
    return element_losses, scalar_loss, scalar_loss.dim()

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.2.4 Exercise 03 - Vector Loss Aggregation

Part 1 - Why this matters

Multi-output predictions produce a vector or matrix of local losses. Aggregation controls how samples and features combine into one training signal.

The aggregation may weight dimensions differently when errors have different importance or units. Treating every component equally is a modeling choice rather than a universal rule.

Part 2 - Mathematical form

For element losses $\boldsymbol{\ell} \in \mathbb{R}^N$ and nonnegative weights $\mathbf{w}$:

$$L = \frac{\sum_{i=1}^{N} w_i \ell_i}{\sum_{i=1}^{N} w_i},$$

provided $\sum_i w_i > 0$. Equal weights recover the ordinary mean.

Part 3 - Hints and Helper

Create element-wise losses without reduction, validate optional weight shape and positivity, and implement an explicit aggregation. Return local contributions as well as the scalar result.

Part 4 - Python code skeleton

```
import torch

def E03(predictions, targets, weights=None):
    element_losses = ...
    if weights is None:
        aggregate = ...
    else:
        aggregate = ...
    return element_losses, aggregate

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.2.5 Exercise 04 - Mean Loss vs Sum Loss

Part 1 - Why this matters

Mean and sum reductions use the same local errors but produce different scalar and gradient scales. Sum grows with the number of elements, while mean normalizes by that count.

This distinction matters when batch size changes or gradients are accumulated. Comparing final loss values without naming the reduction can be misleading.

Part 2 - Mathematical form

For N local losses:

$$L_{sum} = \sum_{i=1}^{N} \ell_i, \qquad L_{mean} = \frac{1}{N} \sum_{i=1}^{N} \ell_i.$$

Therefore:

$$\nabla L_{mean} = \frac{1}{N} \nabla L_{sum}.$$

Part 3 - Hints and Helper

Compute both reductions from the same unreduced tensor. Use separate forward graphs or `torch.autograd.grad()` to compare prediction gradients and verify the expected scaling ratio.

Part 4 - Python code skeleton

```
import torch

def E04(predictions, targets):
    element_losses = ...
    sum_loss = ...
    mean_loss = ...
    sum_gradient = torch.autograd...
    mean_gradient = torch.autograd...
    return (...)

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.2.6 Exercise 05 - Loss Sensitivity Observation

Part 1 - Why this matters

Loss sensitivity describes how strongly the objective changes when a prediction moves away from its target. Squared error becomes increasingly sensitive to large residuals, while absolute error changes at a constant rate away from zero.

Observing values and gradients together explains why a loss reacts strongly to outliers or remains robust. Sensitivity is part of loss design, not an accidental side effect.

Part 2 - Mathematical form

For residual $e = \widehat{y} - y$:

$$L_{square} = e^2, \qquad \frac{\partial L_{square}}{\partial \widehat{y}} = 2e.$$

For absolute loss:

$$L_{absolute} = |e|,$$

whose slope magnitude is one away from $e = 0$.

Part 3 - Hints and Helper

Evaluate several residual sizes on both sides of zero. Record each loss and gradient, then compare how magnitude and sign change without mixing different target values.

Part 4 - Python code skeleton

```
import torch

def E05(prediction_values, target):
    records = []
    for value in prediction_values:
        prediction = torch.tensor(..., requires_grad=True)
        squared_loss = ...
```

```
        ...
        records.append(...)
    return records

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.2.7 Exercise 06 - Loss Landscape Visualization

Part 1 - Why this matters

A loss landscape shows how objective value changes as model parameters vary. For one or two parameters it can reveal minima, slopes, curvature, flat regions, and paths followed by optimization.

Visualization should be generated from a fixed dataset and model definition. Changing data or other parameters while scanning the surface changes the landscape being measured.

Part 2 - Mathematical form

For linear regression $\widehat{y}_i = wx_i + b$:

$$L(w, b) = \frac{1}{N} \sum_{i=1}^{N} (wx_i + b - y_i)^2.$$

Evaluating L over a grid of (w, b) values creates a two-dimensional loss surface.

Part 3 - Hints and Helper

Create parameter grids with `torch.linspace()` and evaluate the loss at every pair without training. Return grid coordinates, loss values, the minimum grid location, and data suitable for a surface or contour plot.

Part 4 - Python code skeleton

```
import torch

def E06(X, targets, weight_values, bias_values):
    landscape = torch...
    for i, weight in enumerate(weight_values):
        for j, bias in enumerate(bias_values):
            predictions = ...
            landscape[i, j] = ...
    minimum = ...
    return landscape, minimum

def main():
    print(E06(...))
```

```
if __name__ == "__main__":
    main()
```

5.2.8 Exercise 07 - Loss Scaling Effect

Part 1 - Why this matters

Multiplying a loss by a constant leaves its minimizer unchanged when the constant is positive, but it scales every gradient and therefore changes optimizer step magnitudes.

Loss scaling can interact with learning rate, clipping, numerical precision, batch accumulation, and mixed-precision training. Equivalent minima do not imply identical training trajectories.

Part 2 - Mathematical form

For scaled loss:

$$\widetilde{L} = \alpha L, \qquad \alpha > 0,$$

the gradient is:

$$\nabla \widetilde{L} = \alpha \nabla L.$$

The gradient-descent update becomes $\Delta\theta = -\eta\alpha\nabla L$.

Part 3 - Hints and Helper

Compute gradients for the original and scaled loss from identical predictions. Verify the scaling ratio, then compare updates while keeping the learning rate fixed.

Part 4 - Python code skeleton

```
import torch

def E07(predictions, targets, scale):
    base_loss = ...
    scaled_loss = ...
    base_gradient = torch.autograd...
    scaled_gradient = torch.autograd...
    return (...)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.2.9 Exercise 08 - Poor Loss Choice Failure Case

Part 1 - Why this matters

A mathematically valid loss can be poorly aligned with the task. It may overemphasize outliers, ignore class imbalance, use incompatible units, or optimize a surrogate unrelated to the desired evaluation behavior.

The resulting model can minimize its training objective while performing poorly on the real goal. Diagnosing this requires comparing loss behavior with task metrics and error cases.

Part 2 - Mathematical form

Suppose one regression outlier has residual M. Under squared error its contribution is:

$$M^2,$$

while a typical residual m contributes m^2. Their ratio is:

$$\frac{M^2}{m^2},$$

which can allow one outlier to dominate the aggregate objective.

Part 3 - Hints and Helper

Construct a dataset with one controlled outlier and compare per-sample MSE and MAE contributions. Explain which samples dominate each loss and relate this to a chosen task requirement.

Part 4 - Python code skeleton

```
import torch

def E08(predictions, targets):
    squared_contributions = ...
    absolute_contributions = ...
    mse = ...
    mae = ...
    dominance_report = ...
    return (...)

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.2.10 Exercise 09 - Loss Design Reasoning Challenge

Part 1 - Why this matters

Designing a loss requires translating task priorities into mathematical penalties while preserving useful gradients and numerical stability. No single loss is optimal for every data distribution or evaluation goal.

A strong design states its assumptions, reduction, weighting, edge-case behavior, and relationship to the task metric. It should also identify failure modes before implementation.

Part 2 - Mathematical form

A composite objective may be:

$$L = \lambda_1 L_1 + \lambda_2 L_2, \qquad \lambda_1, \lambda_2 \geq 0.$$

Its gradient is:

$$\nabla L = \lambda_1 \nabla L_1 + \lambda_2 \nabla L_2.$$

The weights therefore control both objective importance and gradient scale.

Part 3 - Hints and Helper

Given a task description, define prediction and target representations, local penalty, reduction, optional weights, and stability safeguards. Implement only a skeleton and return diagnostic components separately from the final scalar.

Part 4 - Python code skeleton

```
import torch

def E09(predictions, targets, settings):
    primary_loss = ...
    secondary_loss = ...
    weights = ...
    total_loss = ...
    diagnostics = ...
    return total_loss, diagnostics

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.3 LFTL01 - MSE Loss Implementation

Mathematics and Theory

5.3.1 Exercise 00 - Manual MSE Formula Implementation

Part 1 - Why this matters

Implementing mean squared error manually reveals its three stages: compute residuals, square them, and average all selected elements. Each stage affects the final value and gradient.

The exercise provides a reference for validating library functions and custom reductions. Shape agreement must be checked before arithmetic to prevent accidental broadcasting.

Part 2 - Mathematical form

For N prediction-target pairs:

$$L_{MSE} = \frac{1}{N}\sum_{i=1}^{N}(\widehat{y}_i - y_i)^2.$$

The result is nonnegative and equals zero when every prediction matches its target.

Part 3 - Hints and Helper

Validate exact shape equality, calculate residuals and squared errors, then use `torch.mean()` for the scalar reduction. Return the intermediate tensors for inspection.

Part 4 - Python code skeleton

```
import torch

def E00(predictions, targets):
    if ...:
        raise ValueError(...)
    errors = ...
    squared_errors = ...
    mse = torch...
    return errors, squared_errors, mse

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.3.2 Exercise 01 - MSE Using PyTorch

Part 1 - Why this matters

PyTorch provides tested MSE implementations with explicit reduction options. Using them correctly requires understanding that `mean`, `sum`, and `none` produce different shapes and gradient scales.

Comparing library output with the manual formula verifies both the API and the user's interpretation of reduction. Matching numeric values alone is insufficient if shapes or reductions differ.

Part 2 - Mathematical form

With mean reduction:

$$\text{MSE}(\widehat{\mathbf{y}}, \mathbf{y}) = \frac{1}{N}\sum_{i}(\widehat{y}_i - y_i)^2.$$

With no reduction, the output is the element-wise tensor:

$$\ell_i = (\widehat{y}_i - y_i)^2.$$

Part 3 - Hints and Helper

Use `torch.nn.functional.mse_loss()` with multiple reductions. Compare the mean result with a manual implementation and report each output shape.

Part 4 - Python code skeleton

```
import torch

def E01(predictions, targets):
    unreduced = torch.nn.functional...
    mean_loss = torch.nn.functional...
    sum_loss = torch.nn.functional...
    manual = ...
    check = torch...
    return (...)

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.3.3 Exercise 02 - Batch-wise MSE Computation

Part 1 - Why this matters

A batch may require one loss per sample before those values are combined. Batch-wise MSE preserves sample identity by reducing only feature dimensions.

This distinction is useful for sample weighting, outlier detection, and analysis. A global mean instead mixes batch and feature dimensions immediately.

Part 2 - Mathematical form

For predictions $\widehat{\mathbf{Y}} \in \mathbb{R}^{B\times F}$:

$$L_i = \frac{1}{F}\sum_{j=1}^{F}(\widehat{Y}_{ij} - Y_{ij})^2,$$

giving $\mathbf{L} \in \mathbb{R}^B$. The batch mean is:

$$L = \frac{1}{B}\sum_i L_i.$$

Part 3 - Hints and Helper

Compute unreduced squared errors, identify all non-batch axes, and reduce them while retaining one value per sample. Then aggregate the sample losses explicitly.

Part 4 - Python code skeleton

```
import torch

def E02(predictions, targets):
    squared_errors = ...
    sample_losses = torch.mean(..., dim=...)
    batch_loss = torch...
    return sample_losses, batch_loss

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.3.4 Exercise 03 - MSE Gradient Inspection

Part 1 - Why this matters

The MSE gradient is proportional to the residual, so larger errors create larger corrective signals. Mean reduction also divides the gradient by the number of reduced elements.

Inspecting the gradient connects loss values with optimizer behavior. It makes reduction-related scaling visible before a training loop is introduced.

Part 2 - Mathematical form

For mean MSE:

$$L = \frac{1}{N}\sum_i (\widehat{y}_i - y_i)^2,$$

$$\frac{\partial L}{\partial \widehat{y}_i} = \frac{2}{N}(\widehat{y}_i - y_i).$$

Part 3 - Hints and Helper

Use tracked predictions, derive the manual gradient with the correct element count, call backward on the scalar loss, and compare shape, sign, and value.

Part 4 - Python code skeleton

```
import torch

def E03(predictions, targets):
    loss = ...
    manual_gradient = ...
    loss.backward()
    return loss, manual_gradient, predictions.grad

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.3.5 Exercise 04 - Effect of Outliers on MSE

Part 1 - Why this matters

Squaring residuals causes large errors to contribute disproportionately to MSE. One outlier can dominate the loss and gradient even when most predictions are accurate.

This sensitivity may be appropriate when large errors are especially costly, but harmful when targets contain corruption. Per-sample contributions reveal the effect clearly.

Part 2 - Mathematical form

If typical residual magnitude is a and an outlier has magnitude ka, their squared-loss ratio is:

$$\frac{(ka)^2}{a^2} = k^2.$$

Thus a residual ten times larger contributes one hundred times more squared error.

Part 3 - Hints and Helper

Create clean and outlier versions of the same data. Compare unreduced contributions, aggregate MSE, and prediction gradients while changing only one target.

Part 4 - Python code skeleton

```
import torch

def E04(predictions, clean_targets, outlier_targets):
    clean_losses = ...
    outlier_losses = ...
    contribution_ratio = ...
    return clean_losses, outlier_losses, contribution_ratio

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.3.6 Exercise 05 - MSE Stability with Large Values

Part 1 - Why this matters

Squaring very large residuals can overflow limited floating-point formats, producing infinite loss and unusable gradients. Large but finite values may also lose precision.

Numerical diagnosis should inspect residuals before squaring and compare dtypes. Scaling data or choosing a suitable precision addresses different causes from gradient clipping.

Part 2 - Mathematical form

For residual e:

$$L = e^2, \qquad \frac{dL}{d\widehat{y}} = 2e.$$

If $|e| > \sqrt{x_{max}}$ for the dtype, e^2 exceeds the largest representable finite value.

Part 3 - Hints and Helper

Evaluate increasing magnitudes in float32 and float64. Check residual, squared error, loss, and gradient with `torch.isfinite()`, then report the first unstable stage.

Part 4 - Python code skeleton

```
import torch

def E05(values, target, dtypes):
    report = {}
    for dtype in dtypes:
        predictions = torch.tensor(..., dtype=dtype,
                                   requires_grad=True)
        loss = ...
        ...
        report[str(dtype)] = ...
    return report

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.3.7 Exercise 06 - Weighted MSE Loss Challenge

Part 1 - Why this matters

Weighted MSE gives different samples or output dimensions different importance. Weights can represent reliability, priority, or unequal contribution to the task.

The normalization convention must be stated. Dividing by the number of elements and dividing by the total weight define different objectives when weights do not average to one.

Part 2 - Mathematical form

A normalized weighted MSE is:

$$L = \frac{\sum_i w_i(\widehat{y}_i - y_i)^2}{\sum_i w_i}, \qquad w_i \geq 0, \quad \sum_i w_i > 0.$$

Part 3 - Hints and Helper

Validate weight shape, nonnegativity, and positive total weight. Support only intentional broadcasting and return weighted local contributions before reduction.

Part 4 - Python code skeleton

```
import torch

def E06(predictions, targets, weights):
    if ...:
        raise ValueError(...)
    squared_errors = ...
    weighted_errors = ...
    loss = ...
    return weighted_errors, loss

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.3.8 Exercise 07 - MSE vs MAE Comparison

Part 1 - Why this matters

MSE and MAE measure regression error differently. MSE emphasizes large residuals with increasing gradient magnitude, while MAE grows linearly and has constant slope magnitude away from zero.

Their comparison should include loss contributions and gradients, not only aggregate values. The preferred behavior depends on noise, outliers, and task costs.

Part 2 - Mathematical form

For residual e:

$$L_{MSE} = e^2, \qquad L_{MAE} = |e|.$$

Their derivatives away from $e = 0$ are:

$$\frac{dL_{MSE}}{d\widehat{y}} = 2e, \qquad \frac{dL_{MAE}}{d\widehat{y}} = \text{sign}(e).$$

Part 3 - Hints and Helper

Use the same prediction-target pairs, including a controlled outlier. Compare unreduced losses, aggregate values, and gradients from separate graphs.

Part 4 - Python code skeleton

```
import torch

def E07(predictions, targets):
    mse = ...
    mae = ...
    mse_gradient = torch.autograd...
    mae_gradient = torch.autograd...
```

```
    return mse, mae, mse_gradient, mae_gradient

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.3.9 Exercise 08 - MSE Debugging Challenge

Part 1 - Why this matters

MSE bugs often arise from shape broadcasting, wrong target dtype, incorrect reduction axes, stale gradients, detached predictions, or confusion between squared error and root mean squared error.

A systematic diagnosis inspects inputs, unreduced loss, scalar reduction, graph connectivity, and gradients in order. Randomly reshaping tensors can hide the original semantic error.

Part 2 - Mathematical form

The expected invariants are:

$$\text{shape}(\hat{\mathbf{y}}) = \text{shape}(\mathbf{y}),$$

and for scalar mean loss:

$$\dim(L) = 0, \qquad \nabla_{\hat{\mathbf{y}}} L = \frac{2}{N}(\hat{\mathbf{y}} - \mathbf{y}).$$

Part 3 - Hints and Helper

Create one faulty example and print shape, dtype, device, reduction, `requires_grad`, and `grad_fn`. Identify the first violated invariant and fix only its cause.

Part 4 - Python code skeleton

```
import torch

def E08(predictions, targets):
    diagnostics = {
        "shapes": ...,
        "dtypes": ...,
        "devices": ...,
        "graph": ...
    }
    loss = ...
    diagnosis = ...
    return diagnostics, loss, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.3.10 Exercise 09 - Custom MSE Loss Class

Part 1 - Why this matters

A custom loss class packages validation, reduction, and optional weighting into a reusable module. It should preserve Autograd connectivity and follow clear PyTorch shape and reduction conventions.

Building the class demonstrates that custom loss code is ordinary differentiable tensor computation. State should be registered appropriately if persistent weights are used.

Part 2 - Mathematical form

For reduction r:

$$\ell_i = (\widehat{y}_i - y_i)^2,$$

$$L_r = \begin{cases} \boldsymbol{\ell}, & r = \text{none}, \\ \sum_i \ell_i, & r = \text{sum}, \\ \frac{1}{N}\sum_i \ell_i, & r = \text{mean}. \end{cases}$$

Part 3 - Hints and Helper

Subclass `torch.nn.Module`, validate the reduction in `__init__()`, and implement `forward()` with tensor operations. Compare all modes with PyTorch MSE.

Part 4 - Python code skeleton

```
import torch

class CustomMSELoss(torch.nn.Module):
    def __init__(self, reduction="mean"):
        super().__init__()
        if reduction not in (...):
            raise ValueError(...)
        self.reduction = reduction

    def forward(self, predictions, targets):
        squared_errors = ...
        if self.reduction == "none":
            return ...
        if self.reduction == "sum":
            return ...
        return ...

def E09(predictions, targets, reduction):
    criterion = CustomMSELoss(...)
    return criterion(...)

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.4 LFTL02 - Cross-Entropy Logic

Mathematics and Theory

5.4.1 Exercise 00 - Probability Output Validation

Part 1 - Why this matters

Cross-entropy defined on probabilities assumes each sample contains a valid categorical distribution. Values must be finite, nonnegative, no greater than one, and sum to one across the class axis.

Validation separates probabilities from logits. Logits are unrestricted scores and should not be rejected merely because they fall outside the probability interval.

Part 2 - Mathematical form

For probabilities $\mathbf{p} \in \mathbb{R}^C$:

$$0 \leq p_c \leq 1, \qquad \sum_{c=1}^{C} p_c = 1.$$

For a batch $\mathbf{P} \in \mathbb{R}^{B \times C}$, this condition is checked independently for every row.

Part 3 - Hints and Helper

Check dtype, finiteness, bounds, and row sums with a tolerance. Return per-sample validity and avoid applying this validator to raw logits.

Part 4 - Python code skeleton

```
import torch

def E00(probabilities, tolerance):
    finite = ...
    bounds = ...
    row_sums = ...
    normalized = torch...
    valid_rows = ...
    return valid_rows

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.4.2 Exercise 01 - One-Hot Target Encoding

Part 1 - Why this matters

One-hot encoding represents a class index as a vector with one active class. It connects the general cross-entropy sum with the simpler negative log-probability of the correct class.

The number of classes and valid index range must be known. PyTorch cross-entropy commonly expects integer indices directly, so one-hot encoding should be used only when the selected formula requires it.

Part 2 - Mathematical form

For class index $y \in \{0, \ldots, C-1\}$:

$$q_c = \begin{cases} 1, & c = y, \\ 0, & c \neq y. \end{cases}$$

Thus $\sum_c q_c = 1$.

Part 3 - Hints and Helper

Validate integer targets and bounds, then use an appropriate PyTorch encoding operation. Verify output shape, dtype, row sums, and recovered indices.

Part 4 - Python code skeleton

```
import torch

def E01(class_indices, number_of_classes):
    if ...:
        raise ValueError(...)
    one_hot = torch.nn.functional...
    checks = ...
    return one_hot, checks

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.4.3 Exercise 02 - Manual Cross-Entropy Computation

Part 1 - Why this matters

Manual cross-entropy reveals that the loss penalizes low probability assigned to the target distribution. For a one-hot target, only the correct class contributes directly to the sum.

Taking a logarithm requires strictly positive probabilities. Clamping can prevent undefined values for an educational probability-based formula, but stable logits-based computation is preferred in training.

Part 2 - Mathematical form

For target distribution $\mathbf{q}$ and predicted probabilities $\mathbf{p}$:

$$H(\mathbf{q}, \mathbf{p}) = -\sum_{c=1}^{C} q_c \log p_c.$$

For one-hot target y:

$$H = -\log p_y.$$

Part 3 - Hints and Helper

Validate probability and target shapes, clamp only with a documented epsilon, compute per-sample losses, and apply an explicit reduction. Compare one-hot and gathered-index forms.

Part 4 - Python code skeleton

```
import torch

def E02(probabilities, one_hot_targets, epsilon):
    safe_probabilities = torch...
    log_probabilities = torch...
    sample_losses = ...
    loss = ...
    return sample_losses, loss

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.4.4 Exercise 03 - Cross-Entropy Using PyTorch

Part 1 - Why this matters

PyTorch cross-entropy combines stable LogSoftmax and negative log-likelihood. Its usual classification interface expects raw logits shaped by batch and class, plus integer class indices.

Applying Softmax before this function changes the mathematical input and can weaken or distort the intended computation. Knowing the contract prevents a common double-normalization error.

Part 2 - Mathematical form

For logits $\mathbf{z}$ and target class y:

$$L = -z_y + \log \sum_{c=1}^{C} e^{z_c}.$$

This equals:

$$-\log\left(\frac{e^{z_y}}{\sum_c e^{z_c}}\right).$$

Part 3 - Hints and Helper

Use `torch.nn.functional.cross_entropy()` with logits and long class-index targets. Explore `none`, `mean`, and `sum` reductions and verify output shapes.

Part 4 - Python code skeleton

```
import torch

def E03(logits, class_targets):
    unreduced = torch.nn.functional...
    mean_loss = torch.nn.functional...
    sum_loss = torch.nn.functional...
    return unreduced, mean_loss, sum_loss

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.4.5 Exercise 04 - LogSoftmax + NLL Breakdown

Part 1 - Why this matters

Cross-entropy can be decomposed into LogSoftmax followed by negative log-likelihood. The first operation converts logits into stable log-probabilities; the second selects and negates the target-class value.

This decomposition makes intermediate values inspectable without changing the objective. It also explains why NLLLoss expects log-probabilities rather than logits or ordinary probabilities.

Part 2 - Mathematical form

LogSoftmax is:

$$\log p_c = z_c - \log \sum_j e^{z_j}.$$

For target y, NLL is:

$$L = -\log p_y.$$

Therefore $\text{CrossEntropy}(\mathbf{z}, y) = \text{NLL}(\log \text{Softmax}(\mathbf{z}), y)$.

Part 3 - Hints and Helper

Compute `log_softmax(logits, dim=1)` and pass it to `nll_loss`. Compare values and gradients with direct cross-entropy using separate graphs.

Part 4 - Python code skeleton

```
import torch

def E04(logits, targets):
    log_probabilities = torch.nn.functional...
    nll = torch.nn.functional...
    direct = torch.nn.functional...
    comparison = torch...
    return log_probabilities, nll, direct, comparison

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.4.6 Exercise 05 - Numerical Stability (Log-Sum-Exp)

Part 1 - Why this matters

Direct exponentiation of large logits can overflow, while very negative values can underflow. The log-sum-exp transformation computes the same quantity after shifting logits by their maximum.

The shift does not change Softmax probabilities because it affects numerator and denominator equally. Stable computation preserves finite losses and useful gradients over a wider range.

Part 2 - Mathematical form

Let $m = \max_c z_c$. Then:

$$\log \sum_c e^{z_c} = m + \log \sum_c e^{z_c - m}.$$

Since $z_c - m \leq 0$, the exponentials cannot overflow from large positive arguments.

Part 3 - Hints and Helper

Implement naive and stable log-sum-exp on moderate and extreme logits. Compare with `torch.logsumexp()` and report finiteness and numerical error.

Part 4 - Python code skeleton

```
import torch

def E05(logits, dimension):
    naive = torch.log(torch.sum(torch.exp(...), dim=...))
    maximum = torch.max(...).values
    stable = ...
    reference = torch.logsumexp(...)
    return naive, stable, reference

def main():
```

```
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.4.7 Exercise 06 - Batch Cross-Entropy Loss

Part 1 - Why this matters

Batch cross-entropy produces one loss per sample before reduction. Keeping these values visible supports weighting, debugging mislabeled examples, and interpreting how mean and sum scale with batch size.

The class axis and batch axis have different roles. Only the target class is selected per sample, while reduction combines sample losses.

Part 2 - Mathematical form

For logits $\mathbf{Z} \in \mathbb{R}^{B \times C}$ and targets y_i:

$$\ell_i = -Z_{i,y_i} + \log \sum_{c=1}^{C} e^{Z_{ic}}.$$

Mean batch loss is:

$$L = \frac{1}{B} \sum_{i=1}^{B} \ell_i.$$

Part 3 - Hints and Helper

Compute unreduced cross-entropy, verify the result has shape `(B,)`, and aggregate explicitly. Compare mean and sum gradients using separate forward graphs.

Part 4 - Python code skeleton

```
import torch

def E06(logits, targets):
    sample_losses = torch.nn.functional...
    mean_loss = ...
    sum_loss = ...
    return sample_losses, mean_loss, sum_loss

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.4.8 Exercise 07 - Wrong Target Shape Debugging

Part 1 - Why this matters

Classification targets are a frequent source of cross-entropy errors. The usual PyTorch case expects one integer class index per sample, not an extra singleton dimension or a one-hot matrix.

A tensor can contain correct labels but still violate the function's representation contract. Debugging should inspect shape, dtype, range, and correspondence with the logits batch.

Part 2 - Mathematical form

For logits:

$$\mathbf{Z} \in \mathbb{R}^{B \times C},$$

class-index targets should satisfy:

$$\mathbf{y} \in \{0, \ldots, C-1\}^{B}.$$

Thus target shape is (B) and its dtype is integer.

Part 3 - Hints and Helper

Create faulty target examples such as `(B,1)`, floating indices, and one-hot `(B,C)`. Diagnose each before applying a representation-aware correction.

Part 4 - Python code skeleton

```
import torch

def E07(logits, targets):
    diagnostics = {
        "logits_shape": ...,
        "target_shape": ...,
        "target_dtype": ...,
        "target_range": ...
    }
    corrected_targets = ...
    return diagnostics, corrected_targets

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.4.9 Exercise 08 - Class Imbalance Effect

Part 1 - Why this matters

With class imbalance, ordinary mean cross-entropy can be dominated by frequent classes. A model may reduce average loss while learning weak behavior for rare but important classes.

Class weighting changes each target class's contribution to the objective and gradient. Weights must be chosen from task priorities or data statistics and evaluated with class-sensitive metrics.

Part 2 - Mathematical form

With class weight w_c:

$$\ell_i = -w_{y_i} \log p_{i,y_i}.$$

A common inverse-frequency idea is:

$$w_c \propto \frac{1}{n_c},$$

followed by a documented normalization convention.

Part 3 - Hints and Helper

Count class frequencies, construct positive class weights, and compare per-class loss contributions with and without weighting. Keep logits and targets identical.

Part 4 - Python code skeleton

```
import torch

def E08(logits, targets, number_of_classes):
    counts = torch...
    class_weights = ...
    unweighted = torch.nn.functional...
    weighted = torch.nn.functional...
    report = ...
    return class_weights, report

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.4.10 Exercise 09 - Custom Cross-Entropy Loss

Part 1 - Why this matters

A custom cross-entropy module combines stable log-probabilities, target selection, optional class weighting, and reduction. Its output and gradients should match PyTorch for supported cases.

The implementation must avoid explicit Softmax and logarithm of probabilities when logits are available. Shape validation and stable LogSoftmax belong inside the module contract.

Part 2 - Mathematical form

For log-probabilities:

$$\log p_{ic} = Z_{ic} - \log \sum_j e^{Z_{ij}},$$

the sample loss is:

$$\ell_i = -w_{y_i} \log p_{i,y_i},$$

with $w_{y_i} = 1$ when no class weights are supplied.

Part 3 - Hints and Helper

Subclass `torch.nn.Module`, use stable `log_softmax`, gather target entries, apply optional registered weights, and support explicit reduction modes. Compare values and gradients with PyTorch.

Part 4 - Python code skeleton

```
import torch

class CustomCrossEntropy(torch.nn.Module):
    def __init__(self, reduction="mean", class_weights=None):
        super().__init__()
        self.reduction = ...
        self.register_buffer("class_weights", ...)

    def forward(self, logits, targets):
        log_probabilities = ...
        selected = ...
        sample_losses = ...
        if ...:
            return ...
        ...

def E09(logits, targets):
    criterion = CustomCrossEntropy(...)
    return criterion(...)

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.5 LFTL03 - Building Training Loop Manually

Mathematics and Theory

5.5.1 Exercise 00 - Single-Step Training Loop

Part 1 - Why this matters

A single training step contains the complete learning cycle for one batch. It transforms inputs into predictions, measures error, computes gradients, and changes parameters once.

Studying one step makes the order and state transitions visible before repetition is introduced. Every multi-epoch training system is built from this same unit.

Part 2 - Mathematical form

For model f_θ, batch $(\mathbf{X}, \mathbf{y})$, and learning rate η:

$$\widehat{\mathbf{y}} = f_\theta(\mathbf{X}), \quad L = \ell(\widehat{\mathbf{y}}, \mathbf{y}),$$

$$g = \nabla_\theta L, \quad \theta' = \theta - \eta g.$$

Part 3 - Hints and Helper

Use one batch and return predictions, loss, pre-update gradients, and updated parameters. Ensure the update occurs outside gradient tracking and do not reuse stale gradients.

Part 4 - Python code skeleton

```
import torch

def E00(model, X, targets, loss_function, learning_rate):
    predictions = ...
    loss = ...
    ...
    loss.backward()
    gradients = ...
    with torch.no_grad():
        ...
    return predictions, loss, gradients

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.5.2 Exercise 01 - Forward + Loss + Backward Loop

Part 1 - Why this matters

The forward, loss, and backward stages create the information required for learning before any parameter update occurs. Separating them allows each stage to be verified independently.

A valid backward pass needs a scalar loss connected to trainable parameters. Shape, dtype, and graph mistakes should be found before optimization is added.

Part 2 - Mathematical form

At iteration t:

$$\widehat{\mathbf{y}}_t = f_{\theta_t}(\mathbf{X}), \qquad L_t = \ell(\widehat{\mathbf{y}}_t, \mathbf{y}),$$

$$\nabla_{\theta_t} L_t$$

is computed while θ_t remains unchanged.

Part 3 - Hints and Helper

Loop for several iterations but omit parameter updates intentionally. Clear gradients, run forward, compute scalar loss, call backward, and record detached loss and gradient norms.

Part 4 - Python code skeleton

```
import torch

def E01(model, X, targets, loss_function, steps):
    history = []
    for step in range(steps):
        model.zero_grad(...)
        predictions = ...
        loss = ...
        loss.backward()
        history.append(...)
    return history

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.5.3 Exercise 02 - Parameter Update Integration

Part 1 - Why this matters

A training loop learns only when computed gradients are applied to parameters. The update must use current gradients and must not become part of the next computational graph.

Integrating updates reveals the boundary between differentiation and optimization. Parameter identity should be preserved while values change under no-gradient mode.

Part 2 - Mathematical form

For each parameter $\theta^{(i)}$:

$$\theta_{t+1}^{(i)} = \theta_t^{(i)} - \eta \nabla_{\theta^{(i)}} L_t.$$

The displacement must satisfy:

$$\Delta\theta^{(i)} = -\eta\, \theta^{(i)}.grad.$$

Part 3 - Hints and Helper

Clone parameter values before updating, apply updates under `torch.no_grad()`, and compare actual displacement with the expected rule. Skip or diagnose `None` gradients.

Part 4 - Python code skeleton

```
import torch

def E02(model, learning_rate):
    before = ...
    with torch.no_grad():
        for parameter in model.parameters():
            if parameter.grad is not None:
                parameter ...
    after = ...
    return before, after

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.5.4 Exercise 03 - Gradient Zeroing Placement

Part 1 - Why this matters

PyTorch accumulates parameter gradients, so a training loop must clear them once per intended update. Zeroing too late uses stale gradients; zeroing after backward but before step erases the gradients needed for the update.

Clearing before the forward pass or immediately after the completed update can both work when used consistently. The exercise focuses on preserving one batch's gradient for one update.

Part 2 - Mathematical form

Without clearing:

$$g_{stored,t} = g_{stored,t-1} + g_t.$$

For ordinary independent steps, the desired state is:

$$g_{stored,t} = g_t.$$

Part 3 - Hints and Helper

Implement two short loops with correct and incorrect placement. Record gradients before every update and identify accumulation or accidental erasure.

Part 4 - Python code skeleton

```
import torch

def E03(model, batches, loss_function):
    records = []
    for X, targets in batches:
        ...
        predictions = ...
```

```
        loss = ...
        loss.backward()
        records.append(...)
        ...
    return records

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.5.5 Exercise 04 - Training Loop without Optimizer

Part 1 - Why this matters

A manual training loop applies gradient descent directly instead of using `torch.optim`. It exposes gradient clearing, update magnitude, and parameter state in every iteration.

This implementation provides a reference for understanding optimizer classes. It also ensures the reader can separate Autograd's derivative calculation from the chosen update rule.

Part 2 - Mathematical form

At each step:

$$L_t = \ell(f_{\theta_t}(X), y), \quad g_t = \nabla_\theta L_t,$$
$$\theta_{t+1} = \theta_t - \eta g_t.$$

Part 3 - Hints and Helper

Clear gradients, compute the current loss, call backward, update every parameter under no-gradient mode, and log detached values. Do not replace parameters with new tensor objects.

Part 4 - Python code skeleton

```
import torch

def E04(model, X, targets, loss_function,
        learning_rate, steps):
    history = []
    for step in range(steps):
        ...
        with torch.no_grad():
            for parameter in model.parameters():
                parameter ...
        history.append(...)
    return model, history

def main():
    print(E04(...))
```

```
if __name__ == "__main__":
    main()
```

5.5.6 Exercise 05 - Loss Logging per Iteration

Part 1 - Why this matters

Loss history is the primary trace of training behavior. Correct logging records numerical snapshots without retaining the graph from every iteration.

A useful entry also includes iteration, learning rate, and selected diagnostics. Logging live tensors can cause unnecessary memory retention and misleading later values.

Part 2 - Mathematical form

For T iterations, define:

$$\mathcal{H} = \{(t, L_t)\}_{t=0}^{T-1}.$$

An improvement value may be:

$$\Delta_t = L_{t-1} - L_t.$$

Part 3 - Hints and Helper

Store `loss.detach().item()` rather than the loss tensor. Add step and optional gradient norm, then summarize best loss, best step, and number of increases.

Part 4 - Python code skeleton

```
import torch

def E05(training_step, steps):
    history = []
    for step in range(steps):
        loss, gradient_norm = training_step(...)
        history.append({
            "step": step,
            "loss": ...,
            "gradient_norm": ...
        })
    summary = ...
    return history, summary

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.5.7 Exercise 06 - Training Loop Bug Debugging

Part 1 - Why this matters

Training loops can fail through missing updates, missing backward calls, stale gradients, detached losses, wrong modes, or incorrect operation order. Several bugs can produce a flat loss, so symptoms alone are insufficient.

Debugging should inspect each stage and verify that parameters actually change. A minimal deterministic batch makes the first broken invariant easier to locate.

Part 2 - Mathematical form

A valid step must satisfy:

$$L \to \nabla_\theta L \to \Delta\theta.$$

For a trainable parameter, check:

$$\theta.grad \neq \text{None}, \qquad \theta_{after} - \theta_{before} = -\eta\theta.grad$$

for manual gradient descent.

Part 3 - Hints and Helper

Instrument forward shape, loss scalarity, graph metadata, gradients, and parameter displacement. Identify the first failed check and repair only that operation.

Part 4 - Python code skeleton

```
import torch

def E06(model, X, targets, loss_function, learning_rate):
    report = {}
    before = ...
    predictions = ...
    report["forward"] = ...
    loss = ...
    report["loss"] = ...
    ...
    report["gradients"] = ...
    report["updates"] = ...
    report["diagnosis"] = ...
    return report

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.5.8 Exercise 07 - Manual vs Optimizer Loop Comparison

Part 1 - Why this matters

A manual update loop and a library optimizer should match when they implement the same rule with identical initial parameters, data, reduction, learning rate, and gradient clearing.

The comparison validates manual logic and clarifies which responsibilities the optimizer automates. Stateful optimizers require additional state matching, so basic SGD is the cleanest reference.

Part 2 - Mathematical form

For SGD without momentum:

$$\theta_{t+1} = \theta_t - \eta \nabla_\theta L_t.$$

Both loops should generate equal parameter sequences up to floating-point tolerance when every condition is identical.

Part 3 - Hints and Helper

Clone one initial model into two copies. Use a manual update for one and `torch.optim.SGD` for the other, then compare loss and parameters after every step.

Part 4 - Python code skeleton

```
import torch

def E07(model_manual, model_optimizer, batches,
        loss_function, learning_rate):
    optimizer = torch.optim...
    comparisons = []
    for X, targets in batches:
        ...
        comparisons.append(...)
    return comparisons

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.5.9 Exercise 08 - Gradient Explosion inside Loop

Part 1 - Why this matters

A loop can become unstable when gradients or update magnitudes grow rapidly. Detecting this before the optimizer step can prevent non-finite parameters from contaminating later iterations.

Clipping can limit immediate damage but should be accompanied by diagnostics for learning rate, loss scaling, initialization, and data. The loop must record pre-clipping evidence.

Part 2 - Mathematical form

For global gradient norm:

$$G_t = \sqrt{\sum_p \|p.grad\|_2^2}.$$

Norm clipping at c uses:

$$\widetilde{g} = g \min\left(1, \frac{c}{G_t + \varepsilon}\right).$$

Part 3 - Hints and Helper

After backward, compute finiteness and global norm before any update. Stop or clip according to defined rules, record pre- and post-clipping values, and never update with non-finite gradients.

Part 4 - Python code skeleton

```
import torch

def E08(model, X, targets, loss_function,
        learning_rate, max_norm, steps):
    history = []
    for step in range(steps):
        ...
        loss.backward()
        before_norm = ...
        finite = ...
        if not finite:
            break
        torch.nn.utils...
        ...
        history.append(...)
    return history

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.5.10 Exercise 09 - End-to-End Manual Training Loop

Part 1 - Why this matters

The final challenge combines data input, forward computation, loss, gradient management, manual parameter updates, logging, stability checks, and stopping logic in one reproducible loop.

A completed loop should return evidence, not only a trained model. Its history and stopping reason must explain whether training converged, diverged, or exhausted the budget.

Part 2 - Mathematical form

For batches indexed by t:

$$\widehat{y}_t = f_{\theta_t}(X_t), \quad L_t = \ell(\widehat{y}_t, y_t),$$

$$g_t = \nabla_\theta L_t, \quad \theta_{t+1} = \theta_t - \eta g_t.$$

All diagnostics must be detached before storage.

Part 3 - Hints and Helper

Implement without `torch.optim`. Include gradient clearing, scalar loss validation, finite checks, optional clipping, parameter updates, loss logging, and a defined stopping criterion.

Part 4 - Python code skeleton

```
import torch

def E09(model, batches, loss_function, learning_rate,
        max_steps, tolerance, max_grad_norm=None):
    history = []
    status = ...
    for step, (X, targets) in enumerate(batches):
        if step >= max_steps:
            break
        ...
        history.append(...)
        if ...:
            status = ...
            break
    return model, history, status

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.6 LFTL04 - Batching + Epochs

Mathematics and Theory

5.6.1 Exercise 00 - Single-Batch Training

Part 1 - Why this matters

Single-batch training applies one complete update using a selected subset of the dataset. It provides the simplest bridge between an abstract training step and data organized into batches.

The batch dimension must align between inputs and targets. Loss reduction determines whether the update scale depends on the number of samples.

Part 2 - Mathematical form

For batch $\mathcal{B}$ of size B:

$$L_{\mathcal{B}}(\theta) = \frac{1}{B} \sum_{i \in \mathcal{B}} \ell(f_\theta(x_i), y_i).$$

One update uses $\theta' = \theta - \eta \nabla_\theta L_{\mathcal{B}}$.

Part 3 - Hints and Helper

Validate matching batch dimensions, run one forward-loss-backward-update cycle, and return batch size, detached loss, gradient norms, and parameter displacement.

Part 4 - Python code skeleton

```
import torch

def E00(model, X_batch, target_batch,
        loss_function, optimizer):
    optimizer.zero_grad(...)
    predictions = ...
    loss = ...
    loss.backward()
    diagnostics = ...
    optimizer.step()
    return loss, diagnostics

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.6.2 Exercise 01 - Mini-Batch Training Setup

Part 1 - Why this matters

Mini-batching divides a dataset into manageable subsets that produce stochastic gradient estimates. It balances memory use, computational efficiency, and gradient variability.

A correct setup preserves input-target correspondence and defines whether data are shuffled, whether the final batch is kept, and how batch size affects reduction.

Part 2 - Mathematical form

For N samples and batch size B, the number of batches when keeping the remainder is:

$$K = \left\lceil \frac{N}{B} \right\rceil .$$

Batch k contains aligned pairs (X_i, y_i) from the same selected indices.

Part 3 - Hints and Helper

Use `TensorDataset` and `DataLoader` or implement index slicing manually. Inspect every batch shape and verify that all sample indices appear exactly once when shuffling is disabled.

Part 4 - Python code skeleton

```
import torch

def E01(features, targets, batch_size):
    dataset = torch.utils.data...
    loader = torch.utils.data...
    batch_shapes = []
    for X_batch, target_batch in loader:
        batch_shapes.append(...)
    return loader, batch_shapes

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.6.3 Exercise 02 - Epoch Loop Construction

Part 1 - Why this matters

An epoch is one complete pass through the training dataset. The epoch loop nests a batch-training loop and aggregates batch statistics into an epoch-level summary.

A simple average of batch means is biased when the final batch is smaller. Correct epoch loss weights each batch mean by its sample count.

Part 2 - Mathematical form

If batch k has size B_k and mean loss L_k, the epoch mean is:

$$L_{epoch} = \frac{\sum_{k=1}^{K} B_k L_k}{\sum_{k=1}^{K} B_k}.$$

Part 3 - Hints and Helper

Nest the DataLoader loop inside an epoch loop. Accumulate `loss.item() * batch_size` and the total sample count, then divide after the epoch.

Part 4 - Python code skeleton

```
import torch

def E02(model, loader, loss_function, optimizer, epochs):
    epoch_history = []
    for epoch in range(epochs):
        total_loss = ...
        sample_count = ...
        for X_batch, targets in loader:
            ...
        epoch_loss = ...
        epoch_history.append(...)
    return epoch_history

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.6.4 Exercise 03 - Shuffling Data per Epoch

Part 1 - Why this matters

Shuffling changes sample order so batches do not repeatedly contain the same neighboring examples. This reduces order-related bias and changes the stochastic gradient sequence across epochs.

Features and targets must be shuffled with the same permutation. Reproducible experiments should control the random generator while still producing a new order each epoch.

Part 2 - Mathematical form

For epoch e, let π_e be a permutation of:

$$\{0, 1, \ldots, N-1\}.$$

The shuffled dataset uses aligned pairs:

$$(X_{\pi_e(i)}, y_{\pi_e(i)}).$$

Part 3 - Hints and Helper

Use a DataLoader with shuffling and a seeded generator, or apply one shared `randperm`. Record sample identifiers to verify complete coverage, alignment, and changed order across epochs.

Part 4 - Python code skeleton

```
import torch

def E03(features, targets, epochs, seed):
```

```
    generator = torch.Generator().manual_seed(...)
    orders = []
    for epoch in range(epochs):
        permutation = torch...
        shuffled_features = ...
        shuffled_targets = ...
        orders.append(permutation...)
    return orders

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.6.5 Exercise 04 - Batch Size Effect Observation

Part 1 - Why this matters

Batch size changes gradient noise, number of updates per epoch, memory consumption, and throughput. Smaller batches provide more frequent noisy updates, while larger batches provide smoother estimates.

A fair experiment keeps dataset, model initialization, optimizer, epoch count, and loss reduction fixed. Equal epochs do not imply equal numbers of updates across batch sizes.

Part 2 - Mathematical form

For batch gradient:

$$g_{\mathcal{B}} = \frac{1}{|\mathcal{B}|} \sum_{i \in \mathcal{B}} \nabla_\theta \ell_i.$$

As batch size grows, its variance often decreases, while updates per epoch approximately decrease as N/B.

Part 3 - Hints and Helper

Train cloned models with several batch sizes and multiple seeds. Record updates, gradient variance, loss, memory, and elapsed time rather than only final loss.

Part 4 - Python code skeleton

```
import torch

def E04(model_factory, dataset, batch_sizes,
        train_function, seeds):
    results = {}
    for batch_size in batch_sizes:
        trials = []
        for seed in seeds:
            trials.append(train_function(...))
```

```
        results[batch_size] = ...
    return results

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.6.6 Exercise 05 - Gradient Accumulation across Batches

Part 1 - Why this matters

Gradient accumulation combines several micro-batch gradients before one optimizer update, approximating a larger effective batch when memory is limited.

Loss scaling must preserve the intended mean gradient. Optimizer stepping and gradient clearing occur once per accumulation window, including a possibly incomplete final window.

Part 2 - Mathematical form

For K equal micro-batches and mean losses L_k:

$$g = \frac{1}{K} \sum_{k=1}^{K} \nabla_\theta L_k.$$

This can be obtained by backpropagating L_k/K before one update.

Part 3 - Hints and Helper

Divide each micro-batch loss by the accumulation count, call backward repeatedly, and step only at the boundary. Handle the final shorter window with a documented scaling strategy.

Part 4 - Python code skeleton

```
import torch

def E05(model, loader, loss_function,
        optimizer, accumulation_steps):
    optimizer.zero_grad(...)
    records = []
    for batch_index, (X_batch, targets) in enumerate(loader):
        loss = ...
        scaled_loss = ...
        scaled_loss.backward()
        if ...:
            optimizer.step()
            optimizer.zero_grad(...)
        records.append(...)
    return records
```

```
def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.6.7 Exercise 06 - Last Incomplete Batch Handling

Part 1 - Why this matters

When dataset size is not divisible by batch size, the final batch contains fewer samples. Keeping it uses all data, while dropping it creates equal shapes but omits samples each epoch.

Loss aggregation and gradient accumulation must account for the smaller count. Code that assumes every batch has the configured size can fail or misreport epoch metrics.

Part 2 - Mathematical form

For $N = qB + r$ with $0 < r < B$:

$$K = q + 1$$

when the final batch is kept, and its size is r. With `drop_last=True`, only qB samples are processed.

Part 3 - Hints and Helper

Choose a dataset with a nonzero remainder and compare both policies. Record batch sizes, processed sample count, epoch loss weighting, and any model constraints that require fixed size.

Part 4 - Python code skeleton

```
import torch

def E06(features, targets, batch_size, drop_last):
    loader = torch.utils.data...
    batch_sizes = []
    processed = ...
    for X_batch, target_batch in loader:
        batch_sizes.append(...)
        processed += ...
    return batch_sizes, processed

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.6.8 Exercise 07 - Performance vs Batch Size

Part 1 - Why this matters

Batch size affects hardware utilization, memory allocation, data-loading overhead, and the number of optimizer steps. Throughput may improve up to a point and then plateau or exceed memory.

Performance measurement must separate warm-up, data loading, forward/backward time, and synchronization. Training speed should be considered together with optimization quality.

Part 2 - Mathematical form

Sample throughput is:

$$R = \frac{\text{processed samples}}{\text{elapsed time}}.$$

Memory and time per optimizer step can also be recorded, while convergence efficiency considers samples or time required to reach a target metric.

Part 3 - Hints and Helper

Benchmark several batch sizes after warm-up, synchronize CUDA when applicable, and report throughput, peak memory, step time, and loss progress under equal conditions.

Part 4 - Python code skeleton

```
import torch

def E07(model_factory, dataset, batch_sizes, device):
    results = {}
    for batch_size in batch_sizes:
        model = model_factory(...).to(device)
        warmup = ...
        elapsed = ...
        peak_memory = ...
        results[batch_size] = ...
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.6.9 Exercise 08 - Batch-related Bug Debugging

Part 1 - Why this matters

Batch bugs include mismatched feature-target indices, incorrect class axes, fixed-size assumptions, wrong epoch averaging, lost samples, unintended accumulation, and device mismatches.

Many errors occur only on the final batch or after the first update. Diagnostics should include batch index, actual size, shapes, devices, and processed sample identifiers.

Part 2 - Mathematical form

Useful invariants are:

$$X.shape[0] = y.shape[0],$$

$$\sum_k B_k = N$$

when no samples are dropped, and:

$$L_{epoch} = \frac{\sum_k B_k L_k}{\sum_k B_k}.$$

Part 3 - Hints and Helper

Create one faulty loader or loop and inspect every batch, including the remainder. Find the first violated invariant and correct its direct cause rather than forcing a reshape.

Part 4 - Python code skeleton

```
import torch

def E08(loader, expected_sample_count):
    report = []
    processed = ...
    for batch_index, (X_batch, targets) in enumerate(loader):
        checks = ...
        report.append(checks)
        processed += ...
    diagnosis = ...
    return report, processed, diagnosis

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.6.10 Exercise 09 - Full Epoch Training Challenge

Part 1 - Why this matters

The final challenge combines shuffled mini-batches, repeated epochs, correct gradient handling, sample-weighted loss aggregation, final-batch support, and reproducible logging.

A complete pipeline must explain how many samples and updates occurred in each epoch. It should stop safely on non-finite values and return model and training evidence.

Part 2 - Mathematical form

For epochs $e = 1, \ldots, E$:

$$L_e = \frac{\sum_k B_{e,k} L_{e,k}}{\sum_k B_{e,k}}.$$

Each ordinary mini-batch performs:

$$\theta \leftarrow \theta - \eta \nabla_\theta L_{e,k}.$$

Part 3 - Hints and Helper

Use a shuffled DataLoader, call zero-grad, forward, loss, backward, and step for each batch, aggregate epoch loss by sample count, and log update counts and stopping reason.

Part 4 - Python code skeleton

```
import torch

def E09(model, loader, loss_function, optimizer, epochs):
    history = []
    status = ...
    for epoch in range(epochs):
        total_loss = ...
        sample_count = ...
        update_count = ...
        for X_batch, targets in loader:
            ...
        history.append(...)
        if ...:
            break
    return model, history, status

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.7 LFTL05 - Evaluation & Validation Split

Mathematics and Theory

5.7.1 Exercise 00 - Train vs Eval Mode Difference

Part 1 - Why this matters

PyTorch modules can behave differently during training and evaluation. Dropout changes from random masking to deterministic scaling behavior, while batch normalization switches from batch statistics to stored running statistics.

Mode selection is separate from gradient tracking. Calling `eval()` does not disable Autograd, and entering a no-gradient context does not switch the module out of training mode.

Part 2 - Mathematical form

For a model f_θ:

$$\widehat{y}_{train} = f_\theta^{train}(x), \qquad \widehat{y}_{eval} = f_\theta^{eval}(x).$$

The functions may differ for stateful or stochastic layers even though parameters are unchanged.

Part 3 - Hints and Helper

Use a small model containing dropout or batch normalization. Compare repeated outputs in both modes, inspect the `training` flag, and separately test gradient recording.

Part 4 - Python code skeleton

```
import torch

def E00(model, X):
    model.train()
    training_outputs = ...
    model.eval()
    evaluation_outputs = ...
    return training_outputs, evaluation_outputs

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.7.2 Exercise 01 - Validation Dataset Separation

Part 1 - Why this matters

A validation set estimates behavior on data not used for parameter updates. It supports hyperparameter tuning, early stopping, and model selection without directly optimizing on evaluation examples.

Separation must occur before data-dependent preprocessing is fitted. Duplicate entities, future information, or related records crossing the boundary can create leakage and overly optimistic results.

Part 2 - Mathematical form

For dataset $\mathcal{D}$:

$$\mathcal{D}_{train} \cap \mathcal{D}_{val} = \varnothing,$$

and:

$$|\mathcal{D}_{train}| + |\mathcal{D}_{val}| = |\mathcal{D}|.$$

Additional grouping or temporal constraints may be required by the task.

Part 3 - Hints and Helper

Create reproducible split indices with a seeded generator. Verify disjointness, complete coverage, class or group requirements, and fit preprocessing only on the training subset.

Part 4 - Python code skeleton

```
import torch

def E01(features, targets, validation_fraction, seed):
    permutation = torch...
    split_point = ...
    train_indices = ...
    validation_indices = ...
    checks = ...
    return train_indices, validation_indices, checks

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.7.3 Exercise 02 - Validation Loss Computation

Part 1 - Why this matters

Validation loss measures the training objective on held-out data without changing parameters. It must use evaluation mode, disabled gradient recording, and the same loss definition used for comparison.

Epoch validation loss should be weighted by actual batch sizes. Averaging batch means equally biases the result when the final batch is smaller.

Part 2 - Mathematical form

For validation batches with size B_k and mean loss L_k:

$$L_{val} = \frac{\sum_k B_k L_k}{\sum_k B_k}.$$

No optimizer update is performed during this computation.

Part 3 - Hints and Helper

Switch to `eval()`, enter `torch.inference_mode()` or `no_grad()`, accumulate loss times batch size, and restore training mode when appropriate.

Part 4 - Python code skeleton

```
import torch

def E02(model, validation_loader, loss_function):
    model.eval()
    total_loss = ...
    sample_count = ...
    with torch.inference_mode():
        for X_batch, targets in validation_loader:
            predictions = ...
            loss = ...
            total_loss += ...
            sample_count += ...
    return total_loss / sample_count

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.7.4 Exercise 03 - Overfitting Detection

Part 1 - Why this matters

Overfitting occurs when training performance continues improving while validation performance stops improving or becomes worse. The model is fitting training-specific patterns that do not generalize.

Detection requires aligned histories over several epochs. A temporary noisy validation increase is not enough; a persistent generalization gap provides stronger evidence.

Part 2 - Mathematical form

Define the generalization gap:

$$G_e = L_{val,e} - L_{train,e}.$$

A common pattern is decreasing $L_{train,e}$ with increasing or stagnant $L_{val,e}$ and a widening positive G_e.

Part 3 - Hints and Helper

Compare smoothed or patience-based trends over a window. Return the suspected start epoch, gap history, and supporting trend statistics rather than only a Boolean.

Part 4 - Python code skeleton

```
import torch

def E03(training_losses, validation_losses, window, tolerance):
    gaps = ...
```

```
    training_trend = ...
    validation_trend = ...
    overfitting_start = ...
    return gaps, overfitting_start

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.7.5 Exercise 04 - Early Stopping Trigger

Part 1 - Why this matters

Early stopping ends training after validation performance fails to improve for a defined period. It limits wasted computation and can prevent continued movement away from the best generalizing state.

The trigger must preserve the best model, not merely stop at the current model. Minimum improvement and patience prevent small fluctuations from resetting the counter indefinitely.

Part 2 - Mathematical form

For validation loss V_e, improvement occurs when:

$$V_e < V_{best} - \delta.$$

Otherwise wait increases, and stopping is triggered when:

$$wait \geq patience.$$

Part 3 - Hints and Helper

Maintain best loss, best epoch, wait counter, and a deep copy of the best state dictionary. Test the trigger using a predefined validation sequence before integrating it into training.

Part 4 - Python code skeleton

```
import torch

def E04(model, validation_loss, state,
        min_improvement, patience):
    improved = ...
    if improved:
        state["best_loss"] = ...
        state["best_weights"] = ...
        state["wait"] = ...
    else:
        state["wait"] += ...
    stop = ...
```

```
    return stop, state

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.7.6 Exercise 05 - Metric vs Loss Comparison

Part 1 - Why this matters

Loss is a differentiable optimization objective, while a metric communicates task performance. They may respond differently because a metric can be discrete, thresholded, or aligned with a different practical priority.

A lower loss can improve confidence without changing accuracy, while accuracy can hide class imbalance. Training should optimize a suitable loss and report metrics chosen for the task.

Part 2 - Mathematical form

For classification accuracy:

$$A = \frac{1}{N} \sum_{i} \mathbf{1}[\arg\max_{c} z_{ic} = y_i].$$

Cross-entropy instead measures target log-probability and can change even when every predicted class remains the same.

Part 3 - Hints and Helper

Construct logits whose correct classes do not change while confidence changes. Compare cross-entropy and accuracy, then add a class-sensitive metric for imbalanced data.

Part 4 - Python code skeleton

```
import torch

def E05(logits_versions, targets):
    records = []
    for logits in logits_versions:
        loss = ...
        predictions = ...
        accuracy = ...
        records.append(...)
    return records

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.7.7 Exercise 06 - Evaluation without Gradient Tracking

Part 1 - Why this matters

Evaluation requires forward values and metrics but not backward graphs. Disabling gradient tracking reduces memory use and overhead while ensuring validation code cannot accidentally perform backpropagation.

No-gradient execution remains distinct from evaluation mode. Both should normally be used together, with gradient tracking restored automatically after leaving the context.

Part 2 - Mathematical form

During evaluation:

$$\widehat{y} = f_\theta(x)$$

is computed, but no derivative graph for $\nabla_\theta L$ is retained. Model parameters remain unchanged:

$$\theta_{after} = \theta_{before}.$$

Part 3 - Hints and Helper

Clone parameters, run evaluation under `torch.inference_mode()`, inspect output metadata, and verify parameter equality afterward. Confirm normal gradient tracking resumes outside the context.

Part 4 - Python code skeleton

```
import torch

def E06(model, loader):
    model.eval()
    before = ...
    outputs = []
    with torch.inference_mode():
        for X_batch, _ in loader:
            outputs.append(model(...))
    after = ...
    checks = ...
    return outputs, checks

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.7.8 Exercise 07 - Validation Loop Bug Debugging

Part 1 - Why this matters

Validation loops fail through training mode, enabled gradients, parameter updates, shuffled target misalignment, wrong loss aggregation, data leakage, or failure to evaluate all samples.

These errors may not raise exceptions and can produce believable metrics. A diagnostic loop should verify state, sample counts, parameter immutability, and reduction logic.

Part 2 - Mathematical form

Required invariants include:

$$\theta_{after} = \theta_{before}, \quad N_{processed} = N_{validation},$$

and:

$$L_{val} = \frac{\sum_k B_k L_k}{\sum_k B_k}.$$

Part 3 - Hints and Helper

Instrument mode, gradient-enabled state, input-target shapes, processed sample count, batch losses, and parameter checksums. Identify the first violated invariant.

Part 4 - Python code skeleton

```
import torch

def E07(model, validation_loader, loss_function):
    report = {}
    before = ...
    report["mode"] = ...
    report["gradient_enabled"] = ...
    ...
    after = ...
    report["parameters_unchanged"] = ...
    report["diagnosis"] = ...
    return report

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.7.9 Exercise 08 - Model Selection based on Validation

Part 1 - Why this matters

Model selection chooses the checkpoint that performs best on validation evidence rather than the final training state. This separates optimization progress from generalization quality.

Repeatedly choosing from validation results can itself overfit the validation set. A final test set should remain untouched until the selection and tuning process is complete.

Part 2 - Mathematical form

For checkpoints $\theta_1, \ldots, \theta_E$ and minimized validation metric V:

$$e^* = \arg\min_e V(\theta_e), \qquad \theta^* = \theta_{e^*}.$$

Ties require a documented rule such as earliest epoch or secondary metric.

Part 3 - Hints and Helper

Store detached validation records and cloned checkpoint states. Select according to a declared metric direction and restore the corresponding state without inspecting test data.

Part 4 - Python code skeleton

```
import torch

def E08(checkpoints, validation_records,
        metric_name, minimize=True):
    scores = ...
    best_index = ...
    best_checkpoint = ...
    return best_index, best_checkpoint

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.7.10 Exercise 09 - Full Train–Validation Pipeline

Part 1 - Why this matters

A full pipeline alternates parameter-updating training epochs with parameter-preserving validation epochs. It records both histories, manages modes and gradient contexts, selects checkpoints, and supports early stopping.

The final result must restore the best validation model and preserve reproducibility. Training and validation sample accounting should remain separate and explicit.

Part 2 - Mathematical form

For epoch e:

$$\theta_e = \text{TrainEpoch}(\theta_{e-1}, \mathcal{D}_{train}),$$
$$V_e = \text{Evaluate}(\theta_e, \mathcal{D}_{val}).$$

The selected model is θ_{e^*} where e^* optimizes the validation criterion.

Part 3 - Hints and Helper

Implement train and validation phases with correct modes, contexts, sample-weighted losses, and no validation updates. Save the best state and return histories, stopping reason, and selected epoch.

Part 4 - Python code skeleton

```
import torch

def E09(model, train_loader, validation_loader,
        loss_function, optimizer, epochs, early_stopping):
    history = []
    best_state = ...
    status = ...
    for epoch in range(epochs):
        model.train()
        train_result = ...
        model.eval()
        with torch.inference_mode():
            validation_result = ...
        ...
        history.append(...)
        if ...:
            break
    model.load_state_dict(...)
    return model, history, status

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

5.8 LFTL06 - Overfitting Prevention Methods

Mathematics and Theory

5.8.1 Exercise 00 - Detecting Overfitting Pattern

Part 1 - Why this matters

Overfitting occurs when a model reduces error on its training samples without improving its behavior on unseen data. A falling training loss is therefore not sufficient evidence of progress; it must be interpreted together with validation loss across multiple epochs.

A reliable detector looks for a persistent generalization gap rather than reacting to one noisy measurement. Recognizing this pattern early prevents wasted computation and provides evidence for choosing regularization, more data, a smaller model, or early stopping.

Part 2 - Mathematical form

Let the losses at epoch e be $L_{\text{train}}^{(e)}$ and $L_{\text{val}}^{(e)}$. Define

$$G^{(e)} = L_{\text{val}}^{(e)} - L_{\text{train}}^{(e)}.$$

An overfitting signal appears when training loss continues to decrease while validation loss or the persistent gap increases:

$$L_{\text{train}}^{(e)} < L_{\text{train}}^{(e-1)}, \qquad G^{(e)} > G^{(e-1)}.$$

Part 3 - Hints and Helper

Track both histories using the same reduction rule. Examine a window of epochs and require the pattern to persist; one validation fluctuation may only be noise.

Part 4 - Python code skeleton

```
import torch

def E00(train_losses, validation_losses, window):
    train_losses = torch...
    validation_losses = torch...
    gaps = ...
    recent_train_trend = ...
    recent_validation_trend = ...
    is_overfitting = ...
    return is_overfitting, gaps

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

5.8.2 Exercise 01 - Regularization Concept Experiment

Part 1 - Why this matters

Regularization changes the learning objective so that fitting observed samples is no longer the model's only goal. By penalizing unnecessary parameter complexity, it can discourage fragile solutions that memorize training-specific patterns.

A controlled experiment makes the tradeoff visible: weak regularization may leave the generalization gap unchanged, whereas excessive regularization can prevent the model from fitting useful structure. Comparing identical models and data isolates the effect of regularization strength.

Part 2 - Mathematical form

For parameters θ, define

$$J(\theta) = L_{\text{data}}(\theta) + \lambda\Omega(\theta),$$

where $\lambda \geq 0$ controls regularization. For L2 regularization,

$$\Omega(\theta) = \frac{1}{2}\|\theta\|_2^2.$$

Compare $\lambda = 0$ with positive values using both training and validation loss.

Part 3 - Hints and Helper

Keep initialization, split, optimizer, and epochs fixed across runs. Add the penalty to the training objective only, and record data loss and penalty separately.

Part 4 - Python code skeleton

```
import torch

def E01(model, prediction, target, strength):
    data_loss = torch...
    penalty = sum(... for parameter in model.parameters())
    objective = ...
    return objective, data_loss, penalty

def main():
    model = torch.nn...
    print(E01(...))

if __name__ == "__main__":
    main()
```

5.8.3 Exercise 02 - Weight Decay Integration

Part 1 - Why this matters

Weight decay shrinks parameters during optimization and can reduce reliance on excessively large weights. This often produces smoother, less sensitive models and is one of the most common regularization mechanisms in neural-network training.

Its placement matters because optimizers may treat weight decay as either an L2 term coupled to the gradient or a separate shrinkage step. Integrating it deliberately avoids accidental double regularization and makes comparisons meaningful.

Part 2 - Mathematical form

For basic gradient descent with learning rate η and decay λ,

$$\theta_{t+1} = (1 - \eta\lambda)\theta_t - \eta\nabla_\theta L(\theta_t).$$

For plain gradient descent this matches differentiating

$$J(\theta) = L(\theta) + \frac{\lambda}{2}\|\theta\|_2^2,$$

but the equivalence does not automatically extend to every adaptive optimizer.

Part 3 - Hints and Helper

Configure `weight_decay` once and inspect which parameter groups receive it. Biases and normalization parameters are often handled separately.

Part 4 - Python code skeleton

```
import torch

def E02(model, learning_rate, decay):
    decay_parameters = [...]
    no_decay_parameters = [...]
    optimizer = torch.optim...([
        {"params": decay_parameters, "weight_decay": ...},
        {"params": no_decay_parameters, "weight_decay": ...},
    ], lr=...)
    return optimizer

def main():
    model = torch.nn...
    print(E02(...))

if __name__ == "__main__":
    main()
```

5.8.4 Exercise 03 - Dropout Effect Observation

Part 1 - Why this matters

Dropout randomly removes a fraction of activations during training, preventing units from depending too strongly on particular neighboring features. The resulting stochastic subnetworks encourage representations that remain useful under different activation patterns.

The operation behaves differently during evaluation, so this exercise also tests correct model-mode control. Observing several dropout probabilities reveals when the method improves robustness and when it destroys too much information.

Part 2 - Mathematical form

For activation h_i and dropout probability p,

$$m_i \sim \text{Bernoulli}(1-p), \qquad \widetilde{h}_i = \frac{m_i}{1-p} h_i$$

during training. During evaluation, $\widetilde{h}_i = h_i$. Inverted scaling preserves $\mathbb{E}[\widetilde{h}_i] = h_i$.

Part 3 - Hints and Helper

Use `torch.nn.Dropout`. Compare repeated outputs in `model.train()` and `model.eval()` modes, and restore the previous mode if a helper changes it.

Part 4 - Python code skeleton

```
import torch

def E03(features, probability):
    layer = torch.nn.Dropout(p=...)
    layer.train()
```

```
    training_outputs = [layer(features) for _ in range(...)]
    layer.eval()
    evaluation_output = ...
    return training_outputs, evaluation_output

def main():
    features = torch...
    print(E03(...))

if __name__ == "__main__":
    main()
```

5.8.5 Exercise 04 - Data Augmentation Impact

Part 1 - Why this matters

Data augmentation expands the effective training distribution through transformations that preserve the intended target. It teaches the model that irrelevant changes should not alter the prediction.

Useful augmentation must reflect valid invariances of the problem. An unrealistic transformation can corrupt labels, while augmenting validation data makes evaluation unstable and hides true generalization behavior.

Part 2 - Mathematical form

Let $T \sim \mathcal{T}$ be a random label-preserving transformation. The augmented objective is

$$J(\theta) = \mathbb{E}_{(x,y)\sim\mathcal{D}_{\text{train}}} \mathbb{E}_{T\sim\mathcal{T}} \left[\ell(f_\theta(T(x)), y) \right].$$

Its effect is measured by comparing validation metrics for models trained with and without $\mathcal{T}$.

Part 3 - Hints and Helper

Apply transformations only in the training pipeline. Hold the split, initialization, optimizer, and budget constant; compare multiple runs when augmentation is stochastic.

Part 4 - Python code skeleton

```
import torch

def E04(batch, labels, augmentation):
    augmented_batch = augmentation(...)
    original_shape = batch.shape
    valid_shape = ...
    valid_labels = ...
    return augmented_batch, valid_shape, valid_labels

def main():
    batch = torch...
    labels = torch...
```

```
    augmentation = ...
    print(E04(...))

if __name__ == "__main__":
    main()
```

5.8.6 Exercise 05 - Early Stopping Implementation

Part 1 - Why this matters

Early stopping treats validation performance as evidence about when continued fitting stops improving generalization. It can reduce overfitting and training cost by ending optimization after the monitored metric has failed to improve for a defined period.

A correct implementation must preserve the best model, not merely the final model before termination. Patience and a minimum improvement threshold prevent small fluctuations from repeatedly resetting the stopping counter.

Part 2 - Mathematical form

For validation loss V_e, an improvement occurs when

$$V_e < V_{\text{best}} - \delta,$$

where $\delta \geq 0$ is the minimum change. Otherwise $c \leftarrow c + 1$. Training stops when $c \geq P$, where P is patience, and the best parameters are restored.

Part 3 - Hints and Helper

Store a deep copy of `state_dict()` whenever validation loss improves. Ensure the comparison direction matches the monitored metric.

Part 4 - Python code skeleton

```
import torch

def E05(validation_loss, model, state, patience, min_delta):
    improved = ...
    if improved:
        state["best_loss"] = ...
        state["best_model"] = ...
        state["counter"] = ...
    else:
        state["counter"] = ...
    should_stop = ...
    return should_stop, state

def main():
    state = {...}
    print(E05(...))

if __name__ == "__main__":
    main()
```

5.8.7 Exercise 06 - Bias–Variance Tradeoff Inspection

Part 1 - Why this matters

Prediction error can arise because a model is too restricted to represent the underlying relationship or because it changes too much when trained on different samples. These behaviors correspond to high bias and high variance, and they require different remedies.

Inspecting both components prevents blind changes to model capacity or regularization. Repeated training across resampled datasets reveals whether errors are systematic or caused by sensitivity to a particular training set.

Part 2 - Mathematical form

For squared error at input x,

$$\mathbb{E}_{\mathcal{D},\varepsilon}[(y - \widehat{f}_{\mathcal{D}}(x))^2] = \mathrm{Bias}(x)^2 + \mathrm{Var}(x) + \sigma_{\varepsilon}^2,$$

where

$$\mathrm{Bias}(x) = \mathbb{E}_{\mathcal{D}}[\widehat{f}_{\mathcal{D}}(x)] - f(x).$$

The terms can be estimated from models trained on multiple resampled datasets.

Part 3 - Hints and Helper

Stack predictions from independent runs along a run dimension. Estimate mean prediction, squared bias, and variance using a clearly stated variance convention.

Part 4 - Python code skeleton

```
import torch

def E06(run_predictions, reference):
    mean_prediction = torch...
    squared_bias = ...
    variance = torch...
    return squared_bias, variance

def main():
    run_predictions = torch...
    reference = torch...
    print(E06(...))

if __name__ == "__main__":
    main()
```

5.8.8 Exercise 07 - Underfitting vs Overfitting Diagnosis

Part 1 - Why this matters

Underfitting and overfitting can both produce poor validation results, but they represent opposite problems. Underfitting leaves substantial error on training data, whereas overfitting

fits training samples well but fails to transfer that performance.

Correct diagnosis determines the next intervention. Increasing capacity may help an underfit model but worsen an overfit one; stronger regularization may help overfitting but further restrict a model that already has high bias.

Part 2 - Mathematical form

Using final training loss L_T, validation loss L_V, and $G = L_V - L_T$,

$$\begin{cases} L_T \text{ high and } L_V \text{ high} & \text{underfitting,} \\ L_T \text{ low and } G \text{ large} & \text{overfitting,} \\ L_T \text{ low and } G \text{ small} & \text{balanced fit.} \end{cases}$$

The thresholds must be defined relative to the task or a baseline.

Part 3 - Hints and Helper

Accept explicit thresholds instead of embedding unexplained constants. Average several recent epochs and return the measured losses and gap with the diagnosis.

Part 4 - Python code skeleton

```
import torch

def E07(train_losses, validation_losses,
        loss_threshold, gap_threshold, window):
    train_level = torch...
    validation_level = torch...
    gap = ...
    if ...:
        diagnosis = ...
    elif ...:
        diagnosis = ...
    else:
        diagnosis = ...
    return diagnosis, train_level, validation_level, gap

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

5.8.9 Exercise 08 - Regularization Debugging Challenge

Part 1 - Why this matters

Regularization can appear ineffective because of implementation errors rather than a poor method. Common failures include dropout during validation, augmented validation samples, decay on the wrong parameters, or an L2 penalty combined accidentally with optimizer weight

decay.

Debugging should verify the entire data and optimization path, not only the coefficient. Mode changes, parameter groups, loss decomposition, and validation isolation provide evidence about where the intended behavior was lost.

Part 2 - Mathematical form

The intended training objective may be

$$J(\theta) = L_{\text{train}}(\theta) + \lambda\Omega(\theta),$$

while validation measures $V(\theta) = L_{\text{val}}(\theta)$ without training-only penalties or augmentation. A duplicated penalty produces

$$J_{\text{bug}}(\theta) = L_{\text{train}}(\theta) + 2\lambda\Omega(\theta).$$

Part 3 - Hints and Helper

Inspect optimizer groups, model mode, data transforms, and loss components. Detect duplicate parameters and confirm validation uses `model.eval()` with gradients disabled.

Part 4 - Python code skeleton

```
import torch

def E08(model, optimizer, train_transform, validation_transform):
    issues = []
    if model.training ...:
        issues.append(...)
    parameter_ids = [...]
    if ...:
        issues.append(...)
    if validation_transform ...:
        issues.append(...)
    return issues

def main():
    model = torch.nn...
    optimizer = torch.optim...
    print(E08(...))

if __name__ == "__main__":
    main()
```

5.8.10 Exercise 09 - Robust Training Pipeline Design

Part 1 - Why this matters

A robust training pipeline coordinates data separation, regularization, optimization, validation, checkpointing, and reproducibility as one system. Correct individual components can

still interact in ways that cause leakage, unstable metrics, or selection of the wrong model.

The final pipeline should produce evidence that reported performance belongs to unseen data. Training-only augmentation, correct model modes, best-state restoration, and an untouched test set protect that claim while making failures traceable.

Part 2 - Mathematical form

At epoch e, update only with training data:

$$\theta_e = \text{TrainEpoch}(\theta_{e-1}, \mathcal{D}_{\text{train}}).$$

Select the best epoch using validation performance:

$$e^* = \arg\min_e L_{\text{val}}(\theta_e; \mathcal{D}_{\text{val}}).$$

After design decisions are fixed, report

$$R_{\text{test}} = L_{\text{test}}(\theta_{e^*}; \mathcal{D}_{\text{test}}).$$

Part 3 - Hints and Helper

Separate train, validation, and test loaders. Use training augmentation only for training, log metrics, checkpoint the best state, support early stopping, and record seeds and configuration.

Part 4 - Python code skeleton

```
import torch

def E09(model, train_loader, validation_loader, loss_function,
        optimizer, epochs, early_stopper):
    history = []
    best_state = ...
    for epoch in range(epochs):
        model.train()
        train_result = ...
        model.eval()
        with torch.inference_mode():
            validation_result = ...
        history.append(...)
        improved, should_stop = ...
        if improved:
            best_state = ...
        if should_stop:
            break
    model.load_state_dict(...)
    return model, history

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

Book 6

SQL Lessons (PostgreSQL)

6.1 Introduction

6.1.1 What will this book teach you

Artificial intelligence systems do not operate on models alone. They also need a reliable place to store users, permissions, plans, limits, sessions, usage records, configuration values, and the results produced by applications. When this information has clear relationships and must remain consistent, a relational database becomes one of the most important components of the system. This book introduces PostgreSQL as the relational database that will support these responsibilities.

The purpose of this book is not to teach SQL as a collection of commands that must be memorized. You will learn how to think about structured data, how to decide which tables should exist, how those tables should be connected, and how PostgreSQL protects the correctness of the information stored inside them. Every query will represent a decision about the data. Before writing code, you should be able to explain what information you want, where it is stored, which rows are allowed to change, and how you will verify the result.

Python will be the primary programming language throughout the book. SQL statements will be executed from Python so that the database is always treated as part of an application rather than as an isolated tool. You will open connections, execute parameterized queries, retrieve results, handle errors, control transactions, and close resources correctly. Some exercises may show SQL directly to make the database operation clear, but the final implementation and verification will be performed through Python.

You must pay careful attention to safety. A missing condition in an `UPDATE` or `DELETE` statement can modify every row in a table. A poorly chosen data type can allow invalid values or waste storage. A missing constraint can create relationships that should never exist, while an incorrectly managed transaction can leave an application in a partially updated state. For this reason, the exercises require verification after important operations and encourage you to predict the result before executing the query.

This book follows the principle of learning through experimentation. You will create databases and tables, insert valid and invalid records, observe constraint failures, compare query results, test transaction rollback, examine locking behavior, and measure the effect of

indexes. Errors are an intentional part of the learning process. The objective is to understand what PostgreSQL is protecting, why an operation failed, and how the database behaves under different conditions.

The exercises will provide guidance and incomplete Python code skeletons, but they will not provide finished solutions. You are responsible for completing each connection, query, transaction, and validation step. Do not continue merely because a program runs without raising an exception. Inspect the returned rows, confirm the number of affected records, and verify the final database state. A successful command is not necessarily a correct result.

6.1.2 How PostgreSQL supports artificial intelligence systems

PostgreSQL does not train a neural network and does not replace PyTorch. Its role is to provide dependable structured storage around the model. An AI application may use PostgreSQL to store account information, subscription plans, request limits, authentication sessions, experiment metadata, model versions, job states, or usage history. These records require consistency, traceability, and relationships that should be enforced even when several parts of the application access the database simultaneously.

This distinction is important. Large binary files such as datasets and model weights may later be stored in object storage, flexible documents may be stored in a document database, and embeddings may be stored in a vector database. PostgreSQL is used when the information has a relational structure and the application needs strong rules governing that structure. Learning when to use it is as important as learning how to query it.

By the end of the book, you should be able to design a small relational system, connect to it securely from Python, perform safe create, read, update, and delete operations, enforce relationships and limits, use transactions to protect multi-step changes, and investigate query performance. These skills will become part of the data foundation upon which later artificial intelligence applications can be built.

6.1.3 How to approach the exercises

For every exercise, begin by identifying the expected database state before execution and the expected state afterward. Write down which table is affected, which rows should be returned or modified, and which condition prevents unintended changes. After running the Python program, verify these expectations with a separate query. This creates a disciplined cycle of prediction, execution, observation, and correction.

Use parameterized queries whenever values come from Python. Do not construct SQL statements by joining untrusted values into strings. Keep credentials outside the source code, preferably in environment variables, and never upload real passwords to a repository. Use context managers or explicit cleanup so connections and cursors are closed even when an operation fails. When an exercise uses a transaction, deliberately test both the successful path and the rollback path.

Do not rush through the early exercises. Later chapters assume that you understand data types, filtering, aggregation, keys, joins, and constraints. If a later transaction produces an

unexpected result, the true problem may be an incorrect relationship or query condition introduced earlier. The exercises are ordered so that each database behavior becomes a foundation for the next one.

6.1.4 The Chapters (SQL00–SQL03) included in this book

- SQL00 - Relational Data Fundamentals
- SQL01 - Tables, Keys & Schemas
- SQL02 - Users, Plans & Limits Storage
- SQL03 - Query Logic & Transactions

6.1.5 SQL00 - Relational Data Fundamentals

This chapter establishes the operational foundation of PostgreSQL. You will create a database, connect to it from Python, create tables with appropriate data types, insert rows, and verify stored information using `SELECT`. You will then filter, order, paginate, update, and delete records while learning how every condition changes the scope of an operation.

The chapter also introduces missing values, `NULL`, `COALESCE`, aggregate functions, grouping, and group-level filtering. These concepts transform individual rows into useful summaries. By the end of the chapter, you should be able to perform basic data operations safely and explain the difference between filtering rows before aggregation and filtering groups after aggregation.

6.1.6 SQL01 - Tables, Keys & Schemas

This chapter moves from operating on one table to designing a connected relational structure. You will model users, plans, and sessions; create primary keys and unique constraints; establish foreign-key relationships; and observe how different deletion behaviors protect or remove dependent records. Check constraints, default values, and timestamps will move validation closer to the data itself.

You will also normalize tables, create indexes, and combine information using inner and left joins. The goal is to understand that schema design determines which invalid states the database can prevent. By the end of the chapter, you should be able to justify table boundaries, relationships, constraints, and basic indexing decisions rather than creating them by habit.

6.1.7 SQL02 - Users, Plans & Limits Storage

This chapter applies relational design to a realistic application scenario. You will store subscription plans and their limits, assign users to plans, track token and request usage, calculate daily totals, and detect when a user exceeds an allowed limit. Views will be used to expose current limits and usage summaries through reusable queries.

The later exercises introduce transaction-based plan upgrades, audit records, and reports showing the users with the highest usage. This chapter connects database structure with application rules. It prepares you to represent operational policies in a way that can be queried, verified, and traced from Python.

6.1.8 SQL03 - Query Logic & Transactions

This chapter focuses on operations that must remain correct when several changes or users are involved. You will learn how `BEGIN`, `COMMIT`, and `ROLLBACK` define an atomic unit of work. Multi-table inserts, consistency checks, upserts, and transaction-safe usage deduction will demonstrate why related changes must either succeed together or fail together.

You will also simulate concurrent sessions, observe isolation and locking behavior, construct common table expressions, and inspect query execution using `EXPLAIN ANALYZE`. Finally, you will benchmark the effect of an index rather than assuming that every index improves performance. By the end of the chapter, you should be able to reason about correctness, concurrency, and performance as connected properties of a database operation.

6.2 SQL00 - Relational Data Fundamentals

Data Engineering for AI

6.2.1 Exercise 00 - Create Database + Connect Challenge

Part 1 - Why this matters

Every PostgreSQL application begins with a valid database and a dependable connection. The connection is the boundary through which Python sends SQL statements, receives results, and learns whether an operation succeeded or failed.

This first challenge establishes habits that will be used throughout the book: keep credentials outside the source code, connect to an existing maintenance database when creating a new database, verify the connection explicitly, and close resources even when an error occurs.

Part 2 - Technical concept and behavior

A PostgreSQL server can contain several databases. A client connects using parameters such as host, port, database name, user, and password. Because `CREATE DATABASE` cannot run inside a normal transaction block, the creation connection must use autocommit or an equivalent approach. After creation, open a separate connection to the new database and execute a small verification query.

Part 3 - Hints and Helper

Use `psycopg.connect()` and read configuration from environment variables. Connect first to a maintenance database such as `postgres`. Handle the case where the requested database already exists without hiding unrelated errors.

Part 4 - Python code skeleton

```
import os
import psycopg

def E00(database_name):
    admin_connection = psycopg.connect(
```

```
        host=os.getenv(...),
        port=os.getenv(...),
        dbname=...,
        user=os.getenv(...),
        password=os.getenv(...),
        autocommit=...,
    )
    with admin_connection.cursor() as cursor:
        cursor.execute(...)
    admin_connection.close()

    connection = psycopg.connect(...)
    with connection.cursor() as cursor:
        cursor.execute(...)
        verification = cursor.fetchone()
    connection.close()
    return verification

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

6.2.2 Exercise 01 - Create Table with Correct Data Types

Part 1 - Why this matters

A table definition determines which values PostgreSQL can store and how those values behave in later queries. Choosing a type only because it accepts the current example can create invalid states, inaccurate calculations, or unnecessary conversions as the application grows.

In this challenge, the reader translates a small data requirement into a schema. The goal is to distinguish identifiers, text, numeric values, Boolean states, and timestamps, then verify that PostgreSQL created the intended columns rather than assuming the statement was correct.

Part 2 - Technical concept and behavior

PostgreSQL validates inserted values according to each column's data type. Common choices include `INTEGER` or `BIGINT` for whole numbers, `TEXT` for variable-length text, `BOOLEAN` for logical states, `NUMERIC` for exact decimal quantities, and `TIMESTAMPTZ` for timestamps representing real instants. Table definitions may also specify nullability and default behavior.

Part 3 - Hints and Helper

Create a table representing a simple application entity. Use `CREATE TABLE IF NOT EXISTS`, then inspect `information_schema.columns` from Python to verify column names, types, and nullability.

Part 4 - Python code skeleton

```
import psycopg

def E01(connection):
    create_query = """
        CREATE TABLE IF NOT EXISTS ... (
            id ...,
            name ...,
            usage_amount ...,
            is_active ...,
            created_at ...
        )
    """
    with connection.cursor() as cursor:
        cursor.execute(...)
        cursor.execute("""
            SELECT column_name, data_type, is_nullable
            FROM information_schema.columns
            WHERE table_name = %s
            ORDER BY ordinal_position
        """, (...,))
        columns = cursor.fetchall()
    connection.commit()
    return columns

def main():
    connection = psycopg.connect(...)
    print(E01(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.3 Exercise 02 - Insert Rows + Verify with SELECT

Part 1 - Why this matters

Inserting data is useful only when the application can confirm what PostgreSQL stored. Input values may be transformed by defaults, generated identifiers, type conversion, or database rules, so verification should inspect the database result rather than repeat the original Python values.

This challenge also introduces parameterized queries. Separating SQL structure from data values prevents quoting mistakes and protects the application from SQL injection when values originate outside the program.

Part 2 - Technical concept and behavior

An `INSERT` statement creates one or more rows. PostgreSQL can return generated or normalized values through a `RETURNING` clause. A later `SELECT` verifies persistence after the transaction

is committed. Psycopg uses `%s` placeholders for values regardless of the underlying PostgreSQL type.

Part 3 - Hints and Helper

Never add values to an SQL string with concatenation or f-strings. Insert at least two rows with parameters, commit the transaction, and select them using a stable column in the `ORDER BY` clause.

Part 4 - Python code skeleton

```
import psycopg

def E02(connection, rows):
    inserted = []
    with connection.cursor() as cursor:
        for row in rows:
            cursor.execute(
                "INSERT INTO ... (...) VALUES (%s, %s, %s) RETURNING ...",
                (...),
            )
            inserted.append(cursor.fetchone())
    connection.commit()

    with connection.cursor() as cursor:
        cursor.execute("SELECT ... FROM ... ORDER BY ...")
        verified = cursor.fetchall()
    return inserted, verified

def main():
    connection = psycopg.connect(...)
    print(E02(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.4 Exercise 03 - Basic WHERE Filtering Challenge

Part 1 - Why this matters

Applications rarely need every row from a table. Filtering allows PostgreSQL to return only the records that satisfy a precise requirement, reducing transferred data and preventing Python from reproducing work that the database can perform directly.

A correct filter must reflect the intended logic. Confusing `AND` with `OR`, mishandling parentheses, or using unsafe string construction can return the wrong population while the program still appears to work.

Part 2 - Technical concept and behavior

The `WHERE` clause evaluates a Boolean condition for each candidate row. Comparisons, ranges, membership tests, and logical operators may be combined. Operator precedence affects compound expressions, so parentheses should make the intended grouping explicit whenever conditions mix `AND` and `OR`.

Part 3 - Hints and Helper

Accept filter values as Python arguments and pass them as query parameters. Return selected columns rather than using `SELECT *`, and test a condition that returns rows as well as one that returns an empty result.

Part 4 - Python code skeleton

```
import psycopg

def E03(connection, minimum_usage, active_state):
    query = """
        SELECT ...
        FROM ...
        WHERE ... >= %s
          AND ... = %s
        ORDER BY ...
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ...))
        rows = cursor.fetchall()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E03(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.5 Exercise 04 - ORDER BY + LIMIT + OFFSET Challenge

Part 1 - Why this matters

Ordering and pagination allow an application to present large result sets in manageable portions. Without an explicit order, PostgreSQL does not guarantee which rows appear first, so repeated requests can produce unstable pages even when the underlying data has not changed.

This challenge teaches the reader to define deterministic ordering and calculate page boundaries in Python. It also reveals why an offset is a position in an ordered result rather than an identifier of the last row returned.

Part 2 - Technical concept and behavior

`ORDER BY` sorts the result using one or more expressions and directions. `LIMIT` restricts the number of returned rows, while `OFFSET` skips a number of rows after ordering. For one-based page number p and page size s,

$$\text{offset} = (p - 1)s.$$

A unique tie-breaking column makes the order deterministic.

Part 3 - Hints and Helper

Validate that page number and page size are positive. Order by a meaningful value and then by a unique identifier. Pass limit and offset as parameters rather than inserting them into the query string.

Part 4 - Python code skeleton

```
import psycopg

def E04(connection, page_number, page_size):
    if ...:
        raise ValueError(...)
    offset = ...
    query = """
        SELECT ...
        FROM ...
        ORDER BY ... DESC, ... ASC
        LIMIT %s OFFSET %s
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ...))
        page = cursor.fetchall()
    return page

def main():
    connection = psycopg.connect(...)
    print(E04(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.6 Exercise 05 - UPDATE with Condition + Verification

Part 1 - Why this matters

An update changes existing information and can therefore damage many records if its scope is wrong. The most important part of an `UPDATE` statement is often not the new value but the condition that identifies exactly which rows are allowed to change.

Verification makes the modification observable. The program should know how many rows were affected and inspect their final values, allowing it to reject cases where no row or an unexpected number of rows matched the condition.

Part 2 - Technical concept and behavior

An `UPDATE` statement assigns new values to rows satisfying its `WHERE` clause. PostgreSQL's `RETURNING` clause exposes the changed rows without requiring a separate lookup. Psycopg also provides `cursor.rowcount`, but returned identifiers and values offer stronger evidence about what changed.

Part 3 - Hints and Helper

Require a unique identifier or another deliberate condition. Run the update inside a transaction, inspect the returned row before committing, and roll back when the number of matches violates the exercise's expectation.

Part 4 - Python code skeleton

```
import psycopg

def E05(connection, record_id, new_value):
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                UPDATE ...
                SET ... = %s
                WHERE ... = %s
                RETURNING ...
            """, (..., ...))
            changed = cursor.fetchall()
            if len(changed) != ...:
                raise ValueError(...)
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return changed

def main():
    connection = psycopg.connect(...)
    print(E05(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.7 Exercise 06 - DELETE with Safety Condition

Part 1 - Why this matters

Deletion is irreversible after a transaction is committed, making an imprecise `DELETE` one of the most dangerous database operations. A safety condition must be specific enough to protect unrelated rows and should be checked before the final change is accepted.

This challenge treats deletion as a controlled procedure rather than a single command. The reader will preview the target, delete it inside a transaction, verify the affected row, and decide whether the transaction is safe to commit.

Part 2 - Technical concept and behavior

`DELETE FROM table WHERE condition` removes every row for which the condition is true. Without `WHERE`, all rows are eligible. `RETURNING` can report deleted records, while a transaction allows Python to roll back when the affected count differs from the intended count.

Part 3 - Hints and Helper

Do not accept an empty identifier. Select the target first, then delete using the same specific condition. Require exactly one returned row for this exercise and roll back otherwise.

Part 4 - Python code skeleton

```
import psycopg

def E06(connection, record_id):
    if ...:
        raise ValueError(...)
    try:
        with connection.cursor() as cursor:
            cursor.execute("SELECT ... FROM ... WHERE ... = %s", (...,))
            preview = cursor.fetchone()
            cursor.execute(
                "DELETE FROM ... WHERE ... = %s RETURNING ...",
                (...,),
            )
            deleted = cursor.fetchall()
            if ...:
                raise ValueError(...)
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return preview, deleted

def main():
    connection = psycopg.connect(...)
    print(E06(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.8 Exercise 07 - NULL Handling + COALESCE Challenge

Part 1 - Why this matters

A missing database value is not automatically zero, an empty string, or `False`. PostgreSQL represents absence with `NULL`, and treating it as an ordinary value can produce filters and calculations that behave differently from Python expectations.

The reader must learn when to preserve missingness and when to replace it for a particular output. `COALESCE` is useful for presentation and calculations, but replacing every missing value can hide an important distinction in the original data.

Part 2 - Technical concept and behavior

Comparisons with `NULL` produce an unknown logical result, so SQL uses `IS NULL` and `IS NOT NULL`. The expression `COALESCE(a, b, ...)` returns the first non-null argument. Psycopg maps SQL `NULL` to Python `None` when rows are retrieved.

Part 3 - Hints and Helper

Insert or identify rows containing a nullable value. Return both the original column and a derived `COALESCE` value so their meanings remain visible. Compare `IS NULL` with an intentionally incorrect equality test.

Part 4 - Python code skeleton

```
import psycopg

def E07(connection, fallback_value):
    query = """
        SELECT
            ...,
            ... AS original_value,
            COALESCE(..., %s) AS resolved_value,
            ... IS NULL AS was_missing
        FROM ...
        ORDER BY ...
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (...,))
        rows = cursor.fetchall()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E07(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.9 Exercise 08 - Aggregate Basics (COUNT, SUM, AVG)

Part 1 - Why this matters

Applications frequently need summaries rather than individual records. Aggregate functions allow PostgreSQL to calculate counts, totals, and averages close to the stored data, avoiding unnecessary transfer of every row into Python.

Correct interpretation is essential because aggregates do not all treat `NULL` identically. The reader will compare record count with non-null value count and verify that a summary describes the intended population.

Part 2 - Technical concept and behavior

`COUNT(*)` counts input rows, whereas `COUNT(column)` counts only non-null values in that column. `SUM(column)` and `AVG(column)` ignore null inputs and return `NULL` when no non-null values are available. A `WHERE` clause restricts rows before aggregation.

Part 3 - Hints and Helper

Calculate all three aggregates in one query. Include `COUNT(*)` and `COUNT(nullable_column)` to expose their difference, and test both a populated filter and a filter matching no rows.

Part 4 - Python code skeleton

```
import psycopg

def E08(connection, active_state):
    query = """
        SELECT
            COUNT(*) AS row_count,
            COUNT(...) AS value_count,
            SUM(...) AS total_value,
            AVG(...) AS average_value
        FROM ...
        WHERE ... = %s
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (...,))
        summary = cursor.fetchone()
    return summary

def main():
    connection = psycopg.connect(...)
    print(E08(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.2.10 Exercise 09 - Group By + Having Challenge

Part 1 - Why this matters

Grouping transforms rows into category-level summaries, allowing an application to compare plans, statuses, dates, or other dimensions. It is the foundation of usage reports, monitoring dashboards, and many data checks surrounding an artificial intelligence service.

The challenge is to separate row-level logic from group-level logic. Filtering individual rows changes which records contribute to a summary, while filtering after aggregation decides which completed summaries are shown.

Part 2 - Technical concept and behavior

`GROUP BY` creates one group for each distinct combination of grouping expressions. Selected columns must normally be grouped or aggregated. `WHERE` filters rows before groups are formed, whereas `HAVING` filters groups after aggregate values have been calculated.

Part 3 - Hints and Helper

Group records by a categorical column and calculate count, sum, and average. Use a parameterized `WHERE` condition for eligible rows and a separate parameterized `HAVING` condition for the minimum group total. Order the final groups explicitly.

Part 4 - Python code skeleton

```
import psycopg

def E09(connection, active_state, minimum_total):
    query = """
        SELECT
            ... AS category,
            COUNT(*) AS record_count,
            SUM(...) AS total_value,
            AVG(...) AS average_value
        FROM ...
        WHERE ... = %s
        GROUP BY ...
        HAVING SUM(...) >= %s
        ORDER BY total_value DESC, category ASC
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ...))
        groups = cursor.fetchall()
    return groups

def main():
    connection = psycopg.connect(...)
    print(E09(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3 SQL01 - Tables, Keys & Schemas

Data Engineering for AI

6.3.1 Exercise 00 - Design Schema: users + plans + sessions

Part 1 - Why this matters

A relational schema is a model of the application's rules. Separating users, plans, and sessions prevents repeated information and gives each table a clear responsibility, while relationships describe which records are allowed to depend on others.

Good design begins before `CREATE TABLE`. The reader must identify entities, attributes, identifiers, optional fields, and relationship cardinalities, then translate those decisions into PostgreSQL and inspect the resulting schema from Python.

Part 2 - Technical concept and behavior

In this scenario, one plan may belong to many users and one user may own many sessions. Each table needs a primary key, while dependent tables store foreign keys referencing their parent records. Creation order matters because a referenced table must exist before a foreign-key constraint can target it.

Part 3 - Hints and Helper

Write the design in plain language first. Create tables in dependency order: plans, users, then sessions. Use a transaction so an incomplete schema is rolled back, and query PostgreSQL metadata to verify all three tables.

Part 4 - Python code skeleton

```
import psycopg

def E00(connection):
    statements = [
        "CREATE TABLE ...",
        "CREATE TABLE ...",
        "CREATE TABLE ...",
    ]
    try:
        with connection.cursor() as cursor:
            for statement in statements:
                cursor.execute(...)
            cursor.execute("""
                SELECT table_name
                FROM information_schema.tables
                WHERE table_schema = %s
                  AND table_name = ANY(%s)
                ORDER BY table_name
            """, (..., ...))
            tables = cursor.fetchall()
```

```
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return tables

def main():
    connection = psycopg.connect(...)
    print(E00(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.2 Exercise 01 - Primary Key + Unique Constraint Challenge

Part 1 - Why this matters

A primary key gives every row a stable identity, allowing other records and application operations to refer to it without ambiguity. A unique constraint protects business identifiers such as usernames or email addresses from duplication.

Although both constraints enforce uniqueness, they express different meanings. This challenge requires the reader to create both, attempt deliberate duplicates, observe PostgreSQL's response, and confirm that failed inserts do not corrupt the transaction state.

Part 2 - Technical concept and behavior

A table has one primary-key constraint, which implies uniqueness and non-nullability and may contain one or several columns. A table may have multiple unique constraints. PostgreSQL reports a constraint violation when an insert or update would duplicate a protected value.

Part 3 - Hints and Helper

Insert one valid row, then separately test a duplicate primary key and a duplicate unique value. Roll back after each expected failure before using the connection again. Record the constraint name or SQLSTATE for verification.

Part 4 - Python code skeleton

```
import psycopg

def E01(connection, valid_row, duplicate_rows):
    results = []
    with connection.cursor() as cursor:
        cursor.execute("INSERT INTO ... VALUES (...) RETURNING ...", (...))
    connection.commit()

    for row in duplicate_rows:
        try:
            with connection.cursor() as cursor:
```

```
                cursor.execute("INSERT INTO ... VALUES (...)", (...))
            connection.commit()
            results.append(...)
        except psycopg.errors.UniqueViolation as error:
            connection.rollback()
            results.append(...)
    return results

def main():
    connection = psycopg.connect(...)
    print(E01(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.3 Exercise 02 - Foreign Key Relationship Setup

Part 1 - Why this matters

Foreign keys prevent dependent records from referring to parents that do not exist. Without this protection, a user could reference an imaginary plan or a session could remain connected to no valid user, leaving application data internally inconsistent.

This exercise makes referential integrity observable. The reader will create a relationship, insert valid parent and child rows, deliberately attempt an invalid reference, and verify the database state after rollback.

Part 2 - Technical concept and behavior

A foreign key constrains values in child columns to matching values in a referenced primary key or unique key. PostgreSQL checks the relationship on inserts and updates. The child value may still be `NULL` unless its column is also declared `NOT NULL`.

Part 3 - Hints and Helper

Create the parent row before the child row. Test both a valid and nonexistent parent identifier, catch `ForeignKeyViolation`, roll back the failed transaction, and count remaining child records.

Part 4 - Python code skeleton

```
import psycopg

def E02(connection, parent_id, invalid_parent_id):
    with connection.cursor() as cursor:
        cursor.execute("INSERT INTO ... RETURNING ...", (...,))
        cursor.execute("INSERT INTO ... VALUES (..., %s) RETURNING ...",
                       (parent_id,))
        valid_child = cursor.fetchone()
    connection.commit()
```

```
    try:
        with connection.cursor() as cursor:
            cursor.execute("INSERT INTO ... VALUES (..., %s)",
                           (invalid_parent_id,))
        connection.commit()
    except psycopg.errors.ForeignKeyViolation as error:
        connection.rollback()
        failure = ...
    return valid_child, failure

def main():
    connection = psycopg.connect(...)
    print(E02(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.4 Exercise 03 - ON DELETE Behavior (RESTRICT/CASCADE)

Part 1 - Why this matters

Deleting a parent record raises an important design question: should PostgreSQL reject the deletion or automatically remove dependent records? The answer represents an application policy, not merely a convenient SQL option.

This challenge compares restrictive and cascading relationships experimentally. The reader will create isolated test records, attempt both deletion paths, and inspect which rows survive so the consequences are understood before these rules are used with real data.

Part 2 - Technical concept and behavior

`ON DELETE RESTRICT` prevents parent deletion while referenced child rows exist. `ON DELETE CASCADE` deletes matching child rows automatically with the parent. The default behavior is commonly `NO ACTION`, whose timing can differ from `RESTRICT` for deferrable checks.

Part 3 - Hints and Helper

Use separate parent records for the two experiments. Catch and roll back the restricted deletion, then execute the cascading deletion and verify parent and child counts before committing conclusions.

Part 4 - Python code skeleton

```
import psycopg

def E03(connection, restricted_parent, cascading_parent):
    observations = {}
    try:
        with connection.cursor() as cursor:
```

```
            cursor.execute("DELETE FROM ... WHERE id = %s",
                           (restricted_parent,))
        connection.commit()
    except psycopg.errors.ForeignKeyViolation:
        connection.rollback()
        observations["restrict"] = ...

    with connection.cursor() as cursor:
        cursor.execute("DELETE FROM ... WHERE id = %s RETURNING id",
                       (cascading_parent,))
        observations["cascade_parent"] = cursor.fetchone()
        cursor.execute("SELECT COUNT(*) FROM ... WHERE ... = %s",
                       (cascading_parent,))
        observations["cascade_children"] = cursor.fetchone()
    connection.commit()
    return observations

def main():
    connection = psycopg.connect(...)
    print(E03(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.5 Exercise 04 - CHECK Constraints for Data Validation

Part 1 - Why this matters

Application validation can be bypassed by another script, service, or manual database operation. A check constraint places essential rules beside the stored data so every writer must obey the same condition.

The challenge is to encode a rule that is both strict and semantically correct. The reader will test boundary values and missing values, because a condition that seems obvious may still allow `NULL` unless nullability is constrained separately.

Part 2 - Technical concept and behavior

A `CHECK` constraint accepts rows when its Boolean expression is true or unknown and rejects rows when it is false. Therefore, `CHECK (limit >= 0)` does not replace `NOT NULL`. Named constraints make database errors easier to interpret and maintain.

Part 3 - Hints and Helper

Define valid ranges for plan limits or session values. Test the lower boundary, upper boundary, a value outside each boundary, and `None`. Roll back each expected failure and report its constraint name.

Part 4 - Python code skeleton

```
import psycopg

def E04(connection, test_values):
    outcomes = []
    for value in test_values:
        try:
            with connection.cursor() as cursor:
                cursor.execute(
                    "INSERT INTO ... (...) VALUES (%s) RETURNING ...",
                    (value,),
                )
                result = cursor.fetchone()
            connection.commit()
            outcomes.append((value, ...))
        except psycopg.errors.CheckViolation as error:
            connection.rollback()
            outcomes.append((value, ...))
    return outcomes

def main():
    connection = psycopg.connect(...)
    print(E04(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.6 Exercise 05 - Default Values + Timestamps

Part 1 - Why this matters

Defaults let PostgreSQL supply predictable values when an insert intentionally omits a column. They reduce repeated application code and ensure records created by different clients begin with the same state.

Timestamps require particular care because database time, application time, and local display time may differ. This exercise uses PostgreSQL to generate creation times and verifies the difference between omitting a value, explicitly providing one, and explicitly inserting `NULL`.

Part 2 - Technical concept and behavior

A `DEFAULT` expression is evaluated when an insert omits the column or uses the `DEFAULT` keyword. It is not applied when the client explicitly supplies `NULL`. `TIMESTAMPTZ` represents an instant and displays it according to the session time zone.

Part 3 - Hints and Helper

Add a Boolean default and a timestamp default such as `CURRENT_TIMESTAMP`. Insert rows using different column lists, return generated fields, and compare their Python types and values.

Part 4 - Python code skeleton

```
import psycopg

def E05(connection, name):
    with connection.cursor() as cursor:
        cursor.execute("""
            INSERT INTO ... (...)
            VALUES (%s)
            RETURNING ..., ..., ...
        """, (name,))
        generated = cursor.fetchone()
        cursor.execute("""
            INSERT INTO ... (..., ..., ...)
            VALUES (%s, %s, %s)
            RETURNING ..., ..., ...
        """, (..., ..., ...))
        explicit = cursor.fetchone()
    connection.commit()
    return generated, explicit

def main():
    connection = psycopg.connect(...)
    print(E05(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.7 Exercise 06 - Normalize: Split Table into 2NF/3NF

Part 1 - Why this matters

Repeated plan details inside every user row create update anomalies: changing a plan may require many rows to be modified, and inconsistent copies can describe the same plan differently. Normalization separates facts according to what they describe.

This exercise begins with a deliberately mixed table and transforms it into related tables. The reader must preserve data during migration and prove that a join can reconstruct the useful combined view without storing duplicate facts.

Part 2 - Technical concept and behavior

Second Normal Form removes partial dependencies on part of a composite key, while Third Normal Form removes non-key attributes that depend transitively on another non-key attribute. In this scenario, plan limits belong to a plan entity rather than directly to each user entity.

Part 3 - Hints and Helper

Identify functional dependencies before writing SQL. Create normalized tables, insert distinct plan records, migrate users using a lookup or join, compare counts, and keep the migration inside one transaction.

Part 4 - Python code skeleton

```
import psycopg

def E06(connection):
    try:
        with connection.cursor() as cursor:
            cursor.execute("CREATE TABLE ...")
            cursor.execute("CREATE TABLE ...")
            cursor.execute("""
                INSERT INTO ... (...)
                SELECT DISTINCT ...
                FROM ...
            """)
            cursor.execute("""
                INSERT INTO ... (...)
                SELECT ..., ...
                FROM ...
                JOIN ... ON ...
            """)
            cursor.execute("SELECT ...")
            verification = cursor.fetchall()
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return verification

def main():
    connection = psycopg.connect(...)
    print(E06(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.8 Exercise 07 - Create Index + Explain Its Purpose

Part 1 - Why this matters

An index can help PostgreSQL locate rows without scanning an entire table, but it also consumes storage and adds work to inserts, updates, and deletes. Creating an index is therefore a measured design choice, not a universal performance switch.

This challenge connects an index to a real query pattern. The reader will identify columns used for filtering or ordering, create an appropriate index from Python, and inspect PostgreSQL's plan rather than assuming the index must be used.

Part 2 - Technical concept and behavior

A B-tree index supports many equality, range, and ordering operations. Column order matters in a multi-column index. PostgreSQL's planner chooses between index and sequential scans based on table statistics and estimated cost; a small table may correctly use a sequential scan.

Part 3 - Hints and Helper

Write the target query before creating the index. Use `CREATE INDEX IF NOT EXISTS`, run `ANALYZE`, then execute `EXPLAIN` for the parameterized query and return the plan lines.

Part 4 - Python code skeleton

```
import psycopg

def E07(connection, filter_value):
    with connection.cursor() as cursor:
        cursor.execute("""
            CREATE INDEX IF NOT EXISTS ...
            ON ... (..., ...)
        """)
        cursor.execute("ANALYZE ...")
        cursor.execute("""
            EXPLAIN
            SELECT ...
            FROM ...
            WHERE ... = %s
            ORDER BY ...
        """, (filter_value,))
        plan = cursor.fetchall()
    connection.commit()
    return plan

def main():
    connection = psycopg.connect(...)
    print(E07(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.9 Exercise 08 - Join Basics (INNER / LEFT) Challenge

Part 1 - Why this matters

Normalized tables store related facts separately, so joins are required to reconstruct information for an application. The chosen join type controls whether records without a matching relationship disappear or remain visible.

This exercise compares the same data using inner and left joins. The difference becomes clear when a parent record has no matching child, teaching the reader to choose a join according to the question rather than by habit.

Part 2 - Technical concept and behavior

An `INNER JOIN` returns only combinations satisfying its join condition. A `LEFT JOIN` preserves every row from the left input and fills right-side columns with `NULL` when no match exists. A one-to-many relationship can produce several result rows for one parent.

Part 3 - Hints and Helper

Create at least one parent with children and one without children. Run inner and left versions of the query, select explicit columns with aliases, and compare both result counts and identities.

Part 4 - Python code skeleton

```
import psycopg

def E08(connection):
    inner_query = """
        SELECT ...
        FROM ... AS parent
        INNER JOIN ... AS child ON ...
        ORDER BY ...
    """
    left_query = """
        SELECT ...
        FROM ... AS parent
        LEFT JOIN ... AS child ON ...
        ORDER BY ...
    """
    with connection.cursor() as cursor:
        cursor.execute(inner_query)
        inner_rows = cursor.fetchall()
        cursor.execute(left_query)
        left_rows = cursor.fetchall()
    return inner_rows, left_rows

def main():
    connection = psycopg.connect(...)
    print(E08(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.3.10 Exercise 09 - Query with Multi-Table Join + Filters

Part 1 - Why this matters

Real application queries often combine several relationships while applying filters from different tables. A user-session report, for example, may require user identity, plan information, session state, and a time boundary in one result.

Complexity grows when filters interact with outer joins. Placing a child-table condition in `WHERE` can remove unmatched parents and silently change a left join into inner-join behavior, so query structure must reflect the intended result population.

Part 2 - Technical concept and behavior

A multi-table join forms a relational path through foreign keys. Conditions in an `ON` clause control which rows match during that join, whereas `WHERE` filters the combined rows afterward. Table aliases and qualified column names prevent ambiguity and make the relationship path visible.

Part 3 - Hints and Helper

Join users to plans and sessions. Parameterize plan state and time filters, decide whether users without matching sessions should remain, use explicit aliases, and order by a stable combination of columns.

Part 4 - Python code skeleton

```
import psycopg

def E09(connection, plan_name, session_start, include_without_sessions):
    join_type = ...
    query = f"""
        SELECT
            u.... AS user_id,
            u.... AS user_name,
            p.... AS plan_name,
            s.... AS session_time
        FROM ... AS u
        JOIN ... AS p ON ...
        {join_type} JOIN ... AS s
            ON ... AND s.... >= %s
        WHERE p.... = %s
        ORDER BY ...
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ...))
        rows = cursor.fetchall()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E09(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4 SQL02 - Users, Plans & Limits Storage

Data Engineering for AI

6.4.1 Exercise 00 - Implement Plans Table + Limits Columns

Part 1 - Why this matters

An AI service often offers plans that control requests, tokens, storage, or other resources. Storing these limits in PostgreSQL gives the application one consistent source of truth instead of scattering policy values throughout Python code.

The schema must define what every value means. Zero, a positive number, and an unlimited allowance are different states, so the reader must choose an explicit representation and protect invalid negative values with database constraints.

Part 2 - Technical concept and behavior

The plans table requires a stable identifier, unique plan name, limit columns with sufficient numeric range, an active state, and timestamps. If `NULL` represents unlimited usage, queries must handle it deliberately because comparisons with `NULL` do not return true or false in the ordinary way.

Part 3 - Hints and Helper

Use `BIGINT` for potentially large counters and named `CHECK` constraints permitting non-negative values or `NULL`. Create the table from Python, insert several boundary cases, and inspect the stored rows.

Part 4 - Python code skeleton

```
import psycopg

def E00(connection):
    create_query = """
        CREATE TABLE IF NOT EXISTS plans (
            id ...,
            name ...,
            request_limit ...,
            token_limit ...,
            is_active ...,
            created_at ...,
            CONSTRAINT ... CHECK (...),
            CONSTRAINT ... CHECK (...)
        )
    """
    with connection.cursor() as cursor:
        cursor.execute(create_query)
        cursor.execute("INSERT INTO plans (...) VALUES (...) RETURNING ...",
                       (...))
        result = cursor.fetchone()
```

```
    connection.commit()
    return result

def main():
    connection = psycopg.connect(...)
    print(E00(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.2 Exercise 01 - Assign User to Plan + Enforce FK

Part 1 - Why this matters

Assigning a plan to a user connects account identity with service policy. A foreign key ensures that an application cannot assign a plan identifier that does not exist, even if validation is missing from one Python code path.

The relationship also requires a policy for deleted plans and unassigned users. This exercise makes those choices explicit and verifies both valid assignment and deliberate referential failure.

Part 2 - Technical concept and behavior

A `plan_id` column in `users` references `plans(id)`. `NOT NULL` requires every user to have a plan, while a nullable column permits an unassigned state. An `ON DELETE` action determines whether a referenced plan can be removed.

Part 3 - Hints and Helper

Choose the nullability and deletion behavior before altering the table. Insert or update one valid assignment, attempt an invalid plan identifier, roll back the expected failure, and join the tables to verify the surviving relationship.

Part 4 - Python code skeleton

```
import psycopg

def E01(connection, user_id, plan_id, invalid_plan_id):
    with connection.cursor() as cursor:
        cursor.execute("""
            UPDATE users
            SET plan_id = %s
            WHERE id = %s
            RETURNING id, plan_id
        """, (..., ...))
        assigned = cursor.fetchone()
    connection.commit()

    try:
        with connection.cursor() as cursor:
```

```
            cursor.execute("UPDATE users SET plan_id = %s WHERE id = %s",
                           (..., ...))
        connection.commit()
    except psycopg.errors.ForeignKeyViolation as error:
        connection.rollback()
        failure = ...
    return assigned, failure

def main():
    connection = psycopg.connect(...)
    print(E01(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.3 Exercise 02 - Track Usage Table (tokens/requests)

Part 1 - Why this matters

Limits cannot be enforced without trustworthy usage records. Recording each usage event creates evidence for billing, monitoring, debugging, and later aggregation while preserving when and by whom a resource was consumed.

The table must reject impossible values and maintain user relationships. The reader will distinguish an immutable event record from a mutable total, then verify inserted events from Python.

Part 2 - Technical concept and behavior

A usage event can store a user foreign key, request count, token count, event timestamp, and optional request identifier for idempotency. Non-negative checks protect counters, and a unique external request identifier can prevent the same event from being recorded twice.

Part 3 - Hints and Helper

Prefer append-only events for this exercise. Add constraints for counts, choose a timestamp type, and use parameterized inserts with `RETURNING`. Test valid, negative, and duplicate event cases with rollback.

Part 4 - Python code skeleton

```
import psycopg

def E02(connection, user_id, request_id, requests, tokens):
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                INSERT INTO usage_events
                    (user_id, request_id, request_count, token_count, used_at)
                VALUES (%s, %s, %s, %s, ...)
```

```
                RETURNING ...
            """, (..., ..., ..., ...))
            event = cursor.fetchone()
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return event

def main():
    connection = psycopg.connect(...)
    print(E02(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.4 Exercise 03 - Daily Usage Aggregation Query

Part 1 - Why this matters

Raw events explain individual activity, but limit enforcement and reporting often require totals for each user and day. PostgreSQL can group these events efficiently without transferring the entire event history into Python.

The meaning of a day depends on a time zone. A timestamp near midnight may belong to different calendar dates in UTC and the UAE, so the query must state which business time zone defines the aggregation boundary.

Part 2 - Technical concept and behavior

Daily aggregation converts each event timestamp into a business-local date, groups by user and date, and applies `SUM` to request and token counts. A half-open interval $[t_{start}, t_{end})$ avoids overlapping boundary events between consecutive reporting periods.

Part 3 - Hints and Helper

Pass the reporting interval and time-zone name as parameters. Group by both user and derived date, select explicit totals, and order results deterministically. Verify the query with events around midnight.

Part 4 - Python code skeleton

```
import psycopg

def E03(connection, start_time, end_time, timezone_name):
    query = """
        SELECT
            user_id,
            (... AT TIME ZONE %s)::date AS usage_date,
            SUM(request_count) AS total_requests,
```

```
            SUM(token_count) AS total_tokens
        FROM usage_events
        WHERE used_at >= %s AND used_at < %s
        GROUP BY user_id, usage_date
        ORDER BY usage_date, user_id
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ..., ...))
        rows = cursor.fetchall()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E03(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.5 Exercise 04 - Check Limit Breach Query (Over Limit)

Part 1 - Why this matters

A service must compare accumulated usage with the limits belonging to each user's current plan. Performing this comparison in one relational query reduces inconsistent decisions between separate Python lookups.

Boundary semantics matter: reaching a limit and exceeding a limit are different policies. Unlimited values also require explicit handling, so the reader must define the rule before writing the Boolean expression.

Part 2 - Technical concept and behavior

The query joins users with plans and a usage summary. `COALESCE` can convert missing usage to zero, but a null plan limit may represent unlimited usage and should not be converted blindly. A breach condition may use $>$ for over-limit detection or $\geq$ when the next request must be blocked at the limit.

Part 3 - Hints and Helper

Return usage, limits, and separate Boolean flags for requests and tokens. Test below-limit, exactly-at-limit, above-limit, no-usage, and unlimited cases so the policy is observable.

Part 4 - Python code skeleton

```
import psycopg

def E04(connection, user_id, usage_date):
    query = """
        SELECT
            u.id,
```

```
            p.request_limit,
            p.token_limit,
            COALESCE(SUM(e.request_count), 0) AS used_requests,
            COALESCE(SUM(e.token_count), 0) AS used_tokens,
            (...) AS request_limit_breached,
            (...) AS token_limit_breached
        FROM users AS u
        JOIN plans AS p ON ...
        LEFT JOIN usage_events AS e ON ...
        WHERE u.id = %s
        GROUP BY ...
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ...))
        status = cursor.fetchone()
    return status

def main():
    connection = psycopg.connect(...)
    print(E04(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.6 Exercise 05 - Create View: user_current_limits

Part 1 - Why this matters

Applications repeatedly need the current limits attached to each user. A view can give this relationship a stable name and expose a consistent set of columns without duplicating plan data into the users table.

A view is still a query, not an independent stored copy in this exercise. Changes to users or plans become visible through it, allowing the reader to centralize read logic while preserving normalized storage.

Part 2 - Technical concept and behavior

`CREATE VIEW` stores a query definition that PostgreSQL evaluates when the view is queried. The view can join users and plans, rename columns, and expose only fields required by consumers. `CREATE OR REPLACE VIEW` updates a compatible definition without dropping it first.

Part 3 - Hints and Helper

Expose user identity, plan identity, active state, and both limits with unambiguous aliases. Create the view from Python, query it for one user, then modify a plan and verify that the view reflects the change.

Part 4 - Python code skeleton

```
import psycopg

def E05(connection, user_id):
    view_query = """
        CREATE OR REPLACE VIEW user_current_limits AS
        SELECT
            u.... AS user_id,
            u.... AS user_name,
            p.... AS plan_id,
            p.... AS plan_name,
            p.... AS request_limit,
            p.... AS token_limit
        FROM users AS u
        JOIN plans AS p ON ...
    """
    with connection.cursor() as cursor:
        cursor.execute(view_query)
        cursor.execute(
            "SELECT ... FROM user_current_limits WHERE user_id = %s",
            (user_id,),
        )
        row = cursor.fetchone()
    connection.commit()
    return row

def main():
    connection = psycopg.connect(...)
    print(E05(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.7 Exercise 06 - Create View: user_usage_summary

Part 1 - Why this matters

Usage summaries are needed by dashboards, limit checks, and operational reports. Repeating the same aggregation in several Python functions increases the chance that date boundaries or null handling will differ between consumers.

A view can provide a shared relational definition of the summary. The reader must still understand its cost, because an ordinary view does not automatically precompute or cache aggregate results.

Part 2 - Technical concept and behavior

The view groups usage events by user and a defined date representation, then returns request totals, token totals, and event count. An ordinary view executes its underlying query when read. A materialized view behaves differently and is not introduced as a replacement here.

Part 3 - Hints and Helper

Choose and document the view's time-zone convention. Use clear aliases and preserve one row per user per date. Query a date range from Python and compare one row with a direct aggregation.

Part 4 - Python code skeleton

```
import psycopg

def E06(connection, start_date, end_date):
    create_view = """
        CREATE OR REPLACE VIEW user_usage_summary AS
        SELECT
            user_id,
            (...)::date AS usage_date,
            COUNT(*) AS event_count,
            SUM(request_count) AS total_requests,
            SUM(token_count) AS total_tokens
        FROM usage_events
        GROUP BY user_id, usage_date
    """
    with connection.cursor() as cursor:
        cursor.execute(create_view)
        cursor.execute("""
            SELECT ...
            FROM user_usage_summary
            WHERE usage_date >= %s AND usage_date < %s
            ORDER BY usage_date, user_id
        """, (..., ...))
        rows = cursor.fetchall()
    connection.commit()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E06(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.8 Exercise 07 - Plan Upgrade Transaction Challenge

Part 1 - Why this matters

A plan upgrade may require several related changes, such as validating the target plan, changing the user's assignment, and recording when the change occurred. If only part of this work succeeds, account state and history can disagree.

Transactions make the upgrade atomic, while row locking protects the decision from concurrent modifications. The reader will test successful commit and deliberate rollback paths instead of assuming the multi-step operation is safe.

Part 2 - Technical concept and behavior

The transaction selects the target user and plan, validates their states, updates the assignment, and commits only when every step succeeds. `SELECT ... FOR UPDATE` can lock the selected user row until transaction completion, preventing another transaction from changing it concurrently.

Part 3 - Hints and Helper

Do not commit inside intermediate steps. Lock the user, reject a missing or inactive target plan, update with `RETURNING`, and roll back on every exception. Verify the old plan remains after a forced failure.

Part 4 - Python code skeleton

```
import psycopg

def E07(connection, user_id, target_plan_id):
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                SELECT id, plan_id
                FROM users
                WHERE id = %s
                FOR UPDATE
            """, (user_id,))
            user = cursor.fetchone()
            cursor.execute("SELECT id, is_active FROM plans WHERE id = %s",
                           (target_plan_id,))
            plan = cursor.fetchone()
            if ...:
                raise ValueError(...)
            cursor.execute("""
                UPDATE users SET plan_id = %s
                WHERE id = %s
                RETURNING id, plan_id
            """, (..., ...))
            upgraded = cursor.fetchone()
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return user, upgraded

def main():
    connection = psycopg.connect(...)
    print(E07(...))
```

```
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.9 Exercise 08 - Audit Log Table for Plan Changes

Part 1 - Why this matters

Current state answers which plan a user has now, but it does not explain how that state was reached. An audit log preserves plan-change history for support, investigation, policy review, and operational accountability.

The log must be written in the same transaction as the assignment change. Otherwise, a user could be upgraded without history or an audit record could describe a change that was rolled back.

Part 2 - Technical concept and behavior

An audit row can store user identity, previous and new plan identifiers, change timestamp, actor, and reason. It is generally append-only. The previous plan may be nullable for an initial assignment, while foreign-key deletion policies should preserve the desired historical meaning.

Part 3 - Hints and Helper

Create the audit table with named constraints and timestamps. Extend the upgrade transaction to capture the old plan, update the user, and insert the log before one final commit. Force an audit insert failure and verify that the user update rolls back too.

Part 4 - Python code skeleton

```
import psycopg

def E08(connection, user_id, new_plan_id, actor, reason):
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                SELECT plan_id FROM users
                WHERE id = %s FOR UPDATE
            """, (user_id,))
            old_plan_id = ...
            cursor.execute("UPDATE users SET plan_id = %s WHERE id = %s",
                           (..., ...))
            cursor.execute("""
                INSERT INTO plan_change_audit
                    (user_id, old_plan_id, new_plan_id, actor, reason)
                VALUES (%s, %s, %s, %s, %s)
                RETURNING ...
            """, (..., ..., ..., ..., ...))
            audit_row = cursor.fetchone()
        connection.commit()
```

```
    except Exception:
        connection.rollback()
        raise
    return audit_row

def main():
    connection = psycopg.connect(...)
    print(E08(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.4.10 Exercise 09 - Report Query: Top Users by Usage

Part 1 - Why this matters

Usage rankings help an AI service identify heavy workloads, plan adoption, unusual activity, and capacity requirements. A useful report must define its time range and ranking measure so that readers do not mistake an ambiguous total for a meaningful comparison.

This final challenge combines users, plans, and usage events. It requires safe filters, correct aggregation, deterministic ordering, and a limited result set returned to Python with enough context to interpret each ranking.

Part 2 - Technical concept and behavior

The query filters events using a half-open timestamp interval, joins account context, groups by user and plan, and orders by an aggregate such as total tokens. Secondary ordering resolves ties. A left join can retain users with zero usage, while an inner join naturally reports only users with matching events.

Part 3 - Hints and Helper

Parameterize start time, end time, and result limit. Return request total, token total, event count, and plan name. Decide whether inactive or zero-usage users belong in the report and encode that decision explicitly.

Part 4 - Python code skeleton

```
import psycopg

def E09(connection, start_time, end_time, top_n):
    if ...:
        raise ValueError(...)
    query = """
        SELECT
            u.id AS user_id,
            u.... AS user_name,
            p.... AS plan_name,
            COUNT(e.id) AS event_count,
```

```
            COALESCE(SUM(e.request_count), 0) AS total_requests,
            COALESCE(SUM(e.token_count), 0) AS total_tokens
        FROM users AS u
        JOIN plans AS p ON ...
        JOIN usage_events AS e ON ...
        WHERE e.used_at >= %s AND e.used_at < %s
        GROUP BY ...
        ORDER BY total_tokens DESC, user_id ASC
        LIMIT %s
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ..., ...))
        report = cursor.fetchall()
    return report

def main():
    connection = psycopg.connect(...)
    print(E09(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5 SQL03 - Query Logic & Transactions

Data Engineering for AI

6.5.1 Exercise 00 - Transaction Basics (BEGIN/COMMIT/ROLLBACK)

Part 1 - Why this matters

A transaction defines a boundary around database work. Changes inside that boundary remain provisional until commit and can be discarded together with rollback, allowing an application to recover from errors without preserving a partial operation.

This exercise makes transaction state visible rather than treating commit as a routine final line. The reader will perform equivalent changes on commit and rollback paths, then verify their different outcomes using a separate observation query.

Part 2 - Technical concept and behavior

`BEGIN` starts a transaction, `COMMIT` makes its changes durable, and `ROLLBACK` abandons them. Psycopg normally begins a transaction automatically when the first command requires one. After a database error, the transaction remains failed until rollback.

Part 3 - Hints and Helper

Use explicit commit and rollback from Python. Insert a uniquely identifiable row in each path, verify visibility after completion, and demonstrate that the connection can be reused only after a failed transaction is rolled back.

Part 4 - Python code skeleton

```
import psycopg

def E00(connection, committed_value, rolled_back_value):
    with connection.cursor() as cursor:
        cursor.execute("INSERT INTO ... (...) VALUES (%s) RETURNING ...",
                       (committed_value,))
        committed_candidate = cursor.fetchone()
    connection.commit()

    with connection.cursor() as cursor:
        cursor.execute("INSERT INTO ... (...) VALUES (%s) RETURNING ...",
                       (rolled_back_value,))
        rolled_back_candidate = cursor.fetchone()
    connection.rollback()

    with connection.cursor() as cursor:
        cursor.execute("SELECT ... FROM ... WHERE ... = ANY(%s)", (...,))
        verification = cursor.fetchall()
    return committed_candidate, rolled_back_candidate, verification

def main():
    connection = psycopg.connect(...)
    print(E00(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.2 Exercise 01 - Atomic Insert into Multiple Tables

Part 1 - Why this matters

One application action may create records in several tables. Creating a user and its initial session separately can leave an incomplete account when the second insert fails after the first has already committed.

Atomicity requires all related inserts to succeed or none to survive. The reader will pass a generated identifier from the first insert to the second, force a failure, and verify that PostgreSQL removes the earlier provisional work.

Part 2 - Technical concept and behavior

Statements executed through one connection before commit belong to the same transaction. `INSERT ... RETURNING` provides a generated key for dependent inserts. Any exception should lead to one rollback covering every statement in the unit of work.

Part 3 - Hints and Helper

Insert the parent first, obtain its identifier, and insert the child without committing between them. Test a successful path and a path where the child violates a constraint, then query both tables after rollback.

Part 4 - Python code skeleton

```
import psycopg

def E01(connection, user_data, session_data):
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                INSERT INTO users (...) VALUES (...)
                RETURNING id
            """, (...))
            user_id = cursor.fetchone()[0]
            cursor.execute("""
                INSERT INTO sessions (user_id, ...)
                VALUES (%s, ...)
                RETURNING id
            """, (user_id, ...))
            session_id = cursor.fetchone()[0]
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return user_id, session_id

def main():
    connection = psycopg.connect(...)
    print(E01(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.3 Exercise 02 - Consistency Check + Rollback on Failure

Part 1 - Why this matters

Some business rules require reading several values before deciding whether a change is valid. Database constraints should enforce rules they can express, while transaction-level checks protect conditions that depend on current related state.

This challenge adds a deliberate consistency gate before commit. The reader will update provisional data, calculate an invariant, raise an error when it is violated, and prove that rollback restores the original state.

Part 2 - Technical concept and behavior

An invariant is a condition that must hold when the transaction commits. The application may query the provisional state because its own uncommitted changes are visible within the same transaction. If the check fails, rollback discards every preceding modification.

Part 3 - Hints and Helper

Choose an invariant involving limits and usage or related row counts. Lock records when concurrent changes could invalidate the check, perform the update, calculate the invariant, and commit only when it remains true.

Part 4 - Python code skeleton

```
import psycopg

def E02(connection, user_id, proposed_change):
    try:
        with connection.cursor() as cursor:
            cursor.execute("SELECT ... FROM ... WHERE ... = %s FOR UPDATE",
                           (user_id,))
            before = cursor.fetchone()
            cursor.execute("UPDATE ... SET ... WHERE ... = %s RETURNING ...",
                           (..., user_id))
            after = cursor.fetchone()
            cursor.execute("SELECT ...")
            is_consistent = ...
            if not is_consistent:
                raise ValueError(...)
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return before, after

def main():
    connection = psycopg.connect(...)
    print(E02(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.4 Exercise 03 - Isolation Concept Simulation (Two Sessions)

Part 1 - Why this matters

Concurrent requests can read and change the same data through different database sessions. Isolation determines which effects of one transaction another is allowed to observe before and during its own transaction.

The concept becomes clearer through two real connections. The reader will coordinate a writer and reader, observe visibility before and after commit, and repeat the experiment at selected isolation levels without confusing Python connection state with PostgreSQL transaction state.

Part 2 - Technical concept and behavior

At `READ COMMITTED`, each statement sees data committed before that statement begins. At `REPEATABLE READ`, a transaction generally keeps one consistent snapshot. Uncommitted changes from another transaction are not visible at these levels.

Part 3 - Hints and Helper

Open two independent connections and label every observation. Set the isolation level before the transaction begins, use deterministic checkpoints rather than arbitrary sleeps, and always roll back or commit both sessions in a `finally` block.

Part 4 - Python code skeleton

```
import psycopg

def E03(connection_a, connection_b, record_id):
    observations = []
    try:
        with connection_a.cursor() as cursor_a, \
             connection_b.cursor() as cursor_b:
            cursor_b.execute("SET TRANSACTION ISOLATION LEVEL ...")
            cursor_b.execute("SELECT ... WHERE id = %s", (record_id,))
            observations.append(("before", cursor_b.fetchone()))

            cursor_a.execute("UPDATE ... SET ... WHERE id = %s",
                             (record_id,))
            cursor_b.execute("SELECT ... WHERE id = %s", (record_id,))
            observations.append(("uncommitted", cursor_b.fetchone()))
            connection_a.commit()

            cursor_b.execute("SELECT ... WHERE id = %s", (record_id,))
            observations.append(("after_commit", cursor_b.fetchone()))
        connection_b.commit()
    finally:
        connection_a.rollback()
        connection_b.rollback()
    return observations

def main():
    first = psycopg.connect(...)
    second = psycopg.connect(...)
    print(E03(first, second, ...))
    first.close()
    second.close()
```

```
if __name__ == "__main__":
    main()
```

6.5.5 Exercise 04 - Locking Behavior Observation Challenge

Part 1 - Why this matters

Locks protect records while a transaction makes a decision and applies a change. They also cause competing operations to wait, which can become a performance problem or deadlock when lock order is poorly designed.

This exercise observes blocking safely with two connections. A short lock timeout converts indefinite waiting into a controlled error, allowing the reader to inspect behavior and release every lock predictably.

Part 2 - Technical concept and behavior

`SELECT ... FOR UPDATE` acquires row-level locks that conflict with other updates and locking reads on the same rows. Locks normally remain until commit or rollback. `lock_timeout` limits how long a statement waits to acquire a lock; it does not limit total transaction duration.

Part 3 - Hints and Helper

Lock one known row in connection A. Set a local lock timeout in connection B and attempt a conflicting update. Catch the timeout, roll back B, release A, and retry to demonstrate that the same update can then succeed.

Part 4 - Python code skeleton

```
import psycopg

def E04(connection_a, connection_b, record_id):
    observations = []
    try:
        with connection_a.cursor() as cursor_a:
            cursor_a.execute("SELECT ... WHERE id = %s FOR UPDATE",
                             (record_id,))
        try:
            with connection_b.cursor() as cursor_b:
                cursor_b.execute("SET LOCAL lock_timeout = %s", (...,))
                cursor_b.execute("UPDATE ... WHERE id = %s", (record_id,))
            connection_b.commit()
        except psycopg.errors.LockNotAvailable as error:
            connection_b.rollback()
            observations.append(...)
        connection_a.commit()
        with connection_b.cursor() as cursor_b:
            cursor_b.execute("UPDATE ... WHERE id = %s RETURNING ...",
                             (record_id,))
            observations.append(cursor_b.fetchone())
        connection_b.commit()
```

```
    finally:
        connection_a.rollback()
        connection_b.rollback()
    return observations

def main():
    first = psycopg.connect(...)
    second = psycopg.connect(...)
    print(E04(first, second, ...))
    first.close()
    second.close()

if __name__ == "__main__":
    main()
```

6.5.6 Exercise 05 - Upsert Pattern (INSERT...ON CONFLICT)

Part 1 - Why this matters

Applications often receive data that should create a row the first time and update it on later arrivals. Performing a separate check followed by insert or update creates a race window in which another transaction can change the answer.

PostgreSQL's upsert pattern lets one statement resolve a uniqueness conflict atomically. The reader will identify the correct conflict key and ensure that only intended columns change during the update path.

Part 2 - Technical concept and behavior

`INSERT ... ON CONFLICT` uses a unique constraint or index to identify a conflict. `DO NOTHING` skips the conflicting insert, while `DO UPDATE` can reference proposed values through `EXCLUDED`. `RETURNING` reports the resulting row.

Part 3 - Hints and Helper

Use a unique request identifier or other natural idempotency key. Execute the same key twice with changed values, verify that only one row exists, and return the stored values after each execution.

Part 4 - Python code skeleton

```
import psycopg

def E05(connection, external_key, value):
    query = """
        INSERT INTO ... (..., ...)
        VALUES (%s, %s)
        ON CONFLICT (...)
        DO UPDATE SET
            ... = EXCLUDED....,
            ... = ...
```

```
        RETURNING ...
    """
    try:
        with connection.cursor() as cursor:
            cursor.execute(query, (..., ...))
            row = cursor.fetchone()
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return row

def main():
    connection = psycopg.connect(...)
    print(E05(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.7 Exercise 06 - Common Table Expression (CTE) Challenge

Part 1 - Why this matters

Complex reports become difficult to reason about when filtering, aggregation, ranking, and final selection are compressed into one deeply nested query. A Common Table Expression can name an intermediate result and expose the logical stages of the computation.

This challenge uses a CTE to make query intent clearer, not merely to replace a subquery with different syntax. The reader will verify each stage independently before combining it into the final Python-executed statement.

Part 2 - Technical concept and behavior

A non-recursive CTE begins with `WITH name AS (query)` and can be referenced by the following statement. PostgreSQL may inline eligible CTEs, so a CTE is not automatically a materialized temporary result or a performance improvement.

Part 3 - Hints and Helper

Build a CTE that aggregates usage by user, then join or filter it in the outer query. Parameterize the date range and threshold, select explicit columns, and compare its results with a simpler reference query.

Part 4 - Python code skeleton

```
import psycopg

def E06(connection, start_time, end_time, minimum_usage):
    query = """
        WITH usage_totals AS (
```

```
            SELECT
                user_id,
                SUM(...) AS total_usage
            FROM ...
            WHERE ... >= %s AND ... < %s
            GROUP BY user_id
        )
        SELECT
            u....,
            totals.total_usage
        FROM usage_totals AS totals
        JOIN users AS u ON ...
        WHERE totals.total_usage >= %s
        ORDER BY totals.total_usage DESC, u.id
    """
    with connection.cursor() as cursor:
        cursor.execute(query, (..., ..., ...))
        rows = cursor.fetchall()
    return rows

def main():
    connection = psycopg.connect(...)
    print(E06(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.8 Exercise 07 - Query Performance: EXPLAIN ANALYZE

Part 1 - Why this matters

Query speed cannot be understood reliably from SQL appearance alone. PostgreSQL's planner chooses scans, joins, and aggregation strategies using statistics and estimated costs, while actual execution reveals where time and rows were spent.

The reader will compare estimates with actual behavior and look for large discrepancies. Performance analysis must remain controlled because `EXPLAIN ANALYZE` actually executes the statement being examined.

Part 2 - Technical concept and behavior

`EXPLAIN` returns the planned execution tree. Adding `ANALYZE` runs the query and adds actual timing and row counts. Options such as `BUFFERS` report cache and I/O activity. Costs are planner units, not milliseconds.

Part 3 - Hints and Helper

Use `EXPLAIN (ANALYZE, BUFFERS, FORMAT JSON)` on a safe `SELECT`. Run `ANALYZE` on the table first, extract the plan from Python, and compare estimated rows with actual rows at selected nodes.

Part 4 - Python code skeleton

```
import psycopg

def E07(connection, filter_value):
    with connection.cursor() as cursor:
        cursor.execute("ANALYZE ...")
        cursor.execute("""
            EXPLAIN (ANALYZE, BUFFERS, FORMAT JSON)
            SELECT ...
            FROM ...
            WHERE ... = %s
            ORDER BY ...
        """, (filter_value,))
        raw_plan = cursor.fetchone()[0]
    plan = ...
    execution_time = ...
    estimated_rows = ...
    actual_rows = ...
    return plan, execution_time, estimated_rows, actual_rows

def main():
    connection = psycopg.connect(...)
    print(E07(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.9 Exercise 08 - Index Impact Benchmark Challenge

Part 1 - Why this matters

An index should be justified by a workload, not by the belief that indexes always make databases faster. It may improve a selective read while increasing storage and write cost, and PostgreSQL may correctly ignore it for queries returning much of a table.

This challenge creates a controlled before-and-after experiment. The reader will keep data and query constant, collect multiple measurements, inspect plan changes, and avoid treating one warm-cache timing as a reliable conclusion.

Part 2 - Technical concept and behavior

The benchmark compares execution plans and repeated timings before and after creating a candidate index. Selectivity, table size, statistics, cache state, and index column order influence the result. Dropping the index afterward restores the experimental environment.

Part 3 - Hints and Helper

Use a dedicated test table with enough rows to make planning meaningful. Run warm-up and measured trials, call `ANALYZE`, summarize several execution times, and compare read benefit with an observed or discussed write tradeoff.

Part 4 - Python code skeleton

```
import psycopg

def measure(connection, filter_value, repetitions):
    measurements = []
    for _ in range(repetitions):
        with connection.cursor() as cursor:
            cursor.execute("""
                EXPLAIN (ANALYZE, FORMAT JSON)
                SELECT ... FROM ... WHERE ... = %s
            """, (filter_value,))
            plan = cursor.fetchone()[0]
            measurements.append(...)
    return measurements

def E08(connection, filter_value, repetitions):
    before = measure(...)
    with connection.cursor() as cursor:
        cursor.execute("CREATE INDEX ... ON ... (...)")
        cursor.execute("ANALYZE ...")
    connection.commit()
    after = measure(...)
    return before, after

def main():
    connection = psycopg.connect(...)
    print(E08(...))
    connection.close()

if __name__ == "__main__":
    main()
```

6.5.10 Exercise 09 - Transaction-Safe Usage Deduction Scenario

Part 1 - Why this matters

When concurrent requests consume a limited allowance, a read followed later by an update can allow both requests to approve themselves from the same old balance. The final counter may then exceed the plan even though each Python process believed its check was valid.

The final challenge combines conditional SQL, transaction control, row locking or atomic update logic, and auditability. A rejected deduction must change nothing, while an accepted deduction must update all related records exactly once.

Part 2 - Technical concept and behavior

A safe pattern performs the limit condition and counter update atomically, for example with an `UPDATE` whose `WHERE` clause verifies remaining capacity and whose `RETURNING` clause reports success. Another valid pattern locks the relevant row before checking and updating. Related usage events belong in the same transaction.

Part 3 - Hints and Helper

Reject non-positive deductions before SQL. Make one statement decide whether capacity remains, treat no returned row as denial, insert the usage event only after approval, and test two competing connections against the last available capacity.

Part 4 - Python code skeleton

```
import psycopg

def E09(connection, user_id, request_id, requested_tokens):
    if ...:
        raise ValueError(...)
    try:
        with connection.cursor() as cursor:
            cursor.execute("""
                UPDATE ...
                SET used_tokens = used_tokens + %s
                WHERE user_id = %s
                  AND used_tokens + %s <= token_limit
                RETURNING used_tokens, token_limit
            """, (..., ..., ...))
            balance = cursor.fetchone()
            if balance is None:
                connection.rollback()
                return ...
            cursor.execute("""
                INSERT INTO usage_events (...)
                VALUES (...)
                RETURNING ...
            """, (...))
            event = cursor.fetchone()
        connection.commit()
    except Exception:
        connection.rollback()
        raise
    return balance, event

def main():
    connection = psycopg.connect(...)
    print(E09(...))
    connection.close()
```

```
if __name__ == "__main__":
    main()
```

Book 7

NoSQL Lessons (MongoDB)

7.1 Introduction

7.1.1 What will this book teach you

The previous book introduced relational databases, where information is organized into tables and protected through explicitly defined relationships. This book introduces a different data model. MongoDB stores records as documents inside collections, allowing related values, arrays, and nested structures to exist together in one document. This flexibility is useful when application data naturally behaves like an object or when its structure must evolve over time.

The purpose of this book is not to present MongoDB as a replacement for PostgreSQL. Each system solves different problems and imposes different tradeoffs. PostgreSQL is often the stronger choice when relationships, transactions, and strict relational consistency define the core of the data. MongoDB becomes valuable when document-shaped data, nested structures, changing attributes, session memory, event payloads, or rapid schema evolution are central to the application. A good engineer must understand both tools and choose according to the data and access patterns rather than according to popularity.

Python will remain the main programming language throughout the book. You will connect to MongoDB using PyMongo, select databases and collections, insert documents, construct filters, control projections, update selected fields, build aggregation pipelines, create indexes, and inspect operation results. MongoDB query documents and update operators will be written inside Python dictionaries, allowing every exercise to remain part of a real application workflow.

MongoDB is commonly described as schema-less, but this description can be misleading. Documents in one collection may have different fields or shapes, yet the application still depends on assumptions about names, types, nested structures, required values, and versions. If these assumptions are not designed and validated, flexibility becomes inconsistency. This book therefore treats document design as an engineering responsibility rather than permission to store arbitrary data without rules.

The reader will learn through experimentation. You will insert documents with matching and conflicting structures, query missing and optional fields, compare embedded and referenced designs, migrate documents between schema versions, inspect execution plans, and observe how indexes affect performance. Later exercises introduce replica-set and sharding concepts so that

the reader can understand how data behavior changes when one database server becomes a distributed system.

The exercises provide explanations, hints, and incomplete Python skeletons, but not finished solutions. Before executing an operation, predict which documents should match, which fields should change, and what result object PyMongo should return. After execution, inspect both the operation result and the stored documents. A command that completes without an exception may still have matched zero documents or modified the wrong structure.

7.1.2 How MongoDB supports artificial intelligence systems

MongoDB does not train artificial intelligence models and does not calculate neural-network gradients. It supports the application and data layers surrounding those models. An AI system may use MongoDB to store chat messages, session metadata, user preferences, tool-call results, generated content metadata, experiment configurations, model responses, or documents whose fields differ according to their source or type.

Chat applications provide a useful example. Each message may contain a role, text, timestamp, token count, attachments, tool information, or model metadata. These values fit naturally into a document, and additional fields may appear as the system evolves. MongoDB can retrieve recent messages for one session, maintain session activity, expire temporary records, and aggregate message counts. However, the design must still consider ordering, document growth, indexes, retention, and the boundary between one session document and many message documents.

MongoDB will later complement the other data systems in this volume. PostgreSQL can preserve structured users, plans, permissions, and billing relationships. MinIO can store large binary objects such as datasets, images, and model files. Qdrant can store embeddings for semantic retrieval. MongoDB can hold flexible documents and operational context. The objective is not to force all data into one technology, but to understand the responsibility of each component inside a larger artificial intelligence system.

7.1.3 How to approach the exercises

Begin every exercise by describing the expected document shape and access pattern. Decide whether a field is required, optional, nested, repeated as an array, or represented by a reference. Then predict the filter and update behavior before running Python. Afterward, use a separate find operation to verify the final state. This cycle of design, prediction, execution, and verification follows the same experimental learning strategy used in the previous books.

Treat PyMongo result objects as evidence. For insert operations, inspect inserted identifiers. For updates and deletions, distinguish the number of matched documents from the number actually modified or removed. For bulk operations, consider whether ordered execution should stop at the first failure. For queries, define sorting explicitly whenever order matters and request only the fields the application needs.

Keep database addresses and credentials outside the source code, preferably in environment variables. Close clients or use controlled application lifetimes, use timeouts so failed connec-

tions do not wait indefinitely, and avoid storing real secrets in examples or repositories. When an exercise requires replica sets or sharding, use an isolated learning environment because those features require server-side configuration beyond ordinary Python commands.

Do not add an index merely because a field appears in a query. First identify the important read pattern, observe its execution plan, create a candidate index, and measure the result. Every index consumes storage and adds work to writes. Likewise, do not embed or reference documents by habit. Base the decision on ownership, access frequency, update patterns, cardinality, growth, and consistency requirements.

7.1.4 The Chapters (NOSQL00–NOSQL03) included in this book

- NOSQL00 - Document-Based Data Structures
- NOSQL01 - Chat History & Session Memory
- NOSQL02 - Dynamic Storage Models
- NOSQL03 - Scaling with Replica & Sharding

7.1.5 NOSQL00 - Document-Based Data Structures

This chapter introduces databases, collections, and BSON documents through PyMongo. You will create the first collection, insert one or many documents, query with filters, control returned fields with projections, and modify existing data with operators such as `$set`, `$inc`, and `$push`. Safe conditional deletion will reinforce the same verification discipline used with PostgreSQL.

The chapter then moves beyond basic operations into nested-document design and an analysis of schema-less pitfalls. You will observe how inconsistent field names, incompatible types, uncontrolled arrays, and missing assumptions make future queries difficult. By the end, you should be able to perform basic document operations and explain the intended structure of a collection even when MongoDB does not enforce every rule automatically.

7.1.6 NOSQL01 - Chat History & Session Memory

This chapter applies MongoDB to a realistic AI chat scenario. You will design message documents, connect each message to a session, query by session and time, sort messages chronologically, and retrieve a limited history window. These operations form the data foundation for constructing conversation context before a model receives a request.

You will also create a TTL index for expiration, update last-active timestamps, plan an archive strategy, and aggregate message counts per session. The final retrieval pipeline will combine filtering, ordering, limiting, projection, and output preparation. The goal is to understand that session memory is not an unlimited list: it requires retention rules, deterministic ordering, efficient access, and clear separation between active and archived data.

7.1.7 NOSQL02 - Dynamic Storage Models

This chapter studies flexibility as a deliberate design problem. You will handle optional fields, store polymorphic document types, add schema-version fields, and apply partial updates without overwriting unrelated data. Embedded and referenced models will be compared according to how the application reads, writes, owns, and grows its information.

Aggregation with `$group`, migrations between document versions, indexing of dynamic fields, and performance tradeoff evaluation will show the cost of flexibility. By the end of the chapter, you should be able to evolve a collection safely and recognize when variation is meaningful domain structure versus accidental inconsistency.

7.1.8 NOSQL03 - Scaling with Replica & Sharding

This chapter moves from document design on one logical database to the behavior of a distributed MongoDB system. It begins with indexes and query execution plans, providing the performance foundation needed before additional servers are introduced. You will then simulate or inspect replica-set behavior and configure read preference and write concern from Python.

The later exercises examine shard-key selection, chunk distribution, balancer behavior, and the difference between sharding and indexing. Sharding distributes data and workload; it does not repair inefficient queries or replace useful indexes. The chapter concludes with a scalable chat-system design that brings together document structure, access patterns, indexes, replication requirements, shard-key tradeoffs, retention, and failure behavior.

Some exercises in this chapter require multiple MongoDB processes or a configured cluster. Python will still be used to connect, configure supported client behavior, insert test data, and inspect results, but Python cannot replace the server topology itself. The learning environment must therefore be prepared carefully, and every experiment must distinguish client settings from server-side configuration.

7.2 NOSQL00 - Document-Based Data Structures

Data Engineering for AI

7.2.1 Exercise 00 - Create Database and Collection

Part 1 - Why this matters

Every MongoDB application begins by selecting a server, database, and collection. These objects define where documents belong and give Python a stable path through which later inserts, queries, and updates will be executed.

MongoDB creates many resources lazily. Merely obtaining a database or collection object in PyMongo does not necessarily create persistent server metadata, so the reader must verify existence from the server rather than from Python object creation alone.

Part 2 - Technical concept and behavior

`MongoClient` represents access to a MongoDB deployment. Bracket notation selects a database and collection by name. A database normally appears after it contains a collection with stored data, while `create_collection()` can create a collection explicitly. A `ping` command verifies communication with the server.

Part 3 - Hints and Helper

Read the MongoDB URI and names from environment variables. Configure a finite server-selection timeout, ping the server, create the collection only if it is absent, and verify it through `list_collection_names()`.

Part 4 - Python code skeleton

```
import os
from pymongo import MongoClient

def E00(database_name, collection_name):
    client = MongoClient(
        os.getenv(...),
        serverSelectionTimeoutMS=...,
    )
    client.admin.command(...)
    database = client[...]
    if collection_name not in database.list_collection_names():
        database.create_collection(...)
    collections = database.list_collection_names()
    client.close()
    return collections

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

7.2.2 Exercise 01 - Insert Single Document (insertOne)

Part 1 - Why this matters

A single document can preserve related fields, nested values, and arrays as one application record. Inserting one document is the simplest way to observe how a Python dictionary becomes BSON stored by MongoDB.

Verification must use the identifier returned by the server. The stored document may contain an automatically generated `_id`, and checking that record prevents the program from confusing its input dictionary with confirmed database state.

Part 2 - Technical concept and behavior

PyMongo's `insert_one()` sends one mapping to a collection and returns an `InsertOneResult`. If no `_id` is supplied, an identifier is generated. The result's `inserted_id` can be used in `find_one()` to retrieve the stored document.

Part 3 - Hints and Helper

Create a document containing several BSON-compatible types. Insert it, inspect acknowledgement and identifier, retrieve by `_id`, and avoid assuming field order carries application meaning.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
from pymongo import MongoClient

def E01(collection, document):
    result = collection.insert_one(...)
    inserted_id = result.inserted_id
    stored = collection.find_one({"_id": ...})
    return result.acknowledged, inserted_id, stored

def main():
    client = MongoClient(...)
    collection = client[...][...]
    document = {
        "name": ...,
        "active": ...,
        "created_at": datetime.now(timezone.utc),
    }
    print(E01(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.3 Exercise 02 - Insert Multiple Documents (insertMany)

Part 1 - Why this matters

Applications often create batches of events, messages, or imported records. A bulk insert reduces client-server round trips and returns identifiers corresponding to the submitted document order.

Batch failure behavior must be understood. Ordered insertion normally stops at the first failing document, while unordered insertion may continue with independent operations, so verification must inspect what was actually stored rather than treating the batch as automatically atomic.

Part 2 - Technical concept and behavior

`insert_many()` accepts a non-empty iterable of documents and returns `inserted_ids`. The `ordered` option controls whether later inserts are attempted after an error. A bulk operation is not automatically equivalent to a multi-document transaction.

Part 3 - Hints and Helper

Insert a clean batch first and retrieve documents by the returned identifiers. Then use an isolated test collection with a uniqueness rule to compare ordered and unordered failure behavior without contaminating other exercises.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E02(collection, documents, ordered=True):
    if not documents:
        raise ValueError(...)
    result = collection.insert_many(..., ordered=...)
    inserted_ids = result.inserted_ids
    stored = list(collection.find(
        {"_id": {"$in": ...}},
        sort=[("_id", ...)],
    ))
    return inserted_ids, stored

def main():
    client = MongoClient(...)
    collection = client[...][...]
    documents = [{...}, {...}, {...}]
    print(E02(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.4 Exercise 03 - Basic Find Query with Filters

Part 1 - Why this matters

MongoDB filters let an application select documents according to field values, ranges, membership, and logical combinations. Sending the intended filter to the database avoids loading an entire collection and filtering it later in Python.

Document flexibility makes type awareness important. A numeric comparison does not mean the same thing for documents where the field is missing or stored as text, so the reader must inspect the actual matched population.

Part 2 - Technical concept and behavior

`find()` accepts a filter document whose field conditions may use operators such as `$gt`, `$gte`, `$in`, `$and`, and `$or`. Multiple top-level field conditions are combined as a logical AND. The method returns a cursor evaluated as results are consumed.

Part 3 - Hints and Helper

Build filters from controlled Python values, not raw user-supplied operator documents. Combine an equality condition with a numeric range, sort explicitly, materialize the cursor once, and test filters producing many, one, and zero matches.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E03(collection, category, minimum_score):
    query_filter = {
        "category": ...,
        "score": {"$gte": ...},
        "active": ...,
    }
    cursor = collection.find(...).sort([
        ("score", ...),
        ("_id", ...),
    ])
    documents = list(cursor)
    return documents

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E03(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.5 Exercise 04 - Projection: Include / Exclude Fields

Part 1 - Why this matters

An application often needs only part of each document. Projection reduces transferred data and prevents unrelated or sensitive fields from being returned to code that does not require them.

MongoDB distinguishes inclusion and exclusion projection styles. Mixing them incorrectly causes an error or unclear intent, so the reader must design the returned shape as deliberately as the filter.

Part 2 - Technical concept and behavior

An inclusion projection assigns `1` to selected fields, while an exclusion projection assigns `0` to omitted fields. The two styles generally cannot be mixed in one projection, except that `_id` may be excluded from an inclusion projection. Nested fields can be addressed with dot notation.

Part 3 - Hints and Helper

Run one inclusion and one exclusion query against the same filter. Verify keys in every returned document, decide explicitly whether `_id` is required, and avoid using projection as a substitute for access control.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E04(collection, query_filter):
    include_projection = {
        "_id": ...,
        "name": ...,
        "profile.region": ...,
    }
    exclude_projection = {
        "secret": ...,
        "internal_notes": ...,
    }
    included = list(collection.find(..., ...))
    excluded = list(collection.find(..., ...))
    return included, excluded

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E04(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.6 Exercise 05 - Update Document with $set

Part 1 - Why this matters

Replacing an entire document to change one field can accidentally remove fields added by another part of the application. Targeted update operators express exactly which values should change while leaving the rest of the document untouched.

The operation result distinguishes matching from modification. A filter may find a document whose field already contains the requested value, producing one match but zero modifications, which is different from matching no document at all.

Part 2 - Technical concept and behavior

`update_one(filter, update)` updates at most one matching document. The `$set` operator assigns values to selected fields and can target nested paths with dot notation. `matched_count` reports matches, while `modified_count` reports actual changes.

Part 3 - Hints and Helper

Require a specific identifier or another unique condition. Use `$set` for one top-level and one nested field, inspect both counts, then retrieve the document to verify that unrelated fields remain.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E05(collection, document_id, new_status, new_region):
    query_filter = {"_id": ...}
    update = {
        "$set": {
            "status": ...,
            "profile.region": ...,
        }
    }
    result = collection.update_one(..., ...)
    stored = collection.find_one(query_filter)
    return result.matched_count, result.modified_count, stored

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E05(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.7 Exercise 06 - Update with $inc and $push

Part 1 - Why this matters

Counters and arrays are common inside document-based applications. Reading a counter into Python, changing it, and writing it back creates unnecessary race opportunities, while replacing an array can discard elements written by another request.

MongoDB update operators perform these changes on the server. The reader will increment a numeric field and append an array element in one update, then examine type and growth risks rather than assuming every document can accept the operation.

Part 2 - Technical concept and behavior

`$inc` adds a numeric amount to a numeric field and can create a missing field with that amount. `$push` appends an element to an array and can create a missing array field. Both can fail when an existing field has an incompatible type. Unbounded arrays can also cause documents to grow excessively.

Part 3 - Hints and Helper

Use one `update_one()` call containing both operators. Verify counts and final values, test an incompatible field type in an isolated document, and consider `$each` with `$slice` when the application requires a bounded array.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
from pymongo import MongoClient

def E06(collection, document_id, increment, event):
    update = {
        "$inc": {"usage_count": ...},
        "$push": {
            "events": {
                "$each": [...],
                "$slice": ...,
            }
        },
        "$set": {"updated_at": datetime.now(timezone.utc)},
    }
    result = collection.update_one({"_id": ...}, update)
    stored = collection.find_one({"_id": ...})
    return result.matched_count, result.modified_count, stored

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E06(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.8 Exercise 07 - Delete Document with Condition

Part 1 - Why this matters

Deletion removes persistent information and must be scoped more carefully than an ordinary read. A broad or empty filter can remove an unintended document, while a weak condition can delete a valid record that merely shares one field.

This challenge treats deletion as a verified operation. The reader will preview one specific target, delete with the same condition, inspect `deleted_count`, and confirm that neighboring documents remain.

Part 2 - Technical concept and behavior

`delete_one(filter)` removes at most one matching document and returns a `DeleteResult`. If several documents match, which one is removed should not be relied upon without a unique filter. A count of zero means no document matched at deletion time.

Part 3 - Hints and Helper

Reject an empty filter in Python. Require `_id` plus an expected state, preview with `find_one()`, perform the deletion, and verify both absence of the target and preservation of collection count expectations.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E07(collection, document_id, expected_status):
    query_filter = {
        "_id": ...,
        "status": ...,
    }
    if not query_filter:
        raise ValueError(...)
    preview = collection.find_one(query_filter)
    if preview is None:
        return ...
    result = collection.delete_one(query_filter)
    verification = collection.find_one({"_id": ...})
    return preview, result.deleted_count, verification

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E07(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.9 Exercise 08 - Nested Document Design Challenge

Part 1 - Why this matters

Nested documents keep values together when they belong to one conceptual object, such as a user's profile, model configuration, or request metadata. This can make one-document reads natural and preserve the structure already used by Python.

Nesting is not automatically correct for every relationship. Deep structures, frequently changing shared values, and uncontrolled embedded arrays can make updates and indexes difficult, so the reader must justify the boundary of each embedded object.

Part 2 - Technical concept and behavior

BSON documents can contain other documents and arrays. Dot notation addresses nested paths in filters, projections, updates, and indexes. Embedding is most suitable when nested data is owned by the parent, commonly read with it, and bounded in size.

Part 3 - Hints and Helper

Design a document containing profile, preferences, and bounded model settings. Insert it, query by a nested field, project selected nested values, and update one nested path without replacing the parent object.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E08(collection, user_id):
    document = {
        "user_id": ...,
        "profile": {
            "name": ...,
            "region": ...,
        },
        "preferences": {
            "language": ...,
            "notifications": {...},
        },
        "model_settings": {...},
    }
    inserted = collection.insert_one(...)
    matched = collection.find_one(
        {"profile.region": ...},
        {"profile.name": 1, "preferences.language": 1},
    )
    updated = collection.update_one(
        {"_id": inserted.inserted_id},
        {"$set": {"preferences.language": ...}},
    )
    return inserted.inserted_id, matched, updated.modified_count

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E08(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.2.10 Exercise 09 - Schema-less Design Pitfall Analysis

Part 1 - Why this matters

Allowing every document to take an unrelated shape moves complexity into every query and update. Misspelled fields, mixed numeric and string types, inconsistent date formats, and missing version information can silently divide one logical collection into incompatible populations.

The final challenge asks the reader to discover and classify inconsistency before repairing it. The goal is to understand that flexible schema supports controlled evolution, while uncontrolled variation creates hidden data debt.

Part 2 - Technical concept and behavior

MongoDB filters such as `$exists` and `$type` can identify missing or incompatible fields. Aggregation can count shapes or types across a collection. Collection validators can enforce selected rules for future writes, but existing data may require migration before stronger validation is introduced.

Part 3 - Hints and Helper

Create isolated documents containing deliberate field-name, type, and nesting inconsistencies. Produce a report before changing data, define one canonical shape, migrate carefully, and verify that the number of repaired documents matches expectations.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E09(collection):
    missing_field = list(collection.find({"required_field": {"$exists": ...}}))
    wrong_type = list(collection.find({"score": {"$not": {"$type": ...}}}))
    type_pipeline = [
        {"$project": {"observed_type": {"$type": "$score"}}},
        {"$group": {"_id": "$observed_type", "count": {"$sum": 1}}},
        {"$sort": {"count": -1}},
    ]
    type_report = list(collection.aggregate(...))
    migration_result = collection.update_many(..., ...)
    return {
        "missing": missing_field,
        "wrong_type": wrong_type,
        "types": type_report,
        "migrated": migration_result.modified_count,
    }

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E09(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3 NOSQL01 - Chat History & Session Memory

Data Engineering for AI

7.3.1 Exercise 00 - Design Chat Message Document Structure

Part 1 - Why this matters

Chat memory begins with a document structure that can preserve message identity, session membership, speaker role, content, and time. These fields determine whether an application can reconstruct context accurately and distinguish user messages from model or tool outputs.

The design must remain useful as message metadata evolves. Optional token counts, model names, attachments, and tool-call details should not make basic retrieval ambiguous, while uncontrolled embedded histories must not cause one session document to grow without bound.

Part 2 - Technical concept and behavior

This chapter models each message as a separate document linked by `session_id`. Core fields include a stable identifier, role, content, creation timestamp, and optional sequence number or metadata subdocument. Separate message documents support independent insertion, indexing, retention, and pagination.

Part 3 - Hints and Helper

Write the field contract before inserting data. Validate allowed roles and timezone-aware timestamps in Python, keep optional metadata nested, and include a deterministic tie-breaker for messages sharing the same timestamp.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

def E00(session_id, role, content, sequence, metadata=None):
    allowed_roles = {...}
    if role not in allowed_roles:
        raise ValueError(...)
    if ...:
        raise ValueError(...)
    document = {
        "session_id": ...,
        "role": ...,
        "content": ...,
        "sequence": ...,
        "created_at": datetime.now(timezone.utc),
        "metadata": metadata or {},
        "schema_version": ...,
    }
    return document

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

7.3.2 Exercise 01 - Insert Chat Messages with Session ID

Part 1 - Why this matters

Every message must be assigned to the correct conversation. A missing or incorrect session identifier can mix unrelated histories and send another user's context to the model, making session association both a correctness and privacy concern.

This exercise inserts messages through one controlled Python function and verifies them by returned identifiers. It also considers duplicate retries, because a network retry should not silently create the same logical message twice.

Part 2 - Technical concept and behavior

PyMongo stores the message document with `insert_one()`. A unique client-generated message identifier can provide idempotency across retries. An index on session and ordering fields supports later retrieval, while uniqueness on an idempotency key prevents duplicate logical events.

Part 3 - Hints and Helper

Confirm that required fields exist before insertion. Include `session_id` and a unique message key, inspect `inserted_id`, then retrieve by both identifiers to prove the document belongs to the intended session.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E01(collection, message_document):
    required_fields = {...}
    if ...:
        raise ValueError(...)
    result = collection.insert_one(...)
    stored = collection.find_one({
        "_id": result.inserted_id,
        "session_id": message_document["session_id"],
    })
    return result.inserted_id, stored

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E01(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.3 Exercise 02 - Query Messages by Session and Time

Part 1 - Why this matters

An AI application may need only the messages from one session and one time window. Filtering at the database prevents unrelated conversations from entering model context and

avoids transferring a complete message collection into Python.

Time boundaries must be explicit. Half-open intervals prevent one message at a boundary from appearing in two adjacent windows, and timezone-aware values prevent local-time assumptions from changing the meaning of the query.

Part 2 - Technical concept and behavior

The filter combines exact `session_id` equality with a timestamp condition using `$gte` for the start and `$lt` for the end. BSON dates represent instants at millisecond precision. A compound index can support both session selection and chronological range access.

Part 3 - Hints and Helper

Require timezone-aware Python datetimes and validate that start precedes end. Use one filter document, return only message fields needed by the caller, and verify boundary messages deliberately.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E02(collection, session_id, start_time, end_time):
    if ...:
        raise ValueError(...)
    query_filter = {
        "session_id": ...,
        "created_at": {
            "$gte": ...,
            "$lt": ...,
        },
    }
    projection = {...}
    messages = list(collection.find(query_filter, projection))
    return messages

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E02(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.4 Exercise 03 - Sort Messages Chronologically

Part 1 - Why this matters

Conversation meaning depends on order. Returning the correct messages in an unstable sequence can reverse questions and answers, place tool output before its call, or construct invalid

model context.

A timestamp alone may not provide a total order when several messages share its stored precision. The reader must add a deterministic tie-breaker and verify that repeated retrieval returns the same sequence.

Part 2 - Technical concept and behavior

PyMongo cursors use `sort()` with one or more field-direction pairs. Ascending `created_at` provides chronological order, while a sequence number or unique identifier resolves ties. The index order should follow the important equality and sorting pattern.

Part 3 - Hints and Helper

Filter by one session, sort by timestamp and sequence, and insert test messages sharing a timestamp. Compare the returned sequence across repeated executions and inspect the query pattern needed by a compound index.

Part 4 - Python code skeleton

```
from pymongo import ASCENDING, MongoClient

def E03(collection, session_id):
    cursor = collection.find(
        {"session_id": ...},
        {...},
    ).sort([
        ("created_at", ASCENDING),
        ("sequence", ASCENDING),
        ("_id", ASCENDING),
    ])
    messages = list(cursor)
    sequence_values = [...]
    is_ordered = ...
    return messages, is_ordered

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E03(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.5 Exercise 04 - Limit Chat History per Session

Part 1 - Why this matters

Sending an entire long conversation to a model increases latency, token use, and cost, and may exceed the model's context capacity. A retrieval limit gives the application a controlled

recent-memory window.

The latest messages are commonly fetched in reverse order for efficiency, but model context usually requires chronological order. The reader must distinguish database retrieval order from the final order presented to the application.

Part 2 - Technical concept and behavior

The query filters one session, sorts newest first, and applies `limit(n)`. Python then reverses the small result list to restore chronological order. The limit controls document count, not token count, so later systems may require an additional token-budget step.

Part 3 - Hints and Helper

Reject non-positive limits. Sort by timestamp and deterministic tie-breakers in descending order, limit on the server, reverse once in Python, and verify the returned set contains the newest n messages in oldest-to-newest order.

Part 4 - Python code skeleton

```
from pymongo import DESCENDING, MongoClient

def E04(collection, session_id, history_limit):
    if ...:
        raise ValueError(...)
    newest_first = list(
        collection.find({"session_id": ...}, {...})
        .sort([
            ("created_at", DESCENDING),
            ("sequence", DESCENDING),
            ("_id", DESCENDING),
        ])
        .limit(...)
    )
    chronological = ...
    return chronological

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E04(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.6 Exercise 05 - Session Expiration using TTL Index

Part 1 - Why this matters

Temporary sessions should not remain forever when retention rules say they are no longer needed. Automatic expiration reduces stale data and cleanup code, but it must be designed around the correct date field and must not be mistaken for exact scheduling.

TTL deletion is performed asynchronously by MongoDB. An expired document may remain visible briefly, so application correctness or immediate access revocation must not depend only on the background deletion time.

Part 2 - Technical concept and behavior

A TTL index is a special single-field index on a BSON date field. With `expireAfterSeconds`, MongoDB considers documents eligible after the indexed time plus the configured duration. TTL indexes do not provide immediate deletion and unsuitable or missing field values may not expire as expected.

Part 3 - Hints and Helper

Use a dedicated sessions collection and timezone-aware expiration dates. Create the TTL index through PyMongo, inspect its metadata, insert an already expired test session, and poll with a reasonable deadline rather than assuming instant removal.

Part 4 - Python code skeleton

```
import time
from pymongo import ASCENDING, MongoClient

def E05(sessions, expire_after_seconds, deadline_seconds):
    index_name = sessions.create_index(
        [("expires_at", ASCENDING)],
        expireAfterSeconds=...,
        name=...,
    )
    index_info = sessions.index_information()[index_name]
    test_id = sessions.insert_one({...}).inserted_id
    deadline = time.monotonic() + deadline_seconds
    while time.monotonic() < deadline:
        if sessions.find_one({"_id": test_id}) is None:
            return index_info, ...
        ...
    return index_info, ...

def main():
    client = MongoClient(...)
    sessions = client[...][...]
    print(E05(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.7 Exercise 06 - Update Last-Active Timestamp

Part 1 - Why this matters

The last-active time supports expiration, monitoring, and the identification of currently used sessions. Concurrent requests may finish out of order, so blindly setting the field can allow an older event to overwrite a newer timestamp.

This exercise updates activity without moving time backward. It also verifies whether the session existed and whether the stored value changed, preserving the distinction between a missing session and an already newer timestamp.

Part 2 - Technical concept and behavior

The `$max` update operator changes a field only when the proposed value compares greater than the current value. With consistent BSON date types, this supports monotonic last-active timestamps. `matched_count` may be one while `modified_count` is zero for an older proposal.

Part 3 - Hints and Helper

Require a timezone-aware timestamp. Apply `$max` to one uniquely identified session, return the result counts, and test updates in newer-then-older order to prove the stored timestamp does not regress.

Part 4 - Python code skeleton

```
from pymongo import MongoClient, ReturnDocument

def E06(sessions, session_id, activity_time):
    if ...:
        raise ValueError(...)
    document = sessions.find_one_and_update(
        {"session_id": ...},
        {"$max": {"last_active_at": ...}},
        return_document=ReturnDocument.AFTER,
    )
    if document is None:
        return ...
    return document["last_active_at"]

def main():
    client = MongoClient(...)
    sessions = client[...][...]
    print(E06(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.8 Exercise 07 - Archive Old Sessions Strategy

Part 1 - Why this matters

Inactive sessions may need to leave the operational collection without being destroyed. Archiving reduces the active working set while preserving records required for analysis, support, or policy-defined retention.

Copying and deleting are separate risks. The strategy must be restartable, avoid duplicate archive records, verify successful copies before deletion, and define what happens when new messages arrive during archival.

Part 2 - Technical concept and behavior

An archive workflow selects sessions older than a cutoff, writes them to an archive collection using a stable unique key, verifies the archived set, and then deletes only confirmed source records. Multi-document transactions require a supported deployment such as a replica set; otherwise the workflow must use idempotency and recoverable phases.

Part 3 - Hints and Helper

Process a bounded batch. Use upserts keyed by session identity, record archive metadata, compare expected and confirmed identifiers, and construct the source deletion filter from confirmed IDs rather than repeating only the original age condition.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
from pymongo import MongoClient, UpdateOne

def E07(active_sessions, archive_sessions, cutoff, batch_size):
    candidates = list(
        active_sessions.find({"last_active_at": {"$lt": ...}})
        .sort("last_active_at", 1)
        .limit(...)
    )
    operations = [
        UpdateOne(
            {"session_id": document["session_id"]},
            {"$setOnInsert": {...}, "$set": {"archived_at": ...}},
            upsert=True,
        )
        for document in candidates
    ]
    archive_result = archive_sessions.bulk_write(..., ordered=...)
    confirmed_ids = [...]
    delete_result = active_sessions.delete_many({"session_id": {"$in": ...}})
    return archive_result, delete_result.deleted_count

def main():
    client = MongoClient(...)
```

```
    print(E07(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.9 Exercise 08 - Aggregation: Messages Count per Session

Part 1 - Why this matters

Counting messages per session supports monitoring, retention decisions, debugging, and identification of unusually large conversations. Performing the grouping in MongoDB avoids retrieving every message merely to count it in Python.

A useful summary may need a time filter and additional measures such as first and last message time. The reader must recognize that sessions with zero messages do not appear when aggregation starts from the messages collection.

Part 2 - Technical concept and behavior

An aggregation pipeline passes documents through ordered stages. `$match` restricts the input population, `$group` collects documents by `session_id`, and `$sort` orders summary documents. Accumulators such as `$sum`, `$min`, and `$max` calculate group values.

Part 3 - Hints and Helper

Place a selective time filter before grouping. Return session ID, count, first time, and last time, then sort by count and session ID. Compare the total of group counts with a direct count over the same filter.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E08(messages, start_time, end_time):
    pipeline = [
        {"$match": {
            "created_at": {"$gte": ..., "$lt": ...},
        }},
        {"$group": {
            "_id": "$session_id",
            "message_count": {"$sum": 1},
            "first_message_at": {"$min": "$created_at"},
            "last_message_at": {"$max": "$created_at"},
        }},
        {"$sort": {"message_count": -1, "_id": 1}},
    ]
    summary = list(messages.aggregate(...))
    verification_count = messages.count_documents(...)
    return summary, verification_count
```

```
def main():
    client = MongoClient(...)
    messages = client[...][...]
    print(E08(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.3.10 Exercise 09 - Session Memory Retrieval Pipeline

Part 1 - Why this matters

A model should receive a controlled and correctly ordered context, not a raw dump of every stored message. The retrieval pipeline must isolate one session, exclude unusable records, select required fields, take the newest permitted window, and return it chronologically.

This final challenge combines document design, filtering, sorting, projection, and limiting. It also preserves a boundary between database retrieval and later token-budget or prompt-formatting logic.

Part 2 - Technical concept and behavior

The aggregation pipeline uses `$match`, descending `$sort`, `$limit`, and `$project`. A final ascending sort can restore chronological order within MongoDB after the newest window is selected. Stable tie-breakers are required in both ordering stages.

Part 3 - Hints and Helper

Validate the history limit and session identity. Match allowed roles and usable content, select the newest messages first, then reorder only that selected window. Return plain Python records suitable for a later model-input formatter.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E09(messages, session_id, history_limit, allowed_roles):
    if ...:
        raise ValueError(...)
    pipeline = [
        {"$match": {
            "session_id": ...,
            "role": {"$in": ...},
            "content": {"$type": "string", "$ne": ""},
        }},
        {"$sort": {"created_at": -1, "sequence": -1, "_id": -1}},
        {"$limit": ...},
        {"$sort": {"created_at": 1, "sequence": 1, "_id": 1}},
        {"$project": {
            "_id": 0,
```

```
            "role": 1,
            "content": 1,
            "created_at": 1,
            "metadata": 1,
        }},
    ]
    context = list(messages.aggregate(...))
    return context

def main():
    client = MongoClient(...)
    messages = client[...][...]
    print(E09(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4 NOSQL02 - Dynamic Storage Models

Data Engineering for AI

7.4.1 Exercise 00 - Flexible Document Schema Design

Part 1 - Why this matters

Flexible documents allow an application to store records whose optional details differ without creating a column for every possible variation. This is useful for model configurations, tool results, events, and metadata produced by several sources.

Flexibility still requires a stable contract. Identifiers, document type, timestamps, and schema version should remain predictable, while variation should be placed in deliberate nested areas rather than spread across misspelled or incompatible top-level fields.

Part 2 - Technical concept and behavior

A flexible design separates common fields from a type-specific payload. MongoDB permits different document shapes in one collection, and optional collection validation can enforce selected common rules. The design should support known queries and updates while allowing controlled extension.

Part 3 - Hints and Helper

Define required common fields and a bounded payload structure. Create several valid variations, inspect their shapes, and reject documents missing the core contract in Python before considering server-side validation.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

def E00(document_type, owner_id, payload):
    allowed_types = {...}
    if document_type not in allowed_types:
        raise ValueError(...)
    if not isinstance(payload, dict):
        raise TypeError(...)
    document = {
        "document_type": ...,
        "owner_id": ...,
        "schema_version": ...,
        "created_at": datetime.now(timezone.utc),
        "payload": ...,
    }
    required_fields = {...}
    is_valid = ...
    return document, is_valid

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

7.4.2 Exercise 01 - Optional Fields Handling

Part 1 - Why this matters

An optional field may be absent because it does not apply, unknown because its value has not arrived, or explicitly set to null. Collapsing these states without thought can change query results and cause Python to confuse missing information with a meaningful empty value.

This exercise makes each state observable. The reader will query missing, null, and present values separately, then normalize application output without overwriting the original database meaning.

Part 2 - Technical concept and behavior

`$exists` tests whether a field is present. A query for `None` can match explicit null values and, in common equality behavior, documents where the field is absent. Combining existence and type conditions provides more precise populations. Python dictionaries distinguish a missing key from a key whose value is `None`.

Part 3 - Hints and Helper

Insert three isolated documents representing absent, null, and populated states. Query each category explicitly, use `dict.get()` only when its collapsing behavior is intended, and report the original state beside any fallback value.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E01(collection, field_name, fallback):
    missing_filter = {field_name: {"$exists": ...}}
    explicit_null_filter = {
        "$and": [
            {field_name: None},
            {field_name: {"$exists": ...}},
        ]
    }
    present_filter = {field_name: {"$exists": ...}}
    missing = list(collection.find(missing_filter))
    explicit_null = list(collection.find(explicit_null_filter))
    present = list(collection.find(present_filter))
    normalized = [...]
    return missing, explicit_null, present, normalized

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E01(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.3 Exercise 02 - Polymorphic Documents in One Collection

Part 1 - Why this matters

One collection may hold related records with different type-specific fields, such as text, image, and tool-result events. Keeping them together can simplify chronological retrieval when they share ownership, lifecycle, and access patterns.

Polymorphism becomes dangerous when the application must guess a document's type from whichever fields happen to exist. An explicit discriminator allows validation, querying, and Python processing to branch intentionally.

Part 2 - Technical concept and behavior

A discriminator such as `document_type` identifies the variant. Common fields remain stable, while each type owns a defined payload contract. Queries can filter one variant, and compound or partial indexes can support important type-specific access patterns.

Part 3 - Hints and Helper

Define at least three variants with shared metadata. Validate required payload keys according to the discriminator, insert examples, and query each type without relying on field-existence guessing.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def validate_document(document):
    document_type = document.get(...)
    rules = {
        "text": {...},
        "image": {...},
        "tool_result": {...},
    }
    if document_type not in rules:
        return ...
    required_payload_fields = rules[document_type]
    return ...

def E02(collection, documents, requested_type):
    valid_documents = [document for document in documents if ...]
    result = collection.insert_many(...)
    selected = list(collection.find({"document_type": ...}))
    return result.inserted_ids, selected

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E02(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.4 Exercise 03 - Versioned Document Schema Strategy

Part 1 - Why this matters

Application requirements evolve, and a collection may temporarily contain documents written by several software versions. Without an explicit schema version, readers must infer structure from fields and cannot distinguish intentional old shapes from corrupted data.

Versioning makes change visible. Python can route each document through the correct reader or migration path, while new writes use the latest contract without requiring every old document to change immediately.

Part 2 - Technical concept and behavior

A numeric `schema_version` records the document contract version. Read-time adapters can normalize older documents in memory, while write-time migrations persist the new shape. Migrations should advance in ordered steps and remain safe when retried.

Part 3 - Hints and Helper

Define versions 1 and 2 with one meaningful structural difference. Write a dispatcher that rejects unknown future versions, adapts version 1 without mutating the retrieved input, and leaves version 2 unchanged.

Part 4 - Python code skeleton

```
from copy import deepcopy

CURRENT_VERSION = ...

def adapt_v1_to_v2(document):
    adapted = deepcopy(document)
    adapted[...] = ...
    adapted.pop(..., None)
    adapted["schema_version"] = ...
    return adapted

def E03(document):
    version = document.get("schema_version", ...)
    if version == ...:
        normalized = adapt_v1_to_v2(...)
    elif version == CURRENT_VERSION:
        normalized = deepcopy(...)
    else:
        raise ValueError(...)
    return normalized

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

7.4.5 Exercise 04 - Partial Updates without Overwrite

Part 1 - Why this matters

Replacing a document with a partial Python payload can erase fields that the caller did not load or does not own. This becomes especially dangerous in flexible schemas where different components manage different nested values.

Targeted operators allow the application to state which paths should change, be removed, or be initialized. The reader will compare a safe path update with accidental replacement of an entire nested object.

Part 2 - Technical concept and behavior

`$set` changes named fields, `$unset` removes named fields, and dot notation targets nested paths without replacing their sibling fields. Setting a whole embedded document replaces that embedded value, so update granularity must match ownership.

Part 3 - Hints and Helper

Start with a nested document containing several sibling fields. Apply a patch represented by approved paths, reject protected fields such as `_id`, update through `update_one()`, and compare the complete document before and after.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E04(collection, document_id, set_fields, unset_fields):
    protected_paths = {...}
    if ...:
        raise ValueError(...)
    update = {}
    if set_fields:
        update["$set"] = ...
    if unset_fields:
        update["$unset"] = {field: "" for field in ...}
    before = collection.find_one({"_id": ...})
    result = collection.update_one({"_id": ...}, update)
    after = collection.find_one({"_id": ...})
    return before, result.modified_count, after

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E04(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.6 Exercise 05 - Embedded vs Referenced Documents

Part 1 - Why this matters

Embedding keeps related data in one document, while referencing stores it separately and connects it with identifiers. The choice affects read count, update duplication, document growth, consistency, and the ability to share one record among many parents.

There is no universal winner. The reader must base the decision on ownership, cardinality, access patterns, update frequency, and size rather than translating a relational design mechanically into MongoDB.

Part 2 - Technical concept and behavior

Embedded data can be read atomically with its parent and is suitable for owned, bounded substructures. References are useful when data is shared, independently updated, large, or unbounded. MongoDB aggregation can resolve references with `$lookup`, but this adds query work and does not create a foreign-key constraint.

Part 3 - Hints and Helper

Model the same small scenario both ways. Implement one read and one update for each design, count database operations, inspect duplicated data, and write a decision supported by the scenario's expected growth and access pattern.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E05(embedded_collection, parent_collection, child_collection, parent_id):
    embedded_result = embedded_collection.find_one({"_id": ...})
    referenced_pipeline = [
        {"$match": {"_id": ...}},
        {"$lookup": {
            "from": ...,
            "localField": ...,
            "foreignField": ...,
            "as": ...,
        }},
    ]
    referenced_result = list(parent_collection.aggregate(...))
    comparison = {
        "embedded_reads": ...,
        "referenced_reads": ...,
        "duplication": ...,
        "growth_risk": ...,
    }
    return embedded_result, referenced_result, comparison

def main():
    client = MongoClient(...)
    print(E05(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.7 Exercise 06 - Aggregation Pipeline with $group

Part 1 - Why this matters

Dynamic documents often need summaries by type, owner, status, or another shared field. Aggregation allows MongoDB to transform varied documents into consistent analytical results without transferring every source record to Python.

Grouping exposes design inconsistencies as well as useful totals. Missing fields, null values, and incompatible numeric types can create unexpected groups or affect accumulators, so the reader must inspect input quality before trusting the summary.

Part 2 - Technical concept and behavior

An aggregation pipeline processes ordered stages. `$match` selects relevant documents, `$group` creates groups using an `_id` expression, and accumulators calculate count, sum, average, minimum, or maximum. Later stages can project and sort the summaries.

Part 3 - Hints and Helper

Filter to one schema version and numeric type before grouping. Group by a discriminator and status, calculate count and total, rename the group key with `$project`, and compare summed group counts with a direct document count.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E06(collection, schema_version):
    pipeline = [
        {"$match": {
            "schema_version": ...,
            "payload.value": {"$type": ...},
        }},
        {"$group": {
            "_id": {
                "type": "$document_type",
                "status": "$status",
            },
            "document_count": {"$sum": 1},
            "total_value": {"$sum": "$payload.value"},
            "average_value": {"$avg": "$payload.value"},
        }},
        {"$project": {...}},
        {"$sort": {...}},
    ]
    summary = list(collection.aggregate(...))
    return summary

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E06(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.8 Exercise 07 - Data Migration between Schema Versions

Part 1 - Why this matters

When a document contract changes, old records do not update themselves. A migration must transform existing documents without skipping records, corrupting already migrated data, or becoming unsafe when interrupted and restarted.

This exercise treats migration as a controlled batch process. The reader will filter by the exact source version, update only expected shapes, record progress, and verify source and target version counts after each batch.

Part 2 - Technical concept and behavior

An idempotent migration changes documents only when `schema_version` equals the source version. Update pipelines or bulk operations can rename, derive, set, and unset fields. Bounded batches reduce operational impact and allow progress to be resumed.

Part 3 - Hints and Helper

Write the transformation as one version step. Select a stable batch by identifiers, include the old version in every update filter, advance the version only with the successful transformation, and run the migration twice to test idempotency.

Part 4 - Python code skeleton

```
from pymongo import MongoClient, UpdateOne

def E07(collection, source_version, target_version, batch_size):
    candidates = list(
        collection.find(
            {"schema_version": ...},
            {...},
        ).sort("_id", 1).limit(...)
    )
    operations = []
    for document in candidates:
        transformed_fields = ...
        operations.append(UpdateOne(
            {"_id": document["_id"], "schema_version": source_version},
            {"$set": {...}, "$unset": {...}},
        ))
    result = collection.bulk_write(..., ordered=...)
    remaining = collection.count_documents({"schema_version": source_version})
    migrated = collection.count_documents({"schema_version": target_version})
    return result.modified_count, remaining, migrated

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E07(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.4.9 Exercise 08 - Indexing Strategy for Dynamic Fields

Part 1 - Why this matters

Dynamic fields make it tempting to index every possible path, but excessive indexes consume storage, slow writes, and may still fail to support the actual query shape. Index strategy must begin with observed filters and sorts.

Different index types handle variation differently. The reader will compare a focused compound index, a partial index for one document subtype, and a wildcard-index candidate, then inspect which execution plan MongoDB actually selects.

Part 2 - Technical concept and behavior

A compound index supports a known field sequence. A partial index stores entries only for documents matching a filter, while a sparse index omits documents missing the indexed field. A wildcard index can cover many dynamic paths but may cost more and be less focused than workload-specific indexes.

Part 3 - Hints and Helper

Start from three concrete query patterns. Create one candidate at a time in an isolated collection, call `explain()` on matching queries, inspect key and document counts, and record write and storage tradeoffs.

Part 4 - Python code skeleton

```
from pymongo import ASCENDING, MongoClient

def E08(collection, document_type, dynamic_value):
    focused_name = collection.create_index([
        ("document_type", ASCENDING),
        ("payload.dynamic_field", ASCENDING),
    ], name=...)
    partial_name = collection.create_index(
        [("payload.special_field", ASCENDING)],
        partialFilterExpression={"document_type": ...},
        name=...,
    )
    plan = collection.find({
        "document_type": ...,
        "payload.dynamic_field": ...,
    }).explain()
    indexes = collection.index_information()
    return focused_name, partial_name, plan, indexes

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E08(...))
    client.close()
```

```
if __name__ == "__main__":
    main()
```

7.4.10 Exercise 09 - Performance Tradeoff Evaluation

Part 1 - Why this matters

Document design changes read latency, write cost, storage size, network transfer, and migration complexity. A design that makes one query fast may duplicate data or make updates expensive, so performance conclusions require several measures and a stated workload.

The final exercise compares two storage models under controlled conditions. The reader must keep data volume and requested output equivalent, repeat measurements, inspect execution statistics, and avoid declaring a universal winner from one timing.

Part 2 - Technical concept and behavior

Evaluation can compare execution time, documents examined, keys examined, returned-document size, write operations, and index storage. Cache state and dataset size influence observed latency. Functional correctness and operational complexity remain part of the tradeoff even when one path is faster.

Part 3 - Hints and Helper

Define one read-heavy and one update scenario for embedded and referenced designs. Run warm-up and measured trials, collect plans, use equivalent filters and projections, summarize several runs, and document limitations of the experiment.

Part 4 - Python code skeleton

```
from statistics import median
from time import perf_counter
from pymongo import MongoClient

def measure(operation, repetitions):
    timings = []
    for _ in range(repetitions):
        started = perf_counter()
        result = operation()
        timings.append(perf_counter() - started)
    return {"median": median(timings), "runs": timings, "result": result}

def E09(embedded_operation, referenced_operation, repetitions):
    if ...:
        raise ValueError(...)
    embedded = measure(...)
    referenced = measure(...)
    comparison = {
        "embedded": embedded,
        "referenced": referenced,
```

```
        "execution_plans": ...,
        "documents_examined": ...,
        "write_tradeoff": ...,
    }
    return comparison

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

7.5 NOSQL03 - Scaling with Replica & Sharding

Data Engineering for AI

7.5.1 Exercise 00 - Create Index for High-Read Query

Part 1 - Why this matters

A frequently executed chat query can become expensive as message volume grows. An index can reduce examined documents and avoid an in-memory sort, but only when its fields and order match the query's equality, range, and sorting pattern.

Scaling begins by improving access on the current data model. Adding replicas or shards before understanding the query may distribute inefficient work instead of removing it.

Part 2 - Technical concept and behavior

For a query that filters by `session_id` and sorts recent messages by time, a compound index can place the equality field first and ordering fields afterward. The index also adds storage and write maintenance cost, so it should be justified by a high-read workload.

Part 3 - Hints and Helper

Write the target query first. Capture its plan, create one named compound index through PyMongo, run the same query again, and inspect keys examined, documents examined, and whether a blocking sort remains.

Part 4 - Python code skeleton

```
from pymongo import ASCENDING, DESCENDING, MongoClient

def E00(collection, session_id):
    target_filter = {"session_id": ...}
    sort_specification = [
        ("created_at", DESCENDING),
        ("sequence", DESCENDING),
    ]
    before = collection.database.command(...)
```

```
    index_name = collection.create_index([
        ("session_id", ASCENDING),
        ("created_at", DESCENDING),
        ("sequence", DESCENDING),
    ], name=...)
    after = collection.database.command(...)
    return index_name, before, after

def main():
    client = MongoClient(...)
    collection = client[...][...]
    print(E00(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.2 Exercise 01 - Explain Query Execution Plan

Part 1 - Why this matters

An execution plan reveals how MongoDB answered a query rather than how the developer hoped it would. It can show collection scans, index scans, document fetches, sorting, examined records, and differences between estimated access and actual execution.

The reader must interpret evidence instead of searching only for the word "index." An index scan can still examine too many keys, and a collection scan may be reasonable for a tiny or non-selective dataset.

Part 2 - Technical concept and behavior

The `explain` command can return planner information or execution statistics. Important values include winning plan stages, returned documents, total keys examined, and total documents examined. Sharded explain output may include plans from multiple shards.

Part 3 - Hints and Helper

Use the database `explain` command with a safe find operation and execution-statistics verbosity. Write a recursive helper that searches nested plan structures rather than assuming all fields occur at one fixed path.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def collect_stages(node, stages=None):
    stages = stages or []
    if isinstance(node, dict):
        if "stage" in node:
            stages.append(node["stage"])
        for value in node.values():
```

```
            collect_stages(value, stages)
    elif isinstance(node, list):
        for value in node:
            collect_stages(value, stages)
    return stages

def E01(collection, query_filter):
    command = {
        "find": collection.name,
        "filter": ...,
        "sort": {...},
        "limit": ...,
    }
    explanation = collection.database.command(
        "explain", command, verbosity=...,
    )
    stages = collect_stages(...)
    statistics = ...
    return stages, statistics, explanation

def main():
    client = MongoClient(...)
    print(E01(client[...][...], ...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.3 Exercise 02 - Replica Set Concept Simulation

Part 1 - Why this matters

A replica set maintains copies of data across members and can elect a new primary when the current primary becomes unavailable. This improves availability and supports configurable durability, but it does not eliminate replication delay or application retry requirements.

This exercise observes topology rather than pretending one standalone server is a replica set. The reader will connect to an isolated replica-set deployment, identify members and roles, perform a write, and inspect how the driver views the topology.

Part 2 - Technical concept and behavior

Writes normally go to the primary and secondaries replicate the primary's operation log asynchronously. PyMongo discovers replica-set members and performs server selection. Election and failover are server behaviors; Python observes and handles them but does not replace the configured deployment.

Part 3 - Hints and Helper

Use a test replica set with at least three data-bearing members when possible. Connect using a seed list and replica-set name, run `hello`, inspect discovered nodes, insert a uniquely identified record, and avoid forcing failover outside an isolated lab.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def E02(uri, replica_set_name):
    client = MongoClient(
        uri,
        replicaSet=...,
        serverSelectionTimeoutMS=...,
    )
    topology = {
        "primary": client.primary,
        "secondaries": list(client.secondaries),
        "nodes": list(client.nodes),
    }
    hello = client.admin.command("hello")
    collection = client[...][...]
    result = collection.insert_one({...})
    verified = collection.find_one({"_id": result.inserted_id})
    client.close()
    return topology, hello, verified

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

7.5.4 Exercise 03 - Read Preference Configuration

Part 1 - Why this matters

Read preference controls which replica-set members are eligible for a read. Reading from secondaries may distribute read work or improve locality, but asynchronous replication means those reads can return older data.

The correct mode depends on whether the application prioritizes freshness, availability, or workload distribution. Chat context and account state may have different tolerance for stale reads, so one global choice should not be made blindly.

Part 2 - Technical concept and behavior

The default mode is primary. Other modes include primary preferred, secondary, secondary preferred, and nearest. Read preference chooses eligible servers; read concern controls visibility and consistency guarantees. Transactions containing reads must use primary read preference.

Part 3 - Hints and Helper

Create collection handles with different read preferences using `with_options()`. Run the same identifiable read, inspect the preference attached to each handle, and use command monitoring or server information if available to observe selection without claiming that secondary reads are always stale.

Part 4 - Python code skeleton

```
from pymongo import MongoClient, ReadPreference

def E03(collection, query_filter):
    primary_collection = collection.with_options(
        read_preference=ReadPreference....
    )
    secondary_preferred_collection = collection.with_options(
        read_preference=ReadPreference....
    )
    primary_result = primary_collection.find_one(...)
    alternate_result = secondary_preferred_collection.find_one(...)
    return {
        "primary_mode": primary_collection.read_preference,
        "alternate_mode": secondary_preferred_collection.read_preference,
        "primary_result": primary_result,
        "alternate_result": alternate_result,
    }

def main():
    client = MongoClient(...)
    print(E03(client[...][...], ...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.5 Exercise 04 - Write Concern Configuration

Part 1 - Why this matters

Write concern determines the acknowledgment requested before MongoDB reports a write as successful. Stronger acknowledgment can improve durability confidence but may increase latency or reduce availability when required members cannot respond.

Acknowledgment is not the same as application correctness. A majority-acknowledged write can still contain invalid business data, while an unacknowledged write gives Python little evidence about whether the server accepted it.

Part 2 - Technical concept and behavior

Write concern options include `w`, journaling, and a write-concern timeout. `w="majority"` requests acknowledgment from a calculated majority of data-bearing voting members. In multi-document transactions, write concern belongs at transaction level rather than individual operations.

Part 3 - Hints and Helper

Use `with_options()` to create collection handles with explicit write concerns. Compare acknowledged results and latency in an isolated replica set, test an impossible requirement with a timeout, and do not interpret timeout as proof that no member applied the write.

Part 4 - Python code skeleton

```
from time import perf_counter
from pymongo import MongoClient
from pymongo.write_concern import WriteConcern

def E04(collection, document):
    majority_collection = collection.with_options(
        write_concern=WriteConcern(w=..., j=..., wtimeout=...),
    )
    started = perf_counter()
    result = majority_collection.insert_one(...)
    elapsed = perf_counter() - started
    verification = collection.find_one({"_id": result.inserted_id})
    return {
        "acknowledged": result.acknowledged,
        "elapsed": elapsed,
        "stored": verification,
    }

def main():
    client = MongoClient(...)
    print(E04(client[...][...], ...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.6 Exercise 05 - Shard Key Selection Challenge

Part 1 - Why this matters

The shard key determines how documents are partitioned and which queries can be routed to a limited set of shards. A poor key can create uneven distribution, write hotspots, scatter-gather reads, or ranges that are difficult to move.

Shard-key choice is difficult to reverse operationally and cannot be judged from cardinality alone. The reader must evaluate distribution, frequency, monotonic growth, query targeting, and the needs of a real chat workload.

Part 2 - Technical concept and behavior

A shard key is an indexed field or compound field set used to divide key space into ranges. Range-based keys preserve locality, while hashed sharding can spread values more evenly at the cost of some range-query targeting. Queries containing the shard key or a compound-key prefix can often be targeted more efficiently.

Part 3 - Hints and Helper

Compare candidates such as `session_id`, user plus time, and a monotonically increasing timestamp. Calculate cardinality and frequency skew from sample data, map each candidate to the main queries, and return a reasoned score rather than executing sharding automatically.

Part 4 - Python code skeleton

```
from collections import Counter

def evaluate_candidate(documents, field_path, query_patterns):
    values = [...]
    frequencies = Counter(values)
    metrics = {
        "cardinality": ...,
        "maximum_frequency": ...,
        "missing_count": ...,
        "monotonic_risk": ...,
        "targeted_query_count": ...,
    }
    score = ...
    return metrics, score

def E05(documents, candidates, query_patterns):
    evaluations = {
        candidate: evaluate_candidate(...)
        for candidate in candidates
    }
    recommendation = ...
    return evaluations, recommendation

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

7.5.7 Exercise 06 - Chunk Distribution Observation

Part 1 - Why this matters

A sharded collection is divided into non-overlapping shard-key ranges associated with chunks. Observing where those ranges reside helps reveal uneven distribution, insufficient key diversity,

zones, or migrations that have not completed.

Chunk count alone does not equal balanced workload. Chunks can contain different data volumes or receive very different request rates, so metadata observations must be combined with document and workload evidence.

Part 2 - Technical concept and behavior

Chunk ranges have inclusive lower and exclusive upper shard-key bounds. Cluster metadata identifies the sharded collection, its key, and range ownership. Metadata representation can vary by server version, and inspecting it requires connection through `mongos` with suitable privileges.

Part 3 - Hints and Helper

Run only against an isolated sharded cluster. Verify that the client is connected through `mongos`, identify the collection metadata and UUID, inspect chunk or range ownership using supported cluster metadata, and summarize counts by shard without modifying placement.

Part 4 - Python code skeleton

```
from collections import Counter
from pymongo import MongoClient

def E06(client, database_name, collection_name):
    hello = client.admin.command("hello")
    if hello.get("msg") != ...:
        raise RuntimeError(...)
    namespace = f"{database_name}.{collection_name}"
    collection_metadata = client["config"]["collections"].find_one({
        "_id": namespace,
    })
    collection_uuid = collection_metadata.get(...)
    ranges = list(client["config"][...].find({
        ...: collection_uuid,
    }))
    distribution = Counter(range_document[...] for range_document in ranges)
    return collection_metadata, dict(distribution), ranges

def main():
    client = MongoClient(...)
    print(E06(client, ..., ...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.8 Exercise 07 - Balancer Behavior Analysis

Part 1 - Why this matters

The balancer moves shard-key ranges to improve data distribution and respect configured zones. These migrations consume network, storage, and server resources, so balancing behavior must be observed rather than assumed to be free or immediate.

An uneven cluster is not automatically evidence that the balancer is broken. Thresholds, active migrations, zones, jumbo ranges, low data volume, or a poor shard key can explain the current state.

Part 2 - Technical concept and behavior

MongoDB's balancer runs in the background and migrates ranges among shards. Cluster commands expose balancer state, while metadata and logs provide evidence about distribution and migration. Starting or stopping balancing changes cluster behavior and should not be performed casually in a shared environment.

Part 3 - Hints and Helper

Use read-only observations in this challenge. Query balancer status through `mongos`, capture distribution snapshots at controlled intervals, and classify whether the evidence shows movement, stability, or an inconclusive state. Do not block with long sleeps.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
from pymongo import MongoClient

def E07(client, distribution_reader):
    balancer_status = client.admin.command(...)
    before = distribution_reader(...)
    after = distribution_reader(...)
    comparison = {
        "observed_at": datetime.now(timezone.utc),
        "mode": balancer_status.get(...),
        "in_balancing_round": balancer_status.get(...),
        "before": before,
        "after": after,
        "changed": ...,
        "conclusion": ...,
    }
    return comparison

def main():
    client = MongoClient(...)
    print(E07(...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.9 Exercise 08 - Sharding vs Indexing Comparison

Part 1 - Why this matters

Indexes and sharding solve different scaling problems. An index improves access paths within a collection's storage, while sharding distributes data and workload across multiple shards. One does not replace the other.

A sharded query without the right shard-key filter may broadcast work, and each targeted shard may still need suitable indexes. The reader must identify whether a problem comes from local query access, machine capacity, distribution, or all three.

Part 2 - Technical concept and behavior

Indexing affects keys and documents examined on each participating shard. Sharding affects routing and the number of shards participating. A targeted query includes sufficient shard-key information, while a scatter-gather query is sent to multiple shards by `mongos`. Explain output can reveal both routing and local plan behavior.

Part 3 - Hints and Helper

Compare four cases where available: targeted with index, targeted without useful index, scatter-gather with index, and scatter-gather without useful index. Use the same logical result and record participating shards, keys examined, documents examined, and latency.

Part 4 - Python code skeleton

```
from pymongo import MongoClient

def explain_case(collection, query_filter):
    command = {
        "find": collection.name,
        "filter": ...,
        "sort": {...},
        "limit": ...,
    }
    explanation = collection.database.command(
        "explain", command, verbosity=...,
    )
    return {
        "participating_shards": ...,
        "stages": ...,
        "keys_examined": ...,
        "documents_examined": ...,
        "execution_time": ...,
    }

def E08(collection, targeted_filter, scatter_filter):
    targeted = explain_case(...)
    scatter = explain_case(...)
    comparison = ...
```

```
    return targeted, scatter, comparison

def main():
    client = MongoClient(...)
    print(E08(client[...][...], ..., ...))
    client.close()

if __name__ == "__main__":
    main()
```

7.5.10 Exercise 09 - Scalable Chat System Data Design

Part 1 - Why this matters

A scalable chat system must preserve message order and session isolation while supporting heavy writes, recent-history reads, retention, availability, and growth across servers. Optimizing only one requirement can create hotspots, stale context, oversized documents, or expensive broadcast queries.

The final exercise combines the entire MongoDB book into one evidence-based design. The reader must define document boundaries, indexes, replica behavior, shard-key strategy, archive policy, and failure expectations before implementing a small Python validation harness.

Part 2 - Technical concept and behavior

Messages remain separate, bounded documents connected by session identity and deterministic order. Compound indexes support recent-session reads. Replica settings express freshness and durability needs, while a shard key balances write distribution against targeted session retrieval. TTL or archival rules control lifecycle without serving as immediate authorization logic.

Part 3 - Hints and Helper

Write explicit workload assumptions: message rate, session size, read pattern, retention, regions, and consistency tolerance. Return the proposed schemas and index definitions, score shard-key candidates, and run checks for deterministic retrieval, duplicate-message protection, and query targeting.

Part 4 - Python code skeleton

```
from pymongo import ASCENDING, DESCENDING, MongoClient
from pymongo.write_concern import WriteConcern

def E09(client, configuration, sample_messages):
    messages = client[...][...].with_options(
        write_concern=WriteConcern(...),
    )
    index_definitions = [
        [
            ("session_id", ASCENDING),
            ("created_at", DESCENDING),
```

```
            ("sequence", DESCENDING),
        ],
        [...],
    ]
    created_indexes = [messages.create_index(...) for ... in index_definitions]
    inserted = messages.insert_many(...)
    recent_context = list(
        messages.find({"session_id": ...}, {...})
        .sort([...])
        .limit(...)
    )
    explanation = messages.database.command(...)
    validation = {
        "deterministic_order": ...,
        "duplicate_protection": ...,
        "targeted_query": ...,
        "retention_defined": ...,
        "failure_behavior_defined": ...,
    }
    return created_indexes, inserted.inserted_ids, recent_context, explanation, validati

def main():
    client = MongoClient(...)
    print(E09(...))
    client.close()

if __name__ == "__main__":
    main()
```

Book 8

Object Storage Lessons (MinIO)

8.1 Introduction

8.1.1 What will this book teach you

Artificial intelligence systems work with more than rows and documents. They also produce and consume datasets, images, audio, archives, model weights, checkpoints, logs, and other large binary objects. Storing these files only on the local disk of one application server makes them difficult to share, scale, protect, and recover. This book introduces MinIO as an object-storage system for managing that class of data through an S3-compatible interface.

Object storage organizes data differently from PostgreSQL, MongoDB, and an ordinary local filesystem. Every object belongs to a bucket and is identified by an object name. The stored object can contain arbitrary binary data and can also carry metadata, tags, version information, and access rules. Names may contain slash characters that look like folders, but these paths are prefixes inside a flat object namespace rather than ordinary operating-system directories.

Python will remain the primary programming language throughout this book. You will connect to MinIO using its Python SDK, create and inspect buckets, upload and download objects, stream large files, attach metadata, list by prefix, work with versions, generate temporary access links, and integrate object operations into a training pipeline. The MinIO command-line client and terminal commands will be used only when they are necessary for installation, server administration, policy configuration, or direct comparison with Python behavior.

This book does not treat successful upload as sufficient proof. A stored object may have the correct name but incorrect bytes, incomplete metadata, an unintended access policy, or the wrong version. The exercises therefore use verification techniques such as object statistics, content length, hashes, version identifiers, metadata inspection, and controlled download comparisons. The reader should learn to distinguish confirmation from the client library from independent validation of the stored content.

Large objects introduce concerns that do not appear in small database records. Transfers may fail partway, memory cannot hold an entire file, repeated uploads can consume bandwidth, and old checkpoint versions can fill storage. The reader will learn to stream data, reason about multipart uploads, create stable object naming conventions, compare local and network storage

performance, and design lifecycle or garbage-collection strategies that preserve required recovery points.

The final chapter introduces distributed storage and fault tolerance. These exercises must be performed only in an isolated laboratory deployment using disposable test data. Stopping nodes, removing test disks, or changing cluster configuration can cause data loss when the environment is not designed with the required redundancy and quorum. The purpose is to observe failure and recovery safely, not to experiment on production storage.

The exercises provide technical explanations, hints, and incomplete Python skeletons rather than finished solutions. Before every operation, predict the target bucket, object name, version, metadata, and expected result. Afterward, verify the server state and content. This preserves the volume's learning strategy: design, predict, execute, observe, explain, and correct.

8.1.2 How object storage supports artificial intelligence systems

Object storage does not train a model or replace a database. It provides durable, network-accessible storage for large objects surrounding the model. A training system may read dataset partitions from object storage, write checkpoints after selected epochs, publish final weights, store evaluation artifacts, and allow another machine to resume work without depending on the first machine's local disk.

The four data technologies in this volume have different responsibilities. PostgreSQL stores strongly structured relationships such as users, plans, limits, and audits. MongoDB stores flexible documents such as messages, sessions, and evolving metadata. MinIO stores large binary objects such as dataset files, images, archives, weights, and checkpoints. Qdrant, introduced in the next book, stores vectors used for similarity and semantic retrieval. A real AI system may store an object's binary bytes in MinIO while preserving its business record in PostgreSQL, flexible processing metadata in MongoDB, and its embedding in Qdrant.

This separation prevents large files from being forced into systems designed primarily for records or documents. It also prevents MinIO from being misused as a query database. Object metadata and prefixes can support organization and limited filtering, but they do not replace relational joins, document queries, or vector search. The application must decide which system owns each type of information and store stable identifiers that connect those systems safely.

8.1.3 How to approach the exercises

Use a dedicated learning deployment and test buckets. Keep endpoints, access keys, and secret keys outside source files, preferably in environment variables. Never upload real credentials to a repository. Configure TLS and certificate verification for environments beyond local development, and do not disable secure verification merely to silence a connection error.

Object names require deliberate design. Include stable identifiers and meaningful prefixes, but do not depend on folder behavior that object storage does not provide. Avoid placing secrets in object names because names may appear in logs and operational tools. When overwriting an existing name, determine whether versioning is enabled and record the returned version identifier when recovery depends on that exact version.

Treat deletion and public access as high-risk operations. Preview exact targets before deleting, avoid broad recursive operations unless the exercise explicitly requires an isolated test prefix, and understand that deleting the latest object in a versioned bucket may create a delete marker rather than erase every stored version. Generate presigned URLs with short expirations and minimum required permissions, and never mistake possession of a temporary URL for permanent identity-based authorization.

Performance exercises must compare equivalent bytes and environments. Record file size, elapsed time, throughput, number of runs, network conditions, and whether data may be cached. Do not conclude that object storage is universally slower or faster than local storage from one transfer. Local disks and network object storage provide different sharing, durability, scaling, and failure properties.

Distributed exercises require a prepared topology with multiple drives or nodes and an understood parity configuration. A single-node, single-drive learning server does not demonstrate high availability. Before simulating failure, verify redundancy and make an external backup of anything valuable. After failure, validate both availability and byte-level integrity, then observe recovery and healing before declaring the system healthy.

8.1.4 The Chapters (OB00–OB03) included in this book

- OB00 - Binary Data & Large File Storage
- OB01 - Datasets, Weights & Checkpoints
- OB02 - Buckets & Access Structure
- OB03 - Distributed Mode & Fault Tolerance

8.1.5 OB00 - Binary Data & Large File Storage

This chapter establishes the object-storage foundation. You will install and start a learning MinIO server, configure the command-line client, create a bucket, and then perform object operations using Python. Upload, download, listing, prefix filtering, metadata, deletion, and integrity verification will build a complete understanding of the object lifecycle.

The chapter also examines large-file transfer, multipart behavior, bucket versioning, and performance measurement. The Python SDK may manage multipart upload details when a file exceeds relevant thresholds, but the reader must still understand why parts exist, how failed transfers differ from completed objects, and how memory-safe streaming changes the application. By the end, you should be able to store and retrieve binary content reliably and prove that the retrieved bytes match the source.

8.1.6 OB01 - Datasets, Weights & Checkpoints

This chapter applies object storage directly to machine-learning artifacts. You will design bucket and prefix conventions for datasets, upload a local hierarchy without assuming real folders, save model weights after training, and retrieve a checkpoint for resuming execution.

Dataset and checkpoint metadata will connect each object to its source, configuration, and training state.

The later exercises introduce versioned checkpoint strategies, atomic publication patterns, local-versus-object-storage I/O comparison, checkpoint garbage collection, and hash validation. Atomicity requires careful interpretation in object storage: the application should upload a complete candidate under a temporary or immutable name, verify it, and publish a small manifest or final reference only after success. The chapter concludes by integrating these operations into a training pipeline without embedding storage concerns unpredictably throughout the model code.

8.1.7 OB02 - Buckets & Access Structure

This chapter focuses on authorization and controlled sharing. You will configure bucket policies, compare read-only with read-write permissions, create application identities or access keys in a learning environment, and generate presigned URLs for temporary object access. Private and public behavior will be tested explicitly rather than inferred from successful administrator access.

You will also design prefix-based permissions, diagnose denied operations, coordinate access across multiple buckets, rotate credentials, and conduct an access-control audit. The guiding principle is least privilege: each identity should receive only the actions and resources required for its task. Credentials must never be written into exercise output, logs, source repositories, or object metadata.

8.1.8 OB03 - Distributed Mode & Fault Tolerance

This chapter moves from one learning server to a multi-drive or multi-node deployment. You will prepare distributed storage, simulate controlled node and disk failures, verify object availability and integrity, and observe healing after resources return or are replaced. These exercises demonstrate that fault tolerance depends on topology, erasure-set layout, parity, and quorum rather than on the MinIO name alone.

Erasure coding divides object data into data and parity shards distributed across drives. Increasing parity can improve failure tolerance but reduces usable capacity and may affect performance. The reader will measure these tradeoffs and distinguish erasure coding within a deployment from replication or disaster recovery across separate locations.

The final exercises cover high availability, external backup or replication strategy, and an end-to-end fault-tolerance test. A complete test records the initial topology, uploads verified objects, introduces one permitted failure, checks read and write behavior, restores the failed component, observes healing, and validates the same object hashes again. Passing the test requires both service availability and correct data, not merely a running process.

8.2 OB00 - Binary Data & Large File Storage

Data Engineering for AI

8.2.1 Exercise 00 - Install MinIO and Start Server

Part 1 - Why this matters

Before Python can store objects, a reachable MinIO service must be running with a known endpoint and protected credentials. Installation is therefore part of understanding the boundary between the client application and the storage server.

This exercise uses an isolated learning deployment and verifies it programmatically. A running process alone is insufficient; the reader must confirm network access, authentication, and a valid S3-compatible response.

Part 2 - Technical concept and behavior

MinIO exposes an object-storage API endpoint and normally a separate administration console endpoint. The server needs a data path and initial credentials supplied through environment configuration. Deployment commands depend on the selected package, container, and release, so they must be checked against the official documentation for that environment.

Part 3 - Hints and Helper

Use disposable local storage and never place real secrets in the script. Start the server through the chosen supported method, then use the Python SDK to list buckets as an authenticated readiness check. Configure a finite connection timeout.

Part 4 - Python code skeleton

```
import os
from minio import Minio

def E00():
    client = Minio(
        os.getenv(...),
        access_key=os.getenv(...),
        secret_key=os.getenv(...),
        secure=...,
    )
    buckets = client.list_buckets()
    return [bucket.name for bucket in buckets]

def main():
    print(E00())

if __name__ == "__main__":
    main()
```

8.2.2 Exercise 01 - Create Bucket using CLI

Part 1 - Why this matters

A bucket is the top-level namespace and policy boundary for stored objects. Creating it with the command-line client teaches the reader how operators configure storage outside application code while Python verifies the resulting server state.

Bucket creation should be repeatable and safe. The program must distinguish a successful creation from an already existing bucket and must not hide authentication, naming, or connectivity failures.

Part 2 - Technical concept and behavior

The MinIO client uses an alias that combines endpoint and credentials. The `mc mb` command creates a bucket, and an option can make an existing bucket a non-fatal condition. Bucket names follow S3-compatible naming constraints and are shared across all objects in that bucket.

Part 3 - Hints and Helper

Configure the alias outside captured output so credentials are not printed. Use Python's `subprocess.run()` with an argument list, check the return code, and verify creation with the Python SDK rather than trusting command text alone.

Part 4 - Python code skeleton

```
import subprocess
from minio import Minio

def E01(client, alias, bucket_name):
    command = ["mc", "mb", ..., f"{alias}/{bucket_name}"]
    completed = subprocess.run(
        command,
        capture_output=True,
        text=True,
        check=...,
    )
    exists = client.bucket_exists(...)
    return completed.returncode, exists

def main():
    client = Minio(...)
    print(E01(...))

if __name__ == "__main__":
    main()
```

8.2.3 Exercise 02 - Upload Single File (Object Put)

Part 1 - Why this matters

Uploading converts a local file into an object addressed by bucket and object name. The operation must preserve the file bytes while recording enough information for later retrieval and interpretation.

The local path is not automatically the object name. Separating them allows the application to create stable remote naming conventions independent of where a file happened to exist on one machine.

Part 2 - Technical concept and behavior

The Python SDK's `fput_object()` uploads a file from disk and returns information about the stored object. Reusing the same object name may replace the current object or create a new version when versioning is enabled. Content type describes representation but does not validate bytes.

Part 3 - Hints and Helper

Verify that the source is a regular file, define the object name explicitly, supply a suitable content type, inspect the returned ETag and version ID, and call `stat_object()` to verify the stored size.

Part 4 - Python code skeleton

```
from pathlib import Path
from minio import Minio

def E02(client, bucket_name, object_name, source_path, content_type):
    source = Path(source_path)
    if ...:
        raise FileNotFoundError(...)
    result = client.fput_object(
        bucket_name,
        object_name,
        str(source),
        content_type=...,
    )
    stored = client.stat_object(bucket_name, object_name)
    valid_size = stored.size == source.stat().st_size
    return result.etag, result.version_id, valid_size

def main():
    client = Minio(...)
    print(E02(...))

if __name__ == "__main__":
    main()
```

8.2.4 Exercise 03 - Download Object and Verify Integrity

Part 1 - Why this matters

A successful download confirms transfer, but not necessarily identity with the intended source. Integrity verification compares content-derived hashes so corruption or selection of the wrong object version becomes visible.

Hashing must stream data in bounded chunks. Large AI artifacts should not be loaded entirely into memory merely to verify them, and partial output should not replace a trusted local file before validation succeeds.

Part 2 - Technical concept and behavior

`fget_object()` downloads an object to a file. A cryptographic digest such as SHA-256 can be calculated independently for source and destination. ETags are useful object metadata but are not a universal substitute for a client-computed content hash, especially for multipart objects.

Part 3 - Hints and Helper

Download to a temporary path, calculate both hashes with fixed-size reads, compare sizes and digests, then publish or retain the file only when validation succeeds. Delete the temporary file after a failed comparison.

Part 4 - Python code skeleton

```
import hashlib
from pathlib import Path
from minio import Minio

def file_hash(path, chunk_size=1024 * 1024):
    digest = hashlib.sha256()
    with open(path, "rb") as source:
        while chunk := source.read(chunk_size):
            digest.update(...)
    return digest.hexdigest()

def E03(client, bucket_name, object_name, source_path, download_path):
    client.fget_object(...)
    source_digest = file_hash(...)
    downloaded_digest = file_hash(...)
    matches = ...
    return source_digest, downloaded_digest, matches

def main():
    client = Minio(...)
    print(E03(...))

if __name__ == "__main__":
    main()
```

8.2.5 Exercise 04 - List Objects with Prefix Filtering

Part 1 - Why this matters

Object stores can contain millions of names, so applications must request only the relevant namespace. Prefix filtering supports dataset partitions, model runs, dates, and tenants without

pretending that prefixes are true filesystem directories.

Listing is often paginated and may be lazy in the SDK. The reader must consume results deliberately, distinguish recursive from delimiter-based behavior, and avoid broad production listings when a precise prefix is available.

Part 2 - Technical concept and behavior

`list_objects()` returns an iterable of object information. The prefix is a leading string match on object names. Recursive listing returns objects beneath all matching name levels, while non-recursive behavior can expose common prefix groupings.

Part 3 - Hints and Helper

Upload test objects under several prefixes. List one prefix recursively, return names, sizes, and modification times, and verify that every name begins with the requested prefix.

Part 4 - Python code skeleton

```
from minio import Minio

def E04(client, bucket_name, prefix, recursive=True):
    objects = client.list_objects(
        bucket_name,
        prefix=...,
        recursive=...,
    )
    results = [
        {
            "name": item.object_name,
            "size": item.size,
            "modified": item.last_modified,
        }
        for item in objects
    ]
    valid_prefixes = all(... for item in results)
    return results, valid_prefixes

def main():
    client = Minio(...)
    print(E04(...))

if __name__ == "__main__":
    main()
```

8.2.6 Exercise 05 - Delete Object Safely

Part 1 - Why this matters

Deleting the wrong object can remove a dataset, model, or checkpoint required for recovery. Safe deletion therefore begins with an exact bucket, object name, and optional version rather

than a broad prefix or unverified user input.

Versioning changes deletion semantics. Removing the current name may create a delete marker while older versions remain, whereas deleting a specific version targets that stored version directly.

Part 2 - Technical concept and behavior

`remove_object()` requests deletion of one object and can accept a version identifier. Some removal responses are confirmed through later observation rather than a returned object body. A pre-delete stat and post-delete read or listing provide stronger evidence.

Part 3 - Hints and Helper

Reject empty names and require an expected size or ETag before deletion. Preview with `stat_object()`, remove exactly one target, then verify expected behavior while accounting for bucket versioning.

Part 4 - Python code skeleton

```
from minio import Minio
from minio.error import S3Error

def E05(client, bucket_name, object_name, expected_size, version_id=None):
    if not object_name:
        raise ValueError(...)
    preview = client.stat_object(
        bucket_name, object_name, version_id=...,
    )
    if preview.size != expected_size:
        raise ValueError(...)
    client.remove_object(
        bucket_name, object_name, version_id=...,
    )
    try:
        verification = client.stat_object(...)
    except S3Error as error:
        verification = ...
    return preview, verification

def main():
    client = Minio(...)
    print(E05(...))

if __name__ == "__main__":
    main()
```

8.2.7 Exercise 06 - Upload Large File using Multipart

Part 1 - Why this matters

Large files must be transferred without loading their complete contents into memory. Multipart upload divides the transfer into parts, allowing the client and server to handle large objects more efficiently and recover from some transfer interruptions.

The MinIO Python SDK can select multipart behavior automatically for suitable upload methods and sizes. The reader should observe this abstraction and verify the completed object rather than reimplementing the multipart protocol unnecessarily.

Part 2 - Technical concept and behavior

`fput_object()` uploads from a file path and manages multipart transfer when required. `put_object()` can stream from a readable object when length is known or configured appropriately. The final object becomes visible after successful completion; abandoned parts require server or administrative cleanup policies.

Part 3 - Hints and Helper

Generate a disposable file larger than the selected part size without holding it all in RAM. Upload with a documented part size accepted by the SDK, verify stored size and hash, and record memory and elapsed time.

Part 4 - Python code skeleton

```
from pathlib import Path
from time import perf_counter
from minio import Minio

def E06(client, bucket_name, object_name, source_path, part_size):
    source = Path(source_path)
    started = perf_counter()
    result = client.fput_object(
        bucket_name,
        object_name,
        str(source),
        part_size=...,
    )
    elapsed = perf_counter() - started
    stored = client.stat_object(bucket_name, object_name)
    throughput = ...
    return result.etag, stored.size, elapsed, throughput

def main():
    client = Minio(...)
    print(E06(...))

if __name__ == "__main__":
    main()
```

8.2.8 Exercise 07 - Metadata Attachment to Objects

Part 1 - Why this matters

Metadata helps an application interpret binary bytes without opening the complete object. A dataset object may record source, schema version, hash, or run identifier, while a checkpoint may record epoch and framework version.

Metadata should remain small and non-sensitive. It is not a full query database, and changing user metadata may require copying or rewriting the object depending on the storage API.

Part 2 - Technical concept and behavior

Upload methods can attach user metadata as string key-value pairs along with system metadata such as content type. `stat_object()` returns stored headers and metadata. Key normalization may differ from the original Python spelling, so verification should account for the SDK's returned form.

Part 3 - Hints and Helper

Attach a SHA-256 digest, artifact type, and schema version during upload. Do not store credentials or personal information. Retrieve object statistics and compare required metadata values with normalized expectations.

Part 4 - Python code skeleton

```
from minio import Minio

def E07(client, bucket_name, object_name, source_path, metadata):
    safe_keys = {...}
    if not set(metadata).issubset(safe_keys):
        raise ValueError(...)
    result = client.fput_object(
        bucket_name,
        object_name,
        source_path,
        metadata=...,
        content_type=...,
    )
    stored = client.stat_object(bucket_name, object_name)
    verified = ...
    return result.etag, stored.metadata, verified

def main():
    client = Minio(...)
    print(E07(...))

if __name__ == "__main__":
    main()
```

8.2.9 Exercise 08 - Versioning Enablement Challenge

Part 1 - Why this matters

Versioning preserves multiple iterations stored under the same object name. It protects against accidental overwrite and supports recovery of earlier datasets or checkpoints, but every version consumes storage and requires lifecycle management.

Deletion also changes under versioning because a delete marker can hide the latest object without erasing older versions. The reader must record version IDs whenever a workflow depends on an exact artifact.

Part 2 - Technical concept and behavior

Bucket versioning is enabled at bucket level. Each later write to the same object namespace creates a version with its own identifier. The latest version is returned by default, while listing and retrieval can target older versions explicitly.

Part 3 - Hints and Helper

Enable versioning on an isolated bucket using the SDK, verify status, upload two different contents under one name, record both version IDs, and retrieve each version to prove they remain distinct.

Part 4 - Python code skeleton

```
from minio import Minio
from minio.commonconfig import ENABLED
from minio.versioningconfig import VersioningConfig

def E08(client, bucket_name, object_name, first_path, second_path):
    client.set_bucket_versioning(
        bucket_name,
        VersioningConfig(...),
    )
    status = client.get_bucket_versioning(bucket_name)
    first = client.fput_object(bucket_name, object_name, first_path)
    second = client.fput_object(bucket_name, object_name, second_path)
    versions = list(client.list_objects(
        bucket_name,
        prefix=object_name,
        include_version=True,
    ))
    return status.status, first.version_id, second.version_id, versions

def main():
    client = Minio(...)
    print(E08(...))

if __name__ == "__main__":
    main()
```

8.2.10 Exercise 09 - Binary Storage Performance Test

Part 1 - Why this matters

Transfer performance influences dataset loading, checkpoint frequency, and recovery time. One measurement cannot represent the storage system because file size, network state, cache, concurrency, hashing, and server load all affect the result.

The final challenge builds a repeatable benchmark rather than chasing a flattering number. It records both throughput and integrity so a fast but incorrect transfer can never pass.

Part 2 - Technical concept and behavior

Upload throughput is transferred bytes divided by elapsed time, and download throughput is calculated similarly. Warm-up and repeated trials reveal variation. End-to-end timing may include hashing and local I/O, so the benchmark must state exactly which work occurs inside the timed region.

Part 3 - Hints and Helper

Test several file sizes, use unique object names, repeat each operation, report median and individual timings, and clean up only the isolated benchmark prefix after verifying exact targets.

Part 4 - Python code skeleton

```
from statistics import median
from time import perf_counter
from minio import Minio

def measure(operation, byte_count, repetitions):
    trials = []
    for _ in range(repetitions):
        started = perf_counter()
        operation()
        elapsed = perf_counter() - started
        trials.append({"seconds": elapsed, "bytes_per_second": ...})
    return trials

def E09(client, bucket_name, test_cases, repetitions):
    results = {}
    for test_case in test_cases:
        upload_trials = measure(...)
        download_trials = measure(...)
        integrity = ...
        results[test_case["name"]] = {
            "upload": upload_trials,
            "download": download_trials,
            "integrity": integrity,
        }
    return results

def main():
    client = Minio(...)
    print(E09(...))
```

```
if __name__ == "__main__":
    main()
```

8.3 OB01 - Datasets, Weights & Checkpoints

Data Engineering for AI

8.3.1 Exercise 00 - Design Dataset Bucket Structure

Part 1 - Why this matters

A stable object-name structure lets training jobs locate dataset versions and splits without depending on one machine's folders. Poor naming can mix raw and processed data or allow a mutable upload to change the meaning of an earlier experiment.

The design should express ownership, dataset identity, immutable version, split, and artifact name. Buckets should represent meaningful policy or lifecycle boundaries rather than being created for every small folder.

Part 2 - Technical concept and behavior

Object storage uses bucket names and object-name prefixes, not true nested directories. A structure such as dataset, version, split, and relative file path can group objects while a manifest records expected names, sizes, hashes, and schema information.

Part 3 - Hints and Helper

Define naming rules in Python and reject traversal-like components, empty versions, and ambiguous separators. Produce sample names for train, validation, and test splits, plus one manifest name.

Part 4 - Python code skeleton

```
from pathlib import PurePosixPath

def object_name(dataset_name, version, split, relative_path):
    allowed_splits = {...}
    if split not in allowed_splits:
        raise ValueError(...)
    parts = [dataset_name, version, split, relative_path]
    if ...:
        raise ValueError(...)
    return str(PurePosixPath(...))

def E00(dataset_name, version, files_by_split):
    names = [
        object_name(dataset_name, version, split, path)
        for split, paths in files_by_split.items()
        for path in paths
    ]
```

```
    manifest_name = ...
    return names, manifest_name

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

8.3.2 Exercise 01 - Upload Dataset with Folder Hierarchy

Part 1 - Why this matters

Datasets often arrive as local directories containing splits and nested class or partition folders. Uploading them correctly requires preserving relative names while preventing machine-specific absolute paths from entering the object namespace.

A robust uploader must skip directories, handle failures per file, and produce a manifest so the remote dataset can be verified independently from the source tree.

Part 2 - Technical concept and behavior

Python can walk the local tree, compute each file's path relative to the dataset root, convert separators to POSIX-style object names, and upload with `fput_object()`. Object storage does not require separate folder creation.

Part 3 - Hints and Helper

Resolve and validate the root, sort files for reproducibility, refuse symlinks that escape the root, compute size and hash, upload each object, and return a manifest containing success or failure for every file.

Part 4 - Python code skeleton

```
from pathlib import Path, PurePosixPath
from minio import Minio

def E01(client, bucket_name, local_root, remote_prefix):
    root = Path(local_root).resolve()
    manifest = []
    for path in sorted(root.rglob("*")):
        if not path.is_file():
            continue
        relative = path.relative_to(root)
        object_name = str(PurePosixPath(remote_prefix, *relative.parts))
        try:
            result = client.fput_object(...)
            manifest.append({...})
        except Exception as error:
            manifest.append({...})
    return manifest
```

```
def main():
    client = Minio(...)
    print(E01(...))

if __name__ == "__main__":
    main()
```

8.3.3 Exercise 02 - Store Model Weights after Training

Part 1 - Why this matters

Model weights are the learned output of training and must survive beyond one process or GPU machine. Uploading them to object storage makes a named artifact available to evaluation, deployment, and recovery workflows.

Weights should be accompanied by metadata that identifies architecture, training run, epoch, framework version, and integrity hash. A filename alone is not enough to reproduce how the artifact was produced.

Part 2 - Technical concept and behavior

PyTorch can serialize a model's `state_dict()` to a local temporary file or binary stream. The completed bytes are then uploaded under an immutable run-specific object name. Saving only weights differs from saving a complete training checkpoint.

Part 3 - Hints and Helper

Move tensors to a suitable serializable state, save to a temporary file, calculate SHA-256, upload with metadata, verify remote size, and remove only the local temporary file in a `finally` block.

Part 4 - Python code skeleton

```
import tempfile
import torch
from minio import Minio

def E02(client, bucket_name, object_name, model, metadata):
    temporary_path = ...
    try:
        torch.save(model.state_dict(), temporary_path)
        digest = ...
        result = client.fput_object(
            bucket_name,
            object_name,
            temporary_path,
            metadata={**metadata, "sha256": digest},
        )
        verification = client.stat_object(...)
    finally:
```

```
        ...
    return result.version_id, digest, verification

def main():
    model = torch.nn...
    client = Minio(...)
    print(E02(...))

if __name__ == "__main__":
    main()
```

8.3.4 Exercise 03 - Retrieve Checkpoint for Resume Training

Part 1 - Why this matters

Resuming training requires more than model weights. The checkpoint may need optimizer state, epoch, scheduler state, scaler state, and reproducibility information so the new process continues from the intended training state.

Serialized checkpoints can execute unsafe deserialization behavior when loaded through permissive mechanisms. Only trusted artifacts should be loaded, and integrity and provenance must be checked before PyTorch reads the file.

Part 2 - Technical concept and behavior

The application downloads one exact checkpoint name or version, verifies size and cryptographic hash, and then loads it using the safest mode compatible with its controlled checkpoint format. State dictionaries are applied to already constructed model and optimizer objects.

Part 3 - Hints and Helper

Download to a temporary file, compare its hash with trusted metadata or a manifest, reject mismatch, load only trusted content, validate required keys, and restore each state before returning the next epoch.

Part 4 - Python code skeleton

```
import tempfile
import torch
from minio import Minio

def E03(client, bucket_name, object_name, model, optimizer,
        expected_hash, version_id=None):
    temporary_path = ...
    client.fget_object(
        bucket_name, object_name, temporary_path, version_id=...,
    )
    actual_hash = ...
    if actual_hash != expected_hash:
        raise ValueError(...)
    checkpoint = torch.load(temporary_path, ...)
```

```
    required_keys = {...}
    if ...:
        raise ValueError(...)
    model.load_state_dict(...)
    optimizer.load_state_dict(...)
    next_epoch = checkpoint["epoch"] + 1
    return next_epoch, checkpoint.get("metrics")

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

8.3.5 Exercise 04 - Versioned Model Checkpoints Strategy

Part 1 - Why this matters

Checkpoint history supports rollback and comparison, but repeatedly overwriting one name hides which training step produced each artifact and can consume uncontrolled storage when bucket versioning is enabled.

A clear strategy separates immutable checkpoint names from small pointers such as latest or best. The manifest records identity and hash, allowing readers to select an exact artifact rather than trusting whichever bytes happen to be current.

Part 2 - Technical concept and behavior

Immutable names can include run ID, epoch, and content or configuration identity. Bucket versioning may preserve overwrites, while explicit unique names make lineage visible in listings. A latest-manifest object can reference the selected immutable checkpoint and its version ID.

Part 3 - Hints and Helper

Generate deterministic checkpoint names, reject duplicate epoch publication, upload the immutable checkpoint first, verify it, then update a JSON manifest containing name, version ID, hash, epoch, and timestamp.

Part 4 - Python code skeleton

```
import json
from io import BytesIO
from minio import Minio

def E04(client, bucket_name, run_id, epoch, checkpoint_path):
    checkpoint_name = ...
    checkpoint_result = client.fput_object(...)
    checkpoint_hash = ...
    manifest = {
        "run_id": run_id,
        "epoch": epoch,
```

```
        "object_name": checkpoint_name,
        "version_id": checkpoint_result.version_id,
        "sha256": checkpoint_hash,
    }
    payload = json.dumps(manifest).encode("utf-8")
    manifest_result = client.put_object(
        bucket_name,
        ...,
        BytesIO(payload),
        len(payload),
        content_type="application/json",
    )
    return checkpoint_result, manifest_result, manifest

def main():
    client = Minio(...)
    print(E04(...))

if __name__ == "__main__":
    main()
```

8.3.6 Exercise 05 - Atomic Model Save Operation

Part 1 - Why this matters

Consumers must never discover a checkpoint before its bytes and metadata are complete. Object storage does not provide an ordinary atomic filesystem rename, so a local write-then-rename pattern cannot be copied directly.

A safe publication workflow uploads an immutable candidate, verifies it, and only then updates a small manifest or pointer. Readers trust the pointer and therefore see either the previous valid artifact or the newly completed one.

Part 2 - Technical concept and behavior

An object put becomes visible as a complete object after success, but a multi-object workflow is not automatically atomic. Immutable object names avoid destructive overwrite. Publishing a manifest after verification establishes an application-level commit point, especially when versioning preserves manifest history.

Part 3 - Hints and Helper

Upload to a unique final artifact name, not a shared temporary name. Verify size and hash, write the manifest last, and simulate failure before manifest publication to prove readers continue using the previous checkpoint.

Part 4 - Python code skeleton

```
import json
from io import BytesIO
from minio import Minio
```

```
def E05(client, bucket_name, artifact_name, artifact_path, pointer_name):
    artifact_result = client.fput_object(...)
    stored = client.stat_object(...)
    digest = ...
    if ...:
        raise ValueError(...)
    pointer = {
        "object_name": artifact_name,
        "version_id": artifact_result.version_id,
        "sha256": digest,
    }
    payload = json.dumps(pointer).encode()
    pointer_result = client.put_object(
        bucket_name, pointer_name, BytesIO(payload), len(payload),
        content_type="application/json",
    )
    return artifact_result, pointer_result, pointer

def main():
    client = Minio(...)
    print(E05(...))

if __name__ == "__main__":
    main()
```

8.3.7 Exercise 06 - Compare Local vs Object Storage IO

Part 1 - Why this matters

Local storage and object storage serve different goals. Local disks can provide low-latency access on one machine, while object storage provides network sharing, centralized access, and storage-system durability features.

A fair experiment separates first-time transfer from repeated local reads and compares equivalent bytes. The result should explain tradeoffs instead of declaring one technology universally superior.

Part 2 - Technical concept and behavior

The benchmark measures local read time, object download time, and optionally download-then-read time. Throughput equals bytes divided by elapsed seconds. Cache state, network distance, concurrency, and integrity hashing must be recorded as experimental conditions.

Part 3 - Hints and Helper

Use the same checkpoint bytes, perform warm-up and repeated trials, calculate hashes outside or inside timing consistently, report median and raw results, and state what object-storage benefits are not represented by speed alone.

Part 4 - Python code skeleton

```
from statistics import median
from time import perf_counter
from minio import Minio

def timed(operation, repetitions):
    values = []
    for _ in range(repetitions):
        started = perf_counter()
        operation()
        values.append(perf_counter() - started)
    return values

def E06(client, bucket_name, object_name, local_path, repetitions):
    local_trials = timed(...)
    object_trials = timed(...)
    integrity = ...
    return {
        "local": local_trials,
        "object": object_trials,
        "local_median": median(local_trials),
        "object_median": median(object_trials),
        "integrity": integrity,
    }

def main():
    client = Minio(...)
    print(E06(...))

if __name__ == "__main__":
    main()
```

8.3.8 Exercise 07 - Garbage Collection of Old Checkpoints

Part 1 - Why this matters

Frequent checkpointing can exhaust storage, especially when every overwrite creates another version. Garbage collection must reclaim unnecessary artifacts while preserving the latest checkpoint, best checkpoint, protected milestones, and anything referenced by active manifests.

Deletion should be planned from metadata before it is executed. A dry-run report lets the reader verify exact object names and versions and prevents a broad prefix from becoming an uncontrolled destructive operation.

Part 2 - Technical concept and behavior

A retention policy can keep the newest k checkpoints, selected epochs, and manifest-referenced artifacts. Versioned buckets require decisions about specific versions and delete markers. Listing, policy evaluation, and removal should remain separate phases.

Part 3 - Hints and Helper

List one isolated run prefix including versions, build a protected set, sort candidates by trusted metadata, return a dry-run deletion plan, and require explicit execution input before deleting exact name-version pairs.

Part 4 - Python code skeleton

```
from minio import Minio

def build_plan(objects, keep_latest, protected_versions):
    ordered = sorted(objects, key=..., reverse=True)
    protected = set(...)
    candidates = [item for item in ordered if ...]
    return protected, candidates

def E07(client, bucket_name, prefix, keep_latest, execute=False):
    objects = list(client.list_objects(
        bucket_name,
        prefix=prefix,
        recursive=True,
        include_version=True,
    ))
    protected, candidates = build_plan(...)
    if execute:
        for item in candidates:
            client.remove_object(
                bucket_name,
                item.object_name,
                version_id=item.version_id,
            )
    return protected, candidates, execute

def main():
    client = Minio(...)
    print(E07(...))

if __name__ == "__main__":
    main()
```

8.3.9 Exercise 08 - Integrity Validation with Hashes

Part 1 - Why this matters

Hashes provide content identity across local files, uploaded objects, downloads, and manifests. They help detect corruption, wrong versions, and accidental replacement even when names and sizes appear correct.

Trust requires an independent expected digest. Recalculating a hash only after corruption and then storing that new value would verify the corrupted bytes against themselves rather than against the intended artifact.

Part 2 - Technical concept and behavior

SHA-256 processes bytes incrementally and returns a fixed-length digest. The expected digest can be stored in a signed or otherwise trusted manifest and optionally repeated as object metadata. Verification streams the object response and must close and release the HTTP connection.

Part 3 - Hints and Helper

Hash the source before upload, store the expected value, stream the object with `get_object()`, update the digest by chunks, and use `finally` to close and release the response.

Part 4 - Python code skeleton

```
import hashlib
from minio import Minio

def E08(client, bucket_name, object_name, expected_hash, version_id=None):
    response = client.get_object(
        bucket_name,
        object_name,
        version_id=...,
    )
    digest = hashlib.sha256()
    total_bytes = 0
    try:
        for chunk in response.stream(...):
            digest.update(...)
            total_bytes += len(chunk)
    finally:
        response.close()
        response.release_conn()
    actual_hash = digest.hexdigest()
    return actual_hash, total_bytes, actual_hash == expected_hash

def main():
    client = Minio(...)
    print(E08(...))

if __name__ == "__main__":
    main()
```

8.3.10 Exercise 09 - Training Pipeline Object Integration

Part 1 - Why this matters

A training pipeline must coordinate local computation with durable artifact publication without allowing storage failures to corrupt model state or falsely mark an incomplete run as successful. Storage operations need clear boundaries, retries, and verification.

The final challenge connects dataset manifests, periodic checkpoints, best-model selection, resume logic, and final publication. Model code should depend on a small artifact interface instead of calling object-storage operations from unrelated layers.

Part 2 - Technical concept and behavior

The pipeline resolves an immutable dataset version, trains locally, publishes verified checkpoint artifacts, and updates manifests only after successful upload. Resume reads one trusted pointer and exact version. Storage errors are recorded and handled according to policy rather than silently ignored.

Part 3 - Hints and Helper

Create an artifact-store helper with upload, download, verify, and publish methods. Keep credentials outside checkpoints, use run-specific prefixes, save at controlled intervals, restore the best or latest pointer explicitly, and return a complete artifact history.

Part 4 - Python code skeleton

```
import torch
from minio import Minio

class ArtifactStore:
    def __init__(self, client, bucket_name, run_prefix):
        self.client = client
        self.bucket_name = bucket_name
        self.run_prefix = run_prefix

    def upload_verified(self, local_path, object_name, metadata):
        ...

    def publish_pointer(self, pointer_name, artifact):
        ...

    def download_verified(self, artifact, destination):
        ...

def E09(model, optimizer, data_loader, artifact_store, epochs, save_every):
    history = []
    best_artifact = ...
    for epoch in range(epochs):
        training_result = ...
        if ...:
            checkpoint_path = ...
            artifact = artifact_store.upload_verified(...)
            artifact_store.publish_pointer(...)
            history.append(artifact)
        if ...:
            best_artifact = ...
    return model, history, best_artifact
```

```
def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

8.4 OB02 - Buckets & Access Structure

AI Safety / Ethics / Alignment

8.4.1 Exercise 00 - Bucket Policy Configuration

Part 1 - Why this matters

A bucket policy defines which actions are allowed or denied for selected resources and identities. A small mistake can expose private artifacts or block a training pipeline, so policy configuration must be treated as security-sensitive code.

This exercise applies a narrowly scoped test policy and verifies it through an identity that does not possess administrator privileges. Administrator success cannot prove that the application policy works.

Part 2 - Technical concept and behavior

S3-compatible policies are JSON documents containing version, statements, effects, actions, resources, principals, and optional conditions. Explicit deny takes precedence over allow. Bucket and object actions may require different resource forms.

Part 3 - Hints and Helper

Generate JSON with Python's `json` module, restrict resources to one disposable bucket and prefix, validate the serialized document, apply it with `set_bucket_policy()`, and retrieve it for comparison.

Part 4 - Python code skeleton

```
import json
from minio import Minio

def E00(admin_client, bucket_name, principal):
    policy = {
        "Version": ...,
        "Statement": [
            {
                "Effect": ...,
                "Principal": ...,
                "Action": [...],
                "Resource": [...],
            }
        ],
```

```
    }
    policy_json = json.dumps(policy)
    admin_client.set_bucket_policy(bucket_name, policy_json)
    stored_policy = json.loads(admin_client.get_bucket_policy(bucket_name))
    return policy, stored_policy, policy == stored_policy

def main():
    admin_client = Minio(...)
    print(E00(...))

if __name__ == "__main__":
    main()
```

8.4.2 Exercise 01 - Read-Only vs Read-Write Policy

Part 1 - Why this matters

Inference workers may need to download model weights without permission to replace or delete them, while training publishers may need controlled write access. Giving both identities full access violates least privilege and increases the impact of credential compromise.

The reader will test permissions as behavior, not only inspect policy JSON. Each identity must pass allowed operations and fail expected denied operations on the exact resources in scope.

Part 2 - Technical concept and behavior

A read-only policy permits selected list, stat, and get actions. A read-write policy adds controlled put and possibly delete actions. Bucket listing and object retrieval are different permissions, and write permission should not automatically imply administrative policy control.

Part 3 - Hints and Helper

Create two non-admin test clients. Build an operation matrix for list, get, put, and delete under one prefix. Catch access-denied responses separately from missing-object or connectivity failures.

Part 4 - Python code skeleton

```
from minio import Minio
from minio.error import S3Error

def attempt(label, operation):
    try:
        result = operation()
        return {"operation": label, "allowed": True, "result": result}
    except S3Error as error:
        return {"operation": label, "allowed": False, "code": error.code}

def E01(read_client, write_client, bucket_name, object_name, source_path):
    tests = {
```

```
        "read_get": lambda: read_client.stat_object(...),
        "read_put": lambda: read_client.fput_object(...),
        "write_get": lambda: write_client.stat_object(...),
        "write_put": lambda: write_client.fput_object(...),
    }
    outcomes = {name: attempt(name, operation) for name, operation in tests.items()}
    expected = {...}
    return outcomes, ...

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

8.4.3 Exercise 02 - User and Access Key Creation

Part 1 - Why this matters

Applications should use dedicated identities instead of administrator credentials. Separate access keys allow permissions, rotation, revocation, and audit to follow the application or service that actually performs each operation.

Identity creation is administrative and is not provided by ordinary object data operations. Python may orchestrate a supported administrative CLI in the lab, but secrets must not appear in logs, exceptions, repositories, or returned exercise values.

Part 2 - Technical concept and behavior

An access key identifies the principal and a secret key authenticates signed requests. Policies are attached through administrative configuration. The new credentials must be tested with a separate MinIO client whose permissions are limited to the intended resources.

Part 3 - Hints and Helper

Generate a strong temporary secret, pass administrative configuration only through the supported mechanism for the installed release, redact captured output, attach a least-privilege policy, test the client, and remove the identity after the lab.

Part 4 - Python code skeleton

```
import os
import secrets
import subprocess
from minio import Minio

def E02(alias, access_key, policy_name):
    secret_key = secrets.token_urlsafe(...)
    environment = os.environ.copy()
    environment[...] = secret_key
    create_command = ["mc", "admin", "user", "add", alias, access_key, ...]
```

```
    attach_command = ["mc", "admin", "policy", "attach", ...]
    subprocess.run(create_command, env=environment, check=True,
                   stdout=subprocess.DEVNULL, stderr=subprocess.PIPE)
    subprocess.run(attach_command, check=True, capture_output=True)
    application_client = Minio(..., access_key=access_key,
                               secret_key=secret_key, secure=...)
    verification = ...
    return {"access_key": access_key, "verified": verification}

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

8.4.4 Exercise 03 - Temporary Access using Presigned URL

Part 1 - Why this matters

A presigned URL lets a client perform one time-limited object operation without receiving the storage account's secret key. It is useful for controlled downloads or uploads from browsers and external workers.

The URL behaves like a bearer credential until it expires. Anyone who obtains it may use its granted operation, so expiration, object scope, transport security, and log handling matter.

Part 2 - Technical concept and behavior

The SDK signs a request for a specific bucket, object name, HTTP operation, and expiration. The server validates the signature when the URL is used. Revoking the underlying credential or changing object access can affect validity, but the design should assume the URL remains usable for its intended lifetime.

Part 3 - Hints and Helper

Generate a short-lived GET URL for one disposable object. Use Python's HTTP client to download it without MinIO credentials, verify content hash, and confirm that an altered object name or expired URL fails.

Part 4 - Python code skeleton

```
from datetime import timedelta
import hashlib
import urllib.request
from minio import Minio

def E03(client, bucket_name, object_name, expiration):
    if expiration > timedelta(...):
        raise ValueError(...)
    url = client.presigned_get_object(
        bucket_name,
```

```
        object_name,
        expires=...,
    )
    with urllib.request.urlopen(url, timeout=...) as response:
        data = response.read()
    digest = hashlib.sha256(data).hexdigest()
    return url, len(data), digest

def main():
    client = Minio(...)
    print(E03(...))

if __name__ == "__main__":
    main()
```

8.4.5 Exercise 04 - Private vs Public Object Access

Part 1 - Why this matters

Model weights, private datasets, and checkpoints should normally require authenticated access. Public access is suitable only for artifacts intentionally released to everyone and can expose sensitive bytes instantly when a policy is too broad.

Testing with administrator credentials cannot reveal anonymous behavior. This exercise compares authenticated and unsigned HTTP requests and restores private policy after the isolated experiment.

Part 2 - Technical concept and behavior

Private objects require a signed request from an allowed identity. A bucket policy can permit anonymous GET for a selected resource or prefix. Public read does not need to imply public listing, write, delete, or policy modification.

Part 3 - Hints and Helper

Use one harmless test object. Apply a policy granting only anonymous object retrieval for its prefix, test unsigned GET and unsigned PUT separately, then remove the policy and verify GET is denied again.

Part 4 - Python code skeleton

```
import json
import urllib.error
import urllib.request
from minio import Minio

def anonymous_status(url):
    try:
        with urllib.request.urlopen(url, timeout=...) as response:
            return response.status
    except urllib.error.HTTPError as error:
```

```
        return error.code

def E04(admin_client, bucket_name, object_name, public_url):
    private_status = anonymous_status(...)
    public_policy = {...}
    admin_client.set_bucket_policy(bucket_name, json.dumps(public_policy))
    public_status = anonymous_status(...)
    admin_client.delete_bucket_policy(bucket_name)
    restored_status = anonymous_status(...)
    return private_status, public_status, restored_status

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

8.4.6 Exercise 05 - Folder-like Access Control Design

Part 1 - Why this matters

Object names can use prefixes such as team, project, or tenant to organize access without creating real folders. Correct prefix policies can let one identity operate only inside its namespace while sharing the same bucket infrastructure.

Prefix matching must be exact. Ambiguous names, missing separators, or permission to list the entire bucket can reveal objects outside the intended area even when object retrieval is restricted.

Part 2 - Technical concept and behavior

Policies can restrict object resources to an ARN ending with a controlled prefix and wildcard. Bucket-list actions can use conditions on requested prefixes. Naming validation in Python should prevent callers from escaping or impersonating another namespace.

Part 3 - Hints and Helper

Design prefixes as `tenants/<id>/...`, validate identifier characters, create separate list and object statements, and test own-prefix read/write against neighboring and similarly named prefixes.

Part 4 - Python code skeleton

```
import json
import re

def E05(bucket_name, tenant_id, actions):
    if re.fullmatch(..., tenant_id) is None:
        raise ValueError(...)
    prefix = f"tenants/{tenant_id}/"
    policy = {
```

```
        "Version": ...,
        "Statement": [
            {
                "Effect": "Allow",
                "Action": [...],
                "Resource": [f"arn:aws:s3:::{bucket_name}/{prefix}*"],
            },
            {
                "Effect": "Allow",
                "Action": ["s3:ListBucket"],
                "Resource": [f"arn:aws:s3:::{bucket_name}"],
                "Condition": {"StringLike": {"s3:prefix": [...]}},
            },
        ],
    }
    return prefix, json.dumps(policy)

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

8.4.7 Exercise 06 - Access Denial Debugging Challenge

Part 1 - Why this matters

An access-denied response can result from identity policy, bucket policy, explicit deny, incorrect resource name, missing list permission, expired credentials, clock problems, or a request signed for the wrong endpoint. Guessing by granting broader access creates new security risk.

The reader will debug from evidence while preserving least privilege. The objective is to identify the failing action and resource, make the smallest correction, and prove unrelated operations remain denied.

Part 2 - Technical concept and behavior

S3 errors include a code, message, resource, request ID, and host ID where available. Authorization evaluates all relevant policy statements and conditions. A successful administrator retry proves object existence but does not prove the application identity is configured correctly.

Part 3 - Hints and Helper

Capture sanitized error fields, confirm endpoint and identity, reduce the operation to stat, list, get, or put, compare exact resource ARNs and prefixes, and execute a positive and negative regression test after correction.

Part 4 - Python code skeleton

```
from minio.error import S3Error
```

```
def diagnose(operation, expected_action, expected_resource):
    try:
        result = operation()
        return {"status": "allowed", "result": result}
    except S3Error as error:
        evidence = {
            "code": error.code,
            "message": error.message,
            "resource": error.resource,
            "request_id": error.request_id,
        }
        hypotheses = [...]
        return {"status": "denied", "evidence": evidence,
                "hypotheses": hypotheses}

def E06(allowed_operation, denied_operation):
    before = diagnose(...)
    correction = ...
    after_allowed = diagnose(...)
    after_denied = diagnose(...)
    return before, correction, after_allowed, after_denied

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

8.4.8 Exercise 07 - Multi-Bucket Permission Strategy

Part 1 - Why this matters

One pipeline may read datasets, write checkpoints, and publish final models in different buckets. Using identical broad permissions across all three weakens isolation and allows a compromised worker to modify data it should only consume.

The policy should reflect directional data flow. Training identities may read immutable datasets, write only their run prefix, and have no authority to change bucket policies or delete published models.

Part 2 - Technical concept and behavior

A policy can contain several statements, each scoped to actions and bucket or object resources. Bucket-level list permission is distinct from object actions. Explicit deny statements may protect particularly sensitive namespaces in addition to omitted allows.

Part 3 - Hints and Helper

Create an access matrix before JSON. Map each role to dataset, checkpoint, and model operations, generate statements from validated configuration, and test every cell with separate non-admin credentials.

Part 4 - Python code skeleton

```
import json

def statement(effect, actions, resources, conditions=None):
    item = {
        "Effect": effect,
        "Action": actions,
        "Resource": resources,
    }
    if conditions:
        item["Condition"] = conditions
    return item

def E07(dataset_bucket, checkpoint_bucket, model_bucket, run_id):
    access_matrix = {
        "dataset": {"read": True, "write": False, "delete": False},
        "checkpoint": {"read": True, "write": True, "delete": ...},
        "model": {"read": ..., "write": ..., "delete": False},
    }
    statements = [
        statement(...),
        statement(...),
        statement(...),
    ]
    policy = {"Version": ..., "Statement": statements}
    return access_matrix, json.dumps(policy)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

8.4.9 Exercise 08 - Secure Credential Rotation

Part 1 - Why this matters

Credentials must be rotated when they age, leak, or change ownership. Replacing the only active key before clients adopt the new one can cause an outage, while leaving the old key enabled indefinitely defeats the purpose of rotation.

Safe rotation overlaps credentials briefly: create the new credential, attach equivalent least privilege, test it, update the application's secret source, confirm use, revoke the old credential, and verify the old key fails.

Part 2 - Technical concept and behavior

Access-key lifecycle is an administrative operation. Applications should obtain active secrets from a protected secret source rather than hard-coded files. Rotation evidence should record key identifiers and timestamps, never secret values.

Part 3 - Hints and Helper

Use an isolated identity, never print the new secret, and implement the workflow as explicit phases with rollback guidance. Test one allowed and one denied action before revoking the old key.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from datetime import datetime, timezone

@dataclass
class RotationState:
    old_access_key: str
    new_access_key: str
    phase: str
    started_at: object

def E08(admin_create, attach_policy, update_secret_store,
        verify_client, revoke_old, old_access_key):
    new_access_key, new_secret = admin_create(...)
    state = RotationState(old_access_key, new_access_key,
                          "created", datetime.now(timezone.utc))
    attach_policy(...)
    verification = verify_client(...)
    if not verification:
        raise RuntimeError(...)
    update_secret_store(...)
    confirmation = ...
    if confirmation:
        revoke_old(...)
        state.phase = "completed"
    return state, verification

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

8.4.10 Exercise 09 - Access Control Audit Scenario

Part 1 - Why this matters

Access control drifts as identities, buckets, prefixes, and pipeline responsibilities change. An audit compares intended permissions with observed behavior and identifies excessive access, missing controls, stale credentials, and public exposure.

The final challenge produces evidence without revealing secrets. It treats denied tests as expected outcomes when the policy requires denial and separates policy findings from connectivity or missing-object errors.

Part 2 - Technical concept and behavior

An audit inventory includes principals, policies, bucket policies, credential age, public access, and an operation matrix. Findings should include severity, affected resource, evidence, expected state, and a minimal remediation. Audit code should be read-only except inside disposable canary prefixes.

Part 3 - Hints and Helper

Define the expected matrix first, use harmless canary objects for write and delete tests, redact secrets and presigned URLs, detect unexpected allows and denies, and return a deterministic report suitable for later comparison.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

def test_permission(identity, operation_name, operation):
    try:
        operation()
        observed = "allow"
        evidence = ...
    except Exception as error:
        observed = ...
        evidence = ...
    return {"identity": identity, "operation": operation_name,
            "observed": observed, "evidence": evidence}

def E09(expected_matrix, test_operations, credential_metadata):
    observations = [
        test_permission(identity, operation_name, operation)
        for identity, operations in test_operations.items()
        for operation_name, operation in operations.items()
    ]
    findings = [...]
    report = {
        "generated_at": datetime.now(timezone.utc),
        "observations": observations,
        "findings": findings,
        "credential_findings": ...,
    }
    return report
```

```
def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

8.5 OB03 - Distributed Mode & Fault Tolerance

AI Infrastructure and Hardware

8.5.1 Exercise 00 - Start MinIO in Distributed Mode

Part 1 - Why this matters

A distributed object-storage deployment uses several drives or nodes so data availability does not depend on one local disk or process. The topology must be planned before failure testing because resilience comes from failure domains, parity, and quorum.

This exercise starts only an isolated laboratory deployment. Python verifies the resulting service and topology-facing health, while server or container configuration remains an infrastructure responsibility.

Part 2 - Technical concept and behavior

MinIO distributes erasure-coded data and parity shards across an erasure set. A multi-node endpoint list and persistent drives define the deployment. Starting several processes that all use the same unsafe local path does not create meaningful hardware fault tolerance.

Part 3 - Hints and Helper

Use disposable volumes, equal lab node configuration, unique hostnames, synchronized clocks, and protected credentials. Start through a supported orchestration method, wait with a deadline, then verify authenticated bucket and object operations from Python.

Part 4 - Python code skeleton

```
import subprocess
import time
from minio import Minio

def E00(start_command, client_factory, deadline_seconds):
    completed = subprocess.run(start_command, check=...,
                               capture_output=True, text=True)
    deadline = time.monotonic() + deadline_seconds
    observations = []
    while time.monotonic() < deadline:
        try:
            client = client_factory()
            buckets = client.list_buckets()
            observations.append(...)
```

```
            return completed.returncode, observations
        except Exception as error:
            observations.append(...)
            ...
    raise TimeoutError(...)

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

8.5.2 Exercise 01 - Node Failure Simulation

Part 1 - Why this matters

Fault tolerance should be demonstrated through controlled loss within the topology's permitted failure budget. Stopping too many nodes can remove quorum and turn a learning exercise into data loss.

The reader will establish a healthy baseline, stop exactly one designated lab node, test read and write behavior, restore it, and verify the same object bytes again.

Part 2 - Technical concept and behavior

Availability during node loss depends on the erasure-set layout, parity, and read or write quorum. Losing one process does not produce one universal result for every topology. Client retries and load-balanced endpoints also influence observed behavior.

Part 3 - Hints and Helper

Use disposable test objects with known hashes. Resolve the exact container or service target before stopping it, enforce command timeouts, never stop additional nodes after an unexpected result, and restore the node in a `finally` block.

Part 4 - Python code skeleton

```
import subprocess

def E01(client, object_reference, stop_command, start_command):
    baseline = ...
    stopped = False
    try:
        subprocess.run(stop_command, check=True, timeout=...)
        stopped = True
        read_during_failure = ...
        write_during_failure = ...
        integrity_during_failure = ...
    finally:
        if stopped:
            subprocess.run(start_command, check=True, timeout=...)
```

```
    recovered = ...
    return {
        "baseline": baseline,
        "read_during_failure": read_during_failure,
        "write_during_failure": write_during_failure,
        "integrity": integrity_during_failure,
        "recovered": recovered,
    }

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

8.5.3 Exercise 02 - Data Replication Verification

Part 1 - Why this matters

In a distributed erasure-coded deployment, an object is not necessarily stored as one complete copy on every node. Assuming full per-node replicas leads to incorrect tests and dangerous recovery decisions.

This exercise verifies protection through client-visible availability and integrity under an allowed failure. If separate bucket or site replication is configured, that is a different mechanism and requires an additional destination-level check.

Part 2 - Technical concept and behavior

Erasure coding splits bytes into data and parity shards across drives. The service reconstructs the object when enough shards remain. Replication copies object versions to another bucket or site and has independent configuration, versioning, and lag considerations.

Part 3 - Hints and Helper

Record which protection mechanism is under test. For erasure coding, verify one object's hash before, during, and after a permitted node loss. For configured replication, compare exact object name, version, size, metadata, and digest at the destination.

Part 4 - Python code skeleton

```
def verify_object(client, bucket_name, object_name, expected_hash,
                  version_id=None):
    stored = client.stat_object(
        bucket_name, object_name, version_id=version_id,
    )
    actual_hash = ...
    return {
        "size": stored.size,
        "version_id": stored.version_id,
        "hash": actual_hash,
```

```
        "valid": actual_hash == expected_hash,
    }

def E02(source_client, destination_client, reference, expected_hash):
    source = verify_object(...)
    destination = verify_object(...) if destination_client else None
    protected_during_failure = ...
    return source, destination, protected_during_failure

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

8.5.4 Exercise 03 - Healing Process Observation

Part 1 - Why this matters

After a failed drive or node returns or is replaced, missing or damaged shards may need healing. Service availability before healing completes does not mean redundancy has already returned to its original state.

The reader will observe healing without repeatedly starting destructive repair operations. Progress, remaining work, object integrity, and final redundancy evidence belong in the result.

Part 2 - Technical concept and behavior

Healing reconstructs damaged or missing object shards when enough intact data and parity remain. Current MinIO behavior and administrative commands depend on the installed release. Observation should use supported health, admin, and object-inspection interfaces for that deployment.

Part 3 - Hints and Helper

Restore the failed component first. Invoke only documented read or status commands through Python subprocess, parse structured output when available, poll with a bounded deadline, and verify known object hashes throughout the process.

Part 4 - Python code skeleton

```
import json
import subprocess
import time

def E03(status_command, integrity_check, deadline_seconds):
    deadline = time.monotonic() + deadline_seconds
    history = []
    while time.monotonic() < deadline:
        completed = subprocess.run(
            status_command,
```

```
            check=True,
            capture_output=True,
            text=True,
            timeout=...,
        )
        status = ...
        integrity = integrity_check()
        history.append({"status": status, "integrity": integrity})
        if ...:
            return history
        ...
    raise TimeoutError(...)

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

8.5.5 Exercise 04 - Disk Failure Recovery Scenario

Part 1 - Why this matters

Drive failure tests whether data protection extends below the process level. A careless simulation can remove the wrong volume or exceed parity, so the exact disposable drive and recovery procedure must be resolved before any mutation.

Recovery includes more than making the server process run. The replacement storage must join correctly, healing must complete, and previously stored objects must retain their expected bytes and metadata.

Part 2 - Technical concept and behavior

A failed drive removes some shards from its erasure set. Availability depends on remaining shards and quorum. Replacement should use supported procedures and appropriate hardware or lab-volume characteristics; copying internal MinIO storage files manually is not a valid object-level recovery method.

Part 3 - Hints and Helper

Use a disposable mounted volume and external backups. Stop the exact lab node before detaching its test drive, replace only that explicit target, restore the service, observe healing, and compare a fixed integrity manifest before and after.

Part 4 - Python code skeleton

```
from pathlib import Path

def E04(topology, failed_drive_id, manifest, recovery_actions):
    target = topology.resolve_drive(...)
    if not target.is_disposable or target.path in {...}:
```

```
        raise RuntimeError(...)
    baseline = {item.name: ... for item in manifest}
    confirmation = ...
    if not confirmation:
        return ...
    recovery_actions.stop_node(target.node)
    recovery_actions.detach_test_drive(target)
    degraded = ...
    recovery_actions.attach_replacement(target)
    recovery_actions.start_node(target.node)
    healing = ...
    final_validation = {item.name: ... for item in manifest}
    return baseline, degraded, healing, final_validation

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

8.5.6 Exercise 05 - Erasure Coding Concept Experiment

Part 1 - Why this matters

Erasure coding protects data by combining data shards with parity shards. It can tolerate selected shard losses without storing a complete copy on every drive, but higher protection reduces usable capacity and affects quorum.

The reader will model these tradeoffs in Python before touching a cluster. A conceptual simulation makes failure limits visible and prevents parity settings from becoming unexplained configuration values.

Part 2 - Technical concept and behavior

For an erasure set of N shards with P parity shards, the data-shard count is

$$D = N - P.$$

The approximate storage efficiency is D/N. Actual read and write availability follows the deployment's documented quorum rules and must not be inferred from this ratio alone.

Part 3 - Hints and Helper

Validate that shard and parity counts describe a supported conceptual case. Enumerate combinations of missing shards, classify whether loss remains within parity, calculate usable ratio, and compare the model with observed lab behavior.

Part 4 - Python code skeleton

```
from itertools import combinations
```

```
def E05(total_shards, parity_shards):
    if ...:
        raise ValueError(...)
    data_shards = ...
    storage_efficiency = ...
    shard_ids = list(range(total_shards))
    scenarios = []
    for failed_count in range(total_shards + 1):
        for failed in combinations(shard_ids, failed_count):
            theoretically_recoverable = ...
            scenarios.append({
                "failed": failed,
                "recoverable": theoretically_recoverable,
            })
    return data_shards, storage_efficiency, scenarios

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

8.5.7 Exercise 06 - Performance Impact of Replication

Part 1 - Why this matters

Additional protection can increase the work required before or after an upload is considered complete. Replication to another destination consumes bandwidth and storage, while stronger synchronous acknowledgment or parity settings may affect client-visible latency differently.

The experiment must name the mechanism being measured. Erasure coding inside one deployment and asynchronous bucket or site replication are not interchangeable, and their performance results answer different questions.

Part 2 - Technical concept and behavior

Client latency measures how long the originating operation takes. Replication completion lag measures when the same protected version becomes available at the destination. Throughput, destination lag, CPU, network, and integrity can all be relevant; one elapsed time cannot describe the entire cost.

Part 3 - Hints and Helper

Compare equivalent objects with protection disabled and enabled only in a disposable environment. Repeat trials, record source acknowledgment separately from destination verification, and validate exact version hash at both locations.

Part 4 - Python code skeleton

```
from statistics import median
from time import perf_counter, monotonic
```

```
def run_trial(source_client, destination_client, artifact, deadline):
    started = perf_counter()
    result = source_client.fput_object(...)
    source_latency = perf_counter() - started
    replication_started = monotonic()
    destination_version = ...
    while monotonic() < deadline:
        destination_version = ...
        if ...:
            break
        ...
    replication_lag = ...
    integrity = ...
    return source_latency, replication_lag, integrity

def E06(configurations, repetitions):
    results = {}
    for configuration in configurations:
        trials = [run_trial(...) for _ in range(repetitions)]
        results[configuration.name] = ...
    return results

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

8.5.8 Exercise 07 - High Availability Configuration

Part 1 - Why this matters

Storage can remain healthy while applications experience an outage if every client uses one failed endpoint. High availability therefore requires both resilient storage nodes and a client-facing endpoint strategy with health checks and failover.

Configuration must avoid hidden single points of failure in load balancing, DNS, credentials, networking, and monitoring. Availability claims should be tested against defined failures rather than assumed from node count.

Part 2 - Technical concept and behavior

A highly available design distributes failure domains, preserves read and write quorum, and exposes healthy endpoints through supported routing. Clients use retry and timeout policies but must not retry non-idempotent workflows blindly. Monitoring distinguishes degraded service from complete failure.

Part 3 - Hints and Helper

Describe nodes, drives, network paths, parity, endpoint routing, and monitoring. Validate configuration in Python, test one permitted failure at a time, and measure both request success and recovery time objectives.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class HAConfiguration:
    nodes: list
    drives_by_node: dict
    endpoints: list
    parity: int
    health_checks: list

def E07(configuration, probe):
    findings = []
    if len(configuration.nodes) < ...:
        findings.append(...)
    if len(configuration.endpoints) < ...:
        findings.append(...)
    if ...:
        findings.append(...)
    baseline = probe(...)
    failure_scenarios = [...]
    observations = [probe(scenario) for scenario in failure_scenarios]
    return findings, baseline, observations

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

8.5.9 Exercise 08 - Disaster Recovery Backup Strategy

Part 1 - Why this matters

High availability protects service during selected component failures, but it may not protect against site loss, credential compromise, destructive deletion, or a policy error replicated everywhere. Disaster recovery requires an independent recovery copy and a tested restoration process.

A backup that has never been restored is only an assumption. The strategy must define recovery point and time objectives, version retention, encryption, credential separation, and verification of restored bytes.

Part 2 - Technical concept and behavior

Replication can maintain a secondary object destination, while backups may preserve isolated historical copies. Versioning and object locking can reduce some deletion risks but do not replace independent recovery planning. Metadata, policies, manifests, and encryption keys may require separate protection.

Part 3 - Hints and Helper

Build an inventory and integrity manifest, copy to a separately controlled destination, simulate loss only by hiding or deleting disposable source objects, restore to a new bucket, and compare every expected name, version, size, and hash.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

def build_manifest(client, bucket_name, prefix):
    objects = list(client.list_objects(
        bucket_name, prefix=prefix, recursive=True, include_version=True,
    ))
    return [{
        "name": item.object_name,
        "version_id": item.version_id,
        "size": item.size,
        "sha256": ...,
    } for item in objects if ...]

def E08(source_client, backup_client, restore_client,
        source_bucket, backup_bucket, restore_bucket, prefix):
    manifest = build_manifest(...)
    backup_results = [...]
    restore_results = [...]
    restored_manifest = build_manifest(...)
    comparison = ...
    return {
        "created_at": datetime.now(timezone.utc),
        "manifest": manifest,
        "backup": backup_results,
        "restore": restore_results,
        "valid": comparison,
    }

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

8.5.10 Exercise 09 - End-to-End Fault Tolerance Test

Part 1 - Why this matters

An end-to-end test connects topology assumptions with actual application behavior. It checks whether known objects remain correct, whether permitted reads and writes continue, whether recovery occurs, and whether redundancy returns after healing.

Passing requires more than a green process status. The same artifact hashes, metadata, versions, access controls, and recovery objectives must remain valid throughout the allowed failure scenario.

Part 2 - Technical concept and behavior

The test moves through baseline, fault injection, degraded operation, restoration, healing, and final validation. Every phase records timestamps and observations. A stop condition prevents additional faults when an unexpected quorum or integrity failure occurs.

Part 3 - Hints and Helper

Use disposable infrastructure and externally backed-up test data. Resolve one exact failure target, validate the permitted failure budget, guarantee restoration in `finally`, and produce a report that distinguishes availability, durability, integrity, and recovery time.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

def record_phase(name, operation):
    started = datetime.now(timezone.utc)
    try:
        result = operation()
        status = "passed" if ... else "failed"
        error = None
    except Exception as exception:
        result = None
        status = "error"
        error = ...
    return {"phase": name, "started": started,
            "status": status, "result": result, "error": error}

def E09(lab, manifest, failure_target, recovery_objectives):
    report = []
    report.append(record_phase("baseline", lambda: ...))
    if report[-1]["status"] != "passed":
        return report
    fault_active = False
    try:
        report.append(record_phase("fault", lambda: lab.fail(failure_target)))
        fault_active = ...
        report.append(record_phase("degraded", lambda: ...))
    finally:
        if fault_active:
            report.append(record_phase("restore", lambda: lab.restore(failure_target)))
    report.append(record_phase("healing", lambda: ...))
```

```
    report.append(record_phase("final_validation", lambda: ...))
    summary = ...
    return report, summary

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

Book 9

Vector Database Lessons (Qdrant)

9.1 Introduction

9.1.1 What will this book teach you

The previous books established three important data layers: PostgreSQL for structured relationships, MongoDB for flexible documents, and MinIO for large binary objects. This book introduces a fourth layer: vector storage and similarity retrieval. Qdrant stores vectors together with identifiers and payload metadata, then searches for points whose vectors are close to a query according to a configured distance measure.

A vector database does not create meaning by itself. An embedding model converts text, images, or other inputs into numerical vectors. The quality, dimension, normalization behavior, training objective, language coverage, and version of that model determine what relationships may appear in the vector space. Qdrant stores and searches the resulting representations, but it cannot repair a poor embedding model or guarantee that vector proximity matches the application's definition of relevance.

Python will remain the main programming language throughout this book. You will connect through `qdrant-client`, create collections, generate embeddings with a selected model, insert points, attach payloads, retrieve by identifier, execute similarity queries, apply metadata filters, configure indexes, and integrate retrieval into a Retrieval-Augmented Generation pipeline. Docker or terminal commands will be used only when the Qdrant service or a distributed learning environment must be started.

Every collection has a vector configuration. The vector size must match the embedding dimension, and the selected distance metric must match the intended model behavior. Changing from one embedding model to another can change vector size and geometry even when both models accept the same text. For this reason, embedding model identity and version must be recorded as part of the collection or ingestion design. Mixing incompatible vectors inside one unnamed vector space produces results that may look valid but have no consistent meaning.

The reader will learn through controlled experiments rather than relying on impressive demonstrations. You will compare semantically related and unrelated examples, inspect nearest-neighbor rankings, test normalization, measure drift after model or data changes, build small relevance judgments, and evaluate whether retrieved results are actually useful. A search re-

quest that returns results is not evidence that those results are correct.

The book also introduces Retrieval-Augmented Generation, commonly called RAG. In a RAG workflow, source documents are divided into chunks, converted to vectors, stored with provenance metadata, retrieved for a user query, and supplied as context to a language model. Retrieval can improve access to external knowledge, but it does not guarantee truthful answers. Poor chunking, missing documents, weak embeddings, incorrect filters, stale indexes, irrelevant context, and model hallucination can still cause failure.

The final chapter studies scalable retrieval. Approximate vector indexes such as HNSW trade exactness, memory, construction cost, and query latency. Payload indexes accelerate filtering and support query planning, while shards and replicas distribute data and availability responsibilities. These features should be configured only after the reader can measure retrieval quality and understand the workload they are attempting to scale.

The exercises provide explanations, hints, and incomplete Python code skeletons rather than finished solutions. Before inserting a point, predict its identifier, dimension, payload, and collection. Before searching, state which results should be relevant and why. Afterward, inspect scores, payloads, ordering, filters, latency, and relevance judgments. This maintains the volume's experimental learning cycle: design, predict, execute, observe, evaluate, and improve.

9.1.2 How Qdrant supports artificial intelligence systems

Qdrant supports retrieval around artificial intelligence models. It can store embeddings for document chunks, products, images, users, memories, or other items and return nearby candidates for semantic search, recommendations, RAG, deduplication, and similar workflows. It does not replace the embedding model, the source-of-truth database, or the object store containing original files.

A practical system may divide responsibility across all four data technologies. PostgreSQL can store users, permissions, plans, and authoritative document records. MongoDB can store chat sessions and flexible processing metadata. MinIO can store original PDFs, datasets, images, weights, and checkpoints. Qdrant can store embeddings and retrieval payloads that refer back to those authoritative records. Stable source identifiers allow retrieved points to be traced to their original document and verified before they are used.

This separation is important because vectors are derived data. When a source document changes, the corresponding chunks and embeddings may become stale. When an embedding model changes, vectors may need to be regenerated into a new collection or named vector configuration. The system must preserve provenance such as source ID, source version, chunk position, embedding model, embedding version, and ingestion timestamp so stale or incompatible points can be found and replaced.

Payload metadata supports filtering and returning context, but it should not become an uncontrolled duplicate of every source record. Store the fields required for retrieval, authorization filtering, provenance, and display, while keeping authoritative business state in the system designed to own it. Security filters must be applied as part of retrieval; filtering sensitive results only after vector search can leak existence or ranking information and waste candidate capacity.

9.1.3 How to approach the exercises

Use a small, understandable dataset before scaling. Include clearly related pairs, difficult negatives, repeated concepts, short and long texts, and examples from the languages or domain the application must support. Write expected relevance judgments before changing search settings. Without a ground truth or at least human judgments, it is impossible to tell whether one embedding model, distance metric, or index configuration improved retrieval quality.

Record the embedding contract for every experiment: model name, exact version or revision, vector dimension, preprocessing, normalization, and whether the model uses different instructions for documents and queries. Generate document and query embeddings according to the model's intended interface. Two vectors with equal length are not automatically compatible merely because their dimensions match.

Use stable point IDs and payload provenance. Batch ingestion should verify that IDs, vectors, and payloads remain aligned, because a shifted list can attach the correct vector to the wrong source text without producing a server error. Count submitted and stored points, retrieve a sample by ID, and compare its payload with the original source before trusting the collection.

Treat similarity scores as metric- and model-specific values. A threshold chosen for cosine similarity cannot be transferred blindly to Euclidean distance, another embedding model, or another domain. Tune thresholds on labeled examples, inspect false positives and false negatives, and report retrieval metrics such as precision at k, recall at k, Mean Reciprocal Rank, or normalized Discounted Cumulative Gain when the experiment supports them.

RAG exercises must preserve source attribution and context budgets. Chunk boundaries should retain enough meaning, overlap should not create excessive duplication, and retrieval should return source identifiers with text. Empty retrieval must produce a controlled response rather than inviting the language model to invent an answer. Retrieved content should also be treated as untrusted input because source documents can contain misleading or malicious instructions.

Scaling experiments require isolated collections and reproducible datasets. Measure ingestion throughput, indexing time, query latency distribution, memory or disk use, and retrieval quality together. Approximate search that is faster but loses necessary relevant results may not be an improvement. Never simulate index corruption by modifying Qdrant's internal storage files; recovery should be tested with supported snapshots, replicas, backups, and restore procedures.

9.1.4 The Chapters (QD00–QD03) included in this book

- QD00 - Embeddings & Semantic Meaning
- QD01 - Similarity Search Mechanics
- QD02 - RAG Integration Workflow
- QD03 - Indexing & Scalable Retrieval

9.1.5 QD00 - Embeddings & Semantic Meaning

This chapter establishes the vector-storage foundation. You will install and start Qdrant, create a collection with the correct vector size and distance metric, generate embeddings with a chosen model, and insert individual and batched points. Payload metadata and stable identifiers will connect each vector to the object it represents.

The later exercises retrieve points, test vector normalization, observe semantic drift, and evaluate embedding quality. Drift may come from a model revision, preprocessing change, language distribution, domain shift, or changes in the source data. By the end, you should understand that an embedding is a model-dependent representation requiring evaluation and provenance, not a permanent universal encoding of meaning.

9.1.6 QD01 - Similarity Search Mechanics

This chapter studies retrieval behavior through cosine similarity, Euclidean distance, top-k selection, thresholds, and payload filters. You will compare metrics using controlled collections rather than changing the interpretation of one collection unpredictably. The current Qdrant Query API will serve as the main search interface where appropriate.

Performance and quality are examined together. You will benchmark latency, inspect rankings, identify ties and surprising neighbors, and debug mismatches involving vector dimension, model choice, normalization, filters, metric direction, or incompatible query preprocessing. The goal is to explain why a result was returned and whether it should be considered relevant.

9.1.7 QD02 - RAG Integration Workflow

This chapter builds a complete retrieval workflow from source text to model context. You will chunk documents, generate and store chunk embeddings, embed a query using the compatible model path, retrieve candidates, rank context, filter by metadata, and respect a context-size budget. Every chunk will retain provenance so it can be traced to its source.

The final exercises handle empty retrieval, test an end-to-end RAG pipeline, and analyze failure modes. Evaluation separates retrieval failure from generation failure: the system may retrieve the wrong context, retrieve the right context that the model ignores, or retrieve nothing and still produce an unsupported answer. A robust design records evidence for each stage.

9.1.8 QD03 - Indexing & Scalable Retrieval

This chapter studies HNSW configuration, index-build cost, query speed, payload indexes, large-scale ingestion, shards, replicas, and consistency. HNSW performs approximate nearest-neighbor search and exposes tradeoffs through construction and search parameters. Payload indexes help filtering and cardinality estimation; they should be created for fields used meaningfully in filters rather than every payload key.

The distributed exercises compare shard count, replication factor, write consistency, and latency monitoring using isolated deployments. More shards or replicas do not automatically improve every workload, and configuration changes must be evaluated against data volume,

failure behavior, query routing, write throughput, and recovery goals.

The chapter concludes with supported recovery testing and a scalable semantic-search design. The final system must define embedding contracts, collection layout, payload schema, indexes, ingestion idempotency, authorization filters, quality metrics, latency objectives, backup or snapshot recovery, and source-of-truth integration. Scaling is considered successful only when retrieval remains relevant, secure, observable, and recoverable.

9.2 QD00 - Embeddings & Semantic Meaning

Data Engineering for AI

9.2.1 Exercise 00 - Install Qdrant and Start Service

Part 1 - Why this matters

Vector operations require a reachable Qdrant service with persistent storage and known network settings. Starting the service is the first boundary between Python code and the vector database that will hold later collections and points.

The exercise verifies more than a running process. Python must connect, receive service information, and list collections within a deadline so configuration or network failures are visible before data ingestion begins.

Part 2 - Technical concept and behavior

Qdrant exposes HTTP and gRPC interfaces and can run locally through a supported package or container deployment. Persistent storage must be mounted deliberately when data should survive restarts. Production authentication and TLS requirements differ from an isolated local lab.

Part 3 - Hints and Helper

Use the current official installation instructions for the chosen environment. Keep URLs and API keys outside source code, configure a finite timeout, and use `get_collections()` as an authenticated readiness check.

Part 4 - Python code skeleton

```
import os
from qdrant_client import QdrantClient

def E00():
    client = QdrantClient(
        url=os.getenv(...),
        api_key=os.getenv(...),
        timeout=...,
    )
    response = client.get_collections()
    collection_names = [item.name for item in response.collections]
```

```
    return collection_names

def main():
    print(E00())

if __name__ == "__main__":
    main()
```

9.2.2 Exercise 01 - Create Collection with Vector Size

Part 1 - Why this matters

A Qdrant collection defines the contract for stored vectors. Its dimension must match the embedding model, and its distance metric determines how query vectors are compared with stored points.

Creating a collection with a guessed size can block ingestion or, worse, encourage padding or truncation that destroys embedding meaning. The reader must obtain the dimension from the actual model output and verify the stored configuration.

Part 2 - Technical concept and behavior

A collection can define one vector space or several named vector spaces. Each dense vector configuration specifies size and distance such as cosine, Euclidean, or dot product. Additional index and storage settings can be added later when the workload is understood.

Part 3 - Hints and Helper

Generate one sample embedding, validate that it is one-dimensional and finite, and use its length. Refuse to overwrite an existing collection silently; inspect its current configuration or use a disposable name.

Part 4 - Python code skeleton

```
import math
from qdrant_client import QdrantClient, models

def E01(client, collection_name, sample_vector):
    if not sample_vector or not all(math.isfinite(value) for value in sample_vector):
        raise ValueError(...)
    vector_size = len(sample_vector)
    existing = {item.name for item in client.get_collections().collections}
    if collection_name in existing:
        raise ValueError(...)
    client.create_collection(
        collection_name=collection_name,
        vectors_config=models.VectorParams(
            size=...,
            distance=models.Distance....,
        ),
    )
```

```
    information = client.get_collection(collection_name)
    return vector_size, information

def main():
    client = QdrantClient(...)
    print(E01(...))

if __name__ == "__main__":
    main()
```

9.2.3 Exercise 02 - Generate Embeddings using Model

Part 1 - Why this matters

The embedding model determines which relationships are represented by vector proximity. Qdrant receives numbers, not raw understanding, so preprocessing and model configuration must be reproducible and compatible between documents and queries.

This exercise generates embeddings and records their contract. The reader will check shape, finite values, and deterministic behavior before any vector is stored.

Part 2 - Technical concept and behavior

An encoder maps a sequence of texts to a matrix with one vector per input. Some models require different instructions or methods for document and query embeddings. Normalization may be performed by the model or application and must be recorded rather than assumed.

Part 3 - Hints and Helper

Use a local or configured embedding model through one wrapper. Preserve input order, reject empty text according to policy, convert outputs to ordinary finite floats, and return model name, revision, dimension, and normalization setting.

Part 4 - Python code skeleton

```
import math

def E02(encoder, texts, purpose):
    if purpose not in {...}:
        raise ValueError(...)
    if ...:
        raise ValueError(...)
    if purpose == "document":
        raw_vectors = encoder.encode_documents(...)
    else:
        raw_vectors = encoder.encode_queries(...)
    vectors = [[float(value) for value in vector] for vector in raw_vectors]
    dimensions = {len(vector) for vector in vectors}
    valid = len(vectors) == len(texts) and len(dimensions) == 1 and all(
        math.isfinite(value) for vector in vectors for value in vector
    )
```

```
    contract = {...}
    return vectors, contract, valid

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

9.2.4 Exercise 03 - Insert Single Vector Point

Part 1 - Why this matters

A Qdrant point combines an identifier, vector, and optional payload. Stable identity allows the application to update or regenerate derived vectors without losing the connection to the source record.

Insertion must validate the embedding contract before sending data. A point accepted under the wrong source identity or payload can produce semantically plausible but factually incorrect retrieval results.

Part 2 - Technical concept and behavior

`upsert()` inserts a new point or replaces data for an existing point ID. A point can use an integer or UUID-compatible identifier. Setting `wait=True` requests completion before the client continues, after which retrieval can verify vector and payload alignment.

Part 3 - Hints and Helper

Validate vector dimension against collection configuration, use a deterministic source-derived ID policy, insert one `PointStruct`, retrieve it with vectors and payloads, and compare every stored field.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E03(client, collection_name, point_id, vector, payload, expected_size):
    if len(vector) != expected_size:
        raise ValueError(...)
    point = models.PointStruct(
        id=...,
        vector=...,
        payload=...,
    )
    operation = client.upsert(
        collection_name=collection_name,
        points=[point],
        wait=...,
    )
    stored = client.retrieve(
```

```
        collection_name=collection_name,
        ids=[point_id],
        with_vectors=True,
        with_payload=True,
    )
    return operation.status, stored

def main():
    client = QdrantClient(...)
    print(E03(...))

if __name__ == "__main__":
    main()
```

9.2.5 Exercise 04 - Insert Batch of Vectors

Part 1 - Why this matters

Embedding ingestion normally involves many source records. Batch operations reduce request overhead, but they also create a dangerous alignment problem: IDs, vectors, texts, and payloads must refer to the same item at every position.

The reader will validate the complete batch before sending it and verify stored samples afterward. Partial assumptions based only on submitted count are not enough.

Part 2 - Technical concept and behavior

A batch can be represented as a list of point structures or through parallel batch fields. Upsert semantics mean duplicate IDs replace earlier point data. Bounded batches control request size and allow retry or progress tracking.

Part 3 - Hints and Helper

Check equal lengths, unique IDs, fixed vector dimension, finite values, and source ID inside each payload. Split into bounded batches, use `wait=True` for the exercise, count collection points, and retrieve random samples.

Part 4 - Python code skeleton

```
import math
from qdrant_client import QdrantClient, models

def E04(client, collection_name, ids, vectors, payloads, batch_size):
    if not (len(ids) == len(vectors) == len(payloads)):
        raise ValueError(...)
    if len(set(ids)) != len(ids):
        raise ValueError(...)
    operations = []
    for start in range(0, len(ids), batch_size):
        points = [
            models.PointStruct(id=..., vector=..., payload=...)
```

```
            for ... in zip(...)
        ]
        operations.append(client.upsert(
            collection_name=collection_name,
            points=points,
            wait=True,
        ))
    samples = client.retrieve(...)
    return operations, samples

def main():
    client = QdrantClient(...)
    print(E04(...))

if __name__ == "__main__":
    main()
```

9.2.6 Exercise 05 - Attach Payload Metadata to Vectors

Part 1 - Why this matters

Payload metadata gives a retrieved vector provenance and filterable context. Without source ID, version, chunk location, access scope, and embedding information, a nearby point may be impossible to trace or authorize safely.

Payload should remain purposeful. Duplicating complete source systems into Qdrant increases inconsistency, while missing authorization fields can force unsafe post-retrieval filtering.

Part 2 - Technical concept and behavior

Payloads are JSON-like values attached to points and can be inserted with vectors or changed later. Filters can use indexed payload fields. The vector represents similarity; the payload describes and constrains the item represented.

Part 3 - Hints and Helper

Define a required payload contract containing source, source version, tenant, embedding model, and ingestion time. Reject secrets and oversized raw content, update one point's payload, and retrieve it for verification.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
from qdrant_client import QdrantClient, models

def E05(client, collection_name, point_id, source_metadata):
    payload = {
        "source_id": ...,
        "source_version": ...,
        "tenant_id": ...,
        "embedding_model": ...,
```

```
        "embedded_at": datetime.now(timezone.utc).isoformat(),
    }
    required = {...}
    if ...:
        raise ValueError(...)
    client.set_payload(
        collection_name=collection_name,
        payload=payload,
        points=[point_id],
        wait=True,
    )
    stored = client.retrieve(..., with_payload=True)
    return payload, stored

def main():
    client = QdrantClient(...)
    print(E05(...))

if __name__ == "__main__":
    main()
```

9.2.7 Exercise 06 - Retrieve Vector by ID

Part 1 - Why this matters

Direct retrieval confirms that one known point exists and still matches its source record. It is essential for ingestion verification, debugging, updates, deletion checks, and embedding migration.

Vectors can be large, so applications should request them only when needed. Payload-only retrieval is often sufficient for normal workflows, while vector retrieval belongs in validation or specialized processing.

Part 2 - Technical concept and behavior

`retrieve()` accepts one or more point IDs and independent flags for vectors and payloads. Missing IDs simply do not produce corresponding records, so callers must compare requested and returned identities explicitly.

Part 3 - Hints and Helper

Retrieve an existing and missing ID together, build a map by returned ID, validate dimension and finite values for the existing point, and report missing IDs without confusing them with transport failure.

Part 4 - Python code skeleton

```
import math
from qdrant_client import QdrantClient

def E06(client, collection_name, requested_ids, expected_size):
```

```
    records = client.retrieve(
        collection_name=collection_name,
        ids=...,
        with_vectors=True,
        with_payload=True,
    )
    by_id = {record.id: record for record in records}
    missing = [point_id for point_id in requested_ids if point_id not in by_id]
    validations = {
        point_id: len(record.vector) == expected_size and all(
            math.isfinite(value) for value in record.vector
        )
        for point_id, record in by_id.items()
    }
    return by_id, missing, validations

def main():
    client = QdrantClient(...)
    print(E06(...))

if __name__ == "__main__":
    main()
```

9.2.8 Exercise 07 - Vector Normalization Effect Test

Part 1 - Why this matters

Normalization removes vector magnitude and preserves direction. Its effect depends on the metric and embedding model, so applying it automatically can be redundant, useful, or harmful to the model's intended geometry.

The reader will compare rankings produced by original and normalized representations on controlled examples. The experiment records norms and scores rather than assuming cosine and dot-product behavior are interchangeable in every pipeline.

Part 2 - Technical concept and behavior

For a nonzero vector $\mathbf{x}$, L2 normalization is

$$\widehat{\mathbf{x}} = \frac{\mathbf{x}}{\|\mathbf{x}\|_2}.$$

Cosine similarity depends on direction, while dot product also depends on magnitude unless vectors are normalized. Zero vectors cannot be normalized by ordinary division.

Part 3 - Hints and Helper

Implement normalization with PyTorch, reject zero or near-zero norms, create separate test collections for metric configurations, and compare top-k identities and scores before and after normalization.

Part 4 - Python code skeleton

```
import torch
from qdrant_client import QdrantClient

def normalize(vector, epsilon=1e-12):
    tensor = torch.tensor(vector, dtype=torch.float32)
    norm = torch.linalg.vector_norm(tensor)
    if norm <= epsilon:
        raise ValueError(...)
    return (tensor / norm).tolist(), norm.item()

def E07(client, original_collection, normalized_collection,
        query_vector, limit):
    normalized_query, query_norm = normalize(...)
    original_result = client.query_points(
        collection_name=original_collection,
        query=query_vector,
        limit=limit,
    ).points
    normalized_result = client.query_points(
        collection_name=normalized_collection,
        query=normalized_query,
        limit=limit,
    ).points
    comparison = ...
    return query_norm, original_result, normalized_result, comparison

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

9.2.9 Exercise 08 - Semantic Meaning Drift Observation

Part 1 - Why this matters

Embedding behavior can change when the model revision, preprocessing, language distribution, or domain changes. A retrieval system may therefore drift even when its Qdrant query code remains unchanged.

Drift must be measured on stable probe examples. Comparing vector coordinates alone is insufficient when models use different spaces; ranking and relevance changes reveal the application impact more directly.

Part 2 - Technical concept and behavior

Within a compatible vector space, cosine similarity between old and new vectors can measure representation movement. Across incompatible model spaces, use separate collections and compare neighbor overlap, rank movement, and labeled retrieval metrics. Model changes should not mix vectors in one unnamed space.

Part 3 - Hints and Helper

Keep a fixed probe corpus and query set. Generate embeddings under two controlled configurations, store them separately, calculate same-item similarity only when valid, and report top-k overlap and changed relevance.

Part 4 - Python code skeleton

```
import torch

def cosine(left, right):
    left_tensor = torch.tensor(left, dtype=torch.float32)
    right_tensor = torch.tensor(right, dtype=torch.float32)
    return torch.nn.functional.cosine_similarity(
        left_tensor.unsqueeze(0),
        right_tensor.unsqueeze(0),
    ).item()

def E08(old_encoder, new_encoder, probe_texts, probe_queries, searcher):
    old_vectors = old_encoder.encode_documents(...)
    new_vectors = new_encoder.encode_documents(...)
    coordinate_comparison_allowed = ...
    same_item_scores = [...] if coordinate_comparison_allowed else None
    old_rankings = [searcher(..., configuration="old") for query in probe_queries]
    new_rankings = [searcher(..., configuration="new") for query in probe_queries]
    overlap = ...
    rank_movements = ...
    return same_item_scores, overlap, rank_movements

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

9.2.10 Exercise 09 - Embedding Quality Evaluation Challenge

Part 1 - Why this matters

Embedding quality is task-specific. A visually convincing nearest-neighbor example cannot establish whether the model retrieves the correct documents across languages, topics, difficult negatives, and ambiguous queries.

Evaluation requires query relevance judgments and repeatable metrics. The reader will separate model quality from Qdrant latency and compare configurations using the same corpus and ground truth.

Part 2 - Technical concept and behavior

For a query with relevant set R and retrieved top-k set S_k,

$$\text{Precision@}\,k = \frac{|R \cap S_k|}{k}, \qquad \text{Recall@}\,k = \frac{|R \cap S_k|}{|R|}.$$

Ranking-sensitive measures such as MRR or NDCG capture where relevant items appear.

Part 3 - Hints and Helper

Create judgments before tuning. Include easy, difficult, multilingual, and no-answer queries; run each embedding configuration against its own compatible collection; calculate per-query and aggregate metrics; and inspect false positives and false negatives.

Part 4 - Python code skeleton

```
from statistics import mean

def precision_at_k(retrieved_ids, relevant_ids, k):
    selected = retrieved_ids[:k]
    return ...

def recall_at_k(retrieved_ids, relevant_ids, k):
    if not relevant_ids:
        return ...
    return ...

def reciprocal_rank(retrieved_ids, relevant_ids):
    for rank, point_id in enumerate(retrieved_ids, start=1):
        if point_id in relevant_ids:
            return ...
    return 0.0

def E09(searcher, judgments, k):
    per_query = []
    for query_id, item in judgments.items():
        retrieved_ids = searcher(item["query"], k)
        per_query.append({...})
    aggregate = {
        "precision": mean(...),
        "recall": mean(...),
        "mrr": mean(...),
    }
    return per_query, aggregate

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

9.3 QD01 - Similarity Search Mechanics

AI Evaluation and Experimentation

9.3.1 Exercise 00 - Cosine Similarity Search Query

Part 1 - Why this matters

Cosine-based retrieval compares vector direction and is widely used with text embeddings. It can retrieve semantically related items even when they do not share exact words, provided the embedding model represents the relationship well.

The query must use the same embedding contract as the stored points. A valid vector dimension and successful response do not prove compatibility when preprocessing or model revisions differ.

Part 2 - Technical concept and behavior

A collection configured with cosine distance ranks vectors according to cosine-based similarity behavior. Qdrant's query interface returns scored points ordered by its configured metric. Payload and vectors are optional in the response and should be requested only when needed.

Part 3 - Hints and Helper

Create or use a cosine collection, embed one query with the compatible query encoder, call `query_points()`, and return IDs, scores, and source payloads. Compare results with written expectations.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient

def E00(client, collection_name, query_encoder, query_text, limit):
    query_vector = query_encoder.encode_queries([query_text])[0]
    response = client.query_points(
        collection_name=collection_name,
        query=...,
        limit=...,
        with_payload=True,
        with_vectors=False,
    )
    results = [
        {"id": point.id, "score": point.score, "payload": point.payload}
        for point in response.points
    ]
    return query_vector, results

def main():
    client = QdrantClient(...)
    print(E00(...))
```

```
if __name__ == "__main__":
    main()
```

9.3.2 Exercise 01 - Euclidean Distance Search Query

Part 1 - Why this matters

Euclidean distance measures straight-line separation in vector space and is useful when both direction and magnitude have meaning under the selected representation. It should be chosen because it matches the model and task, not simply to produce a different ranking.

The reader will use a collection configured explicitly for Euclidean distance and compare returned neighbors with manually calculated distances on a small dataset.

Part 2 - Technical concept and behavior

For vectors $\mathbf{x}$ and $\mathbf{y}$,

$$d(\mathbf{x}, \mathbf{y}) = \sqrt{\sum_i (x_i - y_i)^2}.$$

Smaller mathematical distance means closer vectors. Qdrant's returned score and threshold behavior must be interpreted according to the configured metric and client documentation.

Part 3 - Hints and Helper

Use a separate Euclidean collection containing the same controlled points. Query it, retrieve vectors for the small test, calculate distances with PyTorch, and verify neighbor order rather than assuming score direction.

Part 4 - Python code skeleton

```
import torch
from qdrant_client import QdrantClient

def euclidean(left, right):
    return torch.linalg.vector_norm(
        torch.tensor(left) - torch.tensor(right)
    ).item()

def E01(client, collection_name, query_vector, limit):
    response = client.query_points(
        collection_name=collection_name,
        query=query_vector,
        limit=limit,
        with_vectors=True,
        with_payload=True,
    )
    manual = [
        (point.id, euclidean(query_vector, point.vector))
        for point in response.points
    ]
```

```
    verified_order = ...
    return response.points, manual, verified_order

def main():
    client = QdrantClient(...)
    print(E01(...))

if __name__ == "__main__":
    main()
```

9.3.3 Exercise 02 - Compare Distance Metrics

Part 1 - Why this matters

Distance metrics impose different geometric assumptions and can change which items are considered neighbors. Comparing them reveals whether vector magnitude contributes useful signal or distorts the application's relevance.

Scores from different metrics are not directly comparable by numeric value. The experiment should compare rankings and labeled quality while each collection preserves its own metric contract.

Part 2 - Technical concept and behavior

Cosine emphasizes angular similarity, Euclidean measures geometric separation, and dot product combines direction with magnitude. Normalized vectors can make some ranking relationships more similar, but storage and scoring behavior must still be evaluated explicitly.

Part 3 - Hints and Helper

Insert identical test vectors and IDs into separate metric collections. Run the same query vector, compare top-k IDs with rank overlap and movement, and evaluate each result against the same relevance judgments.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient

def rank_map(points):
    return {point.id: rank for rank, point in enumerate(points, start=1)}

def E02(client, collections_by_metric, query_vector, limit, relevant_ids):
    results = {
        metric: client.query_points(
            collection_name=collection_name,
            query=query_vector,
            limit=limit,
        ).points
        for metric, collection_name in collections_by_metric.items()
    }
    rankings = {metric: rank_map(points) for metric, points in results.items()}
```

```
    quality = {...}
    overlap = {...}
    return results, rankings, quality, overlap

def main():
    client = QdrantClient(...)
    print(E02(...))

if __name__ == "__main__":
    main()
```

9.3.4 Exercise 03 - Top-K Nearest Neighbors Retrieval

Part 1 - Why this matters

Top-k retrieval limits the candidate set returned to an application. A small k may miss useful context, while a large k increases latency, noise, and downstream processing.

The correct value depends on evaluation and the next pipeline stage. This exercise compares several limits and checks that smaller result sets are consistent prefixes of a stable larger query under unchanged conditions.

Part 2 - Technical concept and behavior

The query `limit` controls the maximum number of scored points returned. Approximate search may introduce variation under some configurations, while deterministic tie-breaking among equal scores should not be assumed without additional analysis.

Part 3 - Hints and Helper

Validate positive k values and ensure they do not exceed the experiment's intended range. Run several limits with identical query parameters, compare IDs and score order, and calculate precision and recall where judgments exist.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient

def E03(client, collection_name, query_vector, k_values):
    if any(k <= 0 for k in k_values):
        raise ValueError(...)
    results = {}
    for k in sorted(set(k_values)):
        response = client.query_points(
            collection_name=collection_name,
            query=query_vector,
            limit=k,
            with_payload=True,
        )
        results[k] = response.points
    largest = results[max(results)]
```

```
    prefix_checks = {
        k: [point.id for point in results[k]] == [...]
        for k in results
    }
    return results, prefix_checks

def main():
    client = QdrantClient(...)
    print(E03(...))

if __name__ == "__main__":
    main()
```

9.3.5 Exercise 04 - Similarity Threshold Filtering

Part 1 - Why this matters

A fixed top-k query returns candidates even when every candidate is weak. A score threshold can reject low-quality neighbors and support an empty-retrieval path instead of forcing irrelevant context into the application.

Thresholds are specific to model, metric, preprocessing, and domain. One convenient number cannot be reused safely across collections without labeled calibration.

Part 2 - Technical concept and behavior

The query interface accepts a `score_threshold`. Whether acceptable values lie above or below a numeric boundary depends on metric semantics, and Qdrant applies the configured metric's threshold behavior. Thresholding trades recall for precision.

Part 3 - Hints and Helper

Collect positive and negative query examples, inspect score distributions, test several thresholds, and calculate accepted true positives, false positives, and false negatives. Preserve an explicit no-result case.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient

def E04(client, collection_name, query_vector, thresholds,
        limit, relevant_ids):
    experiments = []
    for threshold in thresholds:
        points = client.query_points(
            collection_name=collection_name,
            query=query_vector,
            score_threshold=threshold,
            limit=limit,
            with_payload=True,
        ).points
```

```
        retrieved_ids = [point.id for point in points]
        experiments.append({
            "threshold": threshold,
            "results": points,
            "precision": ...,
            "recall": ...,
            "empty": len(points) == 0,
        })
    return experiments

def main():
    client = QdrantClient(...)
    print(E04(...))

if __name__ == "__main__":
    main()
```

9.3.6 Exercise 05 - Payload-based Filtering in Search

Part 1 - Why this matters

Semantic similarity alone may retrieve the wrong tenant, language, source version, or document state. Payload filters constrain vector search to records that are eligible for the current request.

Authorization filters must be applied inside retrieval rather than after top-k selection. Post-filtering can leak information and may leave no useful candidates because disallowed points consumed the result limit.

Part 2 - Technical concept and behavior

Qdrant filters combine conditions such as must, should, and must-not. Field conditions can match keyword, numeric range, Boolean, or other supported payload types. Payload indexes improve filtering and cardinality estimation for important fields.

Part 3 - Hints and Helper

Filter by tenant, language, and active source version. Test a valid tenant and a neighboring tenant using the same vector, verify every returned payload, and distinguish an empty eligible set from poor vector similarity.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E05(client, collection_name, query_vector,
        tenant_id, language, source_version, limit):
    query_filter = models.Filter(
        must=[
            models.FieldCondition(
                key="tenant_id",
```

```
                match=models.MatchValue(value=...),
            ),
            models.FieldCondition(
                key="language",
                match=models.MatchValue(value=...),
            ),
            models.FieldCondition(
                key="source_version",
                match=models.MatchValue(value=...),
            ),
        ]
    )
    points = client.query_points(
        collection_name=collection_name,
        query=query_vector,
        query_filter=query_filter,
        limit=limit,
        with_payload=True,
    ).points
    valid = all(... for point in points)
    return points, valid

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

9.3.7 Exercise 06 - Hybrid Filter + Vector Search

Part 1 - Why this matters

Practical retrieval combines semantic proximity with structured eligibility rules. The vector expresses what is similar, while filters express what is allowed, current, or applicable.

Strict filters can change search planning and result availability. The reader will compare unfiltered and filtered rankings and determine whether quality changed because relevant points were excluded or because the vector representation was weak.

Part 2 - Technical concept and behavior

This exercise uses one dense vector query together with compound payload conditions. It is hybrid in the sense of structured filtering plus vector search, not dense–sparse fusion. Qdrant plans filtered search using vector and payload indexes according to collection state and estimated cardinality.

Part 3 - Hints and Helper

Combine required tenant and status conditions with an exclusion condition for stale sources and an optional category condition. Create payload indexes for real filtering fields before ingestion in a fresh experiment, then compare latency and relevance.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E06(client, collection_name, query_vector, requirements, limit):
    query_filter = models.Filter(
        must=[...],
        should=[...],
        must_not=[...],
    )
    filtered = client.query_points(
        collection_name=collection_name,
        query=query_vector,
        query_filter=query_filter,
        limit=limit,
        with_payload=True,
    ).points
    unfiltered = client.query_points(
        collection_name=collection_name,
        query=query_vector,
        limit=limit,
        with_payload=True,
    ).points
    comparison = ...
    return filtered, unfiltered, comparison

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

9.3.8 Exercise 07 - Search Performance Benchmark

Part 1 - Why this matters

Search performance affects interactive latency and system capacity, but average time hides slow requests. A useful benchmark records latency distribution, throughput, data scale, query mix, filters, index settings, and retrieval quality.

The client benchmark must avoid measuring embedding generation accidentally unless end-to-end latency is the stated target. Warm-up, concurrency, and network location must also be documented.

Part 2 - Technical concept and behavior

Latency percentiles describe how long a chosen fraction of requests completed within. Queries per second describe throughput over an interval. Approximate index parameters can trade recall for speed, so benchmark results must include relevance or exact-search comparison when possible.

Part 3 - Hints and Helper

Precompute query vectors, run warm-up separately, randomize a reproducible query set, measure with a monotonic clock, report p50, p95, p99, and errors, and compare filtered with unfiltered workloads.

Part 4 - Python code skeleton

```
from statistics import median
from time import perf_counter

def percentile(values, fraction):
    ordered = sorted(values)
    index = ...
    return ordered[index]

def E07(search_operation, query_vectors, warmup_count, repetitions):
    for vector in query_vectors[:warmup_count]:
        search_operation(vector)
    latencies = []
    errors = []
    started_all = perf_counter()
    for _ in range(repetitions):
        for vector in query_vectors:
            started = perf_counter()
            try:
                search_operation(vector)
                latencies.append(perf_counter() - started)
            except Exception as error:
                errors.append(...)
    total_time = perf_counter() - started_all
    return {
        "p50": percentile(latencies, 0.50),
        "p95": percentile(latencies, 0.95),
        "p99": percentile(latencies, 0.99),
        "queries_per_second": ...,
        "errors": errors,
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

9.3.9 Exercise 08 - Search Result Ranking Analysis

Part 1 - Why this matters

A ranking can contain the correct item but place it too low to be useful. Analysis examines where relevant and irrelevant items appear, how stable ranks are across configurations, and which query categories fail.

Scores alone cannot explain relevance. The reader must connect every point to a human judgment and inspect difficult negatives that appear close for superficial or domain-specific reasons.

Part 2 - Technical concept and behavior

Rank-based evaluation includes reciprocal rank, precision and recall at k, and NDCG when judgments have graded relevance. Rank correlation or overlap can compare configurations, while per-query inspection reveals failure patterns hidden by aggregate means.

Part 3 - Hints and Helper

Return point ID, score, rank, payload source, and relevance grade. Group errors by language, length, topic, and query type; compare at least two configurations; and preserve examples for future regression tests.

Part 4 - Python code skeleton

```
def analyze_ranking(points, relevance_grades, k):
    rows = []
    for rank, point in enumerate(points, start=1):
        grade = relevance_grades.get(point.id, 0)
        rows.append({
            "rank": rank,
            "id": point.id,
            "score": point.score,
            "grade": grade,
            "source": ...,
        })
    metrics = {
        "precision_at_k": ...,
        "recall_at_k": ...,
        "reciprocal_rank": ...,
        "ndcg_at_k": ...,
    }
    return rows, metrics

def E08(results_by_query, judgments, k):
    analyses = {
        query_id: analyze_ranking(...)
        for query_id, points in results_by_query.items()
    }
    failure_groups = ...
    return analyses, failure_groups

def main():
    print(E08(...))
```

```
if __name__ == "__main__":
    main()
```

9.3.10 Exercise 09 - Similarity Debugging Scenario

Part 1 - Why this matters

Unexpected similarity results can originate from the embedding model, query preprocessing, vector dimension, normalization, distance metric, stale points, payload filters, or index approximation. Changing search parameters before locating the layer can hide the real defect.

The final challenge builds a diagnostic sequence from input text to stored point and returned ranking. Each check produces evidence and stops unsafe conclusions when an earlier contract fails.

Part 2 - Technical concept and behavior

The debugging path validates collection configuration, embedding contract, finite values, vector norms, stored payload provenance, filter cardinality, exact versus approximate results, and labeled relevance. A transport success only proves that Qdrant processed the request.

Part 3 - Hints and Helper

Use one known query and controlled corpus. Compare the query embedding with a freshly generated document embedding, retrieve stored vectors by ID, temporarily run an exact search in the lab, and remove filters one at a time without weakening production authorization.

Part 4 - Python code skeleton

```
import math

def E09(client, collection_name, encoder, query_text,
        expected_contract, known_point_ids, query_filter):
    report = []
    collection_info = client.get_collection(collection_name)
    report.append({"check": "collection_contract", "result": ...})

    query_vector = encoder.encode_queries([query_text])[0]
    report.append({"check": "dimension", "result": ...})
    report.append({"check": "finite", "result": all(
        math.isfinite(value) for value in query_vector
    )})

    stored = client.retrieve(
        collection_name=collection_name,
        ids=known_point_ids,
        with_vectors=True,
        with_payload=True,
    )
    report.append({"check": "stored_provenance", "result": ...})
```

```
    approximate = client.query_points(...).points
    exact = client.query_points(..., search_params=...).points
    report.append({"check": "approximate_vs_exact", "result": ...})
    report.append({"check": "filter_effect", "result": ...})
    diagnosis = ...
    return report, approximate, exact, diagnosis

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

9.4 QD02 - RAG Integration Workflow

Models and Training

9.4.1 Exercise 00 - Chunk Text Data for Embedding

Part 1 - Why this matters

Long documents must be divided into retrievable units before embedding. Chunks that are too large may combine unrelated topics, while chunks that are too small may lose the context required to answer a question.

Chunking is therefore part of retrieval quality, not simple string slicing. Every chunk must preserve source identity, order, offsets, and enough overlap or structural context for later attribution.

Part 2 - Technical concept and behavior

A tokenizer-aware chunker limits each chunk by token count and may retain an overlap with the previous chunk. Structural boundaries such as paragraphs or headings should be preferred when possible. Overlap increases continuity but also storage and duplicate retrieval.

Part 3 - Hints and Helper

Accept a tokenizer function, positive chunk size, and smaller non-negative overlap. Preserve source ID, chunk index, character or token range, and source version. Reconstruct or inspect adjacent chunks to verify no unintended gaps.

Part 4 - Python code skeleton

```
def E00(text, source_id, source_version, tokenizer,
        chunk_size, overlap):
    if chunk_size <= 0 or overlap < 0 or overlap >= chunk_size:
        raise ValueError(...)
    tokens = tokenizer.encode(...)
    chunks = []
```

```
    step = chunk_size - overlap
    for start in range(0, len(tokens), step):
        end = min(start + chunk_size, len(tokens))
        chunk_tokens = tokens[start:end]
        chunk_text = tokenizer.decode(...)
        chunks.append({
            "source_id": source_id,
            "source_version": source_version,
            "chunk_index": len(chunks),
            "token_start": start,
            "token_end": end,
            "text": chunk_text,
        })
        if end == len(tokens):
            break
    return chunks

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

9.4.2 Exercise 01 - Store Document Chunks as Vectors

Part 1 - Why this matters

Each chunk vector must remain aligned with its source text and provenance. A shifted list or reused identifier can store a valid embedding under the wrong chunk, producing convincing but falsely attributed retrieval.

The ingestion function should be idempotent for one source version. Stable point IDs and payload fields allow regeneration, deletion of stale versions, and verification after upload.

Part 2 - Technical concept and behavior

The document encoder produces one vector per chunk. Qdrant points store stable IDs, vectors, and payloads containing source ID, version, chunk index, text, and embedding contract. Bounded upsert batches control request size.

Part 3 - Hints and Helper

Generate deterministic UUIDs from source, version, and chunk index. Verify equal counts and dimensions, include authorization and language fields, upsert with waiting enabled for the exercise, and retrieve samples by ID.

Part 4 - Python code skeleton

```
import uuid
from qdrant_client import QdrantClient, models
```

```
def chunk_id(source_id, source_version, chunk_index):
    identity = f"{source_id}:{source_version}:{chunk_index}"
    return str(uuid.uuid5(uuid.NAMESPACE_URL, identity))

def E01(client, collection_name, encoder, chunks, batch_size):
    vectors = encoder.encode_documents([chunk["text"] for chunk in chunks])
    if len(vectors) != len(chunks):
        raise ValueError(...)
    points = [
        models.PointStruct(
            id=chunk_id(...),
            vector=vector,
            payload={...},
        )
        for chunk, vector in zip(chunks, vectors)
    ]
    operations = []
    for start in range(0, len(points), batch_size):
        operations.append(client.upsert(..., wait=True))
    return points, operations

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

9.4.3 Exercise 02 - Query Embedding Generation

Part 1 - Why this matters

The query vector must live in the same compatible space as document vectors. Some embedding models use separate query instructions, prefixes, or encoder methods, so sending the raw question through the document path can reduce retrieval quality.

This exercise validates query preprocessing and embedding provenance before contacting Qdrant. Empty, non-finite, or dimensionally incompatible vectors must fail early.

Part 2 - Technical concept and behavior

A query encoder maps one question to a fixed-length dense vector. The embedding contract includes model identity, revision, dimension, normalization, language handling, and query instruction. It must match the collection's document space.

Part 3 - Hints and Helper

Normalize whitespace according to a documented policy, reject an empty query, use the model's query method, convert values to finite floats, and compare dimension and model revision with the expected contract.

Part 4 - Python code skeleton

```
import math

def E02(encoder, query_text, expected_contract):
    normalized_text = ...
    if not normalized_text:
        raise ValueError(...)
    raw_vector = encoder.encode_queries([normalized_text])[0]
    vector = [float(value) for value in raw_vector]
    observed_contract = {
        "model": ...,
        "revision": ...,
        "dimension": len(vector),
        "normalized": ...,
    }
    valid = observed_contract == expected_contract and all(
        math.isfinite(value) for value in vector
    )
    if not valid:
        raise ValueError(...)
    return vector, observed_contract

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

9.4.4 Exercise 03 - Retrieve Relevant Context Chunks

Part 1 - Why this matters

Retrieval selects the evidence that a later language model may use. Irrelevant or unauthorized chunks can mislead the answer, while missing provenance prevents the reader from checking where a claim originated.

The retrieval function must return scored chunks and source metadata, not concatenate text immediately. Keeping the intermediate result visible supports thresholding, debugging, evaluation, and attribution.

Part 2 - Technical concept and behavior

Qdrant's query interface receives the compatible query vector, limit, optional threshold, and payload filter. Each scored point can return payload text and provenance. The result remains a candidate set until application relevance checks are applied.

Part 3 - Hints and Helper

Require tenant and active source-version filters, request payload but not stored vectors, preserve rank and score, validate required payload fields, and return an empty list without inventing fallback chunks.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E03(client, collection_name, query_vector,
        tenant_id, limit, score_threshold):
    query_filter = models.Filter(must=[
        models.FieldCondition(
            key="tenant_id",
            match=models.MatchValue(value=tenant_id),
        ),
        ...,
    ])
    response = client.query_points(
        collection_name=collection_name,
        query=query_vector,
        query_filter=query_filter,
        score_threshold=score_threshold,
        limit=limit,
        with_payload=True,
        with_vectors=False,
    )
    chunks = [
        {"rank": rank, "id": point.id, "score": point.score, **point.payload}
        for rank, point in enumerate(response.points, start=1)
    ]
    return chunks

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

9.4.5 Exercise 04 - Context Ranking by Similarity

Part 1 - Why this matters

Initial vector search produces a ranking, but overlapping chunks or semantically broad passages can occupy several top positions. Context selection may need deduplication, source diversity, or a separate reranker.

Reordering must be evaluated because a reranker can improve or damage relevance. The original vector score and rank should remain available for comparison and debugging.

Part 2 - Technical concept and behavior

Candidate generation retrieves a wider set, after which a ranking function can combine vector score, reranker score, source diversity, or duplicate penalty. The final score should not mix incompatible scales without normalization or a documented rule.

Part 3 - Hints and Helper

Retrieve more candidates than the final limit, identify near-duplicate adjacent chunks, apply one transparent ranking rule, preserve original rank and scores, and compare NDCG or another ranking metric before and after.

Part 4 - Python code skeleton

```
def E04(query_text, candidates, reranker, final_limit):
    if final_limit <= 0:
        raise ValueError(...)
    reranker_scores = reranker.score(
        query_text,
        [candidate["text"] for candidate in candidates],
    )
    enriched = []
    for candidate, reranker_score in zip(candidates, reranker_scores):
        enriched.append({
            **candidate,
            "vector_rank": candidate["rank"],
            "reranker_score": float(reranker_score),
            "duplicate_penalty": ...,
            "final_score": ...,
        })
    ranked = sorted(enriched, key=..., reverse=True)
    selected = ...
    comparison = ...
    return selected, comparison

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

9.4.6 Exercise 05 - Metadata Filtering in RAG

Part 1 - Why this matters

RAG retrieval must respect tenant, permission, language, source status, and document version. Semantic similarity cannot decide whether the current user is allowed to receive a chunk.

Security filtering belongs inside the vector query. Retrieving globally and removing unauthorized results afterward can expose ranking information and allow forbidden points to consume the candidate limit.

Part 2 - Technical concept and behavior

Payload filters can combine mandatory identity and version conditions, optional categories, and exclusions. Indexed payload fields improve filtered retrieval and cardinality estimation. The

authoritative permission decision may still originate in PostgreSQL or another access system and be translated into retrieval conditions.

Part 3 - Hints and Helper

Build filters only from validated authorization context, not arbitrary client-supplied Qdrant expressions. Test cross-tenant and stale-version negatives, verify every returned payload, and create payload indexes for important fields.

Part 4 - Python code skeleton

```
from qdrant_client import models

def E05(authorization_context, language, allowed_sources):
    if not authorization_context.is_authenticated:
        raise PermissionError(...)
    query_filter = models.Filter(
        must=[
            models.FieldCondition(
                key="tenant_id",
                match=models.MatchValue(value=...),
            ),
            models.FieldCondition(
                key="language",
                match=models.MatchValue(value=...),
            ),
            models.FieldCondition(
                key="source_id",
                match=models.MatchAny(any=...),
            ),
            ...,
        ],
        must_not=[...],
    )
    return query_filter

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

9.4.7 Exercise 06 - Limit Context Window Size

Part 1 - Why this matters

Retrieved chunks compete with the question, instructions, conversation, and answer for limited model context. Selecting by document count alone can exceed the token budget because chunks have different lengths.

Budgeting should preserve the best evidence while avoiding partial or duplicate context. The reader will count formatted tokens and record why each candidate was included or excluded.

Part 2 - Technical concept and behavior

The usable retrieval budget is the total context allowance minus reserved tokens for other prompt components and the generated answer. Greedy rank-order selection is simple, while diversity-aware selection may use the budget more effectively. Token counts must use the target model's tokenizer and final formatting.

Part 3 - Hints and Helper

Validate a positive budget, format each chunk with source labels before counting, reject a single chunk that exceeds policy, avoid overlapping duplicates, and return selected chunks, token total, and excluded reasons.

Part 4 - Python code skeleton

```
def E06(ranked_chunks, tokenizer, total_limit,
        reserved_prompt_tokens, reserved_answer_tokens):
    available = total_limit - reserved_prompt_tokens - reserved_answer_tokens
    if available <= 0:
        raise ValueError(...)
    selected = []
    excluded = []
    used = 0
    for chunk in ranked_chunks:
        formatted = ...
        token_count = len(tokenizer.encode(formatted))
        if used + token_count <= available and ...:
            selected.append({...})
            used += token_count
        else:
            excluded.append({...})
    return selected, used, available, excluded

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

9.4.8 Exercise 07 - Handle Empty Retrieval Case

Part 1 - Why this matters

Some questions have no eligible or sufficiently similar source. Calling the language model with an empty evidence block encourages unsupported answers and hides whether the knowledge base lacks coverage.

A robust RAG system treats empty retrieval as a normal state with explicit policy. It may abstain, request clarification, suggest another search, or route to an approved alternative source.

Part 2 - Technical concept and behavior

Empty retrieval can result from no indexed source, strict authorization, metadata mismatch, score threshold, stale version removal, or embedding failure. The response should preserve a machine-readable reason and must not weaken security filters automatically.

Part 3 - Hints and Helper

Distinguish zero candidates before filtering from zero eligible candidates after filtering where observability permits. Do not expose forbidden-source details. Ensure the generator callback is never invoked on the abstention path.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class RetrievalOutcome:
    status: str
    chunks: list
    message: str
    diagnostic_code: str

def E07(retrieved_chunks, generator, policy):
    if not retrieved_chunks:
        return RetrievalOutcome(
            status="no_context",
            chunks=[],
            message=...,
            diagnostic_code=...,
        )
    answer = generator(...)
    return RetrievalOutcome(
        status="answered",
        chunks=retrieved_chunks,
        message=answer,
        diagnostic_code="ok",
    )

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

9.4.9 Exercise 08 - End-to-End RAG Pipeline Test

Part 1 - Why this matters

Individual components can pass while their integration fails. A document may be chunked correctly but stored under the wrong tenant, or relevant chunks may be retrieved but omitted from the final prompt.

An end-to-end test preserves evidence from ingestion through answer generation. It evaluates retrieval and answer support separately so a fluent response cannot hide a broken retriever.

Part 2 - Technical concept and behavior

The pipeline performs source validation, chunking, document embedding, point upsert, query embedding, authorized retrieval, ranking, token budgeting, prompt construction, generation, and citation validation. Each stage returns structured traces and timing.

Part 3 - Hints and Helper

Use a tiny source with known questions and answers. Assert deterministic IDs, expected relevant chunk presence, no forbidden payloads, context within budget, generator abstention on empty retrieval, and citations referencing selected sources.

Part 4 - Python code skeleton

```
def E08(source, question, components, authorization_context):
    trace = []
    chunks = components.chunker(...)
    trace.append({"stage": "chunk", "count": len(chunks)})
    ingestion = components.ingester(...)
    trace.append({"stage": "ingest", "result": ingestion})
    query_vector = components.query_encoder(...)
    candidates = components.retriever(
        query_vector,
        authorization_context=authorization_context,
    )
    trace.append({"stage": "retrieve", "candidates": candidates})
    ranked = components.ranker(question, candidates)
    context, budget = components.budgeter(ranked)
    if not context:
        return components.empty_handler(...), trace
    prompt = components.prompt_builder(question, context)
    answer = components.generator(prompt)
    citations_valid = ...
    evaluation = {
        "expected_chunk_retrieved": ...,
        "authorization_valid": ...,
        "budget_valid": ...,
        "citations_valid": citations_valid,
        "answer_supported": ...,
    }
```

```
    return answer, context, trace, evaluation

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

9.4.10 Exercise 09 - RAG Failure Mode Analysis

Part 1 - Why this matters

RAG can fail at source ingestion, chunking, embedding, filtering, retrieval, ranking, context construction, generation, or citation. Treating every wrong answer as a model problem prevents effective diagnosis.

The final challenge injects one controlled fault at a time and records where evidence first diverges from expectations. The purpose is to build observability and targeted remediation, not to tune every component simultaneously.

Part 2 - Technical concept and behavior

Failure modes include missing sources, stale vectors, incompatible embeddings, wrong tenant filters, weak recall, overly strict thresholds, duplicated chunks, context truncation, prompt injection, unsupported generation, and invalid citations. Each has a different detection signal.

Part 3 - Hints and Helper

Create a fault matrix with expected stage, observable signal, safety impact, and remediation. Run a clean baseline, inject exactly one fault, compare traces, and verify that security faults fail closed and empty evidence leads to abstention.

Part 4 - Python code skeleton

```
from copy import deepcopy

def run_scenario(pipeline, test_case, fault):
    configuration = deepcopy(test_case["configuration"])
    fault.apply(configuration)
    result = pipeline.run(test_case["question"], configuration)
    first_divergence = ...
    detected = ...
    safe_behavior = ...
    return {
        "fault": fault.name,
        "expected_stage": fault.expected_stage,
        "first_divergence": first_divergence,
        "detected": detected,
        "safe_behavior": safe_behavior,
        "trace": result.trace,
    }
```

```
def E09(pipeline, baseline_case, faults):
    baseline = pipeline.run(...)
    scenarios = [run_scenario(...) for fault in faults]
    summary = {...}
    return baseline, scenarios, summary

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

9.5 QD03 - Indexing & Scalable Retrieval

AI Infrastructure and Hardware

9.5.1 Exercise 00 - HNSW Index Configuration

Part 1 - Why this matters

HNSW provides approximate nearest-neighbor retrieval by navigating a layered graph instead of comparing every stored vector. Its configuration affects memory, construction effort, latency, and recall.

Larger or more expensive settings are not automatically better. The reader must connect index parameters to a fixed dataset and labeled query workload before changing production configuration.

Part 2 - Technical concept and behavior

The parameter `m` influences graph connectivity, `ef_construct` affects index construction quality and cost, and query-time `hnsw_ef` affects search effort. `full_scan_threshold` helps determine when scanning may be preferable for small segments or candidate sets.

Part 3 - Hints and Helper

Create disposable collections with controlled parameter sets. Keep vectors and queries identical, wait for indexing and optimization state, compare approximate results with exact search, and record build time, memory, latency, and recall.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E00(client, collection_name, vector_size, configuration):
    client.create_collection(
        collection_name=collection_name,
        vectors_config=models.VectorParams(
            size=vector_size,
```

```
            distance=models.Distance.COSINE,
        ),
        hnsw_config=models.HnswConfigDiff(
            m=configuration["m"],
            ef_construct=configuration["ef_construct"],
            full_scan_threshold=configuration["full_scan_threshold"],
        ),
    )
    information = client.get_collection(collection_name)
    verified = ...
    return information, verified

def main():
    client = QdrantClient(...)
    print(E00(...))

if __name__ == "__main__":
    main()
```

9.5.2 Exercise 01 - Index Build vs Query Speed Tradeoff

Part 1 - Why this matters

An index can reduce query latency while requiring construction time, memory, and background optimization. A configuration that builds quickly may provide lower recall, while an expensive index may exceed the needs of the application.

The experiment must measure quality and speed together. Exact search provides a reference neighbor set for recall comparison, not necessarily the desired production mode.

Part 2 - Technical concept and behavior

Index build time spans ingestion and the transition to an indexed or stable collection state. Query-time `hnsw_ef` can vary search effort without rebuilding the index. Recall at k compares approximate IDs with exact top-k IDs.

Part 3 - Hints and Helper

Use identical points in separate collections, poll status with a deadline, precompute query vectors, warm up, and compare exact and approximate results across several `hnsw_ef` values.

Part 4 - Python code skeleton

```
from time import perf_counter, monotonic
from qdrant_client import models

def recall_at_k(approximate_ids, exact_ids):
    if not exact_ids:
        return ...
    return len(set(approximate_ids) & set(exact_ids)) / len(exact_ids)
```

```
def E01(client, collection_name, query_vectors, ef_values, k):
    experiments = []
    for query_vector in query_vectors:
        exact = client.query_points(
            collection_name=collection_name,
            query=query_vector,
            search_params=models.SearchParams(exact=True),
            limit=k,
        ).points
        for ef in ef_values:
            started = perf_counter()
            approximate = client.query_points(
                collection_name=collection_name,
                query=query_vector,
                search_params=models.SearchParams(hnsw_ef=ef, exact=False),
                limit=k,
            ).points
            experiments.append({...})
    return experiments

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

9.5.3 Exercise 02 - Payload Index Creation

Part 1 - Why this matters

Vector indexes accelerate similarity navigation, while payload indexes accelerate and inform structured filtering. A tenant or source filter without an appropriate payload index can become expensive as the collection grows.

Every payload index consumes resources. The reader should create indexes only for fields used in meaningful filters and use the correct schema type for stored values.

Part 2 - Technical concept and behavior

Qdrant payload indexes are defined by field name and schema such as keyword, integer, float, Boolean, datetime, text, or geographic types. They also support cardinality estimation and filtered-search planning. Important payload indexes are best planned before large ingestion.

Part 3 - Hints and Helper

Inspect representative payloads, map tenant and source fields to keyword types and time to datetime where appropriate, create indexes, verify collection payload schema, and benchmark the same filtered queries before and after in isolated collections.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E02(client, collection_name, index_definitions):
    operations = []
    for field_name, schema_type in index_definitions:
        operations.append(client.create_payload_index(
            collection_name=collection_name,
            field_name=field_name,
            field_schema=schema_type,
            wait=True,
        ))
    information = client.get_collection(collection_name)
    payload_schema = information.payload_schema
    verified = all(field in payload_schema for field, _ in index_definitions)
    return operations, payload_schema, verified

def main():
    client = QdrantClient(...)
    definitions = [
        ("tenant_id", models.PayloadSchemaType.KEYWORD),
        ("source_version", models.PayloadSchemaType.KEYWORD),
        (...),
    ]
    print(E02(client, ..., definitions))

if __name__ == "__main__":
    main()
```

9.5.4 Exercise 03 - Large-Scale Vector Ingestion

Part 1 - Why this matters

Large ingestion must balance throughput, memory, request size, retries, index construction, and verification. Sending everything in one request risks failure, while tiny requests waste network overhead.

Idempotent point IDs make retries safe. The reader will checkpoint progress, distinguish failed batches, and verify stored points without trusting only the number submitted.

Part 2 - Technical concept and behavior

Bounded upsert batches write points through Qdrant's write path and WAL. Index and optimizer work may continue after client acknowledgment. Parallel ingestion can improve throughput but may overload the service or reorder application progress reporting.

Part 3 - Hints and Helper

Stream source records, generate deterministic IDs, validate dimension and payload contract, use configurable batch size and bounded concurrency, retry only understood transient failures, and save progress after acknowledged batches.

Part 4 - Python code skeleton

```
from time import perf_counter
from qdrant_client import models

def batched(iterable, batch_size):
    batch = []
    for item in iterable:
        batch.append(item)
        if len(batch) == batch_size:
            yield batch
            batch = []
    if batch:
        yield batch

def E03(client, collection_name, record_stream, encoder,
        batch_size, progress_store):
    statistics = {"submitted": 0, "batches": 0, "errors": []}
    started = perf_counter()
    for records in batched(record_stream, batch_size):
        vectors = encoder.encode_documents([...])
        points = [models.PointStruct(...) for ... in zip(records, vectors)]
        try:
            result = client.upsert(..., wait=True)
            statistics["submitted"] += len(points)
            statistics["batches"] += 1
            progress_store.save(...)
        except Exception as error:
            statistics["errors"].append(...)
            ...
    statistics["elapsed"] = perf_counter() - started
    statistics["verification"] = ...
    return statistics

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

9.5.5 Exercise 04 - Shard Configuration Experiment

Part 1 - Why this matters

Shards partition a collection's points and can distribute storage and processing. Too few shards may limit parallelism or placement, while too many can add overhead and create small segments for a modest dataset.

Shard count must be evaluated on a distributed topology and realistic workload. A single-node experiment can reveal overhead but cannot prove multi-node scalability.

Part 2 - Technical concept and behavior

Collection creation can specify `shard_number`. In a cluster, shard replicas are assigned among peers according to configuration. Sharding affects ingestion and query distribution, while payload-based multitenancy may introduce additional partitioning strategies.

Part 3 - Hints and Helper

Create separate disposable collections with equal data and different shard counts. Record topology, ingestion throughput, collection status, p95 search latency, and retrieval quality. Do not change multiple scaling settings in the same comparison.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def E04(client, base_name, vector_size, shard_counts,
        points, benchmark):
    experiments = []
    for shard_count in shard_counts:
        collection_name = f"{base_name}-shards-{shard_count}"
        client.create_collection(
            collection_name=collection_name,
            vectors_config=models.VectorParams(
                size=vector_size,
                distance=models.Distance.COSINE,
            ),
            shard_number=shard_count,
        )
        ingestion = ...
        status = client.get_collection(collection_name)
        search = benchmark(...)
        experiments.append({...})
    return experiments

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

9.5.6 Exercise 05 - Replication Factor Impact Test

Part 1 - Why this matters

Replication protects a vector search service from losing availability when a node becomes unavailable. A collection with several replicas can continue serving data from another peer, but every additional replica also increases storage consumption, network traffic, and the work

required to confirm writes. Testing this tradeoff helps engineers select a replication factor from measured requirements instead of treating a larger value as automatically better.

This experiment must run only on an isolated distributed Qdrant environment whose failure budget is known in advance. The reader will compare ingestion time, query latency, error rate, and result integrity across collections with different replication factors. A controlled single-peer interruption may be included only when the remaining replicas can safely preserve quorum and the test environment can be restored.

Part 2 - Technical concept and behavior

Let r denote the replication factor, meaning the number of copies maintained for each shard. For each tested value of r, collect comparable measurements under the same dataset, query set, shard count, and hardware conditions:

$$M_r = (T_{\text{ingest}}, L_{50}, L_{95}, E, A, I)$$

where T_{ingest} is ingestion time, L_{50} and L_{95} are query-latency percentiles, E is the error rate, A is observed availability, and I represents integrity checks on returned identifiers and payloads. Replication should be evaluated together with the cluster topology because a requested factor cannot provide resilience if the replicas are not distributed across independent failure domains.

Part 3 - Hints and Helper

Create separate disposable collections rather than repeatedly changing one collection during measurement. In Python, pass `replication_factor` when creating each collection, wait until the collection reports a healthy state, and run the same ingestion and query workload. Record the cluster state before any failure simulation. Never stop more peers than the declared test permits, and always restore the peer before starting the next configuration.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient, models

def create_test_collection(client, name, vector_size, replicas):
    client.create_collection(
        collection_name=name,
        vectors_config=models.VectorParams(
            size=vector_size,
            distance=models.Distance.COSINE,
        ),
        replication_factor=replicas,
        shard_number=...,
    )

def E05(client, dataset, queries, replica_values):
    results = {}
    for replicas in replica_values:
        name = f"replication_test_{replicas}"
        create_test_collection(client, name, ..., replicas)
        ...  # wait for a healthy collection
```

```
            ...  # ingest the same dataset
            ...  # measure normal search behavior
            ...  # optionally perform one approved peer-failure drill
            results[replicas] = ...
    return results

def main():
    client = QdrantClient(url=...)
    print(E05(client, ..., ..., [1, 2, 3]))

if __name__ == "__main__":
    main()
```

9.5.7 Exercise 06 - Consistency vs Performance Tradeoff

Part 1 - Why this matters

Distributed vector databases must decide how much coordination is required before a write is acknowledged and which replicas may answer a read. Stronger coordination can reduce the chance of observing stale state, but it can also add network round trips and make operations more sensitive to slow or unavailable peers. A scalable application therefore needs an explicit consistency policy rather than an undocumented reliance on defaults.

The correct setting depends on the operation. A newly uploaded private document may require strict visibility and access-control guarantees, while an approximate recommendation query may tolerate a short delay in exchange for lower latency. This exercise teaches the reader to measure visibility, correctness, and latency together so that performance improvements do not silently weaken application guarantees.

Part 2 - Technical concept and behavior

For a configuration c, measure the time between a successful write and the first read that observes it:

$$V_c = t_{\text{visible}} - t_{\text{acknowledged}}$$

The experiment also records query latency and operation failures. Write ordering, write consistency, and read consistency describe related but distinct controls; they must not be collapsed into a single label. A useful report associates every observation with the exact collection topology and client options used during that run.

Part 3 - Hints and Helper

Use a distributed test cluster and generate a unique point identifier for every trial. Upsert the point, immediately query or retrieve it using the selected consistency option, and retry with a bounded deadline. Store raw observations rather than only an average. Because client APIs can evolve, consult the installed Qdrant client signature for the supported read-consistency and write-ordering arguments instead of inventing unsupported values.

Part 4 - Python code skeleton

```
import time
from qdrant_client import QdrantClient, models

def observe_visibility(client, collection, point, read_options,
                       write_options, timeout_s):
    acknowledged_at = time.perf_counter()
    client.upsert(
        collection_name=collection,
        points=[point],
        **write_options,
    )
    while time.perf_counter() - acknowledged_at < timeout_s:
        records = client.retrieve(
            collection_name=collection,
            ids=[point.id],
            **read_options,
        )
        if records:
            return ...
    return ...

def E06(client, collection, configurations):
    observations = []
    for config in configurations:
        point = models.PointStruct(id=..., vector=..., payload=...)
        observations.append(
            observe_visibility(client, collection, point, ..., ..., ...)
        )
    return ...  # p50/p95 latency, visibility delay, and errors

def main():
    client = QdrantClient(url=...)
    print(E06(client, ..., ...))

if __name__ == "__main__":
    main()
```

9.5.8 Exercise 07 - Search Latency Monitoring

Part 1 - Why this matters

Average latency can make an unhealthy search service appear acceptable because a small number of very slow requests are hidden by many fast ones. Users experience individual requests, so tail percentiles such as p95 and p99 are essential for detecting pauses caused by filters, index changes, resource pressure, or network instability. Monitoring must also include errors because a fast failed request is not a successful search.

Semantic-search latency should be divided into meaningful stages. Embedding generation, network transfer, Qdrant retrieval, reranking, and response construction have different causes

and remedies. This exercise focuses on retrieval timing while allowing an end-to-end measurement to be recorded separately, preventing an embedding bottleneck from being incorrectly blamed on the vector index.

Part 2 - Technical concept and behavior

For n successful requests with sorted latencies $l_{(1)}, \ldots, l_{(n)}$, percentile p can be estimated from the corresponding ranked observation. Monitoring should report at least:

$$(L_{50}, L_{95}, L_{99}, R_{\text{error}}, QPS)$$

Measurements must be labeled by collection, workload, filter type, result limit, and index parameters. Warm-up traffic should be distinguished from steady-state traffic, and both successful and failed requests must contribute to the request count.

Part 3 - Hints and Helper

Use `time.perf_counter()` for elapsed time and preserve each sample until percentiles are computed. Run representative filtered and unfiltered query groups instead of repeating one vector. Avoid printing inside the timed region. For a production system, export the same concepts to a metrics platform; this exercise keeps them in Python so the calculation remains visible.

Part 4 - Python code skeleton

```
import time

def percentile(sorted_values, fraction):
    index = ...
    return sorted_values[index]

def timed_query(client, collection, query_vector, query_filter=None):
    started = time.perf_counter()
    try:
        response = client.query_points(
            collection_name=collection,
            query=query_vector,
            query_filter=query_filter,
            limit=...,
        )
        return time.perf_counter() - started, True, response
    except Exception as error:
        return time.perf_counter() - started, False, error

def E07(client, collection, workload):

```

9.5.9 Exercise 08 - Index Corruption Recovery Scenario

Part 1 - Why this matters

Search infrastructure can become unavailable because of disk faults, interrupted operations, operator mistakes, or damaged state. A recovery plan is useful only when it has been rehearsed and when the restored collection is checked for semantic correctness, not merely reported as running. Known queries, point counts, payloads, and provenance must survive recovery before downstream applications can trust the service again.

This exercise treats corruption as a safe recovery drill. The reader must not edit, delete, or deliberately damage Qdrant's internal storage files. Instead, the test creates a supported snapshot, simulates the original collection being unavailable in an isolated environment, restores through supported Qdrant mechanisms, and validates the recovered collection. This preserves the lesson without normalizing unsafe manipulation of database internals.

Part 2 - Technical concept and behavior

Let D be the reference set and D' the restored set. Basic recovery validation requires matching identifiers and critical metadata:

$$\{\mathrm{id}(x) : x \in D\} = \{\mathrm{id}(x) : x \in D'\}$$

It should also compare a sample of vectors or stable source hashes and run a fixed query suite against both versions. Recovery time objective measures how long restoration takes, while recovery point objective describes how much data may be absent relative to the snapshot time. Both must be recorded with the snapshot identifier.

Part 3 - Hints and Helper

Use `create_snapshot()` and preserve the returned snapshot metadata. Perform the restore into a clean test collection or test service using the supported snapshot recovery API for your deployment. Keep the actual restore call behind a clearly named helper because local and distributed deployments may use different supported workflows. Abort validation if the snapshot identity or expected collection schema does not match.

Part 4 - Python code skeleton

```
from qdrant_client import QdrantClient

def create_recovery_snapshot(client, collection):
    snapshot = client.create_snapshot(collection_name=collection)
    return snapshot

def restore_with_supported_api(client, snapshot, target_collection):
    ...  # use the documented recovery API for this deployment

def validate_recovery(client, source_manifest, target_collection,
                      known_queries):
    ...  # compare collection configuration and point count
    ...  # compare IDs, payload provenance, and source hashes
    ...  # execute known queries and compare expected results
    return ...

def E08(client, source_collection, target_collection, manifest, queries):
    snapshot = create_recovery_snapshot(client, source_collection)
    ...  # verify and preserve snapshot metadata
    restore_with_supported_api(client, snapshot, target_collection)
    return validate_recovery(client, manifest, target_collection, queries)

def main():
    client = QdrantClient(url=...)
    print(E08(client, ..., ..., ..., ...))

if __name__ == "__main__":
    main()
```

9.5.10 Exercise 09 - Scalable Semantic Search System Design

Part 1 - Why this matters

A scalable semantic-search system is more than a vector collection. It must preserve the embedding contract, ingest data idempotently, enforce tenant and authorization filters, monitor retrieval quality, and recover from infrastructure failures. A weakness in any one of these boundaries can produce irrelevant answers, data leakage, duplicate points, or an outage even when nearest-neighbor search itself works correctly.

The final design challenge joins the chapter's experiments into one defensible architecture. The reader must translate expected dataset size, query volume, latency objectives, availability targets, and update frequency into index, shard, replication, payload, and recovery decisions. Every decision should have a measurable reason and a test that can detect when its assumption stops being true.

Part 2 - Technical concept and behavior

The design can be viewed as a constrained optimization problem:

$$\min C_{\text{system}} \quad \text{subject to} \quad L_{95} \leq L_{\text{SLO}},\ R@k \geq R_{\text{target}},\ A \geq A_{\text{target}}$$

where cost includes compute, storage, and operational complexity. The system must define vector dimensions and distance, payload indexes, HNSW parameters, shard and replica counts, batch ingestion, consistency policy, quality evaluation, latency monitoring, and snapshot recovery. The relational or document source of truth must remain connected to every vector through stable provenance.

Part 3 - Hints and Helper

Begin with a configuration object and validate incompatible values before provisioning. Separate offline evaluation from online monitoring: recall and relevance require labeled or reference queries, while latency and errors require continuous observation. Use deterministic point identifiers so retries are safe, apply authorization filters inside retrieval, and include a recovery drill in the acceptance criteria. Do not claim scalability from one successful query; test representative volume and concurrency.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from qdrant_client import QdrantClient

@dataclass
class SearchSystemConfig:
    collection: str
    vector_size: int
    shard_number: int
    replication_factor: int
    target_p95_ms: float
    target_recall: float

def validate_config(config):
    ...

def provision_collection(client, config):
    ...

def ingest_idempotently(client, config, records):
    ...

def evaluate_quality_and_latency(client, config, evaluation_set):
    ...

def run_recovery_drill(client, config):
    ...

def E09(client, config, records, evaluation_set):
    validate_config(config)
    provision_collection(client, config)
    ingest_idempotently(client, config, records)
    report = evaluate_quality_and_latency(client, config, evaluation_set)
    recovery = run_recovery_drill(client, config)
```

```
    return ...

def main():
    client = QdrantClient(url=...)
    config = SearchSystemConfig(...)
    print(E09(client, config, ..., ...))

if __name__ == "__main__":
    main()
```

Book 10

Linear Regression

10.1 Introduction

10.1.1 What will the book teach you

Linear regression is the first complete machine learning model in this volume. In the previous books, you learned how tensors are represented, how gradients are calculated, how optimization changes parameters, how losses measure error, and how data can be stored and retrieved. This book brings those ideas together inside one model that learns a measurable relationship from data. The objective is no longer to execute an isolated mathematical operation. The objective is to construct a system whose parameters improve through observation, error measurement, and repeated correction.

The basic model may appear simple:

$$\hat{y} = wx + b$$

However, this equation contains the essential structure of supervised learning. The input x contains the information available to the model, the weight w controls how strongly the input affects the prediction, the bias b shifts the prediction independently of the input, and $\hat{y}$ is the value predicted by the model. During training, the prediction is compared with the true target y. The resulting error is converted into a loss, gradients describe how the parameters contributed to that loss, and an optimizer adjusts the parameters in a direction expected to reduce future error.

The reader must understand that linear regression is not limited to drawing a line through a two-dimensional graph. With several input features, the model becomes:

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$$

where $\mathbf{X}$ may contain many samples and many features. The same law can estimate energy consumption from weather conditions, predict demand from historical measurements, approximate a physical relationship, or provide a transparent baseline before a more complex neural network is introduced. In higher-dimensional spaces, the learned relationship forms a hyperplane even when it can no longer be visualized as an ordinary line.

This book will teach the complete lifecycle of a linear regression model rather than presenting only the final PyTorch command. You will begin by constructing the prediction equation

manually, checking tensor shapes, observing the effects of weights and bias, and comparing manual calculations with `torch.nn.Linear`. You will then inspect model parameters, gradient requirements, device placement, state dictionaries, parameter freezing, saving, loading, and the failures caused by incorrect model structure. These experiments will make the internal behavior visible before automation is introduced.

Data preparation is treated as part of the model rather than as an unrelated preliminary step. You will generate controlled synthetic datasets, add noise, scale features, construct training and testing partitions, create batches, and use a `DataLoader`. You will also investigate missing values, incorrect dimensions, data leakage, feature collinearity, numerical precision, caching, and transfer costs between the CPU and GPU. A mathematically correct model can still fail when its data pipeline is incorrect, so every transformation must preserve meaning as well as shape.

After preparing the data, you will build prediction functions for individual samples and batches. You will compare CPU and CUDA execution, disable gradient tracking during inference, test numerical consistency, measure latency and memory use, and examine the behavior of large or streaming workloads. Prediction is not considered correct merely because the program runs. Its output shape, device, data type, numerical stability, and agreement with an independently calculated reference must all be verified.

The book then connects prediction error to learning through the mean squared error loss:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2$$

You will implement this equation manually and compare it with PyTorch, inspect reduction modes, observe the influence of outliers, and study how scale and precision affect the loss. Because squaring gives larger errors greater influence, the loss function does more than report model quality: it determines which mistakes produce the strongest training signal. The reader must therefore learn to interpret a loss value instead of treating it as an unexplained number that should simply decrease.

Gradient-based parameter adjustment follows the loss. You will inspect weight and bias gradients, perform manual updates, compare them with optimizer steps, verify gradients using finite differences, and study accumulation, clipping, noise, frozen parameters, mixed precision, and graph retention. These exercises connect the derivative to a physical change in the model. A gradient is useful only when the reader can explain which parameter it belongs to, why it has its shape and sign, and how the learning rate converts it into an update.

Training will then be extended from one update into a controlled multi-epoch process. You will monitor convergence and divergence, apply early stopping and learning-rate schedules, preserve reproducibility with random seeds, save checkpoints, resume interrupted training, and compare CPU and GPU behavior. The goal is not to obtain a decreasing loss once, but to build a training process that can be repeated, inspected, interrupted, restored, and trusted.

Finally, the trained model will be evaluated and interpreted. You will calculate RMSE and MAE, separate training behavior from evaluation behavior, detect overfitting, use validation strategies, analyze residuals, profile latency and memory, and test robustness under noise. Vi-

sualizations will compare predictions with targets, expose residual patterns, show convergence behavior, and reveal the effects of weights, bias, features, and hyperparameters. A final report must explain not only how well the model performed, but also where it failed and whether the evidence supports using it on unseen data.

Linear regression is intentionally studied in depth because it establishes a reference point for every model that follows. Logistic regression will reuse a linear score but convert it into a probability for classification. The perceptron will reuse weighted inputs and a bias but apply a decision rule. Neural networks will later combine many such transformations into layers. If the reader understands the entire linear regression pipeline, the next models will appear as structured extensions rather than unrelated algorithms.

10.1.2 How to study this book

Every exercise should be treated as an experiment. Before running the code, predict the expected tensor shape, device, data type, numerical direction, and model behavior. After running it, compare the observation with the prediction and explain any difference. When an exercise changes one variable, such as the learning rate, batch size, precision, noise level, or initialization, keep the other conditions fixed so that the result has a clear cause.

Do not use CUDA merely because it is available. Begin with small CPU examples whose values can be checked manually, then repeat selected experiments on the GPU and measure whether the workload is large enough to benefit from parallel execution. Similarly, do not accept a low training loss without testing unseen data. Preserve a clean evaluation split, prevent data leakage, and compare the learned model with a simple baseline.

For every completed challenge, the reader should be able to answer four questions: What mathematical relationship was implemented? What did PyTorch do with the tensors and parameters? What evidence shows that the result is correct? Under what condition could the same code fail? If these questions cannot be answered, the exercise should be repeated before continuing. The purpose of this book is not to memorize a training loop, but to develop the ability to reason about a learning system from its data to its final evaluation.

10.1.3 The Chapters (LR00 - LR08) included in this book

- LR00 - Introduction to Linear Regression
- LR01 - Model Structure and Components
- LR02 - Data Preparation and Feature Inputs
- LR03 - Prediction Function Implementation
- LR04 - Error Measurement and Loss Definition
- LR05 - Parameter Adjustment and Gradient
- LR06 - Training Iterations and Convergence
- LR07 - Model Evaluation and Performance
- LR08 - Result Visualization and Interpretation

10.2 LR00 - Introduction to Linear Regression

Models and Training

10.2.1 Exercise 00 - Define Linear Model $y = wx + b$

Part 1 - Why this matters

Linear regression is the smallest complete model that can learn a relationship between an input and a continuous target. Its simplicity makes every component visible: the input carries evidence, the weight determines how strongly that evidence changes the output, and the bias provides a baseline prediction. Understanding this model prepares the reader to recognize the same weighted transformation inside larger neural networks.

The equation is also a controlled environment for learning model reasoning. A positive weight, a negative weight, a zero weight, and different bias values produce predictable changes. By calculating several outputs manually before using PyTorch, the reader can distinguish mathematical behavior from framework behavior and detect implementation errors early.

Part 2 - Mathematical form

For a scalar input $x \in \mathbb{R}$, define the predicted value:

$$\hat{y} = wx + b$$

where $w \in \mathbb{R}$ is the weight, $b \in \mathbb{R}$ is the bias, and $\hat{y} \in \mathbb{R}$ is the prediction. The weight controls the slope of the line and the bias equals the predicted value when $x = 0$. This exercise defines a forward calculation only; the parameters are not trained yet.

Part 3 - Hints and Helper

Choose small values that can be verified by hand. Calculate the multiplication before adding the bias, and compare the result with the function output. Test at least one positive input, one negative input, and zero. Do not introduce a loss function or optimizer in this exercise.

Part 4 - Python code skeleton

```
def E00(x, w, b):
    y_hat = ...
    return y_hat

def main():
    x = ...
    w = ...
    b = ...
    print(E00(x, w, b))

if __name__ == "__main__":
    main()
```

10.2.2 Exercise 01 - Implement Linear Function in PyTorch

Part 1 - Why this matters

A mathematical model becomes useful in machine learning only when its operations are represented by tensors. PyTorch allows the same linear equation to participate later in automatic differentiation, batching, device transfer, and optimization. Implementing the equation directly first prevents `nn.Linear` from hiding the relationship between the formula and the computed tensor.

This exercise also establishes a verification habit. The reader should inspect the input values, output value, shape, and data type instead of accepting a printed tensor without interpretation. A framework call is correct only when its behavior matches the mathematical model that was intended.

Part 2 - Mathematical form

Let x, w, and b be scalar floating-point tensors. The PyTorch computation represents:

$$\hat{y} = x \odot w + b$$

For scalar tensors, element-wise multiplication and ordinary scalar multiplication are equivalent. The returned value remains a tensor, preserving information required for later tensor operations and gradient tracking.

Part 3 - Hints and Helper

Create all three values with `torch.tensor()` and use the same floating-point data type. Print both the result and its type. Compare it with a manual Python calculation using the same numerical values, but keep the function itself tensor-based.

Part 4 - Python code skeleton

```
import torch

def E01(x, w, b):
    y_hat = torch...
    return y_hat

def main():
    x = torch.tensor(..., dtype=torch.float32)
    w = torch.tensor(..., dtype=torch.float32)
    b = torch.tensor(..., dtype=torch.float32)
    print(E01(x, w, b))

if __name__ == "__main__":
    main()
```

10.2.3 Exercise 02 - Tensor Shape Verification for Inputs

Part 1 - Why this matters

Many model failures are shape failures rather than mathematical failures. Two tensors may contain correct values but organize samples and features differently, causing broadcasting, matrix multiplication, or a linear layer to behave incorrectly. Shape verification creates an explicit contract at the boundary of the model.

A useful validation step should fail early and explain the violated expectation. If an invalid tensor reaches a later operation, the resulting error may mention an internal matrix dimension and hide the real source of the problem. This exercise teaches the reader to identify dimensional meaning before performing the forward pass.

Part 2 - Technical concept and behavior

For a batch containing N samples and F features per sample, the expected input shape is:

$$\mathbf{X} \in \mathbb{R}^{N \times F}$$

The final dimension represents features. For a single-feature model, $F = 1$, so a batch normally has shape $(N, 1)$ rather than $(N,)$. The validation should distinguish the number of dimensions from the size of each dimension.

Part 3 - Hints and Helper

Inspect `x.ndim` and `x.shape`. Accept the expected feature count as an argument instead of hard-coding it. Raise a clear `ValueError` when the tensor is not two-dimensional or its last dimension is incorrect. Test one valid and at least two invalid tensors.

Part 4 - Python code skeleton

```
import torch

def E02(x, expected_features):
    if x.ndim != ...:
        raise ValueError(...)
    if x.shape[-1] != ...:
        raise ValueError(...)
    return x.shape

def main():
    valid_x = torch...
    invalid_x = torch...
    print(E02(valid_x, ...))
    print(E02(invalid_x, ...))

if __name__ == "__main__":
    main()
```

10.2.4 Exercise 03 - Single Sample Forward Pass

Part 1 - Why this matters

A single-sample forward pass is the clearest way to observe how one input becomes one prediction. It removes batching from the problem and allows every multiplication and addition

to be checked manually. This is especially valuable when debugging the first implementation of a model.

Even with one sample, shape conventions remain important. A scalar, a one-dimensional feature vector, and a two-dimensional batch containing one row may represent related data but interact differently with model code. The reader must choose and document one representation rather than relying on accidental broadcasting.

Part 2 - Mathematical form

For one sample with F features, let $\mathbf{x} \in \mathbb{R}^F$ and $\mathbf{w} \in \mathbb{R}^F$. The prediction is:

$$\hat{y} = \sum_{j=1}^{F} x_j w_j + b$$

The dot product produces one scalar prediction. If the implementation retains a batch dimension, the input may instead have shape $(1, F)$ and the output shape should reflect one sample.

Part 3 - Hints and Helper

Use a small feature vector and calculate the expected result by hand. Verify feature-count compatibility before computing the dot product. Print the input shape and output shape, and decide whether the returned prediction should be a scalar tensor or a one-element tensor.

Part 4 - Python code skeleton

```
import torch

def E03(x, weight, bias):
    if x.shape[-1] != ...:
        raise ValueError(...)
    prediction = torch... + ...
    return prediction

def main():
    x = torch.tensor([...], dtype=torch.float32)
    weight = torch.tensor([...], dtype=torch.float32)
    bias = torch.tensor(..., dtype=torch.float32)
    print(E03(x, weight, bias))

if __name__ == "__main__":
    main()
```

10.2.5 Exercise 04 - Batch Input Forward Pass

Part 1 - Why this matters

Training models one sample at a time is often inefficient because tensor hardware is designed to process many values together. A batch forward pass applies the same parameters to several samples in one vectorized operation. This improves throughput and matches the structure used

by most training loops.

Batching must not change the meaning of the model. Each row must receive the same weight vector and bias, and its result should agree with a separate single-sample calculation. Comparing vectorized and row-by-row results is therefore an important correctness test.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{N \times F}$ contain N samples, $\mathbf{w} \in \mathbb{R}^{F \times 1}$ contain the weights, and $b \in \mathbb{R}$. The batch prediction is:

$$\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$$

The matrix product has shape $(N, 1)$. The scalar bias broadcasts across the N predictions without creating a separate parameter for each sample.

Part 3 - Hints and Helper

Use `torch.matmul()` or the `@` operator after validating the inner dimensions. Keep the weight as a column tensor if the expected output is $(N, 1)$. Compare the vectorized output with predictions produced by iterating over the rows only for verification, not as the main solution.

Part 4 - Python code skeleton

```
import torch

def E04(X, weight, bias):
    if X.ndim != ... or weight.ndim != ...:
        raise ValueError(...)
    predictions = torch... + ...
    return predictions

def main():
    X = torch.tensor([...], dtype=torch.float32)
    weight = torch.tensor([...], dtype=torch.float32)
    bias = torch.tensor(..., dtype=torch.float32)
    output = E04(X, weight, bias)
    print(output)
    print(output.shape)

if __name__ == "__main__":
    main()
```

10.2.6 Exercise 05 - Random Weight Initialization Test

Part 1 - Why this matters

Before training begins, a model must start with parameter values. Random initialization prevents every new model from beginning with the same prediction behavior, but it also means the initial output and loss can differ between runs. Observing this variation teaches the reader

that initialization is part of an experiment, not an invisible detail.

Linear regression has a simple loss surface, so poor random values can usually be corrected during training. Nevertheless, initialization affects the starting loss, early gradients, and reproducibility. A controlled test should separate the effect of random weights from changes in data or code.

Part 2 - Technical concept and behavior

A weight vector may be sampled from a distribution such as:

$$\mathbf{w}_0 \sim \mathcal{N}(0, \sigma^2)$$

Different seeds produce different samples, while resetting the same seed before initialization reproduces the same tensor. The experiment compares initial predictions from several weight tensors while holding $\mathbf{X}$ and b constant.

Part 3 - Hints and Helper

Use `torch.manual_seed()` and `torch.randn()`. Run the experiment with repeated and different seeds. Store the weights and predictions, then use `torch.equal()` or `torch.allclose()` to test reproducibility. Do not train the parameters in this exercise.

Part 4 - Python code skeleton

```
import torch

def E05(X, feature_count, seeds):
    observations = []
    for seed in seeds:
        torch.manual_seed(...)
        weight = torch.randn(...)
        prediction = ...
        observations.append(...)
    return observations

def main():
    X = torch...
    print(E05(X, ..., [..., ..., ...]))

if __name__ == "__main__":
    main()
```

10.2.7 Exercise 06 - Effect of Bias Term Experiment

Part 1 - Why this matters

The bias allows a linear model to produce a nonzero prediction when every input feature is zero. Without it, the fitted relationship is forced through the origin, which may be an unjustified restriction on the data. Comparing models with different biases makes this structural role visible.

Bias does not change how rapidly a prediction responds to an input; it shifts all predictions by the same amount. This distinction helps the reader separate slope from intercept and later understand why a linear layer stores weights and bias as different parameters.

Part 2 - Mathematical form

For fixed w and two biases b_1 and b_2:

$$\hat{y}_1 = wx + b_1, \qquad \hat{y}_2 = wx + b_2$$

Their difference is independent of the input:

$$\hat{y}_2 - \hat{y}_1 = b_2 - b_1$$

Therefore, changing only the bias translates the prediction line vertically without changing its slope.

Part 3 - Hints and Helper

Keep the input values and weight fixed. Evaluate at least three biases, including zero, and calculate the pairwise output differences. Include $x = 0$ so the connection between bias and intercept is directly observable.

Part 4 - Python code skeleton

```
import torch

def E06(x, weight, bias_values):
    outputs = {}
    for bias in bias_values:
        outputs[...] = ...
    return outputs

def main():
    x = torch.tensor([...], dtype=torch.float32)
    weight = torch.tensor(..., dtype=torch.float32)
    print(E06(x, weight, [..., ..., ...]))

if __name__ == "__main__":
    main()
```

10.2.8 Exercise 07 - Output Sensitivity to Weight Change

Part 1 - Why this matters

Model sensitivity describes how strongly a prediction reacts when a parameter changes. In a linear model, this relationship can be derived exactly, making it an ideal introduction to the reasoning later used by gradients. A small weight change may have little effect for a small input but a large effect for a large input.

Testing sensitivity also reveals why feature scale matters. If one feature has values thousands of times larger than another, the same change in their weights produces very different output changes. This can influence optimization even when both features are conceptually important.

Part 2 - Mathematical form

If the weight changes from w to $w + \Delta w$, then:

$$\Delta\hat{y} = ((w + \Delta w)x + b) - (wx + b) = x\Delta w$$

Thus the sensitivity of the output to the weight is:

$$\frac{\partial\hat{y}}{\partial w} = x$$

The experiment verifies the finite change against this exact prediction.

Part 3 - Hints and Helper

Evaluate several input magnitudes with one fixed `delta_w`. Compute the original and modified predictions, then compare their difference with `x * delta_w`. Include negative inputs and explain how the sign changes the direction of the response.

Part 4 - Python code skeleton

```
import torch

def E07(x, weight, bias, delta_w):
    original = ...
    changed = ...
    observed_delta = ...
    expected_delta = ...
    return original, changed, observed_delta, expected_delta

def main():
    x = torch.tensor([...], dtype=torch.float32)
    result = E07(x, ..., ..., ...)
    print(result)

if __name__ == "__main__":
    main()
```

10.2.9 Exercise 08 - Linear Model as Matrix Multiplication

Part 1 - Why this matters

A multiple-feature linear model is naturally expressed as matrix multiplication. This representation processes an entire batch without explicit Python loops and connects linear regression to the same operation used inside neural-network layers. Understanding the matrix form makes later models easier to inspect.

The matrix form also forces precise shape reasoning. Samples, input features, output features, and bias values occupy different axes. If these roles are confused, the computation may fail or broadcast into a plausible but incorrect result.

Part 2 - Mathematical form

For N samples, F input features, and O outputs:

$$\mathbf{X} \in \mathbb{R}^{N \times F}, \quad \mathbf{W} \in \mathbb{R}^{F \times O}, \quad \mathbf{b} \in \mathbb{R}^{O}$$

The model is:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W} + \mathbf{b}$$

The output has shape (N, O), and the bias broadcasts across the sample dimension.

Part 3 - Hints and Helper

Write the shapes beside each tensor before coding. Use `torch.matmul()` and verify that the final dimension of $\mathbf{X}$ matches the first dimension of $\mathbf{W}$. Compare one selected output element with a manually calculated dot product plus its bias.

Part 4 - Python code skeleton

```
import torch

def E08(X, W, b):
    if X.shape[-1] != W.shape[...]:
        raise ValueError(...)
    Y_hat = torch.matmul(..., ...) + ...
    return Y_hat

def main():
    X = torch.tensor([...], dtype=torch.float32)
    W = torch.tensor([...], dtype=torch.float32)
    b = torch.tensor([...], dtype=torch.float32)
    print(E08(X, W, b))

if __name__ == "__main__":
    main()
```

10.2.10 Exercise 09 - Manual Prediction vs PyTorch Output

Part 1 - Why this matters

Independent verification protects the reader from trusting an implementation merely because it executes without an exception. A manual prediction exposes the individual products and sums, while the vectorized PyTorch calculation provides the implementation intended for real workloads. Agreement between them is evidence that the tensor formula is correct.

This comparison also introduces numerical tolerance. Floating-point operations may be performed in a different order, so mathematically equivalent implementations can differ by a

very small amount. Exact equality is therefore not always the correct test for floating-point results.

Part 2 - Technical concept and behavior

For sample i, the manual reference is:

$$\hat{y}_i^{\text{manual}} = \sum_{j=1}^{F} X_{ij} w_j + b$$

The vectorized reference is $\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$. Correctness can be tested with:

$$\left| \hat{y}_i^{\text{manual}} - \hat{y}_i^{\text{torch}} \right| \leq \varepsilon$$

for a justified tolerance ε.

Part 3 - Hints and Helper

Build the manual result with explicit indexing or a loop so it is independent of the matrix multiplication being tested. Use `torch.allclose()` for comparison and report the maximum absolute difference. Deliberately alter one weight afterward to confirm that the test can fail.

Part 4 - Python code skeleton

```
import torch

def manual_prediction(X, weight, bias):
    values = []
    for row in X:
        total = ...
        for feature_index in range(...):
            total = ...
        values.append(...)
    return torch...

def E09(X, weight, bias):
    manual = manual_prediction(X, weight, bias)
    vectorized = ...
    matches = torch.allclose(manual, vectorized, atol=..., rtol=...)
    return manual, vectorized, matches

def main():
    X = torch...
    weight = torch...
    bias = torch...
    print(E09(X, weight, bias))

if __name__ == "__main__":
    main()
```

10.2.11 Exercise 10 - Move Model to CUDA Device

Part 1 - Why this matters

CUDA allows compatible PyTorch operations to execute on an NVIDIA GPU, but a model does not move there automatically. Parameters and inputs involved in the same operation must be placed on a compatible device. Making device placement explicit prevents one of the most common runtime errors in model code.

A GPU is not proof of correctness or speed. This exercise is about controlled placement and verification, not benchmarking. The reader will first detect whether CUDA is available, choose a safe fallback, move the model and input together, and confirm where every relevant tensor resides.

Part 2 - Technical concept and behavior

Let d be the selected device:

$$d = \begin{cases} \texttt{cuda}, & \text{if CUDA is available,} \\ \texttt{cpu}, & \text{otherwise.} \end{cases}$$

Calling `model.to(d)` moves registered parameters and buffers. The input must also be moved with `x.to(d)`. The output is created on the device used by the operation.

Part 3 - Hints and Helper

Use `torch.cuda.is_available()` before selecting CUDA. Inspect `next(model.parameters()).devic` `x.device`, and `output.device`. Do not force `cuda:0` on a machine that does not provide CUDA, and do not silently catch device mismatch errors.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E10(model, x):
    device = torch.device("cuda" if ... else "cpu")
    model = model.to(...)
    x = x.to(...)
    output = model(...)
    return output, device

def main():
    model = nn.Linear(..., ...)
    x = torch...
    output, device = E10(model, x)
    print(device, output.device)

if __name__ == "__main__":
    main()
```

10.2.12 Exercise 11 - CPU vs GPU Forward Pass Comparison

Part 1 - Why this matters

CPU and GPU execution have different performance characteristics. GPUs can process large parallel workloads efficiently, but transferring data and launching kernels adds overhead. A tiny linear model may therefore run faster on a CPU even though a larger batch benefits from the GPU.

A fair comparison must also account for asynchronous CUDA execution. Measuring only the time taken to submit GPU work produces an artificially small value. The reader must use identical parameters and inputs, warm up the devices, synchronize at the correct boundaries, and compare numerical outputs as well as elapsed time.

Part 2 - Technical concept and behavior

For device d, approximate average forward latency over R repetitions as:

$$L_d = \frac{t_{\text{end}} - t_{\text{start}}}{R}$$

CUDA synchronization is required before the start and after the end of the timed region. Data-transfer time must either be excluded from both runs or reported as a separate measurement. Speedup is $S = L_{\text{CPU}}/L_{\text{GPU}}$.

Part 3 - Hints and Helper

Copy one model state to both devices so their parameters are identical. Prepare inputs before timing, call `torch.cuda.synchronize()` around CUDA measurement, and use `torch.no_grad()`. Test several batch sizes rather than drawing a conclusion from one tiny tensor.

Part 4 - Python code skeleton

```
import time
import torch
from torch import nn

def measure_forward(model, x, repetitions, use_cuda):
    ...  # warm-up
    if use_cuda:
        torch.cuda.synchronize()
    started = time.perf_counter()
    with torch.no_grad():
        for _ in range(repetitions):
            output = model(x)
    if use_cuda:
        torch.cuda.synchronize()
    return ..., output

def E11(in_features, out_features, batch_sizes):
    if not torch.cuda.is_available():
```

```
        return ...
    base_model = nn.Linear(in_features, out_features)
    ...  # construct identical CPU and GPU models
    return ...

def main():
    print(E11(..., ..., [...]))

if __name__ == "__main__":
    main()
```

10.2.13 Exercise 12 - Precision Difference (float32 vs float64)

Part 1 - Why this matters

Floating-point data types trade numerical precision against memory use and hardware throughput. Double precision can preserve smaller differences and reduce accumulated rounding error, while single precision is commonly faster and consumes half as many bytes per value. The best choice depends on the scale and sensitivity of the problem.

A precision comparison must begin from equivalent values and parameters. If the two models are initialized separately, random differences can be mistaken for numerical differences. This exercise isolates the effect of `float32` and `float64` by converting the same reference data and model state.

Part 2 - Technical concept and behavior

Let $\hat{\mathbf{y}}_{32}$ and $\hat{\mathbf{y}}_{64}$ be predictions computed from equivalent inputs. Compare them after converting to a common precision:

$$D_{\max} = \max_i |\text{float64}(\hat{y}_{32,i}) - \hat{y}_{64,i}|$$

Memory required by a dense tensor is approximately its number of elements multiplied by the bytes per element.

Part 3 - Hints and Helper

Create a reference model, copy its state, and then call `.float()` and `.double()` on separate copies. Match each input dtype to its model dtype. Test ordinary values and values with a wide numerical range, then report maximum absolute and relative differences.

Part 4 - Python code skeleton

```
import copy
import torch
from torch import nn

def E12(model, x):
    model32 = copy.deepcopy(model).float()
    model64 = copy.deepcopy(model).double()
    x32 = x.to(dtype=torch.float32)
```

```
    x64 = x.to(dtype=torch.float64)
    with torch.no_grad():
        y32 = ...
        y64 = ...
    absolute_difference = ...
    relative_difference = ...
    return y32, y64, absolute_difference, relative_difference

def main():
    model = nn.Linear(..., ...)
    x = torch...
    print(E12(model, x))

if __name__ == "__main__":
    main()
```

10.2.14 Exercise 13 - Multiple Feature Linear Model

Part 1 - Why this matters

Real predictions usually depend on several measurements rather than one. Energy demand may depend on temperature, time, occupancy, and previous usage; each feature receives its own weight. A multiple-feature model combines these contributions while remaining interpretable.

Adding features creates new responsibilities. Their order must remain consistent, units can differ greatly, and correlated features can make individual weights difficult to interpret. This exercise focuses on the forward model and records the feature contract explicitly before later chapters address data preparation and training.

Part 2 - Mathematical form

For sample $\mathbf{x} \in \mathbb{R}^F$:

$$\hat{y} = \mathbf{x}^\mathsf{T}\mathbf{w} + b = \sum_{j=1}^{F} x_j w_j + b$$

For a batch $\mathbf{X} \in \mathbb{R}^{N \times F}$, the prediction vector is $\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$. Each weight corresponds to exactly one ordered feature.

Part 3 - Hints and Helper

Define a list of feature names beside the tensor construction. Assert that the number of names, input columns, and weights agree. Calculate the contribution `X * weight` before summing so that the influence of each feature can be inspected.

Part 4 - Python code skeleton

```
import torch

def E13(X, weight, bias, feature_names):
    if X.shape[-1] != len(feature_names):
```

```
        raise ValueError(...)
    if weight.numel() != ...:
        raise ValueError(...)
    contributions = ...
    predictions = contributions.sum(dim=..., keepdim=...) + ...
    return predictions, contributions

def main():
    feature_names = [...]
    X = torch.tensor([...], dtype=torch.float32)
    weight = torch.tensor([...], dtype=torch.float32)
    bias = torch.tensor(..., dtype=torch.float32)
    print(E13(X, weight, bias, feature_names))

if __name__ == "__main__":
    main()
```

10.2.15 Exercise 14 - Verify Output Dimensions

Part 1 - Why this matters

An output can contain reasonable numbers and still have the wrong structure. A missing output dimension may break concatenation, loss computation, or downstream batching, while an unintended extra dimension may trigger broadcasting and produce a larger error tensor than expected. Output validation protects the interface between model stages.

The expected dimension is determined by the model contract, not by appearance when printed. This exercise requires the reader to calculate the correct shape from batch size and output-feature count before executing the forward pass, then enforce that expectation programmatically.

Part 2 - Technical concept and behavior

A linear transformation maps:

$$(*, F_{\text{in}}) \longrightarrow (*, F_{\text{out}})$$

where $*$ represents any preserved leading dimensions. For a two-dimensional batch $\mathbf{X} \in \mathbb{R}^{N \times F_{\text{in}}}$, the expected output is $\hat{\mathbf{Y}} \in \mathbb{R}^{N \times F_{\text{out}}}$.

Part 3 - Hints and Helper

Construct the expected shape from `x.shape[:-1]` and the declared output-feature count. Compare tuples exactly and raise an informative error that includes both expected and observed shapes. Test several batch sizes and at least two output sizes.

Part 4 - Python code skeleton

```
import torch
from torch import nn
```

```
def E14(model, x, expected_out_features):
    output = model(x)
    expected_shape = ... + (...)
    if tuple(output.shape) != expected_shape:
        raise ValueError(
            f"expected {expected_shape}, observed {tuple(output.shape)}"
        )
    return output

def main():
    model = nn.Linear(..., ...)
    x = torch...
    print(E14(model, x, ...).shape)

if __name__ == "__main__":
    main()
```

10.2.16 Exercise 15 - Linear Layer Using nn.Linear

Part 1 - Why this matters

The `torch.nn.Linear` module packages a learnable affine transformation as a reusable model component. It registers its weight and optional bias as parameters, participates in device and dtype conversion, and connects automatically to PyTorch's gradient system. This is the standard bridge from the manually written equation to a trainable layer.

Using the module should not hide its mathematics. The reader must understand how PyTorch stores the weight, how the input's final dimension is interpreted, and how the module's output relates to the matrix equation already studied. A correct comparison requires accounting for the orientation of the stored weight matrix.

Part 2 - Mathematical form

For `nn.Linear(in_features, out_features)`, PyTorch represents:

$$\mathbf{Y} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}$$

where $\mathbf{W} \in \mathbb{R}^{F_{\text{out}} \times F_{\text{in}}}$ and $\mathbf{b} \in \mathbb{R}^{F_{\text{out}}}$. The module preserves leading input dimensions and replaces the final feature dimension.

Part 3 - Hints and Helper

Instantiate `nn.Linear()` with explicit feature counts. Print the parameter shapes before the forward call and compare the module output with `X @ layer.weight.T + layer.bias`. Use `torch.allclose()` to verify agreement.

Part 4 - Python code skeleton

```
import torch
from torch import nn
```

```
def E15(X, in_features, out_features):
    layer = nn.Linear(..., ...)
    module_output = layer(...)
    manual_output = ... @ ... + ...
    matches = torch.allclose(module_output, manual_output)
    return layer, module_output, matches

def main():
    X = torch...
    layer, output, matches = E15(X, ..., ...)
    print(layer.weight.shape, layer.bias.shape)
    print(output, matches)

if __name__ == "__main__":
    main()
```

10.2.17 Exercise 16 - Inspect Weight and Bias Parameters

Part 1 - Why this matters

Training changes parameters, so the reader must be able to identify them before examining gradients or optimizer behavior. A linear layer exposes weight and bias tensors with distinct shapes and roles. Inspection confirms that they are registered, trainable, and located on the expected device.

Parameter inspection is also a debugging tool. A missing bias, unexpected feature count, frozen parameter, or incorrect dtype can be detected immediately rather than after a failed training run. The goal is to produce a structured report, not merely print the entire tensor without context.

Part 2 - Technical concept and behavior

For F_{in} input features and F_{out} outputs:

$$\text{shape}(\mathbf{W}) = (F_{\text{out}}, F_{\text{in}}), \qquad \text{shape}(\mathbf{b}) = (F_{\text{out}})$$

Each registered `Parameter` also has a device, dtype, and `requires_grad` property. The total parameter count is $F_{\text{out}}F_{\text{in}} + F_{\text{out}}$ when bias is enabled.

Part 3 - Hints and Helper

Iterate over `model.named_parameters()` and record the name, shape, number of elements, dtype, device, and gradient flag. Calculate the expected total independently, then compare it with the sum of `numel()`.

Part 4 - Python code skeleton

```
from torch import nn

def E16(model):
    report = []
```

```
    total = 0
    for name, parameter in model.named_parameters():
        report.append({
            "name": ...,
            "shape": ...,
            "count": ...,
            "dtype": ...,
            "device": ...,
            "requires_grad": ...,
        })
        total += ...
    return report, total

def main():
    model = nn.Linear(..., ...)
    report, total = E16(model)
    print(report)
    print(total)

if __name__ == "__main__":
    main()
```

10.2.18 Exercise 17 - Freeze Parameters Test

Part 1 - Why this matters

Freezing a parameter prevents automatic differentiation from storing a gradient for it. This is useful when part of a model should remain fixed during fine-tuning or when an experiment needs to isolate the effect of another parameter. In a linear model, freezing the weight while leaving the bias trainable makes the behavior easy to observe.

Freezing does not remove a parameter from the forward equation. The weight still affects predictions; it simply should not receive a gradient-based update. The reader must distinguish computational participation from trainability and verify both after the backward pass.

Part 2 - Technical concept and behavior

If `weight.requires_grad=False`, the forward model remains:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}$$

but gradient computation targets only trainable parameters. After scalar loss $\mathcal{L}$ is back-propagated, the frozen weight should have no stored gradient, while an unfrozen bias may have $\partial\mathcal{L}/\partial\mathbf{b}$.

Part 3 - Hints and Helper

Set the gradient flag before the forward pass, construct a scalar loss, and call `backward()`. Inspect both `weight.grad` and `bias.grad`. If an optimizer is used for confirmation, build it only from parameters whose gradient flag is true and verify the frozen value remains unchanged.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E17(model, X, target):
    model.weight.requires_grad_(...)
    before_weight = model.weight.detach().clone()
    prediction = model(X)
    loss = ...
    loss.backward()
    return {
        "weight_unchanged": ...,
        "weight_grad": ...,
        "bias_grad": ...,
    }

def main():
    model = nn.Linear(..., ...)
    X = torch...
    target = torch...
    print(E17(model, X, target))

if __name__ == "__main__":
    main()
```

10.2.19 Exercise 18 - Manual Forward Without nn.Module

Part 1 - Why this matters

A model can be computed with ordinary tensors without inheriting from `nn.Module`. Rebuilding the forward pass manually confirms that the framework module is a structured container around the same affine equation, not a different mathematical law. This strengthens the connection between tensor algebra and model code.

The manual version also exposes what `nn.Module` normally provides: parameter registration, convenient device conversion, state dictionaries, mode management, and integration with model utilities. The exercise should reveal both mathematical equivalence and the engineering benefits that are absent.

Part 2 - Mathematical form

Given an input $\mathbf{X}$ and tensors stored in the same orientation as `nn.Linear`:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}$$

If `requires_grad=True` is set on the manual tensors, autograd can still compute gradients. However, these tensors are not automatically returned by `model.parameters()` because no module owns them.

Part 3 - Hints and Helper

Create weight and bias tensors explicitly and implement a plain function. For verification, copy them into an `nn.Linear` layer inside `torch.no_grad()`, then compare outputs. Inspect the objects available from the module and explain what the plain function does not manage.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def manual_forward(X, weight, bias):
    return ... @ ... + ...

def E18(X, weight, bias):
    manual_output = manual_forward(X, weight, bias)
    layer = nn.Linear(..., ...)
    with torch.no_grad():
        layer.weight.copy_(...)
        layer.bias.copy_(...)
    module_output = layer(X)
    return manual_output, module_output, torch.allclose(..., ...)

def main():
    X = torch...
    weight = torch...
    bias = torch...
    print(E18(X, weight, bias))

if __name__ == "__main__":
    main()
```

10.2.20 Exercise 19 - Forward Pass Failure Debugging

Part 1 - Why this matters

A forward pass can fail because of incompatible shapes, devices, data types, missing bias assumptions, or invalid numerical values. Effective debugging begins by turning the model's input contract into observable checks rather than repeatedly changing code until an exception disappears. Fixing only the first visible error may leave the underlying data problem unresolved.

The final exercise combines the chapter's reasoning skills into a diagnostic workflow. The reader will reproduce several controlled failures, classify each cause, and return a concise report. The goal is not to suppress exceptions, but to provide enough evidence to correct the source safely.

Part 2 - Technical concept and behavior

For `nn.Linear(F_in, F_out)`, a valid input must have final dimension F_{in}, a compatible floating-point dtype, and the same device as the parameters. Before the operation, verify:

$$X_{\text{last}} = F_{\text{in}}, \qquad d_X = d_W, \qquad \tau_X = \tau_W$$

The output should also be checked for non-finite values using a deliberate policy.

Part 3 - Hints and Helper

Write a validator that reports shape, dtype, device, expected input features, and whether all values are finite. Test it against wrong feature count, integer input, and device mismatch when CUDA is available. Catch an exception only at the outer experiment boundary so the original error type and message remain visible.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def inspect_forward_contract(model, X):
    parameter = next(model.parameters())
    checks = {
        "shape_valid": ...,
        "dtype_valid": ...,
        "device_valid": ...,
        "finite_input": ...,
    }
    return checks

def E19(model, test_inputs):
    report = []
    for label, X in test_inputs.items():
        checks = inspect_forward_contract(model, X)
        try:
            output = model(X)
            status = ...
        except (RuntimeError, ValueError, TypeError) as error:
            status = {
                "error_type": type(error).__name__,
                "message": str(error),
            }
        report.append((label, checks, status))
    return report

def main():
    model = nn.Linear(..., ...)
    test_inputs = {
        "valid": torch...,
        "wrong_shape": torch...,
        "wrong_dtype": torch...,
    }
    print(E19(model, test_inputs))

if __name__ == "__main__":
    main()
```

10.3 LR01 - Model Structure and Components

Models and Training

10.3.1 Exercise 00 - Separate Weights and Bias Tensors

Part 1 - Why this matters

A linear model contains two parameter roles that should remain conceptually separate. Weights connect input features to outputs, while bias provides an additive baseline. Storing them in different tensors makes their shapes, contributions, and future gradients visible before they are placed inside a model class.

This separation also supports precise debugging. If a prediction is incorrect, the reader can inspect the weighted contribution and the bias contribution independently. It becomes easier to distinguish a wrong matrix shape from an unintended intercept or broadcasting rule.

Part 2 - Mathematical form

For F input features and O outputs:

$$\mathbf{W} \in \mathbb{R}^{O \times F}, \qquad \mathbf{b} \in \mathbb{R}^{O}$$

The batch forward pass is:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}$$

The bias broadcasts across samples but not across unrelated output definitions.

Part 3 - Hints and Helper

Create weight and bias as independent floating-point tensors. Print their shapes and calculate each contribution separately. Keep the storage orientation consistent with `nn.Linear`: output features first and input features second.

Part 4 - Python code skeleton

```
import torch

def E00(X, in_features, out_features):
    weight = torch...
    bias = torch...
    weighted = X @ ...
    output = weighted + ...
    return weight, bias, output

def main():
    X = torch...
    weight, bias, output = E00(X, ..., ...)
    print(weight.shape, bias.shape, output.shape)

if __name__ == "__main__":
    main()
```

10.3.2 Exercise 01 - Parameter Registration in nn.Module

Part 1 - Why this matters

An ordinary tensor assigned to a model attribute is not automatically treated as a trainable parameter. PyTorch uses `nn.Parameter` to mark tensors that belong to a module's learnable state. Registered parameters appear in parameter iterators, move with the module, enter state dictionaries, and can be supplied to an optimizer.

Understanding registration prevents a quiet failure in which the forward pass works but training never changes the intended tensor. The model can produce predictions from an unregistered tensor, so successful execution alone does not prove that the structure is trainable.

Part 2 - Technical concept and behavior

A custom module represents:

$$f(\mathbf{X}; \mathbf{W}, \mathbf{b}) = \mathbf{X}\mathbf{W}^\mathsf{T} + \mathbf{b}$$

When $\mathbf{W}$ and $\mathbf{b}$ are assigned as `nn.Parameter` attributes after calling the parent constructor, they are returned by `named_parameters()`. An ordinary tensor attribute is not included unless registered through an appropriate module mechanism.

Part 3 - Hints and Helper

Subclass `nn.Module`, call `super().__init__()` first, and wrap the learnable tensors with `nn.Parameter`. Add one ordinary tensor attribute for comparison. Inspect `dict(model.named_parameters` and explain why only selected attributes appear.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class LinearModel(nn.Module):
    def __init__(self, in_features, out_features):
        super().__init__()
        self.weight = nn.Parameter(torch...)
        self.bias = nn.Parameter(torch...)
        self.temporary = torch...

    def forward(self, X):
        return ...

def E01(model):
    registered = dict(model.named_parameters())
    return ...

def main():
    model = LinearModel(..., ...)
    print(E01(model))
```

```
if __name__ == "__main__":
    main()
```

10.3.3 Exercise 02 - Inspect requires_grad Flags

Part 1 - Why this matters

The `requires_grad` flag determines whether autograd should track operations needed to calculate a tensor's gradient. A model may contain registered parameters that are intentionally frozen and others that remain trainable. Inspecting the flag makes this training boundary explicit.

Registration and gradient tracking are related but different ideas. A parameter can remain part of the model state while its gradient flag is disabled. Confusing the two can cause incorrect parameter counts, unexpected optimizer behavior, or mistaken conclusions about whether a layer participates in the forward pass.

Part 2 - Technical concept and behavior

For model parameters $\theta_1, \ldots, \theta_P$, define the trainable subset:

$$\Theta_{\text{train}} = \{\theta_i \mid \theta_i.\texttt{requires_grad} = \text{True}\}$$

Only operations involving this subset need to create the corresponding parameter gradients. A frozen parameter still contributes its numerical value to the output.

Part 3 - Hints and Helper

Iterate through `named_parameters()` and return each name with its flag. Freeze only the weight with `requires_grad_()` and repeat the report. Do not use `torch.no_grad()` as a substitute for changing a parameter's trainability.

Part 4 - Python code skeleton

```
from torch import nn

def inspect_flags(model):
    return {
        name: parameter.requires_grad
        for name, parameter in ...
    }

def E02(model):
    before = inspect_flags(model)
    model.weight.requires_grad_(...)
    after = inspect_flags(model)
    return before, after

def main():
    model = nn.Linear(..., ...)
    print(E02(model))
```

```
if __name__ == "__main__":
    main()
```

10.3.4 Exercise 03 - Count Trainable Parameters

Part 1 - Why this matters

Parameter count describes the number of scalar values a model can adjust. It helps estimate model capacity, memory requirements, and optimizer-state cost. Counting only modules or tensor objects is insufficient because one tensor may contain many scalar parameters.

The trainable count can differ from the total registered count when some parameters are frozen. Reporting both values prevents an architectural description from being confused with the subset currently selected for learning.

Part 2 - Mathematical form

For a linear layer with F inputs and O outputs, including bias:

$$P_{\text{total}} = OF + O$$

For an arbitrary module:

$$P_{\text{train}} = \sum_{\theta \in \Theta} \text{numel}(\theta) \mathbb{1}[\theta.\texttt{requires_grad}]$$

Shared parameters should not be counted twice when the objective is unique storage.

Part 3 - Hints and Helper

Use `parameter.numel()` and compute total and trainable counts separately. Compare the result with the analytical formula for one linear layer. Then freeze the bias and confirm that only the trainable count changes.

Part 4 - Python code skeleton

```
from torch import nn

def E03(model):
    total = sum(... for parameter in model.parameters())
    trainable = sum(
        ...
        for parameter in model.parameters()
        if ...
    )
    return total, trainable

def main():
    model = nn.Linear(..., ...)
    print(E03(model))
    model.bias.requires_grad_(...)
```

```
    print(E03(model))

if __name__ == "__main__":
    main()
```

10.3.5 Exercise 04 - Initialize Model on CUDA

Part 1 - Why this matters

A model intended for GPU training should be created or moved to CUDA before the optimizer is constructed. Device conversion affects registered parameters and buffers, and PyTorch documents that CUDA conversion can make associated parameters different objects. Establishing device placement first avoids stale optimizer references.

CUDA availability must never be assumed. A reusable experiment detects support, selects a device explicitly, and provides a CPU fallback. This makes the model runnable across development machines while keeping the chosen execution path visible.

Part 2 - Technical concept and behavior

Select device d as:

$$d = \begin{cases} \texttt{cuda}, & \text{if available,} \\ \texttt{cpu}, & \text{otherwise.} \end{cases}$$

A module initialized with compatible device arguments or moved using `to(d)` should have every registered parameter on d. The optimizer, if introduced later, must be created after this placement step.

Part 3 - Hints and Helper

Use `torch.cuda.is_available()` and `torch.device`. Construct the model, move it to the selected device, and inspect every parameter. Return the device rather than hiding the fallback inside the function.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E04(in_features, out_features):
    device = torch.device("cuda" if ... else "cpu")
    model = nn.Linear(..., ...)
    model = model.to(...)
    parameter_devices = {
        name: parameter.device
        for name, parameter in model.named_parameters()
    }
    return model, device, parameter_devices

def main():
```

```
    model, device, report = E04(..., ...)
    print(device)
    print(report)

if __name__ == "__main__":
    main()
```

10.3.6 Exercise 05 - Verify Parameter Device Placement

Part 1 - Why this matters

Moving a model is useful only when all of its computational state reaches the intended device. Checking one parameter can miss a misplaced submodule or buffer in a larger architecture. A complete device report gives evidence that the model is ready to receive inputs on the same device.

Device verification should include the data used by the forward pass. A perfectly placed model still fails if the input or target remains on another device. This exercise builds a reusable contract check before any expensive training begins.

Part 2 - Technical concept and behavior

For a valid forward operation on device d, require:

$$d_{\theta_i} = d \quad \text{for every parameter } \theta_i, \qquad d_X = d$$

Registered buffers involved in the operation should satisfy the same condition. The verification result is false if even one required tensor differs.

Part 3 - Hints and Helper

Inspect `named_parameters()` and `named_buffers()`. Report the exact name and observed device for failures. Accept the expected device as an argument, and validate an input tensor separately from the model state.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E05(model, X, expected_device):
    mismatches = []
    for name, parameter in model.named_parameters():
        if parameter.device != expected_device:
            mismatches.append(...)
    for name, buffer in model.named_buffers():
        if buffer.device != expected_device:
            mismatches.append(...)
    if X.device != expected_device:
        mismatches.append(...)
    return len(mismatches) == 0, mismatches
```

```
def main():
    device = torch.device(...)
    model = nn.Linear(..., ...).to(device)
    X = torch...
    print(E05(model, X, device))

if __name__ == "__main__":
    main()
```

10.3.7 Exercise 06 - Manual Parameter Update Test

Part 1 - Why this matters

Learning occurs when computed gradients are converted into parameter changes. Performing one manual update exposes the exact arithmetic normally handled by an optimizer. The reader can observe the parameter before the step, its gradient, and the value produced afterward.

A manual update must not become part of the recorded autograd graph. PyTorch parameters requiring gradients are leaf tensors, so modifying them carelessly in place can raise an error or create incorrect graph behavior. The update should occur in a no-gradient context and only after gradients have been calculated.

Part 2 - Mathematical form

For learning rate $\eta > 0$ and parameter θ:

$$\theta_{\text{new}} = \theta_{\text{old}} - \eta \nabla_\theta \mathcal{L}$$

The expected change is:

$$\Delta\theta = -\eta \nabla_\theta \mathcal{L}$$

A test should compare the observed tensor difference with this expression.

Part 3 - Hints and Helper

Clone the parameter before updating it. Compute a scalar loss and call `backward()`, then update inside `torch.no_grad()`. Do not use `.data`. Check that the observed change matches the gradient rule and clear gradients before another experiment.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E06(model, X, target, learning_rate):
    prediction = model(X)
    loss = ...
    loss.backward()
    before = {
```

```
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    with torch.no_grad():
        for parameter in model.parameters():
            parameter -= ...
    observed_changes = ...
    return loss.item(), before, observed_changes

def main():
    model = nn.Linear(..., ...)
    print(E06(model, torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.3.8 Exercise 07 - Parameter Sharing Experiment

Part 1 - Why this matters

Parameter sharing means that several computation paths use the same underlying learnable tensor. It reduces unique storage and forces those paths to learn a common transformation. Shared weights appear in recurrent structures, tied embeddings, and models that apply one operation repeatedly.

Sharing is different from copying equal values. Two independent parameters may begin identically and later diverge, while shared references remain the same object and accumulate gradient contributions from every path that uses them. This exercise makes that distinction observable.

Part 2 - Technical concept and behavior

If one parameter θ contributes through paths f_1 and f_2, then:

$$\frac{\partial \mathcal{L}}{\partial \theta} = \left.\frac{\partial \mathcal{L}}{\partial \theta}\right|_{f_1} + \left.\frac{\partial \mathcal{L}}{\partial \theta}\right|_{f_2}$$

Object identity and storage identity can be inspected separately from numerical equality. Unique-parameter iteration commonly removes duplicates by default.

Part 3 - Hints and Helper

Construct a model that applies the same `nn.Linear` instance twice. Compare it with two independently created layers whose initial state is copied. Inspect object identity, parameter data pointers, unique parameter count, and gradients after a scalar loss.

Part 4 - Python code skeleton

```
import copy
import torch
from torch import nn
```

```
class SharedModel(nn.Module):
    def __init__(self, layer):
        super().__init__()
        self.first = ...
        self.second = ...

    def forward(self, X):
        return self.first(X) + self.second(X)

def E07(X):
    base = nn.Linear(..., ...)
    shared_model = SharedModel(base)
    independent_first = copy.deepcopy(base)
    independent_second = copy.deepcopy(base)
    ...  # compare identity, storage, outputs, and gradients
    return ...

def main():
    print(E07(torch...))

if __name__ == "__main__":
    main()
```

10.3.9 Exercise 08 - Reinitialize Model Weights

Part 1 - Why this matters

Reinitialization returns model parameters to a new starting state without rebuilding the surrounding experiment. It is useful when comparing repeated training runs, recovering from an intentionally bad setup, or applying a defined initialization policy across a model.

Reinitialization must occur before training statistics from the new run are collected. Optimizer state from a previous run may still contain momentum or adaptive estimates, so resetting model weights alone is not equivalent to starting an entirely fresh experiment.

Part 2 - Technical concept and behavior

A chosen initializer samples or assigns new values according to a defined rule. For example:

$$W_{ij} \sim \mathcal{U}(-a, a), \qquad b_j = 0$$

The operation changes parameter values but should preserve parameter shapes, registration, dtype, device, and gradient flags.

Part 3 - Hints and Helper

Write an initialization function for `nn.Linear` and apply it with `model.apply()`. Use `torch.no_grad()` for direct filling. Clone the old values and verify that values changed while structural properties remained constant. Recreate the optimizer after reinitialization if an optimizer had already accumulated state.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def initialize_linear(module):
    if isinstance(module, nn.Linear):
        with torch.no_grad():
            module.weight.uniform_(...)
            if module.bias is not None:
                module.bias.fill_(...)

def E08(model):
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    model.apply(...)
    after = ...
    checks = ...
    return before, after, checks

def main():
    model = nn.Sequential(nn.Linear(..., ...), nn.Linear(..., ...))
    print(E08(model))

if __name__ == "__main__":
    main()
```

10.3.10 Exercise 09 - Effect of Bad Initialization

Part 1 - Why this matters

Initialization values that are excessively large can create huge predictions, losses, and gradients before meaningful learning begins. Values that remove useful distinctions can also produce restricted behavior. The reader should recognize these symptoms from measurements rather than label an initialization bad only after training fails.

Linear regression offers a controlled experiment because the direct effect of parameter scale is easy to calculate. Comparing several starting scales with identical data reveals how initialization changes the initial loss and gradient norm while every other condition remains fixed.

Part 2 - Mathematical form

If weights are scaled by factor c:

$$\hat{\mathbf{Y}}_c = \mathbf{X}(c\mathbf{W})^\top + \mathbf{b}$$

For mean squared error, large prediction magnitudes may produce errors that grow approximately quadratically with scale. The experiment records finite status, loss, and gradient norm for each initialization policy.

Part 3 - Hints and Helper

Use cloned models and identical inputs and targets. Test zero, moderate, and very large weight scales. After each backward pass, calculate a combined gradient norm and check `torch.isfinite()` for predictions, loss, and gradients. Do not perform a long training run.

Part 4 - Python code skeleton

```
import copy
import torch
from torch import nn

def evaluate_initialization(model, X, target, scale):
    candidate = copy.deepcopy(model)
    with torch.no_grad():
        candidate.weight.fill_(...)
        candidate.bias.fill_(...)
    prediction = candidate(X)
    loss = ...
    loss.backward()
    gradient_norm = ...
    return {
        "scale": scale,
        "loss": ...,
        "gradient_norm": ...,
        "finite": ...,
    }

def E09(model, X, target, scales):
    return [evaluate_initialization(model, X, target, s) for s in scales]

def main():
    model = nn.Linear(..., ...)
    print(E09(model, torch..., torch..., [..., ..., ...]))

if __name__ == "__main__":
    main()
```

10.3.11 Exercise 10 - Bias-only Model Behavior

Part 1 - Why this matters

A bias-only model ignores all input variation and predicts the same learned value for every sample. Although extremely limited, it provides a useful baseline: a more complex regression model should demonstrate value beyond a constant prediction.

Freezing or removing the weight also isolates the bias gradient. The reader can observe how one scalar or output vector adjusts toward the overall target level while remaining unable to explain differences between samples.

Part 2 - Mathematical form

With zero or absent weights:

$$\hat{y}_i = b \quad \text{for every sample } i$$

Under mean squared error, the best constant prediction for a dataset is its target mean:

$$b^\star = \frac{1}{N}\sum_{i=1}^{N} y_i$$

This relationship provides a reference for checking the experiment.

Part 3 - Hints and Helper

Construct a module containing only an `nn.Parameter` bias. Use the batch size to expand the prediction without creating separate learnable biases per sample. Compare outputs from very different inputs and verify that input changes do not alter predictions.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class BiasOnlyModel(nn.Module):
    def __init__(self, out_features):
        super().__init__()
        self.bias = nn.Parameter(torch...)

    def forward(self, X):
        batch_shape = X.shape[:-1]
        return self.bias.expand(...)

def E10(X, out_features):
    model = BiasOnlyModel(...)
    output = model(X)
    return model, output

def main():
    X = torch...
    model, output = E10(X, ...)
    print(output)

if __name__ == "__main__":
    main()
```

10.3.12 Exercise 11 - Weight-only Model Behavior

Part 1 - Why this matters

A weight-only linear model has no additive intercept, so every prediction is determined entirely by the input. This forces the learned relationship through the origin. The restriction

can be appropriate in some physical systems but harmful when the target has a nonzero baseline.

Comparing weight-only and full affine models reveals that bias is a structural assumption rather than a decorative parameter. The reader should identify cases where the missing intercept produces systematic residual error even when the slope is reasonable.

Part 2 - Mathematical form

Without bias:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W}^{\mathsf{T}}$$

Consequently:

$$f(\mathbf{0}) = \mathbf{0}$$

A standard linear layer can enforce this structure by setting `bias=False`. Its parameter count is then OF instead of $OF + O$.

Part 3 - Hints and Helper

Create two layers with identical weights, one with bias and one without. Set a known nonzero bias in the full layer, then test zero input and nonzero input. Verify parameter names and counts as well as predictions.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E11(X, in_features, out_features):
    weight_only = nn.Linear(..., ..., bias=False)
    with_bias = nn.Linear(..., ..., bias=True)
    with torch.no_grad():
        with_bias.weight.copy_(weight_only.weight)
        with_bias.bias.fill_(...)
    output_weight_only = ...
    output_with_bias = ...
    return ..., ..., list(weight_only.named_parameters())

def main():
    X = torch...
    print(E11(X, ..., ...))

if __name__ == "__main__":
    main()
```

10.3.13 Exercise 12 - Model Copy vs Reference Test

Part 1 - Why this matters

Assigning a model to another variable creates another reference to the same object; it does not create an independent model. Updating parameters through either name changes the single shared instance. This can invalidate experiments that appear to compare two models but actually modify one.

A deep copy creates independent parameter storage with initially equal values. The reader must verify both identity and behavior because numerical equality at the start does not reveal whether later updates will remain isolated.

Part 2 - Technical concept and behavior

Let $M_2 = M_1$ denote reference assignment. Then both names identify the same object and parameters. For a deep copy $M_3 = \text{deepcopy}(M_1)$:

$$\theta(M_3) = \theta(M_1) \quad \text{initially, but} \quad \theta(M_3) \not\equiv \theta(M_1)$$

where $\not\equiv$ indicates independent object or storage identity.

Part 3 - Hints and Helper

Use `is` to test object identity and compare parameter data pointers for storage. Modify one model inside `torch.no_grad()` and inspect all three afterward. Use `copy.deepcopy()`, not a second variable assignment, for the independent case.

Part 4 - Python code skeleton

```
import copy
import torch
from torch import nn

def E12(model):
    reference = ...
    independent = copy.deepcopy(...)
    before = ...
    with torch.no_grad():
        model.weight.add_(...)
    checks = {
        "same_model_object": ...,
        "reference_changed": ...,
        "independent_changed": ...,
        "shared_storage": ...,
    }
    return checks

def main():
    print(E12(nn.Linear(..., ...)))

if __name__ == "__main__":
    main()
```

10.3.14 Exercise 13 - State Dict Inspection

Part 1 - Why this matters

A state dictionary provides named access to a module's persistent state. It contains registered parameters and persistent buffers, making it the standard boundary for checkpoints, model comparison, and weight transfer. Inspecting its keys reveals the hierarchy encoded by nested module names.

The returned state dictionary is a shallow mapping whose tensor values refer to model state. If the reader needs a frozen in-memory snapshot for later comparison, those tensors must be cloned or deep-copied. Otherwise, later model updates may appear inside the supposed snapshot.

Part 2 - Technical concept and behavior

For module state S:

$$S = \{\text{name} \mapsto \text{tensor}\}$$

A simple linear layer typically exposes `weight` and `bias`. Nested models use qualified keys such as `layer1.weight`. Each entry should be inspected by key, shape, dtype, device, and number of elements.

Part 3 - Hints and Helper

Call `model.state_dict()` and build a metadata report without changing the tensors. Create a cloned snapshot with a dictionary comprehension, update the model, and compare the live state with the snapshot to demonstrate reference behavior safely.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E13(model):
    state = model.state_dict()
    report = {
        key: {
            "shape": ...,
            "dtype": ...,
            "device": ...,
            "count": ...,
        }
        for key, value in state.items()
    }
    snapshot = {
        key: value.detach().clone()
        for key, value in state.items()
    }
    return report, snapshot
```

```
def main():
    model = nn.Sequential(nn.Linear(..., ...), nn.Linear(..., ...))
    report, snapshot = E13(model)
    print(report)

if __name__ == "__main__":
    main()
```

10.3.15 Exercise 14 - Save and Load Model Weights

Part 1 - Why this matters

Saving weights preserves learned state independently of the running Python process. Loading them into a correctly constructed model allows evaluation, resumed training, or deployment without repeating the original optimization. A reliable workflow verifies the restored output instead of assuming that file creation was sufficient.

The architecture and state play different roles. A state dictionary stores parameter and persistent-buffer tensors, but the receiving model must be constructed with a compatible structure. Missing or unexpected keys and incompatible shapes should be treated as meaningful errors.

Part 2 - Technical concept and behavior

If S_A is saved from model A and loaded into compatible model B, then:

$$S_B \leftarrow S_A$$

For the same input $\mathbf{X}$ and deterministic forward behavior, the predictions should satisfy:

$$f_A(\mathbf{X}) \approx f_B(\mathbf{X})$$

within an appropriate floating-point tolerance.

Part 3 - Hints and Helper

Save `model.state_dict()` with `torch.save()`. Construct a fresh compatible model and load using `torch.load(..., map_location=..., weights_only=True)` followed by `load_state_dict()`. Use a caller-provided path, verify the returned key information, and compare predictions.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E14(model, fresh_model, X, checkpoint_path, device):
    with torch.no_grad():
        expected = model(X)
    torch.save(..., checkpoint_path)
    state = torch.load(
        checkpoint_path,
        map_location=device,
```

```
        weights_only=True,
    )
    load_result = fresh_model.load_state_dict(...)
    fresh_model.to(device)
    with torch.no_grad():
        restored = fresh_model(X.to(device))
    return load_result, expected, restored, torch.allclose(..., ...)

def main():
    model = nn.Linear(..., ...)
    fresh_model = nn.Linear(..., ...)
    print(E14(model, fresh_model, torch..., ..., torch.device("cpu")))

if __name__ == "__main__":
    main()
```

10.3.16 Exercise 15 - Device Mismatch Error Debugging

Part 1 - Why this matters

A model and its input may each be valid but incompatible when stored on different devices. The resulting failure often appears during matrix multiplication, yet the real problem is placement rather than shape or mathematics. A preflight check produces a clearer explanation before the forward call.

Debugging should not automatically move every tensor without permission. Silent movement can create unexpected transfer costs or place data on the wrong GPU. The function should report the mismatch and let the caller choose the intended device policy.

Part 2 - Technical concept and behavior

For a forward pass using input $\mathbf{X}$ and parameter $\mathbf{W}$:

$$d_X = d_W$$

must hold. In a model with several parameters and buffers, the check extends to every tensor involved. A mixed-device module is itself a structural warning even before an input is supplied.

Part 3 - Hints and Helper

Collect devices from `named_parameters()` and `named_buffers()`, then compare the input. If CUDA is available, construct a controlled mismatch and capture the original exception at the experiment boundary. Return a diagnostic report before applying the explicit fix.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def inspect_devices(model, X):
```

```
    model_devices = {
        str(tensor.device)
        for tensor in list(model.parameters()) + list(model.buffers())
    }
    return {
        "model_devices": ...,
        "input_device": ...,
        "compatible": ...,
    }

def E15(model, X):
    diagnostic = inspect_devices(model, X)
    try:
        output = model(X)
        result = ...
    except RuntimeError as error:
        result = {"type": type(error).__name__, "message": str(error)}
    return diagnostic, result

def main():
    model = nn.Linear(..., ...)
    X = torch...
    print(E15(model, X))

if __name__ == "__main__":
    main()
```

10.3.17 Exercise 16 - Gradient Flow Verification

Part 1 - Why this matters

A model cannot learn if the loss is disconnected from its trainable parameters. The forward output may look correct even when a detach operation, disabled gradient flag, or non-differentiable conversion has broken the path. Gradient-flow verification checks the learning connection directly.

The presence of a gradient tensor is only the first test. Its shape must match the parameter, its values should be finite, and its magnitude should be interpreted in the context of the input and loss. Zero gradients can be mathematically correct, so the experiment must use data designed to produce a nonzero signal.

Part 2 - Mathematical form

For loss $\mathcal{L}$ and parameter θ, a connected differentiable graph allows:

$$\nabla_\theta \mathcal{L} = \frac{\partial \mathcal{L}}{\partial \theta}$$

After `backward()`, verify gradient existence, shape compatibility, finite values, and norm. A missing gradient is represented by `None`, which differs from a tensor filled with zeros.

Part 3 - Hints and Helper

Clear old gradients, perform a forward pass, create a scalar loss, and call `backward()`. Build a report for every named parameter. Repeat once with an intentionally detached prediction and capture the failure or missing connection without hiding it.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def gradient_report(model):
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        report[name] = {
            "exists": ...,
            "shape_matches": ...,
            "finite": ...,
            "norm": ...,
        }
    return report

def E16(model, X, target):
    model.zero_grad(set_to_none=True)
    prediction = model(X)
    loss = ...
    loss.backward()
    return loss.item(), gradient_report(model)

def main():
    model = nn.Linear(..., ...)
    print(E16(model, torch..., torch...))

if __name__ == "__main__":
    main()
```

10.3.18 Exercise 17 - Manual Backward Call Test

Part 1 - Why this matters

Calling `backward()` begins reverse-mode automatic differentiation from an output. For an ordinary training loss, that output is expected to be scalar, providing the starting value needed to propagate gradients through the graph. Observing one manual backward call links the loss equation to the stored parameter gradients.

Repeated backward calls also reveal that gradients accumulate by default and that a completed graph is normally released. This exercise uses one controlled call first, then tests accumulation only after the baseline behavior is understood.

Part 2 - Mathematical form

For scalar loss $\mathcal{L}$:

$$\mathcal{L}.\texttt{backward()} \quad \Longrightarrow \quad \theta.\texttt{grad} \leftarrow \theta.\texttt{grad} + \nabla_\theta \mathcal{L}$$

If the output is non-scalar, an explicit upstream gradient of compatible shape is required. The exercise uses scalar reduction for the main case.

Part 3 - Hints and Helper

Print `loss.grad_fn` before calling backward and confirm parameter gradients are initially `None`. Save the first gradients, clear them, and recompute the forward pass before a second independent call. Do not reuse a freed graph accidentally.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E17(model, X, target):
    model.zero_grad(set_to_none=True)
    prediction = model(X)
    loss = ...
    before = {
        name: parameter.grad
        for name, parameter in model.named_parameters()
    }
    graph_function = loss.grad_fn
    loss.backward()
    after = {
        name: parameter.grad.detach().clone()
        for name, parameter in model.named_parameters()
    }
    return loss.item(), graph_function, before, after

def main():
    model = nn.Linear(..., ...)
    print(E17(model, torch..., torch...))

if __name__ == "__main__":
    main()
```

10.3.19 Exercise 18 - Parameter Update Order Inspection

Part 1 - Why this matters

The operations in a training step must occur in a meaningful order. Gradients belong to the parameters and forward values that created the loss; updating parameters before backward or forgetting to clear old gradients changes that relationship. A correct sequence makes every

state transition traceable.

Inspection is more informative than memorization. By recording parameters and gradients at each stage, the reader can explain why zeroing occurs before the next backward pass, why the optimizer step follows gradient calculation, and why a new prediction is required to measure the updated model.

Part 2 - Technical concept and behavior

A standard step follows:

$$\text{clear gradients} \rightarrow \text{forward} \rightarrow \text{loss} \rightarrow \text{backward} \rightarrow \text{update}$$

The prediction used to create $\mathcal{L}_t$ belongs to parameters θ_t. After updating to θ_{t+1}, a fresh forward pass is required to calculate $\mathcal{L}_{t+1}$.

Part 3 - Hints and Helper

Record cloned parameters and gradient states before zeroing, after backward, and after the optimizer step. Use one small optimizer only to study order. Do not interpret the old loss tensor as the post-update loss; recompute it explicitly.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def snapshot(model):
    return {
        name: {
            "value": parameter.detach().clone(),
            "grad": ...,
        }
        for name, parameter in model.named_parameters()
    }

def E18(model, optimizer, X, target):
    stages = {}
    stages["start"] = snapshot(model)
    optimizer.zero_grad(set_to_none=True)
    stages["after_zero"] = snapshot(model)
    prediction = model(X)
    loss_before = ...
    loss_before.backward()
    stages["after_backward"] = snapshot(model)
    optimizer.step()
    stages["after_step"] = snapshot(model)
    with torch.no_grad():
        loss_after = ...
    return stages, loss_before.item(), loss_after.item()
```

```
def main():
    model = nn.Linear(..., ...)
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    print(E18(model, optimizer, torch..., torch...))

if __name__ == "__main__":
    main()
```

10.3.20 Exercise 19 - Model Structure Failure Case

Part 1 - Why this matters

Structural errors can leave a model partially functional: it may execute a forward pass while hiding unregistered tensors, omitting expected parameters, or returning an incorrect output shape. These failures are dangerous because they can survive until training or checkpoint loading.

The final challenge turns the chapter into a validation checklist. The reader must inspect inheritance, registration, parameter counts, shapes, devices, gradient flags, state keys, and forward behavior. The report should identify evidence and likely cause rather than return only a generic pass or fail.

Part 2 - Technical concept and behavior

For an expected affine model, structural invariants include:

$$\text{shape}(W) = (O, F), \qquad \text{shape}(b) = (O), \qquad \text{shape}(f(X)) = (*, O)$$

The expected parameters must be registered, compatible with the input device and dtype, and connected to a scalar loss when trainable.

Part 3 - Hints and Helper

Create one deliberately broken custom module, such as one storing weight as an ordinary tensor or transposing it incorrectly. Write independent checks before attempting the forward pass. Capture exceptions at the outer boundary and preserve their types and messages.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def validate_model_structure(model, X, expected_in, expected_out):
    report = {
        "is_module": isinstance(model, nn.Module),
        "registered_names": ...,
        "parameter_count": ...,
        "device_compatible": ...,
        "dtype_compatible": ...,
    }
    try:
```

```
        output = model(X)
        report["output_shape_valid"] = ...
        loss = output.square().mean()
        loss.backward()
        report["gradient_flow"] = ...
    except (RuntimeError, ValueError, TypeError) as error:
        report["failure"] = {
            "type": type(error).__name__,
            "message": str(error),
        }
    return report

def E19(model, X):
    return validate_model_structure(model, X, ..., ...)

def main():
    broken_model = ...
    X = torch...
    print(E19(broken_model, X))

if __name__ == "__main__":
    main()
```

10.4 LR02 - Data Preparation and Feature Inputs

Data Engineering for AI

10.4.1 Exercise 00 - Generate Synthetic Linear Dataset

Part 1 - Why this matters

A synthetic dataset gives the reader complete knowledge of the relationship that generated each target. Because the true weights and bias are known, later training results can be compared with a controlled reference instead of relying only on a decreasing loss. This makes synthetic data ideal for testing a first regression pipeline.

Controlled generation also allows one factor to change at a time. The reader can vary sample count, feature count, parameter scale, or random seed while preserving every other condition. Unexpected behavior can then be traced to the experiment rather than hidden properties of an external dataset.

Part 2 - Mathematical form

Let $\mathbf{X} \in \mathbb{R}^{N \times F}$ be sampled feature data, $\mathbf{w}_{\text{true}} \in \mathbb{R}^{F \times 1}$ the true weights, and $b_{\text{true}} \in \mathbb{R}$. Generate targets by:

$$\mathbf{y} = \mathbf{X}\mathbf{w}_{\text{true}} + b_{\text{true}}$$

The expected target shape is $(N, 1)$. This first dataset is noiseless so every target can be reproduced exactly from its source parameters.

Part 3 - Hints and Helper

Use a local `torch.Generator` with an explicit seed so dataset creation does not unexpectedly alter unrelated global randomness. Validate positive sample and feature counts. Return the true parameters with the features and targets so later exercises can verify provenance.

Part 4 - Python code skeleton

```
import torch

def E00(sample_count, feature_count, seed):
    generator = torch.Generator().manual_seed(...)
    X = torch.randn(..., generator=generator)
    true_weight = torch.randn(..., generator=generator)
    true_bias = torch.randn(..., generator=generator)
    y = ...
    return X, y, true_weight, true_bias

def main():
    X, y, weight, bias = E00(..., ..., ...)
    print(X.shape, y.shape)
    print(weight, bias)

if __name__ == "__main__":
    main()
```

10.4.2 Exercise 01 - Add Noise to Dataset

Part 1 - Why this matters

Real measurements rarely follow a perfect equation. Sensors, unobserved variables, rounding, and natural variation introduce noise into targets. Adding controlled noise makes a synthetic regression problem more realistic while preserving knowledge of the underlying relationship.

Noise should be separated from the signal and recorded as part of the experiment. If the random process is not reproducible, changes in model performance may be caused by a different dataset rather than a different model or training configuration.

Part 2 - Mathematical form

For noiseless target $\mathbf{y}_{\text{clean}}$, define:

$$\mathbf{y}_{\text{noisy}} = \mathbf{y}_{\text{clean}} + \boldsymbol{\epsilon}, \qquad \epsilon_i \sim \mathcal{N}(0, \sigma^2)$$

The standard deviation σ controls noise magnitude. The features and clean targets remain unchanged, allowing signal and noise to be compared directly.

Part 3 - Hints and Helper

Require a nonnegative noise standard deviation and use a seeded generator. Return the sampled noise as well as the noisy target. Verify that zero noise reproduces the clean target

and that the empirical noise mean and standard deviation are reasonable for a sufficiently large sample.

Part 4 - Python code skeleton

```
import torch

def E01(clean_target, noise_std, seed):
    if noise_std < 0:
        raise ValueError(...)
    generator = torch.Generator().manual_seed(...)
    noise = torch.randn(
        clean_target.shape,
        generator=generator,
        dtype=clean_target.dtype,
        device=clean_target.device,
    ) * ...
    noisy_target = ...
    return noisy_target, noise

def main():
    clean_target = torch...
    noisy_target, noise = E01(clean_target, ..., ...)
    print(noisy_target)
    print(noise.mean(), noise.std())

if __name__ == "__main__":
    main()
```

10.4.3 Exercise 02 - Feature Scaling Experiment

Part 1 - Why this matters

Features measured in different units can have dramatically different numerical ranges. A large-scale feature may dominate gradient magnitudes even when it is not more informative. Scaling can make optimization better conditioned and makes the effect of learning-rate choices easier to interpret.

Scaling statistics must be learned from training data only. Using test values to calculate means or standard deviations leaks information from evaluation into preparation. This exercise therefore separates fitting a scaler from applying it to another tensor.

Part 2 - Mathematical form

For training feature j:

$$\mu_j = \frac{1}{N}\sum_{i=1}^{N} X_{ij}, \qquad s_j = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(X_{ij} - \mu_j)^2}$$

Standardized values are:

$$Z_{ij} = \frac{X_{ij} - \mu_j}{s_j}$$

A zero or nearly zero scale requires an explicit policy to avoid division by zero.

Part 3 - Hints and Helper

Create separate `fit_scaler()` and `transform()` functions. Preserve the feature dimension with `keepdim=True`. Detect constant features and replace an unsafe denominator only according to a documented rule. Compare model behavior before and after scaling without changing the split.

Part 4 - Python code skeleton

```
import torch

def fit_scaler(X_train):
    mean = X_train.mean(dim=..., keepdim=True)
    scale = X_train.std(dim=..., keepdim=True, correction=...)
    safe_scale = torch.where(..., ..., ...)
    return mean, safe_scale

def transform(X, mean, scale):
    return ...

def E02(X_train, X_test):
    mean, scale = fit_scaler(X_train)
    train_scaled = transform(...)
    test_scaled = transform(...)
    return train_scaled, test_scaled, mean, scale

def main():
    X_train = torch...
    X_test = torch...
    print(E02(X_train, X_test))

if __name__ == "__main__":
    main()
```

10.4.4 Exercise 03 - Train/Test Split Implementation

Part 1 - Why this matters

A model must be evaluated on samples that were not used to adjust its parameters. A train/test split creates this boundary and provides evidence about generalization. Evaluating on training data alone can make memorization or leakage look like successful learning.

The split must preserve alignment between every feature row and its target. Reproducible random indices allow different model experiments to use the same partitions, while time-dependent data may require chronological splitting instead of random shuffling.

Part 2 - Technical concept and behavior

For N samples and test fraction $r \in (0, 1)$, define a test count such as:

$$N_{\text{test}} = \lfloor rN \rfloor, \qquad N_{\text{train}} = N - N_{\text{test}}$$

A permutation of sample indices is divided into disjoint train and test sets whose union contains every original index exactly once.

Part 3 - Hints and Helper

Validate equal sample counts in $\mathbf{X}$ and $\mathbf{y}$. Generate one permutation with a seeded `torch.Generator`, then index both tensors with the same subsets. Return the indices so disjointness, completeness, and reproducibility can be checked.

Part 4 - Python code skeleton

```
import torch

def E03(X, y, test_fraction, seed):
    if X.shape[0] != y.shape[0]:
        raise ValueError(...)
    if not 0 < test_fraction < 1:
        raise ValueError(...)
    generator = torch.Generator().manual_seed(...)
    indices = torch.randperm(..., generator=generator)
    test_count = ...
    test_indices = ...
    train_indices = ...
    return (
        X[train_indices],
        y[train_indices],
        X[test_indices],
        y[test_indices],
        train_indices,
        test_indices,
    )

def main():
    X = torch...
    y = torch...
    print(E03(X, y, ..., ...))

if __name__ == "__main__":
    main()
```

10.4.5 Exercise 04 - Batch Dataset Creation

Part 1 - Why this matters

Mini-batches divide a dataset into manageable groups that can be processed by a model. They reduce peak memory requirements and allow parameter updates to occur more frequently than full-dataset training. Before introducing a loader, the reader should understand what a valid batch contains.

Features and targets in a batch must refer to the same sample indices. A batching method that slices them differently can produce valid shapes and meaningless supervision. The final incomplete batch also requires a deliberate keep-or-drop policy.

Part 2 - Technical concept and behavior

For N samples and batch size B, the number of batches when the remainder is retained is:

$$K = \left\lceil \frac{N}{B} \right\rceil$$

Batch k uses the aligned slice $[kB : \min((k+1)B, N)]$ from both features and targets. Every sample should occur exactly once when shuffling is disabled.

Part 3 - Hints and Helper

Validate a positive batch size and equal sample counts. Use slicing to construct a list of feature-target pairs. Record original sample identifiers during testing so coverage and order can be verified, especially for the final batch.

Part 4 - Python code skeleton

```
import torch

def E04(X, y, batch_size, drop_last=False):
    if batch_size <= 0 or X.shape[0] != y.shape[0]:
        raise ValueError(...)
    batches = []
    for start in range(0, X.shape[0], batch_size):
        end = min(..., ...)
        if drop_last and end - start < batch_size:
            ...
        batches.append((X[start:end], y[start:end]))
    return batches

def main():
    X = torch...
    y = torch...
    for X_batch, y_batch in E04(X, y, ...):
        print(X_batch.shape, y_batch.shape)

if __name__ == "__main__":
    main()
```

10.4.6 Exercise 05 - Shuffle Dataset per Epoch

Part 1 - Why this matters

When training repeatedly over a dataset, using the same order can preserve unwanted sequence patterns and create highly correlated neighboring batches. Reshuffling changes batch composition between epochs while keeping the dataset itself unchanged.

A correct shuffle must apply one shared permutation to features, targets, and sample identifiers. It should change order without dropping, duplicating, or relabeling samples. Reproducibility also requires control over how random state advances across epochs.

Part 2 - Technical concept and behavior

For epoch e, generate a permutation π_e of $\{0, \ldots, N-1\}$:

$$\mathbf{X}^{(e)} = \mathbf{X}[\pi_e], \qquad \mathbf{y}^{(e)} = \mathbf{y}[\pi_e]$$

Each π_e must be bijective. Different epochs may use different permutations while a repeated experiment with the same seed reproduces the full sequence.

Part 3 - Hints and Helper

Use one `torch.Generator` initialized before the epoch loop rather than resetting the same seed inside every epoch. Preserve sample IDs for validation. Compare sorted IDs before and after each shuffle and confirm that at least two epoch orders differ.

Part 4 - Python code skeleton

```
import torch

def E05(X, y, epochs, seed):
    generator = torch.Generator().manual_seed(...)
    epoch_orders = []
    for epoch in range(epochs):
        permutation = torch.randperm(..., generator=generator)
        X_epoch = ...
        y_epoch = ...
        epoch_orders.append((permutation, X_epoch, y_epoch))
    return epoch_orders

def main():
    X = torch...
    y = torch...
    for order, X_epoch, y_epoch in E05(X, y, ..., ...):
        print(order)

if __name__ == "__main__":
    main()
```

10.4.7 Exercise 06 - Move Dataset to CUDA

Part 1 - Why this matters

A CUDA model requires its input batches and targets on the same GPU. Moving an entire dataset at once can be convenient for small data, but it may exhaust device memory and prevent other model state from fitting. Larger pipelines normally keep data on the CPU and transfer one batch at a time.

This exercise compares those strategies rather than declaring one universally correct. The reader will check CUDA availability, estimate tensor storage, verify device placement, and preserve a CPU fallback. Device transfer is treated as a resource decision.

Part 2 - Technical concept and behavior

Approximate dataset storage is:

$$M = \text{numel}(\mathbf{X})s_X + \text{numel}(\mathbf{y})s_y$$

where s_X and s_y are bytes per element. After transfer to device d, both tensors must report d before they participate in the same loss computation.

Part 3 - Hints and Helper

Use `element_size()` to estimate bytes and `torch.cuda.is_available()` before selecting CUDA. Support `move_all=False` to leave the full dataset on CPU and transfer a chosen batch later. Do not return CUDA tensors from multi-process dataset workers.

Part 4 - Python code skeleton

```
import torch

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def E06(X, y, move_all):
    device = torch.device("cuda" if ... else "cpu")
    estimated_bytes = tensor_bytes(X) + tensor_bytes(y)
    if move_all:
        X = X.to(...)
        y = y.to(...)
    return X, y, device, estimated_bytes

def main():
    X = torch...
    y = torch...
    print(E06(X, y, move_all=...))

if __name__ == "__main__":
    main()
```

10.4.8 Exercise 07 - DataLoader Integration

Part 1 - Why this matters

A `Dataset` defines how samples and targets are stored or retrieved, while a `DataLoader` supplies iteration, automatic batching, optional shuffling, and worker configuration. Separating these roles keeps data code independent from the training loop.

Integration must be verified before training. The reader should inspect the number of batches, feature and target shapes, final-batch behavior, and sample alignment. Loader settings change data delivery, not the mathematical meaning of the examples.

Part 2 - Technical concept and behavior

For a map-style dataset of N samples, batch size B, and `drop_last=False`:

$$K = \left\lceil \frac{N}{B} \right\rceil$$

With `drop_last=True`, $K = \lfloor N/B \rfloor$. The loader yields paired tensors formed from the same indexed samples.

Part 3 - Hints and Helper

Wrap features and targets with `TensorDataset`, then construct `DataLoader`. Begin with `num_workers=0` for transparent debugging. Make `shuffle`, `drop_last`, and `pin_memory` explicit arguments and inspect every batch once.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import DataLoader, TensorDataset

def E07(X, y, batch_size, shuffle, drop_last):
    dataset = TensorDataset(..., ...)
    loader = DataLoader(
        dataset,
        batch_size=...,
        shuffle=...,
        drop_last=...,
        num_workers=...,
        pin_memory=...,
    )
    summary = []
    for X_batch, y_batch in loader:
        summary.append(...)
    return loader, summary

def main():
    X = torch...
    y = torch...
    _, summary = E07(X, y, ..., ..., ...)
```

```
    print(summary)

if __name__ == "__main__":
    main()
```

10.4.9 Exercise 08 - Incorrect Shape Debugging

Part 1 - Why this matters

Data pipelines often produce a one-dimensional target when the model emits a two-dimensional column. PyTorch broadcasting may then compare shapes $(N, 1)$ and (N) as if they were (N, N), creating a loss tensor that is valid to compute but mathematically wrong. Shape errors therefore require validation before the loss.

Debugging should attach meaning to every axis: samples, features, and outputs. Reshaping until an exception disappears is unsafe because it may mix sample values or conceal a wrong feature layout.

Part 2 - Technical concept and behavior

For scalar regression with a batch:

$$\mathbf{X} \in \mathbb{R}^{N \times F}, \qquad \mathbf{y} \in \mathbb{R}^{N \times 1}, \qquad \hat{\mathbf{y}} \in \mathbb{R}^{N \times 1}$$

The sample counts must match, and prediction and target should have identical shapes before element-wise loss evaluation.

Part 3 - Hints and Helper

Build a contract validator that checks dimensions and reports observed shapes. Test targets shaped (N), $(N, 1)$, and $(1, N)$. Apply `unsqueeze()` only when the semantic correction is known, then verify the result exactly.

Part 4 - Python code skeleton

```
import torch

def validate_regression_shapes(X, y, prediction=None):
    errors = []
    if X.ndim != ...:
        errors.append(...)
    if y.ndim != ... or y.shape[-1] != ...:
        errors.append(...)
    if X.shape[0] != y.shape[0]:
        errors.append(...)
    if prediction is not None and prediction.shape != y.shape:
        errors.append(...)
    return errors

def E08(X, y):
    errors_before = validate_regression_shapes(X, y)
```

```
    corrected_y = ...
    errors_after = validate_regression_shapes(X, corrected_y)
    return corrected_y, errors_before, errors_after

def main():
    print(E08(torch..., torch...))

if __name__ == "__main__":
    main()
```

10.4.10 Exercise 09 - Missing Feature Handling

Part 1 - Why this matters

Missing feature values cannot be passed blindly into a linear model because they can create non-finite predictions and losses. Handling them requires a policy based on why data is missing, not only a numerical replacement. Dropping samples, imputing values, and adding missingness indicators carry different assumptions.

Imputation statistics must be fitted on training data only. Filling test values with a mean calculated from the complete dataset leaks information across the evaluation boundary. The fitted values and missing masks should be preserved for auditing.

Part 2 - Technical concept and behavior

For feature j, training-mean imputation may use:

$$\mu_j = \frac{\sum_i X_{ij} \mathbb{1}[X_{ij} \text{ observed}]}{\sum_i \mathbb{1}[X_{ij} \text{ observed}]}$$

Every missing entry in that feature is replaced by μ_j. A feature with no observed training values requires an explicit failure or fallback policy.

Part 3 - Hints and Helper

Detect missing values with `torch.isnan()`. Write separate fit and transform functions, store a boolean mask, and check for all-missing columns. Compare the number of missing entries before and after transformation without altering genuinely observed values.

Part 4 - Python code skeleton

```
import torch

def fit_imputer(X_train):
    missing = torch.isnan(X_train)
    observed_count = (~missing).sum(dim=...)
    if torch.any(observed_count == 0):
        raise ValueError(...)
    fill_values = torch.nanmean(X_train, dim=...)
    return fill_values
```

```
def transform_missing(X, fill_values):
    mask = torch.isnan(X)
    filled = torch.where(mask, ..., X)
    return filled, mask

def E09(X_train, X_test):
    fill_values = fit_imputer(X_train)
    train_filled, train_mask = transform_missing(...)
    test_filled, test_mask = transform_missing(...)
    return ...

def main():
    print(E09(torch..., torch...))

if __name__ == "__main__":
    main()
```

10.4.11 Exercise 10 - Bias Column Injection

Part 1 - Why this matters

An affine model can be rewritten as one matrix multiplication by adding a column of ones to the feature matrix. This connects the explicit bias parameter to ordinary linear algebra and helps explain closed-form formulations of regression.

The transformation must be used deliberately. If a ones column is added while `nn.Linear` also keeps its own bias, the intercept is represented twice. Feature names and shapes must be updated so the injected column is not mistaken for measured data.

Part 2 - Mathematical form

Define the augmented tensors:

$$\tilde{\mathbf{X}} = \begin{bmatrix} \mathbf{X} & \mathbf{1} \end{bmatrix}, \qquad \tilde{\mathbf{w}} = \begin{bmatrix} \mathbf{w} \\ b \end{bmatrix}$$

Then:

$$\tilde{\mathbf{X}}\tilde{\mathbf{w}} = \mathbf{X}\mathbf{w} + b$$

The augmented feature count is $F + 1$.

Part 3 - Hints and Helper

Create the ones column with the same dtype and device as $\mathbf{X}$. Concatenate along the feature dimension and compare augmented prediction with the explicit-bias equation. If later using `nn.Linear`, set `bias=False` for the augmented representation.

Part 4 - Python code skeleton

```
import torch

def E10(X, weight, bias):
    ones = torch.ones(
        (..., ...),
        dtype=X.dtype,
        device=X.device,
    )
    X_augmented = torch.cat((..., ...), dim=...)
    weight_augmented = torch.cat((..., ...), dim=...)
    direct = ...
    augmented = ...
    return X_augmented, weight_augmented, direct, augmented

def main():
    print(E10(torch..., torch..., torch...))

if __name__ == "__main__":
    main()
```

10.4.12 Exercise 11 - High-Dimensional Feature Test

Part 1 - Why this matters

Datasets may contain far more features than can be visualized, and sometimes more features than samples. A linear forward pass still follows the same matrix law, but memory use, rank, optimization behavior, and overfitting risk change substantially.

A high-dimensional test should verify resource requirements before allocation. Generating an unnecessarily enormous tensor can exhaust memory without teaching anything. The experiment scales dimensions gradually and records shape, storage, rank limits, and forward behavior.

Part 2 - Technical concept and behavior

For $\mathbf{X} \in \mathbb{R}^{N \times F}$:

$$\operatorname{rank}(\mathbf{X}) \leq \min(N, F)$$

Tensor storage grows approximately as NFs, where s is bytes per element. When $F > N$, many parameter vectors may explain training data similarly unless additional constraints or information are introduced.

Part 3 - Hints and Helper

Estimate bytes before creating the tensor and enforce a caller-provided memory budget. Test several feature counts with fixed sample count. Record the model parameter count, output shape, and an estimated or computed matrix rank for manageable cases.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def estimated_bytes(shape, dtype):
    element_size = torch.empty((), dtype=dtype).element_size()
    return ... * element_size

def E11(sample_count, feature_counts, memory_budget_bytes):
    results = []
    for feature_count in feature_counts:
        required = estimated_bytes((sample_count, feature_count), ...)
        if required > memory_budget_bytes:
            results.append(...)
            continue
        X = torch.randn(...)
        model = nn.Linear(..., ...)
        output = model(X)
        results.append(...)
    return results

def main():
    print(E11(..., [..., ..., ...], ...))

if __name__ == "__main__":
    main()
```

10.4.13 Exercise 12 - Collinearity Effect Observation

Part 1 - Why this matters

Collinearity occurs when one feature can be closely approximated by other features. A model may still predict accurately, but individual weights can become unstable because several parameter combinations explain nearly the same input variation.

This matters for interpretation. A large coefficient is not automatically evidence that one collinear feature is uniquely important. Small perturbations to data may shift weight between correlated columns while leaving predictions almost unchanged.

Part 2 - Mathematical form

For two nearly dependent features:

$$\mathbf{x}_2 = c\mathbf{x}_1 + \boldsymbol{\delta}$$

with small $\boldsymbol{\delta}$, the design matrix is close to rank deficient. Its singular values may have a large ratio:

$$\kappa(\mathbf{X}) = \frac{\sigma_{\max}}{\sigma_{\min}}$$

A large condition number indicates sensitivity in parameter estimation.

Part 3 - Hints and Helper

Generate one feature from another plus small noise. Compare singular values and condition estimates with an independent-feature dataset. Fit or solve repeated perturbed datasets, then compare changes in weights and predictions separately.

Part 4 - Python code skeleton

```
import torch

def condition_summary(X):
    singular_values = torch.linalg.svdvals(X)
    condition = ...
    return singular_values, condition

def E12(sample_count, perturbation_std, seed):
    generator = torch.Generator().manual_seed(...)
    x1 = torch.randn(..., generator=generator)
    x2 = ... * x1 + torch.randn(..., generator=generator) * ...
    X_collinear = torch.cat((x1, x2), dim=...)
    X_independent = torch.randn(..., generator=generator)
    return {
        "collinear": condition_summary(X_collinear),
        "independent": condition_summary(X_independent),
        "matrices": (..., ...),
    }

def main():
    print(E12(..., ..., ...))

if __name__ == "__main__":
    main()
```

10.4.14 Exercise 13 - Data Precision Impact Test

Part 1 - Why this matters

The dtype chosen for a dataset affects memory, transfer cost, numerical resolution, and compatibility with model parameters. Single precision is common for training, while double precision can expose smaller numerical differences at additional cost.

A fair precision test uses the same underlying values. Creating two random datasets independently would compare sampling variation instead of dtype. The reader should convert one high-precision reference and measure both storage and numerical changes.

Part 2 - Technical concept and behavior

For reference data $\mathbf{X}_{64}$ and its single-precision conversion:

$$\mathbf{X}_{32} = \mathrm{cast}_{32}(\mathbf{X}_{64})$$

Measure reconstruction difference:

$$D_{\max} = \max_{i,j} |X_{64,ij} - \mathrm{cast}_{64}(X_{32,ij})|$$

The `float64` tensor uses twice the element storage of `float32`.

Part 3 - Hints and Helper

Create data in `float64`, convert it to `float32`, then convert back only for difference calculation. Report bytes, maximum absolute difference, and forward-output difference using model states derived from one common reference.

Part 4 - Python code skeleton

```
import copy
import torch
from torch import nn

def E13(X64, model):
    X32 = X64.to(dtype=torch.float32)
    reconstructed = X32.to(dtype=torch.float64)
    data_difference = ...
    model64 = copy.deepcopy(model).double()
    model32 = copy.deepcopy(model).float()
    with torch.no_grad():
        output64 = ...
        output32 = ...
    return {
        "bytes64": ...,
        "bytes32": ...,
        "data_difference": ...,
        "output_difference": ...,
    }

def main():
    X64 = torch.randn(..., dtype=torch.float64)
    model = nn.Linear(..., ...)
    print(E13(X64, model))

if __name__ == "__main__":
    main()
```

10.4.15 Exercise 14 - Large Dataset GPU Transfer Cost

Part 1 - Why this matters

Moving data from host memory to a GPU consumes time and memory bandwidth. If batches are too small, transfer overhead may dominate; if they are too large, device memory may be exhausted. Transfer strategy must therefore be measured on the actual system.

CUDA operations can be asynchronous, so a timer may stop before the copy finishes. A valid benchmark synchronizes at measurement boundaries and distinguishes dataset preparation, optional pinning, transfer, and model computation.

Part 2 - Technical concept and behavior

For M transferred bytes and elapsed copy time T:

$$\text{effective bandwidth} = \frac{M}{T}$$

The experiment compares several batch sizes and transfer options. It should report latency and throughput distributions rather than one unverified timing value.

Part 3 - Hints and Helper

Skip the CUDA benchmark clearly when CUDA is unavailable. Warm up transfers, use `torch.cuda.synchronize()` around timed regions, and reuse allocated source data. When testing `non_blocking=True`, use a justified pinned-memory source and synchronize before reading the result.

Part 4 - Python code skeleton

```
import time
import torch

def measure_transfer(X_cpu, device, non_blocking, repetitions):
    ...  # warm-up
    torch.cuda.synchronize()
    started = time.perf_counter()
    for _ in range(repetitions):
        X_gpu = X_cpu.to(device, non_blocking=non_blocking)
    torch.cuda.synchronize()
    elapsed = time.perf_counter() - started
    bytes_moved = ... * repetitions
    return ..., ...

def E14(shapes, repetitions):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    device = torch.device("cuda")
    results = []
    for shape in shapes:
        X = torch.randn(...)
        ...  # compare supported transfer strategies
        results.append(...)
    return results

def main():
    print(E14([...], ...))

if __name__ == "__main__":
    main()
```

10.4.16 Exercise 15 - Dataset Caching Strategy

Part 1 - Why this matters

Repeated deterministic preprocessing can waste time when the same sample is requested across many epochs. Caching stores a prepared result so later access avoids duplicate work. The benefit depends on preparation cost, access frequency, and available memory.

A cache can also return stale or unsafe data. If transformation settings change, the cache key must change or stored entries must be invalidated. Mutable cached tensors should not be modified by callers in a way that corrupts future samples.

Part 2 - Technical concept and behavior

For uncached preparation cost C_p, cache lookup cost C_l, and hit rate h, a simplified expected access cost is:

$$E[C] = (1 - h)C_p + hC_l$$

Memory use grows with cached sample size and count. A bounded policy should track hits, misses, capacity, and a transformation-version identifier.

Part 3 - Hints and Helper

Create a small custom `Dataset` with an in-memory dictionary. Include sample index and transform version in each key. Return a clone when mutation could be a risk, and clear or replace the cache when preprocessing configuration changes.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import Dataset

class CachedRegressionDataset(Dataset):
    def __init__(self, X, y, transform, version, capacity):
        self.X = X
        self.y = y
        self.transform = transform
        self.version = version
        self.capacity = capacity
        self.cache = {}
        self.hits = 0
        self.misses = 0

    def __len__(self):
        return ...

    def __getitem__(self, index):
        key = (..., ...)
        if key in self.cache:
            self.hits += 1
            return ...
```

```
        self.misses += 1
        item = ...
        ...  # enforce the capacity policy
        return item

def E15(X, y):
    dataset = CachedRegressionDataset(X, y, ..., ..., ...)
    ...  # request repeated indices
    return dataset.hits, dataset.misses, len(dataset.cache)

def main():
    print(E15(torch..., torch...))

if __name__ == "__main__":
    main()
```

10.4.17 Exercise 16 - Dataset Integrity Check

Part 1 - Why this matters

A dataset can have valid tensor shapes while containing corrupted values, misaligned targets, duplicate sample identifiers, or an unexpected dtype. Training on such data produces misleading results and may make a model problem appear to be an optimization problem.

Integrity checks should run at clearly defined pipeline boundaries and produce actionable evidence. They are not a guarantee that data is scientifically correct, but they can detect violations of the structural and numerical contract before training.

Part 2 - Technical concept and behavior

For regression tensors, basic invariants include:

$$N_X = N_y = N_{\mathrm{id}}, \qquad F > 0, \qquad \mathbf{X}, \mathbf{y} \text{ finite}$$

Sample identifiers should satisfy the chosen uniqueness policy, and tensor dtypes should be compatible with the intended model. Target alignment requires stable provenance beyond shape alone.

Part 3 - Hints and Helper

Return a list of named failures instead of stopping at the first one. Check sample counts, dimensions, floating dtype, finite values, duplicate IDs, and target shape. Include summary statistics but do not silently replace invalid values during validation.

Part 4 - Python code skeleton

```
import torch

def E16(X, y, sample_ids):
    failures = []
    if X.ndim != ...:
```

```
        failures.append(...)
    if y.ndim != ...:
        failures.append(...)
    if not (X.shape[0] == y.shape[0] == len(sample_ids)):
        failures.append(...)
    if not torch.isfinite(X).all():
        failures.append(...)
    if not torch.isfinite(y).all():
        failures.append(...)
    if len(set(sample_ids)) != len(sample_ids):
        failures.append(...)
    return {
        "valid": len(failures) == 0,
        "failures": failures,
        "feature_summary": ...,
        "target_summary": ...,
    }

def main():
    print(E16(torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.4.18 Exercise 17 - Manual Batch Iteration

Part 1 - Why this matters

Manual batching exposes the indexing behavior that a loader usually handles. The reader can observe batch boundaries, incomplete final batches, aligned slicing, and total sample coverage without additional abstractions.

This implementation is useful as a correctness reference, not necessarily as the final production pipeline. Comparing it with a `DataLoader` helps separate the essential batching law from multiprocessing, sampling, pinning, and prefetch options.

Part 2 - Technical concept and behavior

For a permutation π and batch index k:

$$I_k = \pi[kB : \min((k+1)B, N)]$$

The batch is $(\mathbf{X}[I_k], \mathbf{y}[I_k])$. Across a full retained epoch, the concatenated indices must contain each sample once.

Part 3 - Hints and Helper

Generate indices first and index both tensors with the same batch indices. Make shuffle and `drop_last` explicit. Yield the indices with each batch so coverage, duplicates, and alignment can be tested after iteration.

Part 4 - Python code skeleton

```
import torch

def manual_batches(X, y, batch_size, shuffle, drop_last, generator):
    indices = (
        torch.randperm(X.shape[0], generator=generator)
        if shuffle else torch.arange(X.shape[0])
    )
    for start in range(0, X.shape[0], batch_size):
        batch_indices = indices[start:start + batch_size]
        if drop_last and batch_indices.numel() < batch_size:
            ...
        yield X[batch_indices], y[batch_indices], batch_indices

def E17(X, y, batch_size):
    generator = torch.Generator().manual_seed(...)
    observed = []
    for X_batch, y_batch, indices in manual_batches(...):
        observed.append(...)
    return observed

def main():
    print(E17(torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.4.19 Exercise 18 - Data Leakage Detection

Part 1 - Why this matters

Data leakage allows information unavailable at prediction time to influence training or preprocessing. It can produce excellent test metrics that disappear in real use. Common sources include duplicate samples across splits, scaling fitted on all data, target-derived features, and future observations placed in a training set.

Leakage detection requires provenance and pipeline reasoning, not a single tensor operation. This exercise implements several observable checks while acknowledging that domain knowledge is still required to identify whether a feature would truly be available at inference time.

Part 2 - Technical concept and behavior

For train and test sample identifiers:

$$I_{\text{train}} \cap I_{\text{test}} = \varnothing$$

Preprocessing parameters must satisfy:

$$\phi = \text{fit}(\mathbf{X}_{\text{train}})$$

and test data may only be transformed by ϕ. For time-ordered forecasting, training timestamps should precede the evaluation window according to the chosen protocol.

Part 3 - Hints and Helper

Check identifier overlap, duplicate feature rows, preprocessing-fit provenance, and forbidden feature names. For temporal data, compare boundary timestamps. Return warnings with evidence rather than automatically deleting suspicious data.

Part 4 - Python code skeleton

```
import torch

def E18(train, test, preprocessing_metadata, forbidden_features):
    warnings = []
    train_ids = set(train["ids"])
    test_ids = set(test["ids"])
    overlap = train_ids.intersection(test_ids)
    if overlap:
        warnings.append(...)
    if preprocessing_metadata["fit_split"] != "train":
        warnings.append(...)
    leaked_names = set(train["feature_names"]).intersection(forbidden_features)
    if leaked_names:
        warnings.append(...)
    ...  # inspect duplicate rows and temporal boundaries
    return {
        "leakage_detected": len(warnings) > 0,
        "warnings": warnings,
    }

def main():
    train = ...
    test = ...
    metadata = ...
    print(E18(train, test, metadata, {...}))

if __name__ == "__main__":
    main()
```

10.4.20 Exercise 19 - Data Pipeline Failure Debugging

Part 1 - Why this matters

A data pipeline can fail during generation, splitting, transformation, batching, transfer, or model input. If all stages are executed inside one opaque function, the final exception provides little evidence about where the data contract was first violated.

The final exercise builds a staged diagnostic pipeline. Each stage records input and output metadata, validates its own invariants, and stops safely when a failure would contaminate later results. The report should identify the earliest failing stage and preserve its cause.

Part 2 - Technical concept and behavior

Represent the pipeline as composed transformations:

$$D_0 \xrightarrow{g_1} D_1 \xrightarrow{g_2} \cdots \xrightarrow{g_K} D_K$$

Every stage g_k has preconditions and postconditions for shape, dtype, device, finite values, alignment, and provenance. Failure at k means later output cannot be trusted even if another stage can still execute.

Part 3 - Hints and Helper

Give every stage a name and validator. Catch expected exceptions only around the individual stage, record the original type and message, and stop or mark downstream stages as skipped. Test wrong shapes, missing values, split overlap, and device mismatch as separate injected failures.

Part 4 - Python code skeleton

```
import torch

def summarize(data):
    return {
        "feature_shape": ...,
        "target_shape": ...,
        "feature_dtype": ...,
        "target_dtype": ...,
        "feature_device": ...,
        "finite": ...,
    }

def run_stage(name, function, data):
    before = summarize(data)
    try:
        output = function(data)
        after = summarize(output)
        return output, {"stage": name, "status": "passed",
                        "before": before, "after": after}
    except (RuntimeError, ValueError, TypeError) as error:
        return None, {
            "stage": name,
            "status": "failed",
            "error_type": type(error).__name__,
            "message": str(error),
            "before": before,
        }

def E19(initial_data, stages):
    reports = []
    current = initial_data
    for name, function in stages:
        current, report = run_stage(name, function, current)
```

```
        reports.append(report)
        if current is None:
            break
    return current, reports

def main():
    initial_data = ...
    stages = [...]
    print(E19(initial_data, stages))

if __name__ == "__main__":
    main()
```

10.5 LR03 - Prediction Function Implementation

Applied AI and Deployment

10.5.1 Exercise 00 - Define Predict(x) Function

Part 1 - Why this matters

A prediction function is the boundary between a trained model and the system that uses it. It accepts prepared features, applies the model, and returns outputs with a documented shape, dtype, and device policy. Defining this boundary early prevents inference logic from being scattered throughout an application.

Prediction is not the same as training. It should not update parameters or accumulate gradients, and it must preserve the preprocessing assumptions used during training. A useful function makes these expectations explicit instead of silently accepting any tensor.

Part 2 - Mathematical form

For a linear model with input $\mathbf{x} \in \mathbb{R}^F$:

$$\text{predict}(\mathbf{x}) = \hat{\mathbf{y}} = \mathbf{x}^\mathsf{T}\mathbf{w} + b$$

For a model object, the function delegates this transformation to its forward computation after validating the input contract. The initial exercise keeps the output as a tensor.

Part 3 - Hints and Helper

Accept the model and tensor as arguments rather than relying on global state. Put the model in evaluation mode and validate the final feature dimension. Use a gradient-disabled context and return metadata with the prediction so the behavior can be inspected.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E00(model, x, expected_features):
```

```
    if x.shape[-1] != expected_features:
        raise ValueError(...)
    model.eval()
    with torch.no_grad():
        prediction = model(...)
    return {
        "prediction": prediction,
        "shape": ...,
        "dtype": ...,
        "device": ...,
    }

def main():
    model = nn.Linear(..., ...)
    x = torch...
    print(E00(model, x, ...))

if __name__ == "__main__":
    main()
```

10.5.2 Exercise 01 - Vectorized Prediction

Part 1 - Why this matters

Vectorized prediction applies one tensor operation to many samples instead of using a Python loop. This aligns the computation with optimized matrix kernels and usually improves throughput while keeping the mathematical structure clear.

Vectorization must preserve sample independence and order. The prediction in row i should equal the result obtained by evaluating only input row i. Comparing vectorized and row-wise references is a useful correctness test.

Part 2 - Mathematical form

For $\mathbf{X} \in \mathbb{R}^{N \times F}$:

$$\hat{\mathbf{Y}} = \mathbf{X}\mathbf{W}^{\mathsf{T}} + \mathbf{b}$$

The same weight and bias are applied to every row. For O outputs, the resulting shape is (N, O).

Part 3 - Hints and Helper

Require a two-dimensional input for this exercise. Perform one model call for the full batch, then build a row-wise reference only for validation. Use `torch.allclose()` and report the maximum absolute difference.

Part 4 - Python code skeleton

```
import torch
```

```
def E01(model, X):
    model.eval()
    with torch.no_grad():
        vectorized = model(...)
        rowwise = torch.cat(
            [model(row.unsqueeze(...)) for row in X],
            dim=...,
        )
    difference = ...
    return vectorized, rowwise, torch.allclose(..., ...), difference

def main():
    model = torch.nn.Linear(..., ...)
    X = torch...
    print(E01(model, X))

if __name__ == "__main__":
    main()
```

10.5.3 Exercise 02 - Batch Prediction on CPU

Part 1 - Why this matters

CPU inference is widely available and can be efficient for small models, low request volume, or environments where GPU transfer overhead would dominate. A controlled CPU implementation also provides a portable reference for later device comparisons.

Batch size changes both throughput and memory use. The prediction function should process all samples exactly once, preserve their order, and handle a final batch that is smaller than the requested size.

Part 2 - Technical concept and behavior

For N samples and batch size B, prediction is divided into:

$$K = \left\lceil \frac{N}{B} \right\rceil$$

batches. Concatenating the ordered batch outputs along the sample dimension should reproduce the full vectorized CPU prediction.

Part 3 - Hints and Helper

Move the model and input explicitly to `cpu`. Iterate by slices, use an inference context, and concatenate outputs. Validate positive batch size and compare with a one-call reference for a manageable dataset.

Part 4 - Python code skeleton

```
import torch

def E02(model, X, batch_size):
```

```
    if batch_size <= 0:
        raise ValueError(...)
    model = model.to("cpu").eval()
    X = X.to("cpu")
    outputs = []
    with torch.inference_mode():
        for start in range(0, X.shape[0], batch_size):
            batch = X[start:start + batch_size]
            outputs.append(model(...))
    predictions = torch.cat(outputs, dim=...)
    return predictions

def main():
    model = torch.nn.Linear(..., ...)
    X = torch...
    print(E02(model, X, ...))

if __name__ == "__main__":
    main()
```

10.5.4 Exercise 03 - Batch Prediction on CUDA

Part 1 - Why this matters

CUDA can accelerate large parallel prediction workloads, but the model and every input batch must be on the same GPU. A reliable function checks availability, controls transfer, and reports when it falls back instead of assuming that CUDA exists.

Keeping the full dataset on the GPU is not always necessary or safe. Batch-wise transfer limits peak device memory and better represents a deployment pipeline in which requests arrive from CPU memory.

Part 2 - Technical concept and behavior

For device $d =$ `cuda`, every batch follows:

$$\mathbf{X}_{k,d} \rightarrow f_d(\mathbf{X}_{k,d}) \rightarrow \hat{\mathbf{Y}}_{k,d}$$

Outputs may remain on the GPU or be copied to CPU according to the function contract. Concatenation requires all returned batch tensors to share a device.

Part 3 - Hints and Helper

Check `torch.cuda.is_available()`. Move the model before prediction and transfer each batch explicitly. Decide whether outputs should be returned on CPU, and do not call `torch.cuda.empty_ca` inside every batch.

Part 4 - Python code skeleton

```
import torch
```

```
def E03(model, X_cpu, batch_size, return_to_cpu=True):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    device = torch.device("cuda")
    model = model.to(device).eval()
    outputs = []
    with torch.inference_mode():
        for start in range(0, X_cpu.shape[0], batch_size):
            batch = X_cpu[start:start + batch_size].to(device)
            prediction = model(batch)
            outputs.append(prediction.cpu() if return_to_cpu else prediction)
    return torch.cat(outputs, dim=...)

def main():
    print(E03(torch.nn.Linear(..., ...), torch..., ...))

if __name__ == "__main__":
    main()
```

10.5.5 Exercise 04 - Shape-Safe Prediction

Part 1 - Why this matters

An inference function should reject ambiguous or incompatible shapes before they reach matrix multiplication. Silent broadcasting or accidental squeezing can return plausible outputs attached to the wrong sample structure. Shape safety turns assumptions into executable checks.

The function must distinguish a single feature vector from a batch. It may normalize supported forms internally, but it should record whether a batch dimension was added and restore only the documented output form.

Part 2 - Technical concept and behavior

For expected feature count F, supported inputs may be:

$$\mathbf{x} \in \mathbb{R}^F \quad \text{or} \quad \mathbf{X} \in \mathbb{R}^{N \times F}$$

A single sample can be normalized to shape $(1, F)$. Any other final dimension is invalid, and rank greater than the declared contract should not be accepted accidentally.

Part 3 - Hints and Helper

Inspect `ndim` and the last dimension. Add a batch dimension only for a one-dimensional sample. Preserve a boolean indicating this normalization and decide whether to remove the output batch dimension afterward.

Part 4 - Python code skeleton

```
import torch

def E04(model, x, expected_features):
```

```
    single_sample = False
    if x.ndim == 1:
        x = x.unsqueeze(...)
        single_sample = True
    if x.ndim != 2 or x.shape[-1] != expected_features:
        raise ValueError(...)
    model.eval()
    with torch.inference_mode():
        output = model(x)
    if single_sample:
        output = output.squeeze(...)
    return output

def main():
    model = torch.nn.Linear(..., ...)
    print(E04(model, torch..., ...))

if __name__ == "__main__":
    main()
```

10.5.6 Exercise 05 - Disable Grad in Inference

Part 1 - Why this matters

Inference does not normally need parameter gradients. Disabling gradient recording reduces autograd overhead and prevents prediction code from accidentally accumulating graph history. This is especially important for long-running services that process repeated requests.

Calling `model.eval()` and disabling gradients solve different problems. Evaluation mode changes the behavior of specific modules such as dropout or batch normalization, while `no_grad` or `inference_mode` controls gradient-related execution. A correct inference function usually considers both.

Part 2 - Technical concept and behavior

During ordinary gradient-enabled execution, an output may carry a graph connection:

$$\hat{\mathbf{Y}}.\texttt{grad_fn} \neq \texttt{None}$$

Inside a gradient-disabled inference context, the returned output should not require gradients. `inference_mode` is more restrictive than `no_grad` and is appropriate when created tensors will remain in inference usage.

Part 3 - Hints and Helper

Run the same model once with gradients enabled and once inside `torch.inference_mode()`. Inspect `requires_grad` and `grad_fn`. Do not change parameter flags merely to perform temporary inference.

Part 4 - Python code skeleton

```
import torch

def E05(model, X):
    model.eval()
    enabled_output = model(X)
    with torch.inference_mode():
        inference_output = model(X)
        mode_enabled = torch.is_inference_mode_enabled()
    report = {
        "enabled_requires_grad": ...,
        "enabled_grad_fn": ...,
        "inference_requires_grad": ...,
        "inference_grad_fn": ...,
        "mode_enabled_inside": mode_enabled,
        "values_match": ...,
    }
    return report

def main():
    print(E05(torch.nn.Linear(..., ...), torch...))

if __name__ == "__main__":
    main()
```

10.5.7 Exercise 06 - Precision Switch During Inference

Part 1 - Why this matters

Changing inference precision affects numerical resolution, memory use, and device performance. A prediction service may choose a dtype different from an analytical experiment, but the model and input must be converted together and the resulting drift must be measured.

Precision conversion cannot be evaluated with independently initialized models. The comparison must begin from one state so observed differences come from representation and arithmetic rather than different weights.

Part 2 - Technical concept and behavior

For equivalent models:

$$D_{\max} = \max_i |\hat{y}_{64,i} - \text{float64}(\hat{y}_{32,i})|$$

The experiment reports absolute and relative differences as well as output dtype. Lower precision should not be selected solely from storage size without an application tolerance.

Part 3 - Hints and Helper

Use `copy.deepcopy()` before converting models with `.float()` and `.double()`. Match input dtype to parameter dtype, run both in inference mode, and compare on a common CPU `float64` representation.

Part 4 - Python code skeleton

```
import copy
import torch

def E06(model, X):
    model32 = copy.deepcopy(model).float().eval()
    model64 = copy.deepcopy(model).double().eval()
    with torch.inference_mode():
        output32 = model32(X.float())
        output64 = model64(X.double())
    output32_as_64 = ...
    absolute = ...
    relative = ...
    return output32, output64, absolute, relative

def main():
    print(E06(torch.nn.Linear(..., ...), torch...))

if __name__ == "__main__":
    main()
```

10.5.8 Exercise 07 - Prediction Consistency Test

Part 1 - Why this matters

A fixed deterministic model should return consistent predictions for the same prepared input. Unexpected differences can reveal accidental parameter mutation, stochastic training-mode behavior, dtype conversion, device changes, or nondeterministic operations.

Consistency is defined by a tolerance and context rather than exact equality in every environment. The test should record model state, input metadata, and maximum difference so a failure can be investigated instead of reduced to one boolean.

Part 2 - Technical concept and behavior

For repeated predictions $\hat{\mathbf{Y}}^{(1)}, \ldots, \hat{\mathbf{Y}}^{(R)}$, compare each with the first:

$$D_r = \max_i \left| \hat{Y}_i^{(r)} - \hat{Y}_i^{(1)} \right|$$

Consistency holds when every D_r lies within selected absolute and relative tolerances and the model state remains unchanged.

Part 3 - Hints and Helper

Set evaluation mode, use inference mode, and clone the state dictionary before testing. Run several repetitions without modifying the input. Compare outputs with `torch.allclose()` and verify parameters still match the snapshot.

Part 4 - Python code skeleton

```
import torch
```

```
def E07(model, X, repetitions, atol, rtol):
    snapshot = {
        key: value.detach().clone()
        for key, value in model.state_dict().items()
    }
    outputs = []
    model.eval()
    with torch.inference_mode():
        for _ in range(repetitions):
            outputs.append(model(X).clone())
    differences = [...]
    outputs_match = all(
        torch.allclose(outputs[0], output, atol=atol, rtol=rtol)
        for output in outputs[1:]
    )
    state_unchanged = ...
    return outputs_match, state_unchanged, differences

def main():
    print(E07(torch.nn.Linear(..., ...), torch..., ..., ..., ...))

if __name__ == "__main__":
    main()
```

10.5.9 Exercise 08 - Streaming Prediction Simulation

Part 1 - Why this matters

Some applications receive samples continuously rather than as one complete dataset. Streaming inference must preserve order, associate each prediction with its request identifier, and prevent an unbounded queue from exhausting memory.

Micro-batching can improve throughput by grouping nearby requests, but it introduces waiting time. This exercise simulates the data path and records batch formation without requiring a network service or hiding the tradeoff behind an API framework.

Part 2 - Technical concept and behavior

For stream items $(i_t, \mathbf{x}_t)$, a micro-batch B_k contains a bounded consecutive group. The model produces:

$$\hat{\mathbf{Y}}_k = f(\mathbf{X}_k)$$

and each row must be paired back with its original identifier. The buffer is flushed when it reaches the batch limit or the stream ends.

Part 3 - Hints and Helper

Represent the stream with a Python generator yielding `(id, tensor)`. Accumulate only up to `max_batch_size`, stack features, predict once, and yield paired outputs. Validate feature shapes before adding an item to the buffer.

Part 4 - Python code skeleton

```
import torch

def stream_source(sample_count, feature_count):
    for sample_id in range(sample_count):
        yield sample_id, torch...

def predict_buffer(model, identifiers, samples):
    batch = torch.stack(samples, dim=...)
    with torch.inference_mode():
        outputs = model(batch)
    return list(zip(identifiers, outputs))

def E08(model, stream, max_batch_size):
    buffer_ids, buffer_samples = [], []
    for sample_id, sample in stream:
        ...
        if len(buffer_samples) == max_batch_size:
            yield from predict_buffer(...)
            buffer_ids, buffer_samples = [], []
    if buffer_samples:
        yield from predict_buffer(...)

def main():
    model = torch.nn.Linear(..., ...)
    print(list(E08(model, stream_source(..., ...), ...)))

if __name__ == "__main__":
    main()
```

10.5.10 Exercise 09 - Prediction Latency Benchmark

Part 1 - Why this matters

Average inference latency can hide slow requests that determine user experience. A meaningful benchmark reports percentile distributions, separates warm-up from steady-state execution, and labels batch size, dtype, and device.

CUDA timing requires synchronization because kernel launches are asynchronous. CPU and GPU comparisons are also affected by data transfer, so the benchmark must state whether transfer is included rather than combining different measurement boundaries.

Part 2 - Technical concept and behavior

For ordered latency samples $l_{(1)}, \ldots, l_{(R)}$, report:

$$(L_{50}, L_{95}, L_{99})$$

alongside throughput and error count. Warm-up iterations are excluded from measured samples but their number remains part of benchmark metadata.

Part 3 - Hints and Helper

Use `time.perf_counter()`, evaluation mode, and inference mode. Synchronize immediately before and after a timed CUDA forward pass. Avoid printing inside the measured region and test multiple batch sizes with identical model state.

Part 4 - Python code skeleton

```
import time
import torch

def percentile(values, fraction):
    ordered = sorted(values)
    index = ...
    return ordered[index]

def benchmark(model, X, warmup, repetitions):
    device = next(model.parameters()).device
    with torch.inference_mode():
        for _ in range(warmup):
            model(X)
        samples = []
        for _ in range(repetitions):
            if device.type == "cuda":
                torch.cuda.synchronize()
            started = time.perf_counter()
            model(X)
            if device.type == "cuda":
                torch.cuda.synchronize()
            samples.append(time.perf_counter() - started)
    return {"p50": ..., "p95": ..., "p99": ...}

def E09(model, inputs):
    return ...

def main():
    print(E09(torch.nn.Linear(..., ...), ...))

if __name__ == "__main__":
    main()
```

10.5.11 Exercise 10 - Predict with Frozen Model

Part 1 - Why this matters

A frozen model has parameters whose gradient flags are disabled, preventing them from being selected for gradient-based training. This is useful when a model should serve predictions without accidental fine-tuning or when only another component may learn.

Freezing and inference mode are not interchangeable. Freezing changes parameter trainability, while inference mode temporarily changes autograd execution for the prediction. A robust test verifies both parameter flags and unchanged values.

Part 2 - Technical concept and behavior

For every model parameter θ_i, freezing enforces:

$$\theta_i.\texttt{requires_grad} = \text{False}$$

The forward equation remains unchanged. Predictions should match the pre-freeze model for identical state and input because freezing does not alter parameter values.

Part 3 - Hints and Helper

Clone the state before freezing, call `model.requires_grad_(False)`, and inspect all flags. Predict in inference mode, then compare state values with the snapshot. Do not rebuild the model or change its dtype during this test.

Part 4 - Python code skeleton

```
import torch

def E10(model, X):
    before = {
        key: value.detach().clone()
        for key, value in model.state_dict().items()
    }
    model.requires_grad_(...)
    flags = {
        name: parameter.requires_grad
        for name, parameter in model.named_parameters()
    }
    model.eval()
    with torch.inference_mode():
        output = model(X)
    unchanged = ...
    return output, flags, unchanged

def main():
    print(E10(torch.nn.Linear(..., ...), torch...))

if __name__ == "__main__":
    main()
```

10.5.12 Exercise 11 - CPU-to-GPU Prediction Sync Check

Part 1 - Why this matters

Equivalent CPU and GPU models should produce numerically close predictions when they use the same parameters, input values, and dtype. A mismatch may reveal incomplete state

transfer, device-specific precision effects, or an incorrect comparison boundary.

Synchronization has two meanings in this experiment. CUDA work must complete before timing or reading results, and model states must be synchronized by copying one reference state rather than initializing each device independently.

Part 2 - Technical concept and behavior

For CPU and GPU predictions:

$$D_{\max} = \max_i |\hat{y}_{\mathrm{CPU},i} - \mathrm{CPU}(\hat{y}_{\mathrm{GPU},i})|$$

The outputs are compared using justified tolerances. Exact equality is not required for floating-point kernels executed by different backends.

Part 3 - Hints and Helper

Deep-copy one model to the GPU, move the same input values, and use inference mode. Call `torch.cuda.synchronize()` before final GPU timing boundaries and copy the result to CPU before comparison. Report maximum absolute and relative differences.

Part 4 - Python code skeleton

```
import copy
import torch

def E11(model, X, atol, rtol):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    cpu_model = copy.deepcopy(model).cpu().eval()
    gpu_model = copy.deepcopy(model).cuda().eval()
    with torch.inference_mode():
        cpu_output = cpu_model(X.cpu())
        gpu_output = gpu_model(X.cuda())
        torch.cuda.synchronize()
        gpu_on_cpu = gpu_output.cpu()
    return {
        "matches": torch.allclose(..., ..., atol=atol, rtol=rtol),
        "max_absolute_difference": ...,
        "max_relative_difference": ...,
    }

def main():
    print(E11(torch.nn.Linear(..., ...), torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.5.13 Exercise 12 - Large Batch Prediction Stress Test

Part 1 - Why this matters

Increasing batch size can improve throughput until memory pressure or kernel behavior becomes limiting. A stress test discovers practical boundaries, but it must not allocate recklessly or treat an out-of-memory crash as the only measurement.

A safe experiment estimates required tensor and output storage, imposes a memory budget, increases batch size gradually, and stops before exceeding the approved limit. Results should include latency, throughput, and peak memory rather than only the largest completed batch.

Part 2 - Technical concept and behavior

Approximate input and output storage for batch size B is:

$$M_B \approx B(F_{\text{in}} + F_{\text{out}})s$$

where s is bytes per element. Actual inference memory includes parameters, temporary workspace, allocator state, and framework overhead, so the estimate is a lower bound.

Part 3 - Hints and Helper

Accept an explicit maximum byte budget and pre-check each candidate shape. On CUDA, reset and read peak allocated memory for each approved run and synchronize timing. Stop when the budget is crossed; do not automatically keep doubling after a resource failure.

Part 4 - Python code skeleton

```
import time
import torch

def estimate_io_bytes(batch_size, in_features, out_features, dtype):
    element_size = torch.empty((), dtype=dtype).element_size()
    return ... * element_size

def E12(model, batch_sizes, in_features, max_bytes):
    device = next(model.parameters()).device
    results = []
    for batch_size in batch_sizes:
        estimate = estimate_io_bytes(...)
        if estimate > max_bytes:
            results.append({"batch_size": batch_size, "status": "skipped"})
            break
        X = torch.randn(batch_size, in_features,
                        device=device, dtype=next(model.parameters()).dtype)
        ...  # measure synchronized latency, throughput, and peak memory
        results.append(...)
    return results

def main():
    print(E12(torch.nn.Linear(..., ...), [...], ..., ...))

if __name__ == "__main__":
    main()
```

10.5.14 Exercise 13 - Numerical Drift Detection

Part 1 - Why this matters

Predictions can drift when model state, preprocessing, dtype, library behavior, or input distribution changes. A service may continue returning finite values while no longer matching its validated reference. Numerical drift detection turns a known prediction set into a regression test.

Not every tiny difference is a failure. Floating-point comparisons require tolerances chosen from application risk and baseline measurements. The report should distinguish output drift from input-data drift and model-state changes.

Part 2 - Technical concept and behavior

For baseline $\hat{\mathbf{Y}}_0$ and current output $\hat{\mathbf{Y}}_t$:

$$D_{\max} = \max_i |\hat{Y}_{t,i} - \hat{Y}_{0,i}|, \qquad D_{\text{mean}} = \frac{1}{N}\sum_i |\hat{Y}_{t,i} - \hat{Y}_{0,i}|$$

Drift is flagged when selected metrics exceed documented tolerances or when state and preprocessing identifiers differ.

Part 3 - Hints and Helper

Store baseline predictions, input checksum or identifier, model version, preprocessing version, dtype, and device metadata. Run the same reference set later and compare with `torch.allclose()`. Deliberately perturb one parameter to confirm detection.

Part 4 - Python code skeleton

```
import torch

def E13(model, reference_X, baseline, atol, rtol, metadata):
    model.eval()
    with torch.inference_mode():
        current = model(reference_X)
    absolute = (current - baseline).abs()
    report = {
        "matches": torch.allclose(current, baseline,
                                  atol=atol, rtol=rtol),
        "max_absolute": ...,
        "mean_absolute": ...,
        "model_version": ...,
        "preprocessing_version": ...,
    }
    return report

def main():
    model = torch.nn.Linear(..., ...)
    X = torch...
    baseline = torch...
```

```
    print(E13(model, X, baseline, ..., ..., ...))

if __name__ == "__main__":
    main()
```

10.5.15 Exercise 14 - Prediction with Missing Features

Part 1 - Why this matters

A prediction request may omit features because of sensor failure, incomplete user input, or an upstream schema change. Passing missing values directly can create non-finite output, while silently substituting arbitrary zeros can change the model's meaning.

Inference must reuse the missing-value policy fitted during training. The same feature order, fill values, and optional missingness indicators are part of the deployed model contract and should be versioned with it.

Part 2 - Technical concept and behavior

For stored training fill values $\boldsymbol{\mu}$ and missing mask $\mathbf{M}$:

$$X'_{ij} = \begin{cases} \mu_j, & M_{ij} = 1, \\ X_{ij}, & M_{ij} = 0. \end{cases}$$

The model receives $\mathbf{X}'$ only after checking that every required feature position exists. A completely absent required field is different from a present field containing `NaN`.

Part 3 - Hints and Helper

Validate feature count and names first. Use the stored training imputer values rather than recalculating them from prediction requests. Return the missing mask with the output so the caller can audit how much of each prediction was imputed.

Part 4 - Python code skeleton

```
import torch

def prepare_missing(X, fill_values):
    if X.shape[-1] != fill_values.numel():
        raise ValueError(...)
    mask = torch.isnan(X)
    prepared = torch.where(mask, fill_values.expand_as(X), X)
    if not torch.isfinite(prepared).all():
        raise ValueError(...)
    return prepared, mask

def E14(model, X, fill_values):
    prepared, mask = prepare_missing(X, fill_values)
    model.eval()
    with torch.inference_mode():
        prediction = model(prepared)
```

```
    return prediction, mask

def main():
    print(E14(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.5.16 Exercise 15 - Prediction Error Propagation

Part 1 - Why this matters

Input measurements contain error, and a linear model transfers that error into its prediction according to the learned weights. Understanding this propagation helps determine whether a prediction is sensitive to uncertain sensors or rounded features.

This is different from model residual error. Input uncertainty describes variation before the model is evaluated, while residuals describe disagreement between predictions and observed targets. A useful report keeps these sources separate.

Part 2 - Mathematical form

For perturbed input $\mathbf{x} + \Delta\mathbf{x}$:

$$\Delta\hat{y} = (\mathbf{x} + \Delta\mathbf{x})^{\mathsf{T}}\mathbf{w} + b - (\mathbf{x}^{\mathsf{T}}\mathbf{w} + b) = \Delta\mathbf{x}^{\mathsf{T}}\mathbf{w}$$

If feature errors are independent with variances σ_j^2, a simple propagated prediction variance is:

$$\sigma_{\hat{y}}^2 = \sum_j w_j^2 \sigma_j^2$$

Part 3 - Hints and Helper

Use a known linear layer and input perturbation. Compare the observed prediction change with the analytical change from the weights. Then accept per-feature standard deviations and calculate the expected output standard deviation under the stated independence assumption.

Part 4 - Python code skeleton

```
import torch

def E15(model, X, input_delta, feature_std):
    model.eval()
    with torch.inference_mode():
        original = model(X)
        perturbed = model(X + input_delta)
    observed_change = ...
    analytical_change = input_delta @ model.weight.T
    propagated_variance = ...  # use squared weights and variances
    propagated_std = torch.sqrt(...)
```

```
    return {
        "observed_change": observed_change,
        "analytical_change": analytical_change,
        "propagated_std": propagated_std,
        "matches": torch.allclose(..., ...),
    }

def main():
    print(E15(torch.nn.Linear(..., ...), torch..., torch..., torch...))

if __name__ == "__main__":
    main()
```

10.5.17 Exercise 16 - TorchScript Prediction Export

Part 1 - Why this matters

Exporting a prediction graph can separate inference from the original Python model definition and support deployment workflows. TorchScript historically provided scripting and tracing for this purpose, so understanding a simple trace remains useful when maintaining existing systems.

TorchScript is now deprecated in current PyTorch documentation in favor of `torch.export`. This exercise therefore treats TorchScript as a legacy compatibility task, verifies its limitations, and requires the reader to record the migration alternative rather than presenting it as the default for new systems.

Part 2 - Technical concept and behavior

Tracing observes tensor operations executed for example input $\mathbf{X}_e$ and produces a traced module T. Validation requires:

$$T(\mathbf{X}_{\text{test}}) \approx f(\mathbf{X}_{\text{test}})$$

for representative supported inputs. A trace may not correctly preserve unobserved data-dependent Python control flow.

Part 3 - Hints and Helper

Use a simple evaluated linear module and representative example input. Create a trace with `torch.jit.trace()`, save and load it using TorchScript APIs, then compare eager and loaded outputs on more than the tracing input. Add a note that new export work should evaluate `torch.export`.

Part 4 - Python code skeleton

```
import torch

def E16(model, example_input, test_inputs, export_path):
    model.eval()
    traced = torch.jit.trace(..., ...)
```

```
    torch.jit.save(..., export_path)
    loaded = torch.jit.load(...)
    comparisons = []
    with torch.inference_mode():
        for X in test_inputs:
            eager_output = model(X)
            exported_output = loaded(X)
            comparisons.append(torch.allclose(..., ...))
    return traced, comparisons

def main():
    model = torch.nn.Linear(..., ...)
    print(E16(model, torch..., [...], ...))

if __name__ == "__main__":
    main()
```

10.5.18 Exercise 17 - Inference Memory Profiling

Part 1 - Why this matters

Inference memory includes model parameters, input batches, outputs, and temporary workspace. A function that succeeds with one request may fail under a larger batch or concurrent workload. Profiling establishes a measured capacity boundary.

Memory numbers must be labeled by device and measurement method. Python object tracking does not describe all native tensor storage, while CUDA allocator statistics do not represent CPU memory. This exercise uses tensor estimates everywhere and device-specific peak statistics when CUDA is used.

Part 2 - Technical concept and behavior

Known tensor storage is:

$$M_{\text{known}} = \sum_{T \in \{\theta, X, \hat{Y}\}} \text{numel}(T)\,\text{element_size}(T)$$

Peak device allocation can exceed this value because operations may require temporary buffers. The experiment compares known storage with measured CUDA peak allocation where available.

Part 3 - Hints and Helper

Calculate parameter, input, and output bytes separately. On CUDA, reset peak memory statistics before the forward pass, synchronize after it, and read the peak allocation. Repeat after warm-up and do not confuse reserved memory with allocated memory.

Part 4 - Python code skeleton

```
import torch
```

```
def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def E17(model, X):
    device = next(model.parameters()).device
    parameter_bytes = sum(tensor_bytes(p) for p in model.parameters())
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats(device)
    with torch.inference_mode():
        output = model(X)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        peak_allocated = torch.cuda.max_memory_allocated(device)
    else:
        peak_allocated = None
    known_bytes = parameter_bytes + tensor_bytes(X) + tensor_bytes(output)
    return {
        "known_bytes": known_bytes,
        "peak_allocated": peak_allocated,
        "output": output,
    }

def main():
    print(E17(torch.nn.Linear(..., ...), torch...))

if __name__ == "__main__":
    main()
```

10.5.19 Exercise 18 - Prediction API Wrapper

Part 1 - Why this matters

An application should not call a model directly from unvalidated external data. A prediction wrapper enforces feature names and order, preprocessing version, batch limits, dtype, device placement, and a stable response structure.

The wrapper is also the correct place to attach model-version metadata and controlled error messages. It should not expose internal tensors or silently repair an incompatible request. This exercise builds the Python boundary without requiring a web framework.

Part 2 - Technical concept and behavior

Represent a request as records with a declared schema and transform them into:

$$\mathbf{X}_{\text{validated}} \rightarrow P_{\text{versioned}} \rightarrow f_{\text{versioned}} \rightarrow \hat{\mathbf{Y}}$$

The response pairs predictions with request identifiers and model metadata. Validation occurs before device transfer or model execution.

Part 3 - Hints and Helper

Create a class that owns the model, expected feature list, preprocessing object, version, device, and maximum batch size. Validate missing and extra fields, preserve request IDs, build a tensor in fixed order, predict in inference mode, and convert outputs to ordinary Python values only at the response boundary.

Part 4 - Python code skeleton

```
import torch

class PredictionWrapper:
    def __init__(self, model, feature_names, preprocessor,
                 model_version, device, max_batch_size):
        self.model = model.to(device).eval()
        self.feature_names = feature_names
        self.preprocessor = preprocessor
        self.model_version = model_version
        self.device = device
        self.max_batch_size = max_batch_size

    def validate(self, records):
        ...

    def build_tensor(self, records):
        ...

    def predict(self, records):
        self.validate(records)
        X = self.build_tensor(records)
        X = self.preprocessor.transform(X).to(self.device)
        with torch.inference_mode():
            output = self.model(X)
        return {
            "model_version": self.model_version,
            "predictions": ...,
        }

def E18(wrapper, records):
    return wrapper.predict(records)

def main():
    wrapper = PredictionWrapper(...)
    print(E18(wrapper, ...))

if __name__ == "__main__":
    main()
```

10.5.20 Exercise 19 - Prediction Failure Debugging

Part 1 - Why this matters

Prediction failures can originate in request schema, preprocessing, shape, dtype, device, model state, non-finite values, or resource limits. Handling all failures as one generic model error hides the stage that must be corrected.

The final exercise creates a diagnostic path that validates each boundary in order and records structured evidence. It must preserve unexpected programming errors rather than catching every exception indiscriminately, while expected input and runtime failures receive controlled reports.

Part 2 - Technical concept and behavior

Inference can be represented as:

$$R \xrightarrow{\text{validate}} X \xrightarrow{\text{prepare}} X' \xrightarrow{\text{place}} X'_d \xrightarrow{f} \hat{Y} \xrightarrow{\text{serialize}} S$$

Each transition has preconditions and postconditions. The earliest failed transition determines which later outputs are untrustworthy.

Part 3 - Hints and Helper

Give each stage a name and record shapes, dtype, device, finite status, and elapsed time where relevant. Catch expected `ValueError`, `TypeError`, and selected `RuntimeError` cases at the outer request boundary. Test wrong feature count, NaN input, device mismatch, and oversized batch separately.

Part 4 - Python code skeleton

```
import time
import torch

def inspect_tensor(X):
    return {
        "shape": tuple(X.shape),
        "dtype": str(X.dtype),
        "device": str(X.device),
        "finite": bool(torch.isfinite(X).all()),
    }

def E19(model, request, prepare, device, max_batch_size):
    report = {"stages": []}
    try:
        ...  # validate request schema and batch size
        X = prepare(request)
        report["stages"].append(("prepared", inspect_tensor(X)))
        ...  # verify features, dtype, and finite values
        X = X.to(device)
        report["stages"].append(("placed", inspect_tensor(X)))
        model = model.to(device).eval()
        with torch.inference_mode():
            output = model(X)
        ...  # validate and serialize output
```

```
        report["status"] = "passed"
    except (ValueError, TypeError, RuntimeError) as error:
        report["status"] = "failed"
        report["error"] = {
            "type": type(error).__name__,
            "message": str(error),
        }
    return report

def main():
    print(E19(torch.nn.Linear(..., ...), ..., ..., ..., ...))

if __name__ == "__main__":
    main()
```

10.6 LR04 - Error Measurement and Loss Definition

Models and Training

10.6.1 Exercise 00 - Define MSE Loss Manually

Part 1 - Why this matters

Mean squared error converts the difference between regression predictions and targets into one scalar training objective. Implementing it manually exposes the subtraction, squaring, and reduction that a library function normally combines.

The formula also reveals the behavior of the loss. Squaring removes the error sign and gives large errors disproportionate influence. The reader should understand this consequence before using MSE as an automatic default.

Part 2 - Mathematical form

For N scalar predictions:

$$\text{MSE} = \frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2$$

For tensors with several output elements per sample, the ordinary element-wise mean divides by the total number of compared elements. Prediction and target shapes must match exactly.

Part 3 - Hints and Helper

Validate equal shapes before subtracting to prevent accidental broadcasting. Calculate and return the residuals, squared errors, and scalar mean so every stage can be inspected. Use floating-point tensors.

Part 4 - Python code skeleton

```
import torch

def E00(prediction, target):
    if prediction.shape != target.shape:
        raise ValueError(...)
    residual = ...
    squared_error = ...
    mse = ...
    return residual, squared_error, mse

def main():
    prediction = torch...
    target = torch...
    print(E00(prediction, target))

if __name__ == "__main__":
    main()
```

10.6.2 Exercise 01 - MSE via PyTorch

Part 1 - Why this matters

PyTorch provides tested MSE implementations that integrate with autograd and support standard reduction modes. Comparing the framework result with the manual equation verifies that the reader understands what the loss object calculates.

A loss function does not correct wrong tensor semantics. PyTorch may warn or broadcast incompatible shapes, so the calling code remains responsible for validating prediction and target structure before evaluation.

Part 2 - Technical concept and behavior

With default mean reduction, `nn.MSELoss` computes:

$$\mathcal{L} = \text{mean}\left((\hat{\mathbf{Y}} - \mathbf{Y})^2\right)$$

The result is a scalar tensor connected to the prediction graph when the prediction requires gradients.

Part 3 - Hints and Helper

Construct `nn.MSELoss(reduction="mean")` and compare its result with the manual calculation. Inspect the output shape, dtype, device, `requires_grad`, and `grad_fn`.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E01(prediction, target):
    if prediction.shape != target.shape:
```

```
        raise ValueError(...)
    criterion = nn.MSELoss(reduction=...)
    pytorch_loss = criterion(..., ...)
    manual_loss = ...
    return pytorch_loss, manual_loss, torch.allclose(..., ...)

def main():
    prediction = torch.tensor(..., requires_grad=True)
    target = torch...
    print(E01(prediction, target))

if __name__ == "__main__":
    main()
```

10.6.3 Exercise 02 - Loss Reduction Modes

Part 1 - Why this matters

Reduction controls how individual squared errors become a returned loss. The choice changes loss scale, gradient scale, and how batch results should be aggregated. It is therefore part of the mathematical definition, not a display option.

The unreduced form preserves every element and supports masks or custom weighting. Sum reduction grows with the number of elements, while mean reduction normalizes by that count. Comparing all three modes makes these relationships visible.

Part 2 - Mathematical form

Let $l_i = (\hat{y}_i - y_i)^2$. Then:

$$\mathcal{L}_{\text{none}} = (l_1, \ldots, l_N), \qquad \mathcal{L}_{\text{sum}} = \sum_i l_i, \qquad \mathcal{L}_{\text{mean}} = \frac{1}{N} \sum_i l_i$$

Thus $\mathcal{L}_{\text{sum}} = N\mathcal{L}_{\text{mean}}$ when N counts every output element.

Part 3 - Hints and Helper

Compute all modes from the same tensors using `nn.MSELoss`. Record output shapes and verify the sum-mean identity with `prediction.numel()`. Do not assume N means only batch size when there are multiple outputs.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E02(prediction, target):
    losses = {}
    for reduction in ("none", "sum", "mean"):
        criterion = nn.MSELoss(reduction=reduction)
        losses[reduction] = criterion(...)
```

```
    relation_holds = torch.allclose(
        losses["sum"],
        losses["mean"] * ...,
    )
    return losses, relation_holds

def main():
    print(E02(torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.4 Exercise 03 - Batch Loss Computation

Part 1 - Why this matters

Computing a mean loss for each batch and then averaging those means can bias an epoch result when the final batch is smaller. The epoch loss must represent all compared elements with the intended weighting.

Correct aggregation also affects comparisons between batch sizes. The same predictions and targets should produce the same dataset-level MSE regardless of how they were divided into batches.

Part 2 - Mathematical form

For batches with squared-error sums S_k and element counts n_k:

$$\mathcal{L}_{\text{epoch}} = \frac{\sum_k S_k}{\sum_k n_k}$$

If every sample has one output, accumulating `batch_mean * batch_size` is equivalent. For general outputs, element count is the safer denominator.

Part 3 - Hints and Helper

Use sum reduction inside the loop and accumulate `prediction.numel()`. Divide only after all batches. Compare the result with MSE calculated in one call over the concatenated dataset and test an incomplete final batch.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import DataLoader, TensorDataset

def E03(model, loader):
    total_squared_error = 0.0
    total_elements = 0
    for X_batch, y_batch in loader:
        prediction = model(X_batch)
        batch_sum = torch.nn.functional.mse_loss(
            prediction, y_batch, reduction="sum"
```

```
        )
        total_squared_error += ...
        total_elements += ...
    return total_squared_error / ...

def main():
    dataset = TensorDataset(torch..., torch...)
    loader = DataLoader(dataset, batch_size=..., drop_last=False)
    model = torch.nn.Linear(..., ...)
    print(E03(model, loader))

if __name__ == "__main__":
    main()
```

10.6.5 Exercise 04 - Loss on CUDA

Part 1 - Why this matters

CUDA can compute predictions and loss on the GPU, but model parameters, input, target, and resulting operations must share a compatible device. Explicit placement prevents hidden transfers and device mismatch failures.

The scalar loss often remains on the GPU until its value is needed by Python. Calling `loss.item()` transfers a scalar value and should not be inserted unnecessarily inside a tightly timed region.

Part 2 - Technical concept and behavior

For device d:

$$d_\theta = d_X = d_y = d_{\mathcal{L}}$$

must hold during the CUDA loss calculation. Numerical comparison with CPU should use tolerances because floating-point results across devices are not guaranteed to be bitwise identical.

Part 3 - Hints and Helper

Check CUDA availability and return a clear skipped status otherwise. Move model, features, and target explicitly. Compute the loss, inspect every device, and synchronize before timing or comparing completed results.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E04(model, X, target):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    device = torch.device("cuda")
```

```
    model = model.to(device)
    X = X.to(device)
    target = target.to(device)
    prediction = model(X)
    loss = nn.MSELoss()(..., ...)
    return {
        "loss": loss,
        "model_device": next(model.parameters()).device,
        "prediction_device": ...,
        "target_device": ...,
        "loss_device": ...,
    }

def main():
    print(E04(nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.6 Exercise 05 - Loss Gradient Inspection

Part 1 - Why this matters

The loss gradient tells the model how each prediction contributed to error. For MSE, the gradient grows with residual magnitude and points away from the target, explaining why gradient descent moves predictions toward observed values.

Inspecting this derivative directly connects the loss equation to autograd. It also helps detect unintended reduction, broadcasting, or scaling because each of those choices changes the expected gradient.

Part 2 - Mathematical form

For N compared elements:

$$\mathcal{L} = \frac{1}{N}\sum_i (\hat{y}_i - y_i)^2$$

and:

$$\frac{\partial \mathcal{L}}{\partial \hat{y}_i} = \frac{2}{N}(\hat{y}_i - y_i)$$

The parameter gradient then follows through the model by the chain rule.

Part 3 - Hints and Helper

Create a leaf prediction tensor requiring gradients. Use `torch.autograd.grad()` or call backward and inspect its gradient. Calculate the analytical value independently and compare shapes and values.

Part 4 - Python code skeleton

```
import torch

def E05(prediction, target):
    loss = torch.nn.functional.mse_loss(
        prediction, target, reduction="mean"
    )
    automatic = torch.autograd.grad(loss, prediction)[0]
    analytical = ...
    return loss, automatic, analytical, torch.allclose(..., ...)

def main():
    prediction = torch.tensor(..., requires_grad=True)
    target = torch...
    print(E05(prediction, target))

if __name__ == "__main__":
    main()
```

10.6.7 Exercise 06 - Outlier Impact on Loss

Part 1 - Why this matters

Because MSE squares residuals, one extreme error can dominate many ordinary errors. This makes the loss responsive to serious mistakes but also sensitive to corrupted targets or rare events.

The correct response is not automatically to remove the outlier. The reader should quantify its contribution, investigate its provenance, and compare a robust reference such as absolute error before making a data or loss decision.

Part 2 - Mathematical form

For residuals e_i, each MSE contribution is e_i^2. The fraction contributed by selected outlier o is:

$$q_o = \frac{e_o^2}{\sum_i e_i^2}$$

As $|e_o|$ grows, its squared contribution can approach the entire loss sum.

Part 3 - Hints and Helper

Compute unreduced squared and absolute errors for a clean target and a copy containing one controlled outlier. Report total losses and the outlier contribution fraction. Keep predictions identical in both cases.

Part 4 - Python code skeleton

```
import torch

def summarize_errors(prediction, target, outlier_index):
```

```
    squared = torch.nn.functional.mse_loss(
        prediction, target, reduction="none"
    )
    absolute = (prediction - target).abs()
    fraction = squared[outlier_index] / squared.sum()
    return squared.mean(), absolute.mean(), fraction

def E06(prediction, clean_target, outlier_index, outlier_change):
    changed_target = clean_target.clone()
    changed_target[outlier_index] += ...
    return {
        "clean": summarize_errors(...),
        "with_outlier": summarize_errors(...),
    }

def main():
    print(E06(torch..., torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.6.8 Exercise 07 - Loss Scaling Effects

Part 1 - Why this matters

Changing the numerical scale of regression targets changes the numerical scale of MSE and its gradients. Two datasets describing the same relationship in different units can therefore produce losses that are not directly comparable.

This effect influences learning-rate selection and monitoring thresholds. A large loss may reflect units rather than a worse relative model, so the target scale must accompany every interpretation.

Part 2 - Mathematical form

If every residual is multiplied by constant c:

$$e'_i = ce_i$$

then:

$$\mathrm{MSE}' = c^2\,\mathrm{MSE}$$

while the gradient with respect to the scaled prediction is proportional to c. The experiment verifies these expected ratios.

Part 3 - Hints and Helper

Scale both prediction and target by the same nonzero factor so residuals scale consistently. Compare loss ratio with c^2 and gradient norms with the analytical expectation. Test both a larger and smaller unit scale.

Part 4 - Python code skeleton

```
import torch

def loss_and_gradient(prediction, target):
    prediction = prediction.detach().clone().requires_grad_(True)
    loss = torch.nn.functional.mse_loss(prediction, target)
    gradient = torch.autograd.grad(loss, prediction)[0]
    return loss, gradient

def E07(prediction, target, scale):
    base_loss, base_gradient = loss_and_gradient(...)
    scaled_loss, scaled_gradient = loss_and_gradient(
        prediction * scale,
        target * scale,
    )
    return {
        "loss_ratio": ...,
        "expected_loss_ratio": ...,
        "gradient_norm_ratio": ...,
    }

def main():
    print(E07(torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.6.9 Exercise 08 - Loss Precision Comparison

Part 1 - Why this matters

MSE performs subtraction, squaring, and reduction, so rounding effects can accumulate across many values. Comparing single and double precision reveals whether the chosen dtype materially changes the loss for a specific numerical range.

PyTorch does not guarantee bitwise-identical floating-point results across devices or mathematically equivalent computation orders. The comparison should use meaningful tolerances and one common source of values.

Part 2 - Technical concept and behavior

Let:

$$\mathcal{L}_{32} = \mathrm{MSE}(\hat{\mathbf{y}}_{32}, \mathbf{y}_{32}), \qquad \mathcal{L}_{64} = \mathrm{MSE}(\hat{\mathbf{y}}_{64}, \mathbf{y}_{64})$$

Compare absolute and relative difference after converting $\mathcal{L}_{32}$ to double precision.

Part 3 - Hints and Helper

Create prediction and target in `float64`, then derive `float32` copies. Test ordinary values and a difficult range with large baselines and small residuals. Report dtypes and both difference measures.

Part 4 - Python code skeleton

```
import torch

def E08(prediction64, target64):
    prediction32 = prediction64.float()
    target32 = target64.float()
    loss64 = torch.nn.functional.mse_loss(prediction64, target64)
    loss32 = torch.nn.functional.mse_loss(prediction32, target32)
    absolute = ...
    relative = ...
    return loss32, loss64, absolute, relative

def main():
    prediction64 = torch.tensor(..., dtype=torch.float64)
    target64 = torch.tensor(..., dtype=torch.float64)
    print(E08(prediction64, target64))

if __name__ == "__main__":
    main()
```

10.6.10 Exercise 09 - Loss Stability Test

Part 1 - Why this matters

Finite predictions do not guarantee a finite squared loss. Large residuals can overflow when squared, while NaN or infinite inputs propagate through the reduction. A stable pipeline checks numerical validity before backward contaminates gradients.

The objective is to identify a safe operating range and failure symptoms, not to hide invalid values with arbitrary replacement. Higher precision, scaling, clipping upstream data, or revising the model may be appropriate depending on the cause.

Part 2 - Technical concept and behavior

For maximum representable finite value M in a dtype, residual magnitude larger than approximately $\sqrt{M}$ may overflow when squared. The stability report tests:

$$\text{isfinite}(\hat{\mathbf{y}}), \quad \text{isfinite}(\mathbf{y}), \quad \text{isfinite}(\mathcal{L})$$

and, when backward is performed, finite gradients.

Part 3 - Hints and Helper

Generate controlled residual magnitudes across several scales. Use `torch.finfo(dtype)` to inspect the dtype range and `torch.isfinite()` at each stage. Stop before backward when the loss is non-finite.

Part 4 - Python code skeleton

```
import torch

def test_scale(dtype, residual_scale):
    prediction = torch.full((...), residual_scale, dtype=dtype,
                            requires_grad=True)
    target = torch.zeros_like(prediction)
    loss = torch.nn.functional.mse_loss(prediction, target)
    report = {
        "scale": residual_scale,
        "finite_prediction": ...,
        "finite_loss": ...,
    }
    if torch.isfinite(loss):
        loss.backward()
        report["finite_gradient"] = ...
    return report

def E09(dtypes, scales):
    return [test_scale(dtype, scale)
            for dtype in dtypes for scale in scales]

def main():
    print(E09([...], [..., ..., ...]))

if __name__ == "__main__":
    main()
```

10.6.11 Exercise 10 - Custom Loss Class

Part 1 - Why this matters

A custom loss module can enforce shape checks, expose a controlled reduction policy, and remain reusable inside training code. Reimplementing MSE as a class shows how a mathematical objective becomes an `nn.Module` without introducing hidden state.

Custom code also creates responsibility. Its forward values and gradients must match a trusted reference, and invalid reduction names or mismatched shapes should fail clearly before producing misleading results.

Part 2 - Mathematical form

The class calculates element-wise loss:

$$L = (\hat{\mathbf{Y}} - \mathbf{Y})^2$$

and returns L, $\sum L$, or $\text{mean}(L)$ according to the configured reduction. It has no learnable parameters.

Part 3 - Hints and Helper

Validate the reduction in `__init__()` and shapes in `forward()`. Compare every mode with `nn.MSELoss` using both values and gradients. Do not call `.item()` inside the forward method.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class CustomMSELoss(nn.Module):
    def __init__(self, reduction="mean"):
        super().__init__()
        if reduction not in {...}:
            raise ValueError(...)
        self.reduction = reduction

    def forward(self, prediction, target):
        if prediction.shape != target.shape:
            raise ValueError(...)
        elementwise = ...
        if self.reduction == "none":
            return elementwise
        if self.reduction == "sum":
            return ...
        return ...

def E10(prediction, target):
    custom = CustomMSELoss(...)
    reference = nn.MSELoss(reduction=...)
    return custom(...), reference(...)

def main():
    print(E10(torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.12 Exercise 11 - Loss with Masked Samples

Part 1 - Why this matters

Some targets may be unavailable or intentionally excluded from a loss. A mask allows valid elements to contribute while ignored elements produce no training signal. This is common in partially labeled or quality-controlled datasets.

Multiplying errors by a mask and then taking an ordinary mean is usually wrong because masked zeros remain in the denominator. The correct mean divides by the number or weight of valid elements and must define what happens when none are valid.

Part 2 - Mathematical form

For binary mask $m_i \in \{0, 1\}$:

$$\mathcal{L}_{\text{masked}} = \frac{\sum_i m_i(\hat{y}_i - y_i)^2}{\sum_i m_i}$$

The denominator must be positive. Mask shape must match the loss elements or follow an explicitly documented expansion rule.

Part 3 - Hints and Helper

Convert a boolean mask to the loss dtype only for arithmetic. Validate exact shape and at least one valid element. Return the valid count and compare with manually selecting the valid entries before calling MSE.

Part 4 - Python code skeleton

```
import torch

def E11(prediction, target, mask):
    if prediction.shape != target.shape or mask.shape != prediction.shape:
        raise ValueError(...)
    valid_count = mask.sum()
    if valid_count == 0:
        raise ValueError(...)
    squared = ...
    masked_sum = (squared * mask.to(squared.dtype)).sum()
    masked_mean = masked_sum / ...
    selected_reference = torch.nn.functional.mse_loss(
        prediction[mask], target[mask]
    )
    return masked_mean, selected_reference, valid_count

def main():
    print(E11(torch..., torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.13 Exercise 12 - Loss Backward Pass Check

Part 1 - Why this matters

A scalar loss is useful for training only if backward propagation reaches the intended model parameters. Checking gradients after MSE verifies that the prediction graph is connected and that every trainable component receives a finite, correctly shaped signal.

A missing gradient differs from a zero gradient. `None` indicates no stored gradient, while zeros may be the mathematically correct derivative for a perfectly fitted sample or zero-valued input.

Part 2 - Mathematical form

For $\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$:

$$\nabla_{\mathbf{w}}\mathcal{L} = \mathbf{X}^{\intercal}\frac{2}{N}(\hat{\mathbf{y}} - \mathbf{y})$$

and the bias gradient sums the prediction-gradient contributions across samples. Shapes must match their respective parameters.

Part 3 - Hints and Helper

Clear gradients to `None`, compute prediction and scalar MSE, then call backward once. Report gradient existence, shape, finiteness, and norm for every parameter. Use a small case to compare the weight gradient manually.

Part 4 - Python code skeleton

```
import torch

def E12(model, X, target):
    model.zero_grad(set_to_none=True)
    prediction = model(X)
    loss = torch.nn.functional.mse_loss(prediction, target)
    loss.backward()
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        report[name] = {
            "exists": gradient is not None,
            "shape_matches": ...,
            "finite": ...,
            "norm": ...,
        }
    analytical_weight_gradient = ...
    return loss.item(), report, analytical_weight_gradient

def main():
    print(E12(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.14 Exercise 13 - Loss Accumulation Debugging

Part 1 - Why this matters

Loss accumulation and gradient accumulation are separate processes. Summing tensor losses across many batches can retain their computation graphs and consume memory, while repeated backward calls without clearing gradients intentionally or accidentally add parameter gradients.

For logging, detached scalar values should be accumulated. For training, the gradient-clear schedule must match the intended effective batch size. This exercise contrasts these states so a memory or optimization bug can be identified precisely.

Part 2 - Technical concept and behavior

Logging epoch loss may accumulate:

$$S_{\text{loss}} \leftarrow S_{\text{loss}} + \text{detach}(S_k)$$

while gradients follow:

$$g \leftarrow g + \nabla_\theta \mathcal{L}_k$$

until explicitly cleared. These operations should not be confused merely because both use addition.

Part 3 - Hints and Helper

Accumulate `loss.item()` or a detached sum for metrics. Record gradient norms before backward, after backward, and after zeroing. Demonstrate two batches with and without zeroing, but do not retain every graph in an epoch-level tensor.

Part 4 - Python code skeleton

```
import torch

def gradient_norm(model):
    values = [
        parameter.grad.norm()
        for parameter in model.parameters()
        if parameter.grad is not None
    ]
    return ... if values else ...

def E13(model, batches, accumulate_gradients):
    logged_loss_sum = 0.0
    stages = []
    model.zero_grad(set_to_none=True)
    for X, target in batches:
        if not accumulate_gradients:
            model.zero_grad(set_to_none=True)
        loss = torch.nn.functional.mse_loss(model(X), target)
        logged_loss_sum += ...
        before = gradient_norm(model)
        loss.backward()
        after = gradient_norm(model)
        stages.append((before, after))
    return logged_loss_sum, stages

def main():
    print(E13(torch.nn.Linear(..., ...), ..., ...))

if __name__ == "__main__":
    main()
```

10.6.15 Exercise 14 - Loss Memory Footprint

Part 1 - Why this matters

Unreduced loss preserves one value per prediction element, while mean and sum reductions return a scalar. On large outputs, retaining element-wise losses or their computation graphs can substantially increase memory use.

The returned loss tensor is only part of the footprint. Autograd may retain intermediate values required for backward, so the experiment distinguishes visible output storage from measured peak allocation on CUDA.

Part 2 - Technical concept and behavior

For N compared elements and element size s:

$$M_{\text{none}} \approx Ns, \qquad M_{\text{mean}} \approx s$$

for returned tensor storage. Actual training memory includes prediction, target, model parameters, gradients, and graph intermediates.

Part 3 - Hints and Helper

Compute losses with `none`, `sum`, and `mean` from the same tensors. Report `numel() * element_size()` for each output. On CUDA, optionally reset peak statistics and synchronize around each isolated case.

Part 4 - Python code skeleton

```
import torch

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def E14(prediction, target):
    results = {}
    for reduction in ("none", "sum", "mean"):
        loss = torch.nn.functional.mse_loss(
            prediction, target, reduction=reduction
        )
        results[reduction] = {
            "shape": tuple(loss.shape),
            "visible_bytes": tensor_bytes(loss),
            "requires_grad": loss.requires_grad,
        }
        ...  # optionally measure isolated CUDA peak allocation
    return results

def main():
    prediction = torch.randn(..., requires_grad=True)
    target = torch...
    print(E14(prediction, target))
```

```
if __name__ == "__main__":
    main()
```

10.6.16 Exercise 15 - CPU vs GPU Loss Parity

Part 1 - Why this matters

The same model state and data should produce numerically close losses on CPU and GPU. Differences beyond a justified tolerance may indicate unequal parameters, dtype changes, incomplete transfers, or an incorrect comparison procedure.

Floating-point computations are not guaranteed to be bitwise identical across devices. Parity therefore means acceptable numerical agreement under a documented tolerance, not exact equality in every environment.

Part 2 - Technical concept and behavior

For equivalent inputs and states:

$$D = |\mathcal{L}_{\text{CPU}} - \mathcal{L}_{\text{GPU}}|$$

The comparison also records prediction difference so the reader can determine whether loss drift originated before or during reduction.

Part 3 - Hints and Helper

Deep-copy one reference model, preserve dtype, and move copies to each device. Use the same input values, synchronize CUDA, and return GPU results to CPU. Report absolute and relative differences for predictions and loss.

Part 4 - Python code skeleton

```
import copy
import torch

def E15(model, X, target, atol, rtol):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    cpu_model = copy.deepcopy(model).cpu()
    gpu_model = copy.deepcopy(model).cuda()
    cpu_prediction = cpu_model(X.cpu())
    cpu_loss = torch.nn.functional.mse_loss(
        cpu_prediction, target.cpu()
    )
    gpu_prediction = gpu_model(X.cuda())
    gpu_loss = torch.nn.functional.mse_loss(
        gpu_prediction, target.cuda()
    )
    torch.cuda.synchronize()
    return {
```

```
        "loss_matches": torch.allclose(
            cpu_loss, gpu_loss.cpu(), atol=atol, rtol=rtol
        ),
        "prediction_difference": ...,
        "loss_difference": ...,
    }

def main():
    print(E15(torch.nn.Linear(..., ...), torch..., torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.6.17 Exercise 16 - Loss under Mixed Precision

Part 1 - Why this matters

Automatic mixed precision allows selected operations to use lower precision while numerically sensitive operations use a safer dtype. This can improve CUDA performance and reduce memory use, but the resulting loss and gradients must remain finite and close to a full-precision reference.

PyTorch's autocast policy may run a linear operation in lower precision and MSE loss in float32. The reader should inspect actual output and loss dtypes instead of assuming that every operation uses one global dtype.

Part 2 - Technical concept and behavior

Compare full-precision loss $\mathcal{L}_{32}$ with autocast loss $\mathcal{L}_{\text{AMP}}$:

$$D = |\mathcal{L}_{32} - \mathcal{L}_{\text{AMP}}|$$

For float16 training, gradient scaling can multiply the loss before backward to reduce underflow risk, then unscale gradients before the optimizer update.

Part 3 - Hints and Helper

Use current `torch.autocast(device_type="cuda")` and `torch.amp.GradScaler("cuda")` APIs. Do not manually call `half()` on model or inputs when using autocast. Skip clearly without CUDA and inspect finite loss and gradients.

Part 4 - Python code skeleton

```
import copy
import torch

def E16(model, X, target):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    model = copy.deepcopy(model).cuda()
    X, target = X.cuda(), target.cuda()
```

```
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    scaler = torch.amp.GradScaler("cuda")
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        prediction = model(X)
        loss = torch.nn.functional.mse_loss(prediction, target)
    scaler.scale(loss).backward()
    ...  # inspect, unscale, verify, and optionally step
    return {
        "prediction_dtype": prediction.dtype,
        "loss_dtype": loss.dtype,
        "finite_loss": ...,
        "finite_gradients": ...,
    }

def main():
    print(E16(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.6.18 Exercise 17 - Loss Curve Logging

Part 1 - Why this matters

A loss curve reveals whether training is improving, oscillating, diverging, or reaching a plateau. Reliable logging records comparable epoch-level values without retaining autograd graphs or allowing unequal batch sizes to bias the result.

The curve is diagnostic evidence, not proof of generalization. Training and validation losses should be stored separately with configuration and epoch identifiers so the source of each point remains clear.

Part 2 - Technical concept and behavior

For epoch e:

$$\mathcal{L}_e = \frac{\sum_k S_{e,k}}{\sum_k n_{e,k}}$$

where $S_{e,k}$ is squared-error sum and $n_{e,k}$ is compared-element count. Logging a detached Python number prevents the history from retaining computation graphs.

Part 3 - Hints and Helper

Accumulate sum-reduced losses using `.item()` and element counts. Append the final mean once per epoch. Record phase, epoch, learning rate, and timestamp or run ID in a structured dictionary.

Part 4 - Python code skeleton

```
import torch

def evaluate_epoch_loss(model, loader, device):
    total_sum = 0.0
    total_elements = 0
    model.eval()
    with torch.inference_mode():
        for X, target in loader:
            X, target = X.to(device), target.to(device)
            prediction = model(X)
            total_sum += torch.nn.functional.mse_loss(
                prediction, target, reduction="sum"
            ).item()
            total_elements += prediction.numel()
    return total_sum / ...

def E17(model, loaders, epochs, device):
    history = []
    for epoch in range(epochs):
        ...  # perform or receive the training epoch
        train_loss = evaluate_epoch_loss(...)
        validation_loss = evaluate_epoch_loss(...)
        history.append({...})
    return history

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

10.6.19 Exercise 18 - Loss Exploding Case

Part 1 - Why this matters

An exploding loss may result from excessive learning rate, large unscaled features, extreme initialization, corrupted targets, or repeated unstable updates. Detecting the first non-finite or rapidly increasing value is more useful than observing that training eventually crashed.

The exercise uses bounded synthetic conditions and stops before applying an unsafe update. It records predictions, residuals, loss, and gradient norms so the cause can be separated from the final symptom.

Part 2 - Technical concept and behavior

A simple growth indicator is:

$$r_t = \frac{\mathcal{L}_t}{\max(\mathcal{L}_{t-1}, \varepsilon)}$$

A policy may flag loss when it becomes non-finite or exceeds a chosen growth ratio for a defined number of steps. Thresholds must be tied to the experiment scale.

Part 3 - Hints and Helper

Create separate scenarios for large input scale, large target scale, and large parameter scale. Check `torch.isfinite()` before backward and again on gradients. Skip the optimizer step when the safety condition fails.

Part 4 - Python code skeleton

```
import torch

def E18(model, X, target, optimizer, previous_loss,
        growth_threshold):
    optimizer.zero_grad(set_to_none=True)
    prediction = model(X)
    loss = torch.nn.functional.mse_loss(prediction, target)
    report = {
        "finite_prediction": ...,
        "finite_loss": ...,
        "loss": ...,
    }
    if not torch.isfinite(loss):
        report["action"] = "stop"
        return report
    loss.backward()
    gradient_norm = ...
    growth_ratio = ...
    report.update({
        "gradient_norm": gradient_norm,
        "growth_ratio": growth_ratio,
        "safe_to_step": ...,
    })
    if report["safe_to_step"]:
        optimizer.step()
    return report

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

10.6.20 Exercise 19 - Loss Failure Debugging

Part 1 - Why this matters

Loss failures often begin before the loss function: wrong target shape, integer dtype, device mismatch, NaN values, detached predictions, or an incorrect reduction can all produce errors

or misleading training behavior. A structured diagnostic should examine the contract before calling backward.

The final exercise combines value checks with graph checks. A finite scalar loss is not sufficient if it has no path to trainable parameters, and a connected graph is not useful if gradients become non-finite.

Part 2 - Technical concept and behavior

Required invariants include:

$$\text{shape}(\hat{\mathbf{Y}}) = \text{shape}(\mathbf{Y}), \quad d_{\hat{Y}} = d_Y, \quad \hat{\mathbf{Y}}, \mathbf{Y}, \mathcal{L} \text{ finite}$$

For training, the reduced loss should be scalar and connected to parameters expected to learn.

Part 3 - Hints and Helper

Validate shape, floating dtype, device, finite values, reduction, and gradient connection in sequence. Catch expected exceptions at the outer test boundary and preserve their type and message. Inject one failure at a time.

Part 4 - Python code skeleton

```
import torch

def diagnose_loss(model, prediction, target, reduction):
    checks = {
        "shape_match": ...,
        "dtype_valid": ...,
        "device_match": ...,
        "finite_prediction": ...,
        "finite_target": ...,
        "reduction_valid": reduction in {...},
    }
    if not all(checks.values()):
        return {"status": "invalid_input", "checks": checks}
    try:
        loss = torch.nn.functional.mse_loss(
            prediction, target, reduction=reduction
        )
        checks["scalar_for_backward"] = loss.ndim == 0
        checks["finite_loss"] = bool(torch.isfinite(loss).all())
        if checks["scalar_for_backward"] and checks["finite_loss"]:
            loss.backward()
            checks["finite_gradients"] = ...
        return {"status": ..., "checks": checks}
    except (RuntimeError, ValueError, TypeError) as error:
        return {
            "status": "failed",
            "checks": checks,
```

```
            "error_type": type(error).__name__,
            "message": str(error),
        }

def E19(model, X, target, reduction):
    prediction = model(X)
    return diagnose_loss(model, prediction, target, reduction)

def main():
    print(E19(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7 LR05 - Parameter Adjustment and Gradient

Models and Training

10.7.1 Exercise 00 - Backward on Scalar Loss

Part 1 - Why this matters

Backward propagation begins from a loss and calculates how every connected trainable parameter contributed to it. A scalar loss provides the ordinary starting point for reverse-mode differentiation in a training step.

Calling backward is a state-changing operation because gradients are stored on leaf parameters and accumulate with existing values. The reader must inspect gradient state before and after the call rather than treating backward as a function that merely returns a result.

Part 2 - Mathematical form

For scalar loss $\mathcal{L}$ and parameters θ:

$$\mathcal{L}.\texttt{backward()} \Longrightarrow \theta.\texttt{grad} \leftarrow \theta.\texttt{grad} + \nabla_\theta \mathcal{L}$$

The computational graph links the model output to the loss and then to weight and bias parameters.

Part 3 - Hints and Helper

Clear gradients to `None`, calculate prediction and mean loss, and verify the loss has zero dimensions. Record `grad_fn` before backward and parameter gradient metadata afterward.

Part 4 - Python code skeleton

```
import torch

def E00(model, X, target):
    model.zero_grad(set_to_none=True)
    prediction = model(X)
```

```
    loss = torch.nn.functional.mse_loss(prediction, target)
    if loss.ndim != 0:
        raise ValueError(...)
    before = {name: p.grad for name, p in model.named_parameters()}
    graph_function = loss.grad_fn
    loss.backward()
    after = {
        name: p.grad.detach().clone()
        for name, p in model.named_parameters()
    }
    return loss.item(), graph_function, before, after

def main():
    print(E00(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.2 Exercise 01 - Inspect Weight Gradients

Part 1 - Why this matters

The weight gradient connects feature values and prediction residuals to parameter adjustment. Its sign describes the local direction of change, while its magnitude reflects input scale, error scale, and loss reduction.

Inspecting only one gradient norm can hide shape or element-level problems. A complete report compares the autograd tensor with an analytical reference for a small batch and checks finiteness before any update.

Part 2 - Mathematical form

For $\hat{\mathbf{y}} = \mathbf{X}\mathbf{w} + b$ and mean squared error over N scalar outputs:

$$\nabla_{\mathbf{w}}\mathcal{L} = \frac{2}{N}\mathbf{X}^{\mathsf{T}}(\hat{\mathbf{y}} - \mathbf{y})$$

The gradient shape must equal the weight shape, accounting for the orientation used by `nn.Linear`.

Part 3 - Hints and Helper

Use a one-output linear layer and a small matrix. Call backward, calculate the analytical gradient independently, transpose only according to stored weight orientation, and compare using `torch.allclose()`.

Part 4 - Python code skeleton

```
import torch

def E01(model, X, target):
    model.zero_grad(set_to_none=True)
```

```
    prediction = model(X)
    residual = prediction - target
    loss = residual.square().mean()
    loss.backward()
    automatic = model.weight.grad.detach().clone()
    analytical = ...
    return {
        "automatic": automatic,
        "analytical": analytical,
        "shape_valid": ...,
        "finite": ...,
        "matches": torch.allclose(..., ...),
    }

def main():
    print(E01(torch.nn.Linear(..., 1), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.3 Exercise 02 - Inspect Bias Gradients

Part 1 - Why this matters

The bias gradient aggregates error signals across the batch because one bias value affects every sample for its output. This makes it structurally different from a sample-specific adjustment.

A wrong target shape or unintended broadcasting can multiply the number of residual contributions and produce an unexpected bias gradient. Comparing with the analytical sum is therefore a sensitive shape check.

Part 2 - Mathematical form

For scalar-output MSE:

$$\frac{\partial \mathcal{L}}{\partial b} = \frac{2}{N} \sum_{i=1}^{N} (\hat{y}_i - y_i)$$

For multiple outputs, this sum is calculated independently for each output column, producing a gradient with the bias shape.

Part 3 - Hints and Helper

Use exact prediction-target shape equality. Retain the residual before backward and calculate its reduction over the batch dimension. Compare values, shape, dtype, and device with `bias.grad`.

Part 4 - Python code skeleton

```
import torch
```

```
def E02(model, X, target):
    model.zero_grad(set_to_none=True)
    prediction = model(X)
    if prediction.shape != target.shape:
        raise ValueError(...)
    residual = prediction - target
    loss = residual.square().mean()
    loss.backward()
    automatic = model.bias.grad.detach().clone()
    analytical = ...
    return automatic, analytical, torch.allclose(..., ...)

def main():
    print(E02(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.4 Exercise 03 - Zero Grad Correctly

Part 1 - Why this matters

PyTorch accumulates parameter gradients, so each independent training step normally clears old gradients before backward. Forgetting this changes the update into a sum of current and previous signals.

Setting gradients to `None` and filling existing tensors with zero are not identical states. The default `set_to_none=True` can reduce memory use and reveals which parameters received no gradient in the next backward pass.

Part 2 - Technical concept and behavior

Before an independent step, apply:

$$g_\theta \leftarrow \texttt{None} \quad \text{or} \quad g_\theta \leftarrow 0$$

according to policy. With `None`, an optimizer may skip a parameter that receives no new gradient; a zero tensor represents an explicitly present zero gradient.

Part 3 - Hints and Helper

Create gradients with one backward call, inspect them, call `optimizer.zero_grad(set_to_none=True)` and inspect again. Repeat with `False`. Do not assume both reports should be identical.

Part 4 - Python code skeleton

```
import torch

def gradient_states(model):
    return {
        name: ("none" if p.grad is None else p.grad.detach().clone())
```

```
        for name, p in model.named_parameters()
    }

def E03(model, optimizer, X, target):
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    after_backward = gradient_states(model)
    optimizer.zero_grad(set_to_none=True)
    after_none = gradient_states(model)
    ...  # recreate gradients
    optimizer.zero_grad(set_to_none=False)
    after_zero = gradient_states(model)
    return after_backward, after_none, after_zero

def main():
    model = torch.nn.Linear(..., ...)
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    print(E03(model, optimizer, torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.5 Exercise 04 - Manual Gradient Update

Part 1 - Why this matters

A manual gradient update exposes the exact operation used by basic gradient descent. The reader can verify that parameters move opposite the local gradient and that the observed change equals learning rate times gradient.

The update should not be recorded in the autograd graph and should not use the unsafe `.data` shortcut. It belongs after backward and inside a no-gradient context.

Part 2 - Mathematical form

For parameter θ_t:

$$\theta_{t+1} = \theta_t - \eta g_t, \qquad g_t = \nabla_\theta \mathcal{L}_t$$

The observed difference should satisfy $\theta_{t+1} - \theta_t = -\eta g_t$.

Part 3 - Hints and Helper

Clone parameter values and gradients before updating. Apply the update under `torch.no_grad()`, then compare observed and expected changes for every named parameter. Clear gradients before starting another step.

Part 4 - Python code skeleton

```
import torch
```

```
def E04(model, X, target, learning_rate):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    before = {name: p.detach().clone()
              for name, p in model.named_parameters()}
    gradients = {name: p.grad.detach().clone()
                 for name, p in model.named_parameters()}
    with torch.no_grad():
        for parameter in model.parameters():
            parameter -= ...
    checks = {
        name: torch.allclose(
            parameter.detach() - before[name],
            -learning_rate * gradients[name],
        )
        for name, parameter in model.named_parameters()
    }
    return loss.item(), checks

def main():
    print(E04(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7.6 Exercise 05 - Learning Rate Sensitivity

Part 1 - Why this matters

The learning rate converts a gradient into a parameter step. A very small value may produce negligible progress, while a very large value can overshoot the minimum and increase loss.

A fair sensitivity test begins from identical model state and uses identical data. Comparing separately initialized models would mix learning-rate effects with initialization variation.

Part 2 - Mathematical form

For candidate rates η_j:

$$\theta'_j = \theta - \eta_j \nabla_\theta \mathcal{L}$$

A one-step experiment records parameter-change norm and freshly recomputed post-update loss for each candidate. The old loss tensor does not represent updated parameters.

Part 3 - Hints and Helper

Deep-copy one model for every rate. Compute one gradient and update per copy, then perform a new forward pass for post-step loss. Include zero, small, moderate, and deliberately large but bounded rates.

Part 4 - Python code skeleton

```
import copy
import torch

def one_rate(model, X, target, learning_rate):
    candidate = copy.deepcopy(model)
    before = [p.detach().clone() for p in candidate.parameters()]
    loss_before = torch.nn.functional.mse_loss(candidate(X), target)
    loss_before.backward()
    with torch.no_grad():
        for parameter in candidate.parameters():
            parameter -= ...
        loss_after = torch.nn.functional.mse_loss(candidate(X), target)
    change_norm = ...
    return {...}

def E05(model, X, target, learning_rates):
    return [one_rate(model, X, target, rate)
            for rate in learning_rates]

def main():
    print(E05(torch.nn.Linear(..., ...), torch..., torch..., [...]))

if __name__ == "__main__":
    main()
```

10.7.7 Exercise 06 - Gradient Clipping

Part 1 - Why this matters

Gradient clipping limits update magnitude when gradient norms become excessive. It can protect a training step from a transient spike, but it does not fix the data scale, learning rate, or numerical error that caused repeated explosions.

Norm clipping rescales all participating gradients together when their combined norm exceeds a threshold. The reader should measure norms before and after clipping and confirm that direction is preserved when scaling occurs.

Part 2 - Mathematical form

For combined gradient vector g and limit c:

$$g' = g \min\left(1, \frac{c}{\|g\|_2}\right)$$

PyTorch's `clip_grad_norm_()` modifies gradients in place and returns the total norm measured before clipping.

Part 3 - Hints and Helper

Calculate loss and backward first. Call `torch.nn.utils.clip_grad_norm_()` before optimizer step, use `error_if_nonfinite=True`, and compute the post-clip norm independently.

Part 4 - Python code skeleton

```
import torch

def total_gradient_norm(model):
    gradients = [p.grad for p in model.parameters() if p.grad is not None]
    return ...

def E06(model, X, target, max_norm):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    measured_before = torch.nn.utils.clip_grad_norm_(
        model.parameters(),
        max_norm=...,
        error_if_nonfinite=True,
    )
    measured_after = total_gradient_norm(model)
    return measured_before, measured_after

def main():
    print(E06(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7.8 Exercise 07 - Gradient Accumulation

Part 1 - Why this matters

Gradient accumulation combines several micro-batches before one optimizer step, approximating or reproducing a larger effective batch when memory is limited. It differs from accidentally forgetting to clear gradients because the accumulation window and scaling are deliberate.

Simply averaging every micro-batch loss equally is incorrect when micro-batches contain different element counts. Exact equivalence to one mean-reduced large batch requires weighting each squared-error sum by the total element count across the window.

Part 2 - Mathematical form

For micro-batches with sums S_k and counts n_k:

$$\mathcal{L}_{\text{window}} = \frac{\sum_k S_k}{\sum_k n_k}$$

Backward may be applied to each $S_k / \sum_j n_j$, allowing gradients to accumulate to the same result as one concatenated batch.

Part 3 - Hints and Helper

Know the total valid element count for the accumulation window. Clear once before it, backpropagate correctly scaled batch sums, and step once afterward. Compare gradients with a single concatenated reference batch.

Part 4 - Python code skeleton

```
import copy
import torch

def E07(model, micro_batches):
    accumulated_model = copy.deepcopy(model)
    reference_model = copy.deepcopy(model)
    total_elements = sum(target.numel() for _, target in micro_batches)
    accumulated_model.zero_grad(set_to_none=True)
    for X, target in micro_batches:
        batch_sum = torch.nn.functional.mse_loss(
            accumulated_model(X), target, reduction="sum"
        )
        (batch_sum / ...).backward()
    reference_X = torch.cat([...], dim=0)
    reference_target = torch.cat([...], dim=0)
    reference_loss = torch.nn.functional.mse_loss(
        reference_model(reference_X), reference_target
    )
    reference_loss.backward()
    return ...  # compare every gradient

def main():
    print(E07(torch.nn.Linear(..., ...), ...))

if __name__ == "__main__":
    main()
```

10.7.9 Exercise 08 - Gradient Noise Injection

Part 1 - Why this matters

Adding controlled random noise to gradients is an experimental way to study update robustness and stochastic behavior. It can perturb optimization away from an exact deterministic path, but it should never be introduced without a reproducible scale and a baseline comparison.

Noise injection changes the optimizer input rather than the loss itself. The original gradients should be preserved for measurement, and noise must be added only to trainable parameters with existing finite gradients.

Part 2 - Mathematical form

For gradient g:

$$g' = g + \epsilon, \qquad \epsilon \sim \mathcal{N}(0, \sigma^2)$$

The experiment records signal norm, noise norm, and their ratio. Zero σ should reproduce the original gradient exactly.

Part 3 - Hints and Helper

Use a seeded generator compatible with the gradient device. Clone original gradients, sample matching noise tensors, and add them inside a no-gradient context. Do not inject noise before AMP gradients have been unscaled.

Part 4 - Python code skeleton

```
import torch

def E08(model, X, target, noise_std, seed):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    generator = torch.Generator(device=...).manual_seed(...)
    report = {}
    with torch.no_grad():
        for name, parameter in model.named_parameters():
            if parameter.grad is None:
                continue
            original = parameter.grad.clone()
            noise = torch.randn(
                original.shape,
                device=original.device,
                dtype=original.dtype,
                generator=generator,
            ) * ...
            parameter.grad.add_(noise)
            report[name] = ...
    return report

def main():
    print(E08(torch.nn.Linear(..., ...), torch..., torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.7.10 Exercise 09 - Gradient Check via Finite Difference

Part 1 - Why this matters

Finite differences estimate a derivative from nearby loss values without using autograd. Comparing this numerical estimate with the automatic gradient is a powerful way to detect wrong equations, detached paths, or custom differentiation errors.

The perturbation size must balance truncation error and floating-point cancellation. Double precision and central differences usually provide a clearer reference for this small diagnostic experiment.

Part 2 - Mathematical form

For parameter element θ_j and step h:

$$\frac{\partial \mathcal{L}}{\partial \theta_j} \approx \frac{\mathcal{L}(\theta_j + h) - \mathcal{L}(\theta_j - h)}{2h}$$

Every perturbed value must be restored before moving to the next element.

Part 3 - Hints and Helper

Use a tiny double-precision model. Compute autograd gradients once, then perturb selected parameter elements under `torch.no_grad()`. Restore the original value exactly and report absolute and relative errors.

Part 4 - Python code skeleton

```
import torch

def loss_value(model, X, target):
    return torch.nn.functional.mse_loss(model(X), target)

def E09(model, X, target, step):
    model = model.double()
    X, target = X.double(), target.double()
    model.zero_grad(set_to_none=True)
    loss_value(model, X, target).backward()
    automatic = model.weight.grad.detach().clone()
    numerical = torch.zeros_like(automatic)
    for index in ...:
        original = model.weight[index].item()
        with torch.no_grad():
            model.weight[index] = original + step
        plus = loss_value(model, X, target).item()
        with torch.no_grad():
            model.weight[index] = original - step
        minus = loss_value(model, X, target).item()
        with torch.no_grad():
            model.weight[index] = original
        numerical[index] = ...
    return automatic, numerical, ...

def main():
    print(E09(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7.11 Exercise 10 - Optimizer Step vs Manual Step

Part 1 - Why this matters

A basic SGD optimizer step should match the manual rule when momentum, weight decay, dampening, and other modifiers are disabled. This comparison verifies understanding of what the optimizer automates.

Both paths must begin from identical parameters and use gradients from identical data. Any extra optimizer option changes the expected equation and invalidates the simple parity test.

Part 2 - Mathematical form

For plain SGD:

$$\theta' = \theta - \eta \nabla_\theta \mathcal{L}$$

The manual model and optimizer model should have numerically equal parameters after one step within floating-point tolerance.

Part 3 - Hints and Helper

Deep-copy one base model. Calculate gradients independently for each copy. Update one inside `torch.no_grad()` and update the other with `torch.optim.SGD` configured with zero momentum and zero weight decay.

Part 4 - Python code skeleton

```
import copy
import torch

def E10(model, X, target, learning_rate):
    manual_model = copy.deepcopy(model)
    optimizer_model = copy.deepcopy(model)
    ...  # calculate matching gradients
    with torch.no_grad():
        for parameter in manual_model.parameters():
            parameter -= ...
    optimizer = torch.optim.SGD(
        optimizer_model.parameters(),
        lr=learning_rate,
        momentum=0.0,
        weight_decay=0.0,
    )
    optimizer.step()
    comparisons = ...
    return comparisons

def main():
    print(E10(torch.nn.Linear(..., ...), torch..., torch..., ...))
```

```
if __name__ == "__main__":
    main()
```

10.7.12 Exercise 11 - CUDA Gradient Sync Check

Part 1 - Why this matters

Equivalent CPU and CUDA computations should produce numerically close gradients when state, data, dtype, and loss definition match. This test can expose incomplete state copying or unintended device-specific settings.

CUDA execution is asynchronous, so synchronization is required before timing and before assuming a benchmarked backward pass has completed. Numerical parity still uses tolerances rather than bitwise equality.

Part 2 - Technical concept and behavior

For corresponding gradients:

$$D_{\max} = \max_j |g_{\mathrm{CPU},j} - g_{\mathrm{CUDA},j}|$$

Every named parameter should be compared after moving CUDA gradients to CPU. Missing gradients are reported separately.

Part 3 - Hints and Helper

Deep-copy one model to each device, use identical input values, calculate the same scalar loss, and call backward. Synchronize CUDA, then compare gradients by parameter name with absolute and relative tolerances.

Part 4 - Python code skeleton

```
import copy
import torch

def E11(model, X, target, atol, rtol):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    cpu_model = copy.deepcopy(model).cpu()
    gpu_model = copy.deepcopy(model).cuda()
    cpu_loss = torch.nn.functional.mse_loss(
        cpu_model(X.cpu()), target.cpu()
    )
    gpu_loss = torch.nn.functional.mse_loss(
        gpu_model(X.cuda()), target.cuda()
    )
    cpu_loss.backward()
    gpu_loss.backward()
    torch.cuda.synchronize()
    report = {}
    for (cpu_name, cpu_parameter), (gpu_name, gpu_parameter) in zip(
```

```
        cpu_model.named_parameters(), gpu_model.named_parameters()
    ):
        ...  # compare names, existence, values, and maximum difference
    return report

def main():
    print(E11(torch.nn.Linear(..., ...), torch..., torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.7.13 Exercise 12 - Frozen Parameter Gradient Test

Part 1 - Why this matters

A frozen parameter remains part of the forward computation but should not receive a stored gradient or update. This distinction supports fine-tuning and controlled experiments.

Testing only `requires_grad` is insufficient. The reader should verify the parameter value stays unchanged across backward and optimizer step while an unfrozen parameter receives and applies a gradient.

Part 2 - Technical concept and behavior

For frozen weight W_f:

$$W_f.\texttt{requires_grad} = \text{False}, \qquad W_f.\texttt{grad} = \texttt{None}, \qquad W_f' = W_f$$

The bias can remain trainable and change normally.

Part 3 - Hints and Helper

Freeze the weight before constructing the optimizer, pass only trainable parameters, and clone weight and bias values. Perform one step, then inspect gradient states and value changes separately.

Part 4 - Python code skeleton

```
import torch

def E12(model, X, target, learning_rate):
    model.weight.requires_grad_(False)
    optimizer = torch.optim.SGD(
        (p for p in model.parameters() if p.requires_grad),
        lr=learning_rate,
    )
    weight_before = model.weight.detach().clone()
    bias_before = model.bias.detach().clone()
    optimizer.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
```

```
    optimizer.step()
    return {
        "weight_grad": model.weight.grad,
        "bias_grad_exists": ...,
        "weight_unchanged": ...,
        "bias_changed": ...,
    }

def main():
    print(E12(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7.14 Exercise 13 - Gradient Explosion Scenario

Part 1 - Why this matters

Exploding gradients can produce enormous parameter updates, non-finite state, and rapid divergence. In linear regression they may arise from large feature scale, target scale, parameter magnitude, or learning rate.

The exercise should detect unsafe gradients before stepping. Clipping may protect one update, but the report must retain evidence about the underlying scale problem rather than hiding it.

Part 2 - Technical concept and behavior

Track total norm:

$$G_t = \left(\sum_{\theta} \|\nabla_\theta \mathcal{L}_t\|_2^2 \right)^{1/2}$$

A scenario is flagged when G_t is non-finite or exceeds a documented threshold relative to the experiment.

Part 3 - Hints and Helper

Generate separate bounded cases for large inputs and large residuals. Check loss and gradients with `torch.isfinite()`, record the norm, and skip optimizer step when unsafe. Optionally compare the clipped norm without claiming the cause is solved.

Part 4 - Python code skeleton

```
import torch

def E13(model, X, target, threshold):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    report = {"finite_loss": bool(torch.isfinite(loss))}
    if not torch.isfinite(loss):
```

```
        return report
    loss.backward()
    gradients = [p.grad for p in model.parameters() if p.grad is not None]
    total_norm = ...
    report.update({
        "total_norm": total_norm,
        "finite_gradients": ...,
        "exploding": ...,
        "safe_to_step": ...,
    })
    return report

def main():
    print(E13(torch.nn.Linear(..., ...), torch..., torch..., ...))

if __name__ == "__main__":
    main()
```

10.7.15 Exercise 14 - Gradient Vanishing Scenario

Part 1 - Why this matters

Very small gradients can make parameter changes indistinguishable from numerical noise or too slow to improve within a practical number of steps. In a linear model, small feature values, small residuals, loss scaling, or a perfect fit can all produce small gradients.

A small gradient is not automatically a defect. Near an optimum it is expected. Diagnosis must compare gradient magnitude with loss, parameter scale, and the observed effect of one update.

Part 2 - Mathematical form

For linear MSE:

$$\nabla_w \mathcal{L} = \frac{2}{N} X^\top (\hat{y} - y)$$

Scaling X or residuals toward zero reduces the gradient. An update may satisfy:

$$\|\eta g\| \ll \|\theta\|$$

and create negligible relative change.

Part 3 - Hints and Helper

Construct a perfect-fit case and a non-perfect case with tiny input scale. Report loss, gradient norm, proposed update norm, and relative update size. Distinguish expected convergence from a scale-induced optimization problem.

Part 4 - Python code skeleton

```
import torch

def E14(model, X, target, learning_rate, threshold):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        update_norm = learning_rate * gradient.norm()
        parameter_norm = parameter.detach().norm()
        report[name] = {
            "gradient_norm": ...,
            "update_norm": ...,
            "relative_update": ...,
            "below_threshold": ...,
        }
    return loss.item(), report

def main():
    print(E14(torch.nn.Linear(..., ...), torch..., torch..., ..., ...))

if __name__ == "__main__":
    main()
```

10.7.16 Exercise 15 - Mixed Precision Backward

Part 1 - Why this matters

Float16 gradients can underflow or overflow during training. Automatic mixed precision chooses operation dtypes, while gradient scaling multiplies the loss before backward so small gradients are more likely to remain representable.

Clipping and inspection must occur after gradients are unscaled. Otherwise, measured norms and clipping thresholds refer to scaled values rather than the gradients that would update parameters.

Part 2 - Technical concept and behavior

With scale s:

$$\nabla_\theta(s\mathcal{L}) = s\nabla_\theta\mathcal{L}$$

The scaler later unscales gradients before the optimizer step. It may skip an unsafe step and adjust its scale when non-finite gradients are detected.

Part 3 - Hints and Helper

Use `torch.autocast(device_type="cuda")` and `torch.amp.GradScaler("cuda")`. Scale loss, call backward, unscale the optimizer, inspect or clip gradients, then call scaler step and update. Skip clearly when CUDA is unavailable.

Part 4 - Python code skeleton

```
import torch

def E15(model, X, target, optimizer, max_norm):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    model, X, target = model.cuda(), X.cuda(), target.cuda()
    scaler = torch.amp.GradScaler("cuda")
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        prediction = model(X)
        loss = torch.nn.functional.mse_loss(prediction, target)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), max_norm, error_if_nonfinite=True
    )
    scaler.step(optimizer)
    scaler.update()
    return {"loss": loss.item(), "unscaled_norm": norm, "scale": ...}

def main():
    model = torch.nn.Linear(..., ...)
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    print(E15(model, torch..., torch..., optimizer, ...))

if __name__ == "__main__":
    main()
```

10.7.17 Exercise 16 - Backward Graph Retention

Part 1 - Why this matters

Autograd normally frees saved graph data after backward because a new graph is built on the next forward pass. Retaining a graph allows another backward traversal, but it increases memory lifetime and is often unnecessary in ordinary training.

Using `retain_graph=True` to silence an error can hide incorrect control flow. The reader should first determine whether repeated derivatives genuinely require the same graph or whether a fresh forward pass is the correct solution.

Part 2 - Technical concept and behavior

Two backward calls on the same graph require retention during the first call:

$$\mathcal{L}\texttt{.backward(retain_graph=True)}$$

Gradients accumulate across both traversals unless cleared. Retention preserves graph data, not a copy of parameter gradients.

Part 3 - Hints and Helper

Run one controlled repeated-backward case with retention and record the doubled or accumulated gradient. Compare with two fresh forward passes. Also capture the expected error when attempting an unsupported second backward without retention.

Part 4 - Python code skeleton

```
import torch

def E16(model, X, target):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward(retain_graph=True)
    first = {name: p.grad.detach().clone()
             for name, p in model.named_parameters()}
    loss.backward()
    second = {name: p.grad.detach().clone()
              for name, p in model.named_parameters()}
    accumulation_checks = ...
    ...  # compare with fresh-forward behavior
    return first, second, accumulation_checks

def main():
    print(E16(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.18 Exercise 17 - Gradient Memory Profiling

Part 1 - Why this matters

Gradients require storage comparable to trainable parameter storage, and backward may need additional saved tensors and temporary workspace. Profiling helps determine whether batch size, precision, or model structure fits the available device memory.

Visible gradient tensor bytes are only a lower bound on backward memory. CUDA peak allocation captures more of the runtime footprint, while CPU profiling requires a separately chosen measurement method.

Part 2 - Technical concept and behavior

Known gradient storage is:

$$M_g = \sum_{\theta:\theta.grad\neq \texttt{None}} \text{numel}(\theta.grad)\,\text{element_size}(\theta.grad)$$

Peak allocated memory is measured around an isolated forward-backward operation after warm-up.

Part 3 - Hints and Helper

Calculate parameter and gradient bytes separately. On CUDA, reset peak memory statistics before the measured pass and synchronize afterward. Compare `set_to_none=True` with zero tensors only after controlling all other variables.

Part 4 - Python code skeleton

```
import torch

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def E17(model, X, target):
    device = next(model.parameters()).device
    model.zero_grad(set_to_none=True)
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats(device)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        peak = torch.cuda.max_memory_allocated(device)
    else:
        peak = None
    gradient_bytes = sum(
        tensor_bytes(p.grad)
        for p in model.parameters()
        if p.grad is not None
    )
    return {"gradient_bytes": gradient_bytes, "peak_allocated": peak}

def main():
    print(E17(torch.nn.Linear(..., ...), torch..., torch...))

if __name__ == "__main__":
    main()
```

10.7.19 Exercise 18 - Multi-Batch Gradient Behavior

Part 1 - Why this matters

Gradients across batches can represent independent updates, an accumulated effective batch, or an accidental mixture of past data. Observing these alternatives clarifies how the location of `zero_grad()` changes training mathematics.

Batch means also create weighting issues when batch sizes differ. The reader should compare independent batch gradients, their correctly weighted combination, and the gradient of the concatenated data.

Part 2 - Mathematical form

For full mean loss across batches:

$$g_{\text{full}} = \sum_k \frac{n_k}{\sum_j n_j} g_k$$

where g_k is the gradient of the mean loss for batch k and n_k is its number of loss elements. An unweighted average is correct only when counts are equal.

Part 3 - Hints and Helper

Use model copies with identical state. Calculate each batch gradient independently, combine it with count weights, and compare against one concatenated batch. Then demonstrate accumulation without clearing as a separate state.

Part 4 - Python code skeleton

```
import copy
import torch

def gradient_for_batch(model, X, target):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X), target)
    loss.backward()
    return {name: p.grad.detach().clone()
            for name, p in model.named_parameters()}

def E18(model, batches):
    individual = []
    counts = []
    for X, target in batches:
        individual.append(gradient_for_batch(copy.deepcopy(model), X, target))
        counts.append(target.numel())
    weighted = ...
    full_model = copy.deepcopy(model)
    full_gradient = gradient_for_batch(
        full_model,
        torch.cat([...], dim=0),
        torch.cat([...], dim=0),
    )
    return individual, weighted, full_gradient, ...

def main():
    print(E18(torch.nn.Linear(..., ...), ...))

if __name__ == "__main__":
    main()
```

10.7.20 Exercise 19 - Gradient Debugging Case

Part 1 - Why this matters

Gradient failures can appear as `None`, zero, non-finite, wrong-shaped, stale, excessively large, or unexpectedly accumulated values. Each symptom has different causes, so debugging requires structured evidence from the graph and training-step order.

The final exercise diagnoses the first broken boundary rather than applying random fixes. It checks parameter registration and flags before forward, graph connection after loss, gradient properties after backward, and update safety before optimizer step.

Part 2 - Technical concept and behavior

For every trainable parameter θ:

$$\theta.grad \neq \texttt{None}, \quad \text{shape}(\theta.grad) = \text{shape}(\theta), \quad \text{isfinite}(\theta.grad)$$

should normally hold after a connected valid backward pass. Magnitude thresholds remain experiment-specific.

Part 3 - Hints and Helper

Record named parameters, `requires_grad`, loss shape, `grad_fn`, gradient state, and norm. Inject detach, frozen parameters, wrong zeroing order, and non-finite data separately. Skip optimizer step when validation fails.

Part 4 - Python code skeleton

```
import torch

def inspect_gradients(model):
    report = {}
    for name, parameter in model.named_parameters():
        gradient = parameter.grad
        report[name] = {
            "requires_grad": parameter.requires_grad,
            "exists": gradient is not None,
            "shape_matches": ...,
            "finite": ...,
            "norm": ...,
        }
    return report

def E19(model, X, target, optimizer):
    report = {"before": inspect_gradients(model)}
    optimizer.zero_grad(set_to_none=True)
    try:
        prediction = model(X)
        loss = torch.nn.functional.mse_loss(prediction, target)
        report["loss_scalar"] = loss.ndim == 0
        report["loss_grad_fn"] = str(loss.grad_fn)
        loss.backward()
        report["after_backward"] = inspect_gradients(model)
        report["safe_to_step"] = ...
```

```
        if report["safe_to_step"]:
            optimizer.step()
    except (RuntimeError, ValueError, TypeError) as error:
        report["error"] = {
            "type": type(error).__name__,
            "message": str(error),
        }
    return report

def main():
    model = torch.nn.Linear(..., ...)
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    print(E19(model, torch..., torch..., optimizer))

if __name__ == "__main__":
    main()
```

10.8 LR06 - Training Iterations and Convergence

Models and Training

10.8.1 Exercise 00 - Single-Epoch Training

Part 1 - Why this matters

A single epoch processes the training dataset once and applies a sequence of parameter updates. It is the smallest complete training unit containing mode selection, gradient clearing, forward prediction, loss, backward propagation, and optimizer step.

The returned epoch loss must represent all samples rather than an unweighted average of batch means. This is especially important when the final batch is smaller.

Part 2 - Technical concept and behavior

For batch k with squared-error sum S_k and element count n_k:

$$\mathcal{L}_{\text{epoch}} = \frac{\sum_k S_k}{\sum_k n_k}$$

Every training batch follows clear, forward, loss, backward, and update in that order.

Part 3 - Hints and Helper

Call `model.train()` once before iteration. Use mean loss for backward if desired, but separately accumulate sum-reduced detached loss and element count for reporting. Verify gradient finiteness before stepping.

Part 4 - Python code skeleton

```
import torch

def E00(model, loader, optimizer, device):
    model.train()
    total_sum = 0.0
    total_elements = 0
    for X, target in loader:
        X, target = X.to(device), target.to(device)
        optimizer.zero_grad(set_to_none=True)
        prediction = model(X)
        loss = torch.nn.functional.mse_loss(prediction, target)
        loss.backward()
        ...  # verify gradients
        optimizer.step()
        total_sum += torch.nn.functional.mse_loss(
            prediction.detach(), target, reduction="sum"
        ).item()
        total_elements += prediction.numel()
    return total_sum / ...

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

10.8.2 Exercise 01 - Multi-Epoch Training Loop

Part 1 - Why this matters

Multiple epochs allow repeated parameter refinement. The loop must preserve a history of comparable measurements so improvement, instability, and overfitting can be observed rather than inferred from the final state alone.

Training and validation have different execution rules. Validation uses evaluation mode and no gradient tracking, while training creates gradients and updates parameters. Mixing these phases can corrupt results.

Part 2 - Technical concept and behavior

For epochs $e = 0, \ldots, E-1$, record:

$$H_e = (\mathcal{L}_{\text{train},e}, \mathcal{L}_{\text{validation},e}, \eta_e)$$

The history should contain detached numerical values and run metadata, not loss tensors retaining graphs.

Part 3 - Hints and Helper

Reuse a single-epoch training function and a separate evaluation function. Record losses, current learning rate, and elapsed time. Keep the test set outside all training decisions.

Part 4 - Python code skeleton

```
import time
import torch

def evaluate(model, loader, device):
    model.eval()
    ...  # calculate element-weighted mean under inference_mode

def E01(model, train_loader, validation_loader,
        optimizer, device, epochs):
    history = []
    for epoch in range(epochs):
        started = time.perf_counter()
        train_loss = ...
        validation_loss = evaluate(...)
        history.append({
            "epoch": epoch,
            "train_loss": train_loss,
            "validation_loss": validation_loss,
            "learning_rate": ...,
            "seconds": time.perf_counter() - started,
        })
    return history

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

10.8.3 Exercise 02 - Convergence Criterion Check

Part 1 - Why this matters

Training needs a defined stopping condition. Reaching the maximum epoch count is a limit, not evidence of convergence. A useful criterion observes whether meaningful improvement has stopped or gradients have become sufficiently small.

A single tiny loss change may be noise, so convergence should usually require a condition to hold for several checks. The criterion must be chosen before inspecting test performance.

Part 2 - Mathematical form

For monitored loss L_e, define improvement:

$$\Delta_e = L_{e-1} - L_e$$

A patience-based criterion may declare convergence after p consecutive epochs with $\Delta_e < \delta$, optionally combined with gradient norm below $g_{\min}$.

Part 3 - Hints and Helper

Track best or previous validation loss, minimum meaningful improvement, and a counter. Treat non-finite values as failure rather than convergence. Return a reason and epoch, not only a boolean.

Part 4 - Python code skeleton

```
import math

class ConvergenceMonitor:
    def __init__(self, min_improvement, patience, gradient_threshold=None):
        self.min_improvement = min_improvement
        self.patience = patience
        self.gradient_threshold = gradient_threshold
        self.previous = None
        self.count = 0

    def update(self, loss_value, gradient_norm):
        if not math.isfinite(loss_value):
            return {"converged": False, "reason": "non_finite"}
        improvement = ...
        ...  # update counter using loss and optional gradient condition
        return {"converged": ..., "reason": ..., "improvement": ...}

def E02(loss_history, gradient_history, monitor):
    return [monitor.update(loss, grad)
            for loss, grad in zip(loss_history, gradient_history)]

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

10.8.4 Exercise 03 - Divergence Detection

Part 1 - Why this matters

Divergence can turn a recoverable training problem into corrupted parameters if updates continue after loss or gradients become non-finite. Early detection protects checkpoints and provides evidence about learning rate, scaling, or data failures.

One increasing epoch does not prove divergence. The policy should combine non-finite checks with sustained or extreme growth relative to a stable reference.

Part 2 - Mathematical form

Define growth ratio:

$$r_e = \frac{L_e}{\max(L_{\text{best}}, \varepsilon)}$$

Training can be stopped when loss or gradients are non-finite, or when r_e exceeds a threshold for a declared number of checks.

Part 3 - Hints and Helper

Monitor training and validation losses, gradient norm, and parameter finiteness. Preserve the last known-good checkpoint before risky steps. Return severity, evidence, and recommended action without automatically altering hyperparameters.

Part 4 - Python code skeleton

```
import math
import torch

def E03(loss_history, model, gradient_norm,
        growth_threshold, consecutive_limit):
    report = {
        "finite_loss": all(math.isfinite(v) for v in loss_history),
        "finite_parameters": all(
            torch.isfinite(p).all() for p in model.parameters()
        ),
        "finite_gradient_norm": math.isfinite(gradient_norm),
    }
    best = min(loss_history)
    growth_ratios = [...]
    consecutive_growth = ...
    report["diverging"] = ...
    report["growth_ratios"] = growth_ratios
    report["action"] = ...  # continue, warn, or stop
    return report

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

10.8.5 Exercise 04 - Early Stopping

Part 1 - Why this matters

Early stopping ends training when validation performance no longer improves meaningfully. It can reduce wasted computation and limit continued fitting after the best observed generalization point.

The final epoch is not necessarily the best epoch. A correct implementation preserves a deep copy of the best model state and restores it after stopping instead of returning the most recent state.

Part 2 - Technical concept and behavior

Let best validation loss be $L^\star$. Improvement occurs when:

$$L_e < L^\star - \delta$$

Otherwise a patience counter increases. Stopping triggers when the counter reaches p, and the stored state associated with $L^\star$ is restored.

Part 3 - Hints and Helper

Clone every tensor in the best state dictionary or use a deep copy. Store best epoch and loss, reset patience on real improvement, and never use test loss for the decision.

Part 4 - Python code skeleton

```
import copy
import torch

class EarlyStopping:
    def __init__(self, patience, min_delta):
        self.patience = patience
        self.min_delta = min_delta
        self.best_loss = float("inf")
        self.best_state = None
        self.best_epoch = None
        self.counter = 0

    def update(self, model, validation_loss, epoch):
        if validation_loss < self.best_loss - self.min_delta:
            self.best_loss = ...
            self.best_state = copy.deepcopy(model.state_dict())
            self.best_epoch = ...
            self.counter = 0
        else:
            self.counter += 1
        return self.counter >= self.patience

def E04(model, validation_losses, stopper):
    for epoch, loss in enumerate(validation_losses):
        if stopper.update(model, loss, epoch):
            break
        ...  # simulation may update model state
    model.load_state_dict(...)
    return model, stopper.best_epoch, stopper.best_loss

def main():
```

```
    print(E04(...))

if __name__ == "__main__":
    main()
```

10.8.6 Exercise 05 - Learning Rate Schedule

Part 1 - Why this matters

A learning-rate schedule changes update size as training progresses. Large early steps may accelerate movement, while smaller later steps can refine parameters near a minimum.

Scheduler timing is part of its definition. Most epoch-based PyTorch schedulers step after optimizer updates; calling them before the optimizer can skip the first scheduled value.

Part 2 - Technical concept and behavior

For step decay:

$$\eta_e = \eta_0 \gamma^{\lfloor e/s \rfloor}$$

where s is the step interval and γ the decay factor. The experiment records the rate actually used for each epoch.

Part 3 - Hints and Helper

Use a scheduler such as `StepLR`, call `optimizer.step()` during training, then `scheduler.step()` at the documented boundary. Record optimizer group rates and `get_last_lr()`.

Part 4 - Python code skeleton

```
import torch

def E05(model, loader, optimizer, scheduler, epochs, device):
    history = []
    for epoch in range(epochs):
        learning_rate_used = optimizer.param_groups[0]["lr"]
        ...  # train the epoch, including optimizer steps
        scheduler.step()
        history.append({
            "epoch": epoch,
            "learning_rate_used": learning_rate_used,
            "next_learning_rates": scheduler.get_last_lr(),
            "loss": ...,
        })
    return history

def main():
    model = torch.nn.Linear(..., ...)
    optimizer = torch.optim.SGD(model.parameters(), lr=...)
    scheduler = torch.optim.lr_scheduler.StepLR(
```

```
        optimizer, step_size=..., gamma=...
    )
    print(E05(model, ..., optimizer, scheduler, ..., ...))

if __name__ == "__main__":
    main()
```

10.8.7 Exercise 06 - Training on CUDA End-to-End

Part 1 - Why this matters

End-to-end CUDA training requires model, batches, targets, loss, and gradients to remain device compatible throughout every step. Moving only the model is insufficient.

The data pipeline should normally keep multi-process loader outputs on CPU and transfer batches in the training process. Pinned memory and non-blocking copies may help, but they must be benchmarked rather than assumed.

Part 2 - Technical concept and behavior

For every batch on device d:

$$d_\theta = d_X = d_y = d_{\mathcal{L}} = d_g$$

The epoch metric may be transferred as detached scalar values, while training computations remain on CUDA.

Part 3 - Hints and Helper

Check CUDA availability, move the model before constructing the optimizer, and transfer each batch. Validate devices and finite gradients. Synchronize only for accurate timing, not after every operation unnecessarily.

Part 4 - Python code skeleton

```
import time
import torch

def E06(model, loader, learning_rate):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    device = torch.device("cuda")
    model = model.to(device)
    optimizer = torch.optim.SGD(model.parameters(), lr=learning_rate)
    model.train()
    torch.cuda.synchronize()
    started = time.perf_counter()
    for X, target in loader:
        X = X.to(device, non_blocking=...)
        target = target.to(device, non_blocking=...)
        optimizer.zero_grad(set_to_none=True)
```

```
        loss = torch.nn.functional.mse_loss(model(X), target)
        loss.backward()
        ...  # verify and update
    torch.cuda.synchronize()
    return {"seconds": time.perf_counter() - started, "loss": ...}

def main():
    print(E06(torch.nn.Linear(..., ...), ..., ...))

if __name__ == "__main__":
    main()
```

10.8.8 Exercise 07 - CPU vs GPU Convergence

Part 1 - Why this matters

CPU and GPU training should follow similar convergence behavior when they begin from identical state and consume the same batches. Exact trajectories may differ slightly because floating-point kernels are not guaranteed to be bitwise identical.

A fair comparison controls initialization, sample order, dtype, optimizer settings, and number of updates. Timing and convergence quality are separate outputs.

Part 2 - Technical concept and behavior

For loss histories L_e^C and L_e^G, compare:

$$D_e = |L_e^C - L_e^G|$$

along with final parameter and prediction differences. Tolerances should be declared before observing the result.

Part 3 - Hints and Helper

Deep-copy one initial model, precompute batch index order, and feed equivalent tensors to each device. Synchronize CUDA timing. Report both loss curves and final numerical differences.

Part 4 - Python code skeleton

```
import copy
import torch

def train_with_fixed_batches(model, batches, device, epochs, lr):
    model = model.to(device)
    optimizer = torch.optim.SGD(model.parameters(), lr=lr)
    history = []
    for epoch in range(epochs):
        ...  # use identical batch order
        history.append(...)
    return model, history
```

```
def E07(base_model, batches, epochs, lr):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    cpu_model, cpu_history = train_with_fixed_batches(
        copy.deepcopy(base_model), batches, torch.device("cpu"), epochs, lr
    )
    gpu_model, gpu_history = train_with_fixed_batches(
        copy.deepcopy(base_model), batches, torch.device("cuda"), epochs, lr
    )
    return ...  # compare histories, parameters, and predictions

def main():
    print(E07(torch.nn.Linear(..., ...), ..., ..., ...))

if __name__ == "__main__":
    main()
```

10.8.9 Exercise 08 - Batch Size Impact

Part 1 - Why this matters

Batch size changes gradient variance, number of optimizer updates per epoch, memory use, and hardware utilization. Comparing batch sizes without controlling the training budget can confuse these effects.

The reader should decide whether experiments use equal epochs, equal optimizer steps, or equal processed samples. Each answers a different question and must be recorded.

Part 2 - Technical concept and behavior

For dataset size N and batch size B:

$$U_{\text{epoch}} = \left\lceil \frac{N}{B} \right\rceil$$

optimizer updates occur per epoch when every batch steps once. Larger B usually reduces update count and may reduce gradient noise.

Part 3 - Hints and Helper

Start every candidate from the same state, use the same split, and log update count, samples processed, loss, time, and peak memory. Do not change learning rate silently with batch size.

Part 4 - Python code skeleton

```
import copy
import torch
from torch.utils.data import DataLoader

def run_batch_size(base_model, dataset, batch_size, epochs, lr, device):
    model = copy.deepcopy(base_model).to(device)
    loader = DataLoader(dataset, batch_size=batch_size,
```

```
                        shuffle=..., generator=...)
    optimizer = torch.optim.SGD(model.parameters(), lr=lr)
    updates = 0
    samples = 0
    ...  # train and record time, losses, updates, and samples
    return {...}

def E08(base_model, dataset, batch_sizes, epochs, lr, device):
    return [run_batch_size(base_model, dataset, size, epochs, lr, device)
            for size in batch_sizes]

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

10.8.10 Exercise 09 - Noise Robustness Test

Part 1 - Why this matters

A regression model should be evaluated under realistic feature or target noise rather than only on perfectly generated data. Robustness testing measures how performance changes as controlled noise increases.

One random draw can be misleading. Repeated seeds allow the reader to report variability and distinguish a general trend from one favorable or unfavorable sample.

Part 2 - Mathematical form

For noise level σ:

$$X' = X + \epsilon_X \quad \text{or} \quad y' = y + \epsilon_y, \qquad \epsilon \sim \mathcal{N}(0, \sigma^2)$$

Report metric distribution across seeds for each σ, while keeping clean evaluation data as a reference.

Part 3 - Hints and Helper

Separate training noise from evaluation noise and label which is applied. Clone the base dataset and model state per run. Record mean and standard deviation of final clean and noisy losses.

Part 4 - Python code skeleton

```
import copy
import torch

def run_noise_case(base_model, clean_data, noise_std, seed, config):
    generator = torch.Generator().manual_seed(seed)
    ...  # create an independent noisy dataset
```

```
    model = copy.deepcopy(base_model)
    ...  # train under the declared noise policy
    return {
        "noise_std": noise_std,
        "seed": seed,
        "clean_loss": ...,
        "noisy_loss": ...,
    }

def E09(base_model, clean_data, noise_levels, seeds, config):
    results = []
    for level in noise_levels:
        for seed in seeds:
            results.append(run_noise_case(...))
    return ...  # aggregate without discarding raw runs

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

10.8.11 Exercise 10 - Reproducibility with Seeds

Part 1 - Why this matters

Reproducible experiments help determine whether a result changed because of code or configuration rather than a different random initialization or shuffle order. Seeds are part of the experiment record.

A seed does not guarantee identical results across PyTorch versions, platforms, or CPU and GPU. Deterministic algorithms may also reduce performance or reject unsupported operations, so the reproducibility scope must be documented.

Part 2 - Technical concept and behavior

For fixed environment and deterministic execution, repeated runs aim for:

$$H^{(1)} = H^{(2)}$$

or agreement within declared tolerance. Sources include model initialization, synthetic data, loaders, Python randomness, and external libraries.

Part 3 - Hints and Helper

Seed Python, PyTorch, and any used NumPy generators. Give `DataLoader` an explicit generator and worker-seeding policy. Optionally enable deterministic algorithms and record environment versions and device.

Part 4 - Python code skeleton

```
import random
import torch

def configure_reproducibility(seed, deterministic):
    random.seed(seed)
    torch.manual_seed(seed)
    if deterministic:
        torch.use_deterministic_algorithms(...)
        torch.backends.cudnn.benchmark = ...
    generator = torch.Generator().manual_seed(seed)
    return generator

def E10(run_training, seed, deterministic):
    generator = configure_reproducibility(seed, deterministic)
    first = run_training(generator)
    generator = configure_reproducibility(seed, deterministic)
    second = run_training(generator)
    return {
        "history_matches": ...,
        "state_matches": ...,
        "scope": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

10.8.12 Exercise 11 - Checkpoint Save per Epoch

Part 1 - Why this matters

An epoch checkpoint preserves a recoverable training boundary. Saving only model weights is enough for inference, but resuming training also requires optimizer and scheduler state, completed epoch, configuration, and random state.

Checkpoint frequency trades storage and write time against potential lost work. A partially written file should not replace the last good checkpoint, so production workflows use an atomic replacement strategy.

Part 2 - Technical concept and behavior

After completed epoch e, store:

$$C_e = (S_{\text{model}}, S_{\text{optimizer}}, S_{\text{scheduler}}, e, H, R, \Gamma)$$

where H is history, R random state, and Γ configuration metadata.

Part 3 - Hints and Helper

Save state dictionaries rather than whole model objects. Include CPU RNG state and CUDA RNG states when available. Write to a temporary path and atomically replace the intended checkpoint only after success.

Part 4 - Python code skeleton

```
import os
import torch

def build_checkpoint(model, optimizer, scheduler,
                     completed_epoch, history, config):
    return {
        "model_state": model.state_dict(),
        "optimizer_state": optimizer.state_dict(),
        "scheduler_state": None if scheduler is None else scheduler.state_dict(),
        "completed_epoch": completed_epoch,
        "history": history,
        "config": config,
        "torch_rng_state": torch.get_rng_state(),
        "cuda_rng_states": (
            torch.cuda.get_rng_state_all() if torch.cuda.is_available() else None
        ),
    }

def E11(checkpoint, final_path):
    temporary_path = ...
    torch.save(checkpoint, temporary_path)
    ...  # verify the temporary checkpoint
    os.replace(temporary_path, final_path)
    return final_path

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

10.8.13 Exercise 12 - Resume Training from Checkpoint

Part 1 - Why this matters

Resuming should continue the same optimization process rather than merely begin from similar weights. Momentum, scheduler position, random state, history, and the next epoch index all influence the continuation.

The receiving model and optimizer must be constructed compatibly before loading state. The checkpoint should be validated before it replaces live training state.

Part 2 - Technical concept and behavior

If checkpoint records completed epoch e, continuation begins at:

$$e_{\text{start}} = e + 1$$

Restored optimizer and scheduler states ensure the next update and learning rate follow the original sequence.

Part 3 - Hints and Helper

Load with an explicit `map_location` and `weights_only=True` when the checkpoint contains supported tensor and primitive state. Validate keys and configuration, load model before optimizer state, restore scheduler and RNG states, and return the next epoch.

Part 4 - Python code skeleton

```
import torch

def E12(checkpoint_path, model, optimizer, scheduler, device):
    checkpoint = torch.load(
        checkpoint_path,
        map_location=device,
        weights_only=True,
    )
    required_keys = {...}
    if not required_keys.issubset(checkpoint):
        raise ValueError(...)
    model.load_state_dict(checkpoint["model_state"])
    optimizer.load_state_dict(checkpoint["optimizer_state"])
    if scheduler is not None and checkpoint["scheduler_state"] is not None:
        scheduler.load_state_dict(...)
    torch.set_rng_state(...)
    if device.type == "cuda" and checkpoint["cuda_rng_states"] is not None:
        torch.cuda.set_rng_state_all(...)
    next_epoch = checkpoint["completed_epoch"] + 1
    return next_epoch, checkpoint["history"], checkpoint["config"]

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

10.8.14 Exercise 13 - Long-Run Stability Test

Part 1 - Why this matters

A training loop that succeeds for a few epochs may still leak memory, drift numerically, corrupt state, or become unstable after many updates. A long-run test observes trends under a bounded resource and time budget.

The test should stream summaries rather than retain every tensor. Periodic known-good checkpoints allow recovery and comparison if a later failure occurs.

Part 2 - Technical concept and behavior

At interval q, record:

$$M_e = (L_{\text{train}}, L_{\text{validation}}, \|g\|, \|\theta\|, \eta, M_{\text{memory}}, T)$$

Non-finite values, sustained memory growth, and severe loss growth trigger a controlled stop.

Part 3 - Hints and Helper

Define maximum epochs, wall time, memory budget, and checkpoint interval before running. Store detached scalars only, sample memory consistently, and validate parameters after each checkpoint boundary.

Part 4 - Python code skeleton

```
import time
import torch

def E13(model, train_epoch, evaluate, save_checkpoint,
        max_epochs, max_seconds, checkpoint_interval):
    started = time.perf_counter()
    history = []
    last_good = None
    for epoch in range(max_epochs):
        if time.perf_counter() - started > max_seconds:
            break
        metrics = train_epoch(model)
        validation = evaluate(model)
        record = {...}
        history.append(record)
        safe = ...
        if not safe:
            return {"status": "stopped", "history": history,
                    "last_good": last_good}
        if (epoch + 1) % checkpoint_interval == 0:
            last_good = save_checkpoint(...)
    return {"status": "completed", "history": history,
            "last_good": last_good}

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

10.8.15 Exercise 14 - Loss Plateau Analysis

Part 1 - Why this matters

A plateau is a period of little measured improvement. It may indicate convergence, a learning rate that is too small, noisy validation estimates, insufficient model capacity, or poor feature scaling.

Declaring a plateau from two points is unreliable. The analysis needs a window, meaningful improvement threshold, and supporting signals such as gradient norm and learning rate.

Part 2 - Mathematical form

For window length w, total window improvement is:

$$\Delta_w = L_{e-w} - L_e$$

A simple plateau policy flags when $|\Delta_w| < \delta$ and variability inside the window remains within a declared range for enough checks.

Part 3 - Hints and Helper

Use validation loss rather than test loss. Report window slope or improvement, variability, current learning rate, and gradient norm. Return possible interpretations rather than automatically changing the optimizer.

Part 4 - Python code skeleton

```
import torch

def E14(loss_history, learning_rates, gradient_norms,
        window_size, min_improvement, max_variation):
    if len(loss_history) < window_size:
        return {"plateau": False, "reason": "insufficient_history"}
    window = torch.tensor(loss_history[-window_size:], dtype=torch.float64)
    improvement = ...
    variation = ...
    plateau = ...
    return {
        "plateau": plateau,
        "improvement": improvement,
        "variation": variation,
        "learning_rate": learning_rates[-1],
        "gradient_norm": gradient_norms[-1],
        "possible_causes": ...,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

10.8.16 Exercise 15 - Throughput Benchmark

Part 1 - Why this matters

Training throughput measures how much useful data is processed per unit time. It helps compare batch sizes, devices, data-loader settings, and precision modes, but it does not measure convergence quality by itself.

A valid benchmark excludes warm-up, synchronizes asynchronous CUDA work, and reports both samples and optimizer updates. Data loading may be included or isolated depending on the stated boundary.

Part 2 - Mathematical form

For N processed samples over elapsed time T:

$$Q_{\text{samples}} = \frac{N}{T}$$

Updates per second are U/T. The report labels device, batch size, dtype, worker count, and whether transfer is included.

Part 3 - Hints and Helper

Warm up several steps, use `time.perf_counter()`, and synchronize CUDA before starting and stopping. Avoid logging inside the timed region and repeat trials to report median throughput.

Part 4 - Python code skeleton

```
import time
import torch

def benchmark_trial(train_step, loader, device, warmup_steps, measured_steps):
    iterator = iter(loader)
    for _ in range(warmup_steps):
        batch = next(iterator)
        train_step(batch)
    if device.type == "cuda":
        torch.cuda.synchronize()
    started = time.perf_counter()
    samples = 0
    updates = 0
    for _ in range(measured_steps):
        batch = next(iterator)
        train_step(batch)
        samples += ...
        updates += 1
    if device.type == "cuda":
        torch.cuda.synchronize()
    elapsed = time.perf_counter() - started
    return {"samples_per_second": ..., "updates_per_second": ...}
```

```
def E15(...):
    ...

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

10.8.17 Exercise 16 - Gradient Drift Over Epochs

Part 1 - Why this matters

Gradient magnitude and direction change as model parameters move through the loss surface. Tracking these changes can reveal convergence, oscillation, sudden data shifts, or an unstable learning rate.

A norm alone cannot describe direction. Comparing consecutive flattened gradient vectors with cosine similarity provides a second view, but zero gradients require an explicit undefined or special policy.

Part 2 - Mathematical form

For consecutive epoch reference gradients g_{e-1} and g_e:

$$\cos(g_{e-1}, g_e) = \frac{g_{e-1}^{\mathsf{T}} g_e}{\|g_{e-1}\|_2 \|g_e\|_2}$$

Also record norm ratio and absolute difference. Reference gradients should be computed on the same fixed probe batch.

Part 3 - Hints and Helper

After each epoch, clear gradients and calculate one gradient on an unchanged probe batch without stepping. Flatten named gradients in a stable order, detach them, and compare with the previous epoch.

Part 4 - Python code skeleton

```
import torch

def probe_gradient(model, X_probe, y_probe):
    model.zero_grad(set_to_none=True)
    loss = torch.nn.functional.mse_loss(model(X_probe), y_probe)
    loss.backward()
    vectors = [
        parameter.grad.detach().reshape(-1)
        for _, parameter in model.named_parameters()
        if parameter.grad is not None
    ]
```

```
    return torch.cat(vectors)

def E16(model, train_epoch, probe_batch, epochs):
    history = []
    previous = None
    for epoch in range(epochs):
        train_epoch(model)
        current = probe_gradient(model, *probe_batch)
        similarity = ... if previous is not None else None
        history.append({...})
        previous = current.clone()
    return history

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

10.8.18 Exercise 17 - Mixed Precision Training

Part 1 - Why this matters

Mixed precision can improve CUDA throughput and reduce memory by selecting lower precision for suitable operations while retaining safer precision for sensitive reductions. Gradient scaling helps protect float16 backward values.

The training loop must unscale gradients before clipping or inspecting them. It must also monitor skipped updates and numerical agreement rather than assuming mixed precision is stable for every scale.

Part 2 - Technical concept and behavior

For loss scale s:

$$\nabla_\theta(s\mathcal{L}) = s\nabla_\theta\mathcal{L}$$

The scaler unscales before the effective update and adjusts s according to gradient finiteness.

Part 3 - Hints and Helper

Use `torch.autocast(device_type="cuda")` and `torch.amp.GradScaler("cuda")`. Keep master parameters in their normal dtype, unscale before clipping, and record loss, scale, throughput, and finite status.

Part 4 - Python code skeleton

```
import torch

def E17(model, loader, optimizer, epochs, max_grad_norm):
    if not torch.cuda.is_available():
```

```
        return {"skipped": ...}
    model = model.cuda()
    scaler = torch.amp.GradScaler("cuda")
    history = []
    for epoch in range(epochs):
        for X, target in loader:
            X, target = X.cuda(), target.cuda()
            optimizer.zero_grad(set_to_none=True)
            with torch.autocast(device_type="cuda", dtype=torch.float16):
                prediction = model(X)
                loss = torch.nn.functional.mse_loss(prediction, target)
            scaler.scale(loss).backward()
            scaler.unscale_(optimizer)
            norm = torch.nn.utils.clip_grad_norm_(...)
            scaler.step(optimizer)
            scaler.update()
        history.append({"loss": ..., "scale": ..., "gradient_norm": ...})
    return history

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

10.8.19 Exercise 18 - Training Failure Recovery

Part 1 - Why this matters

A recoverable training system stops when it detects unsafe state, preserves diagnostics, and restores a validated checkpoint. Recovery should not continue from non-finite parameters or retry forever without changing the failure condition.

The recovery policy must distinguish transient infrastructure errors from deterministic data or configuration failures. Restoring the same checkpoint and replaying the same bad batch indefinitely is not recovery.

Part 2 - Technical concept and behavior

Let $C^\star$ be the last validated checkpoint. On failure at step t:

$$(\theta_t, S_t) \leftarrow C^\star$$

then validate restored model, optimizer, scheduler, and next data position. A bounded retry policy decides whether to resume or terminate.

Part 3 - Hints and Helper

Save checkpoint identity and batch identifier in the report. Restore all training state, run a fixed validation probe, and enforce a maximum retry count. Require caller approval or declared policy for hyperparameter changes.

Part 4 - Python code skeleton

```
import torch

def validate_restored_state(model, probe_batch):
    ...  # finite parameters, prediction, and loss

def E18(train_step, load_checkpoint, checkpoint_path,
        model, optimizer, scheduler, batches, max_retries):
    report = []
    retries = 0
    for batch_id, batch in enumerate(batches):
        try:
            metrics = train_step(batch)
            if not metrics["safe"]:
                raise RuntimeError("unsafe training state")
        except RuntimeError as error:
            report.append({...})
            if retries >= max_retries:
                return {"status": "failed", "events": report}
            checkpoint = load_checkpoint(checkpoint_path)
            ...  # restore model, optimizer, scheduler, epoch, and RNG
            if not validate_restored_state(model, ...):
                return {"status": "invalid_checkpoint", "events": report}
            retries += 1
            ...  # follow the declared replay or skip policy
    return {"status": "completed", "events": report}

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

10.8.20 Exercise 19 - Full Training Debug Scenario

Part 1 - Why this matters

A full training failure may originate in data, model mode, device placement, loss shape, gradient state, optimizer order, scheduler timing, checkpoint state, or validation leakage. Debugging requires evidence from the whole pipeline.

The final challenge creates a structured trace instead of printing disconnected values. Each stage records its contract, and the first unsafe stage prevents later mutation such as an optimizer step or checkpoint replacement.

Part 2 - Technical concept and behavior

The training state transition is:

$$D \to f_\theta(D) \to \mathcal{L} \to \nabla_\theta \mathcal{L} \to \theta' \to V(\theta') \to C$$

Every arrow requires shape, dtype, device, finite, and ordering invariants appropriate to that stage.

Part 3 - Hints and Helper

Record sample IDs, tensor metadata, loss, gradient norms, learning rate, parameter changes, validation metric, and checkpoint identity. Inject one failure at a time, including leakage, wrong target shape, device mismatch, stale gradients, scheduler order, and non-finite values.

Part 4 - Python code skeleton

```
import torch

def E19(model, batch, optimizer, scheduler,
        validate, checkpoint, device):
    trace = []
    try:
        X, target, sample_ids = batch
        trace.append({"stage": "data", ...})
        ...  # validate split provenance, shape, dtype, and finite values
        X, target = X.to(device), target.to(device)
        optimizer.zero_grad(set_to_none=True)
        prediction = model(X)
        trace.append({"stage": "forward", ...})
        loss = torch.nn.functional.mse_loss(prediction, target)
        trace.append({"stage": "loss", ...})
        loss.backward()
        trace.append({"stage": "backward", ...})
        safe = ...
        if not safe:
            return {"status": "stopped", "trace": trace}
        before = ...
        optimizer.step()
        scheduler.step()
        trace.append({"stage": "update", ...})
        validation = validate(model)
        ...  # save only if the complete state is valid
        return {"status": "passed", "trace": trace}
    except (RuntimeError, ValueError, TypeError) as error:
        trace.append({
            "stage": "failure",
            "type": type(error).__name__,
            "message": str(error),
        })
        return {"status": "failed", "trace": trace}

def main():
```

```
    print(E19(...))

if __name__ == "__main__":
    main()
```

10.9 LR07 - Model Evaluation and Performance

Models and Training

10.9.1 Exercise 00 - Compute RMSE Metric

Part 1 - Why this matters

Root Mean Squared Error measures the typical prediction error while penalizing large residuals more strongly than small ones. Because the square root returns the result to the target's original unit, RMSE can be interpreted alongside the values the model predicts.

A correct implementation must aggregate squared errors across every evaluated element before taking the square root. Averaging separate batch RMSE values can produce a biased result when batch sizes differ.

Part 2 - Mathematical definition

For targets y_i, predictions $\hat{y}_i$, and N evaluated elements:

$$\text{RMSE} = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(\hat{y}_i - y_i)^2}$$

The square root is applied once after the global mean squared error is computed.

Part 3 - Hints and Helper

Run evaluation without gradient tracking. Accumulate `reduction="sum"` squared error and the number of prediction elements, then divide and apply `torch.sqrt`. Check that prediction and target shapes match exactly.

Part 4 - Python code skeleton

```
import torch

def E00(model, loader, device):
    model.eval()
    squared_error_sum = 0.0
    element_count = 0
    with torch.inference_mode():
        for X, target in loader:
            X, target = X.to(device), target.to(device)
            prediction = model(X)
            ...
            squared_error_sum += torch.nn.functional.mse_loss(
```

```
                prediction, target, reduction="sum"
            ).item()
            element_count += prediction.numel()
    return (squared_error_sum / ...) ** 0.5

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

10.9.2 Exercise 01 - Compute MAE Metric

Part 1 - Why this matters

Mean Absolute Error reports the average magnitude of prediction errors without squaring them. It is easier to interpret than a squared loss and is less dominated by a small number of unusually large errors.

MAE and RMSE reveal different properties of the same model. Comparing both helps determine whether performance is broadly weak or whether a few severe failures are responsible for most of the error.

Part 2 - Mathematical definition

For residual $r_i = \hat{y}_i - y_i$:

$$\text{MAE} = \frac{1}{N}\sum_{i=1}^{N}|r_i|$$

A dataset-level MAE requires the absolute-error sum and total element count across all batches.

Part 3 - Hints and Helper

Use `torch.nn.functional.l1_loss(..., reduction="sum")`. Do not average batch means unless all batches contain exactly the same number of evaluated elements. Return both MAE and the count used to make the result auditable.

Part 4 - Python code skeleton

```
import torch

def E01(model, loader, device):
    model.eval()
    absolute_error_sum = 0.0
    element_count = 0
    with torch.inference_mode():
        for X, target in loader:
            X, target = X.to(device), target.to(device)
            prediction = model(X)
```

```
            if prediction.shape != target.shape:
                raise ValueError(...)
            absolute_error_sum += torch.nn.functional.l1_loss(
                prediction, target, reduction="sum"
            ).item()
            element_count += ...
    return {"mae": absolute_error_sum / element_count,
            "elements": element_count}

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

10.9.3 Exercise 02 - Evaluation without Grad

Part 1 - Why this matters

Evaluation needs forward predictions but does not need gradients or a backward graph. Disabling gradient tracking reduces unnecessary graph construction and can lower memory use during validation and inference.

This optimization does not replace evaluation mode. Gradient state controls automatic differentiation, whereas `model.eval()` controls the behavior of modules whose training and evaluation rules differ.

Part 2 - Technical concept and behavior

An evaluation function should satisfy:

$$\text{gradient tracking} = \text{disabled}, \qquad \text{model.training} = \text{False}$$

Its predictions should not require gradients, and model parameter gradients should remain unchanged.

Part 3 - Hints and Helper

Save copies of existing parameter gradients before evaluation. Use `model.eval()` with `torch.inference_mode()` or `torch.no_grad()`, verify `prediction.requires_grad` is false, and confirm the stored gradients were not modified.

Part 4 - Python code skeleton

```
import torch

def E02(model, X):
    previous = [
        None if p.grad is None else p.grad.detach().clone()
        for p in model.parameters()
    ]
```

```
    model.eval()
    with torch.no_grad():
        prediction = model(X)
        tracked = prediction.requires_grad
    unchanged = []
    for parameter, old_grad in zip(model.parameters(), previous):
        ...
    return {"prediction": prediction,
            "requires_grad": tracked,
            "gradients_unchanged": all(unchanged)}

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

10.9.4 Exercise 03 - Train vs Eval Mode

Part 1 - Why this matters

PyTorch modules can behave differently during training and evaluation. Dropout changes activations stochastically during training, while batch normalization changes how its statistics are selected. A forgotten mode switch can therefore invalidate evaluation results.

A simple linear layer may produce identical outputs in both modes, so the reader must not infer that mode selection is universally irrelevant. The experiment should use a model containing a mode-sensitive component.

Part 2 - Technical concept and behavior

The state flag follows:

`model.train()` ⇒ `model.training=True`

`model.eval()` ⇒ `model.training=False`

Evaluation mode is equivalent to calling `model.train(False)`, but it does not disable gradients by itself.

Part 3 - Hints and Helper

Use a small model with dropout, keep the input fixed, and collect repeated outputs in both modes. Measure variation across repetitions. Wrap only the evaluation experiment in a no-gradient context.

Part 4 - Python code skeleton

```
import torch

def E03(model, X, repeats=20):
```

```
    model.train()
    train_outputs = [model(X).detach() for _ in range(repeats)]
    model.eval()
    with torch.inference_mode():
        eval_outputs = [model(X) for _ in range(repeats)]
    train_stack = torch.stack(train_outputs)
    eval_stack = torch.stack(eval_outputs)
    return {
        "train_variation": train_stack.std(dim=0).mean().item(),
        "eval_variation": ...,
        "mode_after_test": model.training,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

10.9.5 Exercise 04 - Overfitting Detection

Part 1 - Why this matters

Overfitting occurs when a model continues improving on training data while its performance on unseen data stops improving or becomes worse. A low training loss alone is therefore not evidence that the model has learned a useful relationship.

Detection requires comparable measurements collected over time. Training and validation metrics must use consistent reductions and fixed validation data, otherwise an apparent generalization gap may be caused by measurement changes.

Part 2 - Technical concept and behavior

At epoch t, define the generalization gap:

$$G_t = \mathcal{L}_{\text{validation},t} - \mathcal{L}_{\text{training},t}$$

A persistent increase in G_t combined with improving training loss is evidence of possible overfitting, not an automatic proof.

Part 3 - Hints and Helper

Accept training and validation histories of equal length. Compare recent windows rather than one noisy epoch. Report the best validation epoch, final gap, training trend, validation trend, and the rule that triggered the warning.

Part 4 - Python code skeleton

```
import torch

def E04(train_losses, validation_losses, window=5, tolerance=0.0):
```

```
    train = torch.as_tensor(train_losses, dtype=torch.float64)
    validation = torch.as_tensor(validation_losses, dtype=torch.float64)
    if train.shape != validation.shape or train.numel() < window + 1:
        raise ValueError(...)
    recent_train = train[-window:].mean()
    earlier_train = train[-2 * window:-window].mean()
    train_change = recent_train - earlier_train
    validation_change = ...
    gap = validation - train
    suspected = bool(
        train_change < -tolerance and validation_change > tolerance
    )
    return {"overfitting_suspected": suspected,
            "best_validation_epoch": int(validation.argmin()),
            "final_gap": gap[-1].item()}

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

10.9.6 Exercise 05 - Cross-Validation Split

Part 1 - Why this matters

A single train–validation split may give an unusually optimistic or pessimistic estimate, especially when a dataset is small. Cross-validation rotates the validation subset so every sample can contribute to evaluation.

The method is only trustworthy when information does not leak between folds. Model parameters, optimizer state, and transformations learned from data must be rebuilt using only the training portion of each fold.

Part 2 - Mathematical definition

For K disjoint folds $F_1, \ldots, F_K$, fold k uses:

$$D^{(k)}_{\text{validation}} = F_k, \qquad D^{(k)}_{\text{train}} = \bigcup_{j \neq k} F_j$$

The final estimate can be reported as the mean and standard deviation of the fold metrics.

Part 3 - Hints and Helper

Shuffle indices once with a seeded generator, then use `torch.tensor_split` so uneven sizes are handled. Create a new model and optimizer inside every fold. Fit scalers only on that fold's training indices.

Part 4 - Python code skeleton

```
import torch

def E05(dataset, folds, seed, model_factory, train_fold, evaluate_fold):
    generator = torch.Generator().manual_seed(seed)
    indices = torch.randperm(len(dataset), generator=generator)
    fold_indices = torch.tensor_split(indices, folds)
    scores = []
    for k in range(folds):
        validation_indices = fold_indices[k]
        training_indices = torch.cat([
            fold_indices[j] for j in range(folds) if j != k
        ])
        model = model_factory()
        ...  # train only on training_indices
        score = evaluate_fold(model, dataset, validation_indices)
        scores.append(score)
    values = torch.tensor(scores, dtype=torch.float64)
    return {"scores": scores, "mean": ..., "std": ...}

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

10.9.7 Exercise 06 - Performance on Noisy Data

Part 1 - Why this matters

Real measurements contain sensor error, rounding, transmission artifacts, and other disturbances. A model that performs well only on perfectly clean inputs may fail as soon as it leaves the controlled training environment.

Noise testing should change one condition at a time and repeat random experiments. Otherwise, one lucky noise sample can be mistaken for genuine robustness or one unlucky sample can exaggerate weakness.

Part 2 - Technical concept and behavior

For clean input $\mathbf{x}$ and Gaussian perturbation:

$$\tilde{\mathbf{x}} = \mathbf{x} + \sigma\boldsymbol{\epsilon}, \qquad \boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$$

Performance degradation at level σ can be measured relative to the clean metric.

Part 3 - Hints and Helper

Evaluate a fixed model at several noise levels and several seeded trials per level. Do not add noise to protected identifier or categorical columns. Report mean metric, standard deviation, and degradation from the clean baseline.

Part 4 - Python code skeleton

```
import torch

def E06(model, X, target, noise_levels, trials, seed):
    model.eval()
    results = {}
    with torch.inference_mode():
        clean_prediction = model(X)
        clean_rmse = ...
        for level in noise_levels:
            trial_scores = []
            for trial in range(trials):
                generator = torch.Generator(device=X.device)
                generator.manual_seed(seed + trial)
                noise = torch.randn(
                    X.shape, generator=generator,
                    device=X.device, dtype=X.dtype
                )
                prediction = model(X + level * noise)
                trial_scores.append(...)
            results[level] = {"mean_rmse": ..., "std_rmse": ...}
    return {"clean_rmse": clean_rmse, "noise_results": results}

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

10.9.8 Exercise 07 - Performance Scaling with Data Size

Part 1 - Why this matters

A learning curve reveals whether additional training data is likely to improve a model. If validation error continues falling as the training set grows, more data may be valuable; if both errors remain high and close, model capacity or features may be the stronger limitation.

A fair experiment must keep the validation set and training procedure fixed while changing training size. Randomly changing every condition at once makes the source of improvement impossible to identify.

Part 2 - Technical concept and behavior

For nested training subsets:

$$D_1 \subset D_2 \subset \cdots \subset D_m$$

record training and validation metrics as functions of $|D_j|$. Repeated seeds provide uncertainty around each point.

Part 3 - Hints and Helper

Create one seeded ordering and use prefixes so subsets are nested. Reinitialize the model for every size and seed, keep the validation set fixed, and use the same epoch or update budget. Record runtime as well as accuracy.

Part 4 - Python code skeleton

```
import torch

def E07(train_dataset, validation_loader, sizes, seeds,
        model_factory, train_model, evaluate):
    records = []
    for seed in seeds:
        generator = torch.Generator().manual_seed(seed)
        order = torch.randperm(len(train_dataset), generator=generator)
        for size in sizes:
            subset_indices = order[:size]
            model = model_factory()
            ...  # train with a controlled budget
            metric = evaluate(model, validation_loader)
            records.append({
                "seed": seed,
                "training_size": int(size),
                "validation_metric": metric,
            })
    return records

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

10.9.9 Exercise 08 - Inference Throughput Test

Part 1 - Why this matters

Inference throughput measures how many samples a system processes per unit of time. It matters when predictions arrive in large batches or when a service must handle sustained demand.

A valid benchmark separates warm-up from measurement and accounts for asynchronous accelerator execution. It also records batch size, dtype, device, and total work because throughput numbers without conditions cannot be compared responsibly.

Part 2 - Mathematical definition

If N samples complete in elapsed time T:

$$\text{throughput} = \frac{N}{T} \quad \text{samples per second}$$

Several timed repetitions should be used after warm-up.

Part 3 - Hints and Helper

Set evaluation mode and disable gradients. Warm up the model, synchronize CUDA before starting and after finishing, use `time.perf_counter()`, and report both total throughput and benchmark conditions.

Part 4 - Python code skeleton

```
import time
import torch

def E08(model, X, warmup=10, repetitions=100):
    model.eval()
    device = X.device
    with torch.inference_mode():
        for _ in range(warmup):
            model(X)
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        start = time.perf_counter()
        for _ in range(repetitions):
            model(X)
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        elapsed = time.perf_counter() - start
    samples = X.shape[0] * repetitions
    return {"samples_per_second": ...,
            "elapsed_seconds": elapsed,
            "batch_size": X.shape[0],
            "device": str(device)}

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

10.9.10 Exercise 09 - Latency Profiling on CUDA

Part 1 - Why this matters

Latency measures the time required for an individual request or batch. A system may have high throughput but still respond too slowly for an interactive application, so throughput and latency must be evaluated separately.

CUDA operations are asynchronous with respect to the CPU. Measuring ordinary wall-clock time without synchronization can stop the timer before GPU work finishes and produce misleadingly small latency values.

Part 2 - Technical concept and behavior

For measured latencies $t_1, \ldots, t_R$, report more than the mean:

$$\bar{t} = \frac{1}{R} \sum_{r=1}^{R} t_r$$

Percentiles such as the median, p_{95}, and p_{99} expose tail behavior hidden by the mean.

Part 3 - Hints and Helper

Require a CUDA tensor and perform warm-up iterations. Create two CUDA events with timing enabled. Record both events, synchronize before reading elapsed time, and calculate percentiles from all repetitions.

Part 4 - Python code skeleton

```
import torch

def E09(model, X, warmup=20, repetitions=100):
    if X.device.type != "cuda":
        raise ValueError(...)
    model.eval()
    latencies_ms = []
    with torch.inference_mode():
        for _ in range(warmup):
            model(X)
        torch.cuda.synchronize(X.device)
        for _ in range(repetitions):
            start = torch.cuda.Event(enable_timing=True)
            end = torch.cuda.Event(enable_timing=True)
            start.record()
            model(X)
            end.record()
            torch.cuda.synchronize(X.device)
            latencies_ms.append(start.elapsed_time(end))
    values = torch.tensor(latencies_ms)
    return {"mean_ms": values.mean().item(),
            "p50_ms": ..., "p95_ms": ..., "p99_ms": ...}

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

10.9.11 Exercise 10 - Memory Usage Profiling

Part 1 - Why this matters

Memory limits determine which models, dtypes, and batch sizes can run on an accelerator. An evaluation may be numerically correct yet unusable because it exhausts memory or leaves too little capacity for concurrent requests.

PyTorch distinguishes memory occupied by live tensors from memory reserved by its caching allocator. Both current and peak values matter, and external tools may report reserved memory even after individual tensors are released.

Part 2 - Technical concept and behavior

For a controlled evaluation region, record:

$$M_{\text{allocated}}^{\text{peak}} \quad \text{and} \quad M_{\text{reserved}}^{\text{peak}}$$

The first describes tensor allocations tracked by PyTorch; the second describes memory managed by the caching allocator.

Part 3 - Hints and Helper

Require CUDA, complete warm-up first, synchronize, and reset the peak CUDA memory statistics. Measure baseline, current, and peak values. Do not treat cache clearing as a way to free memory still owned by live tensors.

Part 4 - Python code skeleton

```
import torch

def E10(model, X):
    if X.device.type != "cuda":
        raise ValueError(...)
    model.eval()
    with torch.inference_mode():
        model(X)
        torch.cuda.synchronize(X.device)
        baseline = torch.cuda.memory_allocated(X.device)
        torch.cuda.reset_peak_memory_stats(X.device)
        output = model(X)
        torch.cuda.synchronize(X.device)
        report = {
            "baseline_allocated_bytes": baseline,
            "current_allocated_bytes":
                torch.cuda.memory_allocated(X.device),
            "peak_allocated_bytes": ...,
            "peak_reserved_bytes": ...,
        }
    return report

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

10.9.12 Exercise 11 - Error Distribution Analysis

Part 1 - Why this matters

A single average metric hides how errors are distributed. Two models can share the same MAE while one makes consistent moderate errors and the other is usually accurate but occasionally fails catastrophically.

Examining signed and absolute errors reveals bias, spread, asymmetry, and extreme cases. This helps connect a numerical score to the actual behavior users may experience.

Part 2 - Mathematical definition

For residuals $r_i = \hat{y}_i - y_i$, useful summaries include:

$$\bar{r} = \frac{1}{N}\sum_{i=1}^{N} r_i, \qquad q_p(|r|) = p\text{th quantile of absolute error}$$

A positive mean residual indicates systematic overprediction under this sign convention.

Part 3 - Hints and Helper

Flatten and concatenate detached residuals from all batches. Report count, mean, standard deviation, minimum, maximum, and absolute-error quantiles. Also construct histogram counts with explicit bin boundaries.

Part 4 - Python code skeleton

```
import torch

def E11(model, loader, device, bins=20):
    model.eval()
    residual_parts = []
    with torch.inference_mode():
        for X, target in loader:
            X, target = X.to(device), target.to(device)
            residual = model(X) - target
            residual_parts.append(residual.detach().cpu().reshape(-1))
    residuals = torch.cat(residual_parts)
    absolute = residuals.abs()
    histogram = torch.histogram(residuals, bins=bins)
    return {
        "count": residuals.numel(),
        "mean_residual": residuals.mean().item(),
        "std_residual": ...,
        "absolute_q50": torch.quantile(absolute, 0.50).item(),
        "absolute_q95": ...,
        "histogram_counts": histogram.hist.tolist(),
        "histogram_edges": histogram.bin_edges.tolist(),
    }

def main():
```

```
    print(E11(...))

if __name__ == "__main__":
    main()
```

10.9.13 Exercise 12 - Residual Analysis

Part 1 - Why this matters

Residual analysis checks whether the remaining errors look random or still contain structure the model failed to learn. Trends, curves, changing variance, or clusters in residuals can reveal missing features, an unsuitable model form, or data quality problems.

Linear regression assumptions cannot be judged from training loss alone. Residuals should be examined against predictions and important inputs, while remembering that visual or correlation evidence is diagnostic rather than a complete statistical proof.

Part 2 - Technical concept and behavior

The residual is defined as:

$$r_i = y_i - \hat{y}_i$$

A desirable residual pattern is centered near zero without a systematic relationship to fitted values or relevant features.

Part 3 - Hints and Helper

Collect targets, predictions, and inputs in the same order. Compute residual mean and correlations with predictions and each feature. Divide predictions into bins and compare the residual mean and variance inside each bin.

Part 4 - Python code skeleton

```
import torch

def correlation(a, b):
    a = a - a.mean()
    b = b - b.mean()
    return (a * b).sum() / ...

def E12(model, X, target, bin_count=10):
    model.eval()
    with torch.inference_mode():
        prediction = model(X)
    residual = target - prediction
    flat_prediction = prediction.reshape(-1).double()
    flat_residual = residual.reshape(-1).double()
    edges = torch.linspace(
        flat_prediction.min(), flat_prediction.max(),
        bin_count + 1, device=flat_prediction.device
```

```
    )
    bin_summary = []
    for index in range(bin_count):
        mask = ...
        bin_summary.append({
            "count": int(mask.sum()),
            "mean_residual": ...,
            "residual_std": ...,
        })
    return {"mean_residual": flat_residual.mean().item(),
            "prediction_correlation":
                correlation(flat_prediction, flat_residual).item(),
            "bins": bin_summary}

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

10.9.14 Exercise 13 - Model Robustness Test

Part 1 - Why this matters

Robustness describes whether model behavior remains acceptable when inputs differ slightly from ideal evaluation data. Small measurement changes, feature dropout, or bounded shifts should not cause uncontrolled prediction changes.

A robustness test must define realistic perturbations and acceptance limits. Arbitrary extreme corruption measures failure outside the intended operating range and may say little about the model's practical reliability.

Part 2 - Technical concept and behavior

For perturbation $\boldsymbol{\delta}$ bounded by ϵ:

$$\|\boldsymbol{\delta}\|_\infty \leq \epsilon$$

measure both metric degradation and prediction sensitivity:

$$S = \frac{\|f(\mathbf{x} + \boldsymbol{\delta}) - f(\mathbf{x})\|}{\|\boldsymbol{\delta}\| + \eta}$$

where η prevents division by zero.

Part 3 - Hints and Helper

Define several domain-relevant perturbation functions, preserve immutable features, and evaluate them on the same examples. Report clean score, perturbed score, degradation, maximum prediction shift, and pass or fail against explicit thresholds.

Part 4 - Python code skeleton

```
import torch

def E13(model, X, target, perturbations, max_degradation):
    model.eval()
    results = {}
    with torch.inference_mode():
        clean_prediction = model(X)
        clean_rmse = torch.sqrt(
            torch.mean((clean_prediction - target) ** 2)
        ).item()
        for name, transform in perturbations.items():
            changed_X = transform(X.clone())
            changed_prediction = model(changed_X)
            changed_rmse = ...
            shift = (changed_prediction - clean_prediction).abs()
            degradation = changed_rmse - clean_rmse
            results[name] = {
                "rmse": changed_rmse,
                "degradation": degradation,
                "max_prediction_shift": shift.max().item(),
                "passed": degradation <= ...,
            }
    return {"clean_rmse": clean_rmse, "tests": results}

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

10.9.15 Exercise 14 - Performance Regression Detection

Part 1 - Why this matters

A code or model update can silently reduce accuracy, throughput, or memory efficiency. Performance regression testing converts known acceptable behavior into automated checks before a new version is accepted.

Thresholds must reflect measurement noise and metric direction. Lower RMSE is better, higher throughput is better, and benchmark variability means exact equality is usually an inappropriate requirement.

Part 2 - Technical concept and behavior

For a lower-is-better metric with baseline b, candidate c, and allowed relative increase τ:

$$\frac{c - b}{|b| + \epsilon} \leq \tau$$

Higher-is-better metrics require the corresponding allowed relative decrease rule.

Part 3 - Hints and Helper

Store baseline values with hardware and configuration metadata. Repeat timing tests and compare robust summaries such as medians. Define metric direction and tolerance in a specification rather than hard-coding one rule for every value.

Part 4 - Python code skeleton

```
def E14(baseline, candidate, specification, epsilon=1e-12):
    checks = {}
    for metric, rule in specification.items():
        old = baseline[metric]
        new = candidate[metric]
        relative_change = (new - old) / (abs(old) + epsilon)
        if rule["direction"] == "lower":
            passed = relative_change <= rule["tolerance"]
        elif rule["direction"] == "higher":
            passed = relative_change >= -rule["tolerance"]
        else:
            raise ValueError(...)
        checks[metric] = {
            "baseline": old,
            "candidate": new,
            "relative_change": relative_change,
            "passed": ...,
        }
    return {"passed": all(x["passed"] for x in checks.values()),
            "checks": checks}

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

10.9.16 Exercise 15 - GPU Utilization Monitoring

Part 1 - Why this matters

A CUDA workload can be slower than expected even when the model is correct. Low utilization may indicate tiny batches, input pipeline delays, excessive synchronization, or CPU work that leaves the GPU waiting.

Utilization is a sampled system measurement rather than an exact per-operation property. The sampling interval and other processes on the same device must be recorded before conclusions are drawn.

Part 2 - Technical concept and behavior

For utilization samples $u_1, \ldots, u_m$ expressed as percentages, summarize:

$$\bar{u} = \frac{1}{m} \sum_{j=1}^{m} u_j$$

Also report minimum, maximum, sample count, throughput, and device identity.

Part 3 - Hints and Helper

Check CUDA availability and warm up the workload. Sample CUDA utilization while repeated inference is active, not only after it finishes. Handle unsupported monitoring environments clearly instead of inventing a zero value.

Part 4 - Python code skeleton

```
import threading
import time
import torch

def E15(model, X, repetitions=500, interval=0.1):
    if X.device.type != "cuda":
        raise ValueError(...)
    samples = []
    stop = threading.Event()

    def monitor():
        while not stop.is_set():
            samples.append(torch.cuda.utilization(X.device))
            time.sleep(interval)

    worker = threading.Thread(target=monitor)
    model.eval()
    worker.start()
    try:
        with torch.inference_mode():
            for _ in range(repetitions):
                model(X)
        torch.cuda.synchronize(X.device)
    finally:
        stop.set()
        worker.join()
    values = torch.tensor(samples, dtype=torch.float32)
    return {"mean_utilization_percent": ...,
            "minimum_percent": ..., "maximum_percent": ...,
            "samples": len(samples)}

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

10.9.17 Exercise 16 - Metric Precision Comparison

Part 1 - Why this matters

Floating-point dtype affects metric values because reductions combine many finite-precision operations. Differences are often small, but they can matter when errors are extremely large, extremely small, or close to a release threshold.

A precision comparison should use identical prediction data cast to different dtypes. Re-running the full model in different dtypes mixes metric-reduction effects with possible changes in model computation.

Part 2 - Technical concept and behavior

For a metric computed in two dtypes:

$$\Delta_{\text{abs}} = |M_{64} - M_{32}|, \qquad \Delta_{\text{rel}} = \frac{|M_{64} - M_{32}|}{|M_{64}| + \epsilon}$$

Float64 is useful as a higher-precision comparison, not an assumption of exact arithmetic.

Part 3 - Hints and Helper

Create one set of predictions and targets, detach them, then compute MAE and RMSE in float32 and float64. Test ordinary, large-magnitude, and small-error cases. Report absolute and relative differences.

Part 4 - Python code skeleton

```
import torch

def metrics(prediction, target, dtype):
    error = prediction.to(dtype) - target.to(dtype)
    return {
        "mae": error.abs().mean().item(),
        "rmse": torch.sqrt((error ** 2).mean()).item(),
    }

def E16(prediction, target, epsilon=1e-15):
    fp32 = metrics(prediction.detach(), target.detach(), torch.float32)
    fp64 = metrics(prediction.detach(), target.detach(), torch.float64)
    differences = {}
    for name in fp32:
        absolute = abs(fp64[name] - fp32[name])
        differences[name] = {
            "absolute": absolute,
            "relative": absolute / (... + epsilon),
        }
    return {"float32": fp32, "float64": fp64,
            "differences": differences}

def main():
```

```
    print(E16(...))

if __name__ == "__main__":
    main()
```

10.9.18 Exercise 17 - Evaluation Pipeline Automation

Part 1 - Why this matters

An automated evaluation pipeline applies the same data handling, model state, metrics, and benchmark rules to every model candidate. This reduces manual mistakes and makes results reproducible enough to compare over time.

Automation also creates evidence. A useful output contains configuration, environment, dataset identity, metric definitions, sample counts, and failures rather than only one final score.

Part 2 - Technical concept and behavior

A pipeline can be viewed as a deterministic mapping:

$$(\text{model}, \text{dataset}, \text{configuration}) \longrightarrow (\text{metrics}, \text{diagnostics}, \text{metadata})$$

Each stage should validate its inputs and return a structured result.

Part 3 - Hints and Helper

Separate data validation, metric evaluation, robustness checks, and speed benchmarks into functions. Use one configuration dictionary, fixed seeds, and a stable result schema. Capture exceptions per optional check while failing immediately on invalid core metrics.

Part 4 - Python code skeleton

```
import platform
import time
import torch

def E17(model, loader, device, config):
    started = time.time()
    report = {
        "metadata": {
            "torch_version": torch.__version__,
            "python": platform.python_version(),
            "device": str(device),
            "seed": config["seed"],
        },
        "metrics": {},
        "diagnostics": {},
        "status": "running",
    }
    try:
        ...  # validate data and model output
```

```
        report["metrics"]["rmse"] = ...
        report["metrics"]["mae"] = ...
        report["diagnostics"]["residuals"] = ...
        report["status"] = "passed"
    except Exception as error:
        report["status"] = "failed"
        report["error"] = {"type": type(error).__name__,
                           "message": str(error)}
    report["duration_seconds"] = time.time() - started
    return report

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

10.9.19 Exercise 18 - Evaluation Failure Debugging

Part 1 - Why this matters

Evaluation can fail through shape broadcasting, device mismatch, non-finite values, empty loaders, incorrect model mode, or biased batch aggregation. Some of these bugs produce plausible numbers instead of exceptions, making structured debugging essential.

The debugging goal is to locate the first broken invariant. Checking inputs, outputs, and accumulators batch by batch is more informative than modifying several parts of the pipeline at once.

Part 2 - Technical concept and behavior

Before metric accumulation, require:

$$\text{shape}(\hat{\mathbf{y}}) = \text{shape}(\mathbf{y}), \qquad \text{isfinite}(\hat{\mathbf{y}}) = \text{True}$$

Device, dtype, batch count, and accumulated element count should also be validated.

Part 3 - Hints and Helper

Return a diagnostic record containing the failing stage and batch index. Check loader emptiness, evaluation mode, devices, shapes, finiteness, and accumulator counts in a fixed order. Never silently reshape predictions merely to make an error disappear.

Part 4 - Python code skeleton

```
import torch

def E18(model, loader, device):
    model.eval()
    diagnostics = {"batches": 0, "elements": 0, "errors": []}
    with torch.inference_mode():
```

```
        for batch_index, (X, target) in enumerate(loader):
            diagnostics["batches"] += 1
            try:
                X, target = X.to(device), target.to(device)
                prediction = model(X)
                if prediction.shape != target.shape:
                    raise ValueError(
                        f"shape mismatch: {prediction.shape} vs "
                        f"{target.shape}"
                    )
                if not torch.isfinite(prediction).all():
                    raise FloatingPointError(...)
                diagnostics["elements"] += prediction.numel()
                ...
            except Exception as error:
                diagnostics["errors"].append({
                    "batch": batch_index,
                    "type": type(error).__name__,
                    "message": str(error),
                })
                break
    if diagnostics["batches"] == 0:
        diagnostics["errors"].append({"type": "EmptyLoader", ...})
    return diagnostics

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

10.9.20 Exercise 19 - Final Evaluation Report

Part 1 - Why this matters

A final report turns disconnected measurements into a decision-ready description of model quality and operational behavior. It should state what was evaluated, under which conditions, and where the model fails, not simply announce that performance is good.

The report must preserve both strengths and limitations. Accuracy, residual behavior, robustness, latency, throughput, and memory answer different questions and should remain separately visible before an overall conclusion is made.

Part 2 - Technical concept and behavior

A complete report combines:

$$R = \{\text{data}, \text{metrics}, \text{residuals}, \text{robustness}, \text{performance}, \text{decision}\}$$

The final decision should follow explicit acceptance criteria and identify every failed check.

Part 3 - Hints and Helper

Build the report from structured outputs of earlier exercises. Include sample counts, RMSE, MAE, error quantiles, robustness results, latency percentiles, throughput, peak memory, configuration, and warnings. Save machine-readable data separately from the human summary.

Part 4 - Python code skeleton

```
import json
from datetime import datetime, timezone

def E19(model_name, dataset_name, results, acceptance):
    checks = {
        "rmse": results["metrics"]["rmse"] <= acceptance["max_rmse"],
        "mae": results["metrics"]["mae"] <= acceptance["max_mae"],
        "p95_latency": (
            results["performance"]["p95_latency_ms"]
            <= acceptance["max_p95_latency_ms"]
        ),
        "robustness": ...,
    }
    report = {
        "generated_at": datetime.now(timezone.utc).isoformat(),
        "model": model_name,
        "dataset": dataset_name,
        "results": results,
        "acceptance_checks": checks,
        "decision": "accepted" if all(checks.values()) else "rejected",
        "failed_checks": [name for name, passed in checks.items()
                          if not passed],
    }
    return report

def main():
    report = E19(...)
    print(json.dumps(report, indent=2))

if __name__ == "__main__":
    main()
```

10.10 LR08 - Result Visualization and Interpretation

Models and Training

10.10.1 Exercise 00 - Plot Predictions vs Targets

Part 1 - Why this matters

A predictions-versus-targets plot shows whether a regression model follows the correct scale and direction across the evaluation set. Points near the identity line indicate close agreement, while systematic displacement can reveal bias or calibration problems.

The graph must preserve equal meaning on both axes. Unequal limits or an incorrect reference line can visually exaggerate good performance, so the plotted range should be computed from both targets and predictions.

Part 2 - Visual and mathematical interpretation

For a perfect prediction:

$$\hat{y}_i = y_i$$

Therefore, the reference line is $y = x$. Vertical distance from this line represents the signed prediction error under the plotted coordinate convention.

Part 3 - Hints and Helper

Evaluate the model without gradients, flatten predictions and targets, move only detached values to CPU, and create a scatter plot. Use common minimum and maximum limits, equal axis scaling, labels, a legend, and a descriptive title.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E00(model, loader, device, output_path):
    model.eval()
    predictions, targets = [], []
    with torch.inference_mode():
        for X, target in loader:
            prediction = model(X.to(device))
            predictions.append(prediction.detach().cpu().reshape(-1))
            targets.append(target.detach().cpu().reshape(-1))
    prediction = torch.cat(predictions)
    target = torch.cat(targets)
    lower = torch.minimum(prediction.min(), target.min()).item()
    upper = ...
    fig, ax = plt.subplots()
    ax.scatter(target.numpy(), prediction.numpy(), alpha=0.5)
    ax.plot([lower, upper], [lower, upper], "--", label="Ideal")
    ax.set(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E00(...)

if __name__ == "__main__":
    main()
```

10.10.2 Exercise 01 - Plot Loss Curve

Part 1 - Why this matters

A loss curve shows how optimization develops across epochs. It can reveal rapid improvement, slow learning, plateaus, instability, or divergence that would be hidden by reporting only the final loss.

Training and validation loss should be shown together when available. Their separation helps distinguish optimization progress from generalization, but only if both series use the same metric definition and epoch alignment.

Part 2 - Visual and mathematical interpretation

For epoch index t, plot:

$$(t, \mathcal{L}_{\text{train},t}) \quad \text{and} \quad (t, \mathcal{L}_{\text{validation},t})$$

A logarithmic vertical scale may clarify changes across several orders of magnitude, but it requires strictly positive values.

Part 3 - Hints and Helper

Validate that histories have equal, nonzero length. Start epoch labels at one, add labels and a legend, and optionally support a logarithmic scale. Mark the epoch with the lowest validation loss.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E01(train_loss, validation_loss, output_path, log_scale=False):
    train = torch.as_tensor(train_loss, dtype=torch.float64)
    validation = torch.as_tensor(validation_loss, dtype=torch.float64)
    if train.shape != validation.shape or train.numel() == 0:
        raise ValueError(...)
    epochs = torch.arange(1, train.numel() + 1)
    best = int(validation.argmin())
    fig, ax = plt.subplots()
    ax.plot(epochs.numpy(), train.numpy(), label="Train")
    ax.plot(epochs.numpy(), validation.numpy(), label="Validation")
    ax.scatter(..., label="Best validation")
    if log_scale:
        ax.set_yscale("log")
    ax.set(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E01(...)
```

```
if __name__ == "__main__":
    main()
```

10.10.3 Exercise 02 - Plot Residuals

Part 1 - Why this matters

A residual plot tests whether prediction errors contain patterns that the model did not learn. Curvature, clusters, or changing spread can indicate nonlinearity, missing variables, unequal variance, or problematic observations.

Residual plots support diagnosis rather than automatic proof. A visible pattern suggests a question to investigate, while a random-looking plot does not guarantee that every modeling assumption is satisfied.

Part 2 - Visual and mathematical interpretation

Using residual definition:

$$r_i = y_i - \hat{y}_i$$

plot $(\hat{y}_i, r_i)$ and add the horizontal reference $r = 0$. Balanced points around zero are preferable to a systematic positive or negative band.

Part 3 - Hints and Helper

Detach and move prediction and target tensors to CPU before plotting. Use transparency for overlapping points, include the zero line, and report residual mean in the title or returned metadata.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E02(prediction, target, output_path):
    prediction = prediction.detach().cpu().reshape(-1)
    target = target.detach().cpu().reshape(-1)
    if prediction.shape != target.shape:
        raise ValueError(...)
    residual = target - prediction
    fig, ax = plt.subplots()
    ax.scatter(prediction.numpy(), residual.numpy(),
               alpha=0.5, s=16)
    ax.axhline(0.0, color="black", linestyle="--")
    ax.set_xlabel(...)
    ax.set_ylabel(...)
    ax.set_title(f"Residual mean: {residual.mean().item():.4f}")
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"mean_residual": ..., "count": residual.numel()}
```

```
def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

10.10.4 Exercise 03 - Visualization with Large Batches

Part 1 - Why this matters

Plotting millions of points can consume excessive memory, produce an unreadable solid region, and make figure generation slower than model evaluation. A visualization should preserve the important distribution without displaying every observation.

Sampling must be explicit and reproducible. Selecting only the first batch can introduce ordering bias, while random sampling without a recorded seed makes figures difficult to compare.

Part 2 - Technical concept and behavior

For N available points and budget $M < N$, select indices:

$$I \subset \{1, \ldots, N\}, \qquad |I| = M$$

The sample should represent the full evaluation stream or use aggregation such as bins when density itself is important.

Part 3 - Hints and Helper

Use reservoir sampling or collect a seeded random subset after concatenation when memory allows. State the total and displayed counts in the title. Consider a two-dimensional histogram instead of scatter for very dense data.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E03(prediction, target, max_points, seed, output_path):
    prediction = prediction.detach().cpu().reshape(-1)
    target = target.detach().cpu().reshape(-1)
    total = prediction.numel()
    generator = torch.Generator().manual_seed(seed)
    if total > max_points:
        indices = torch.randperm(total, generator=generator)[:max_points]
    else:
        indices = torch.arange(total)
    shown_prediction = prediction[indices]
    shown_target = ...
    fig, ax = plt.subplots()
    ax.scatter(shown_target.numpy(), shown_prediction.numpy(),
```

```
                s=8, alpha=0.25)
    ax.set_title(f"Displayed {indices.numel()} of {total} points")
    ax.set(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E03(...)

if __name__ == "__main__":
    main()
```

10.10.5 Exercise 04 - CPU vs GPU Visualization Parity

Part 1 - Why this matters

Model predictions may be computed on CPU or CUDA, but the final visual interpretation should remain consistent within a justified numerical tolerance. A device-specific mismatch can reveal dtype, model-state, checkpoint, or data-transfer mistakes.

Exact equality is usually the wrong requirement for floating-point computation across devices. The comparison should measure numerical differences first, then verify that both plots use identical samples, limits, and styling.

Part 2 - Technical concept and behavior

For CPU and GPU predictions:

$$\Delta_{\max} = \max_i |\hat{y}_i^{\mathrm{CPU}} - \hat{y}_i^{\mathrm{GPU}}|$$

Parity passes when the selected absolute and relative tolerances are satisfied and both plotted datasets are aligned.

Part 3 - Hints and Helper

Create equivalent model copies with the same state dictionary, use evaluation mode and no gradients, and bring both outputs to CPU. Use `torch.allclose` before drawing their difference plot.

Part 4 - Python code skeleton

```
import copy
import matplotlib.pyplot as plt
import torch

def E04(model, X, output_path, atol=1e-5, rtol=1e-4):
    if not torch.cuda.is_available():
        return {"skipped": ...}
    cpu_model = copy.deepcopy(model).cpu().eval()
    gpu_model = copy.deepcopy(model).cuda().eval()
    with torch.inference_mode():
```

```
        cpu_prediction = cpu_model(X.cpu()).cpu()
        gpu_prediction = gpu_model(X.cuda()).cpu()
    difference = (cpu_prediction - gpu_prediction).reshape(-1)
    parity = torch.allclose(
        cpu_prediction, gpu_prediction, atol=atol, rtol=rtol
    )
    fig, ax = plt.subplots()
    ax.plot(difference.numpy())
    ax.axhline(0.0, color="black", linestyle="--")
    ax.set(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"parity": parity, "maximum_difference": ...}

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

10.10.6 Exercise 05 - Visualize Convergence Speed

Part 1 - Why this matters

Convergence speed describes how quickly training reaches a useful performance level, not merely which run has the lowest final loss. Visualizing it helps compare optimizers, learning rates, and initialization choices under controlled budgets.

Epoch count alone can be misleading when configurations process data at different speeds. A complete view can compare loss against epochs, optimizer steps, and elapsed training time.

Part 2 - Visual and mathematical interpretation

For threshold τ, define time to target:

$$t_\tau = \min\{t : \mathcal{L}_t \leq \tau\}$$

If the threshold is never reached, the report should mark it as unreached rather than substitute the final epoch.

Part 3 - Hints and Helper

Accept aligned loss and elapsed-time histories for several runs. Plot each run with a distinct label, draw the threshold, and mark the first crossing. Do not compare runs trained on different data splits without stating it.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch
```

```
def E05(run_histories, threshold, output_path):
    fig, ax = plt.subplots()
    summary = {}
    for name, history in run_histories.items():
        times = torch.as_tensor(history["seconds"])
        losses = torch.as_tensor(history["loss"])
        if times.shape != losses.shape:
            raise ValueError(...)
        ax.plot(times.numpy(), losses.numpy(), label=name)
        reached = torch.nonzero(losses <= threshold).reshape(-1)
        first = int(reached[0]) if reached.numel() else None
        summary[name] = {
            "time_to_threshold": None if first is None
            else times[first].item()
        }
        if first is not None:
            ax.scatter(... )
    ax.axhline(threshold, color="black", linestyle="--")
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return summary

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

10.10.7 Exercise 06 - Hyperparameter Impact Plot

Part 1 - Why this matters

Hyperparameters influence accuracy, stability, speed, and resource use. A structured plot helps reveal useful ranges and tradeoffs that are difficult to understand from a table of isolated experiments.

The horizontal axis must represent the actual parameter scale. Learning rates spanning several powers of ten are usually clearer on a logarithmic axis, while categorical settings require discrete positions.

Part 2 - Visual and mathematical interpretation

For hyperparameter value λ_j and repeated score $M_{j,r}$, plot:

$$\bar{M}_j = \frac{1}{R}\sum_{r=1}^{R} M_{j,r}$$

with uncertainty such as standard deviation across runs rather than showing only the best trial.

Part 3 - Hints and Helper

Group records by hyperparameter value, compute mean and standard deviation, and use error bars. Preserve all failed trials in the metadata. Label whether a lower or higher metric is better.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E06(records, parameter_name, metric_name, output_path,
        logarithmic_x=False):
    grouped = {}
    for record in records:
        grouped.setdefault(record[parameter_name], []).append(
            record[metric_name]
        )
    values = sorted(grouped)
    means, deviations = [], []
    for value in values:
        scores = torch.tensor(grouped[value], dtype=torch.float64)
        means.append(scores.mean().item())
        deviations.append(scores.std(unbiased=False).item())
    fig, ax = plt.subplots()
    ax.errorbar(values, means, yerr=deviations, marker="o")
    if logarithmic_x:
        ax.set_xscale("log")
    ax.set_xlabel(...)
    ax.set_ylabel(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E06(...)

if __name__ == "__main__":
    main()
```

10.10.8 Exercise 07 - Data Noise Visualization

Part 1 - Why this matters

Noise visualization shows how observed data deviates from an underlying relationship and how that disturbance affects fitted predictions. It can separate model limitations from irreducible variation in the measurements.

The graph should distinguish clean signal, noisy observations, and model output. Mixing them with identical styling or plotting unrelated samples can create a false impression of agreement.

Part 2 - Visual and mathematical interpretation

A synthetic noisy target may follow:

$$y_i = wx_i + b + \epsilon_i, \qquad \epsilon_i \sim \mathcal{N}(0, \sigma^2)$$

Increasing σ widens the observations around the clean line without changing the intended slope or intercept.

Part 3 - Hints and Helper

Sort one-dimensional inputs before drawing lines, but keep scatter points paired with their targets. Use a fixed random seed and shared inputs across noise levels. Include σ in labels or titles.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E07(X, clean_target, noisy_targets, prediction, output_path):
    x = X.detach().cpu().reshape(-1)
    clean = clean_target.detach().cpu().reshape(-1)
    predicted = prediction.detach().cpu().reshape(-1)
    order = torch.argsort(x)
    fig, ax = plt.subplots()
    ax.plot(x[order].numpy(), clean[order].numpy(),
            label="Clean relationship")
    ax.plot(x[order].numpy(), predicted[order].numpy(),
            label="Model prediction")
    for label, noisy_target in noisy_targets.items():
        noisy = noisy_target.detach().cpu().reshape(-1)
        ax.scatter(x.numpy(), noisy.numpy(), s=10, alpha=0.25,
                   label=...)
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E07(...)

if __name__ == "__main__":
    main()
```

10.10.9 Exercise 08 - Error Distribution Plot

Part 1 - Why this matters

An error-distribution plot reveals center, spread, asymmetry, and tails that a single average metric cannot show. It helps identify whether most predictions are acceptable while a small

group produces severe failures.

Histogram appearance depends on bin boundaries and count normalization. The chosen bins must therefore be stated, and comparisons between datasets should use consistent boundaries or density definitions.

Part 2 - Visual and mathematical interpretation

For residuals $r_i = y_i - \hat{y}_i$, the empirical histogram estimates how frequently residuals fall inside intervals:

$$c_j = \sum_{i=1}^{N} \mathbf{1}[a_j \leq r_i < a_{j+1}]$$

The zero reference identifies unbiased error under this residual convention.

Part 3 - Hints and Helper

Validate finite residuals, use explicit shared bin edges, add a zero line, and mark the mean and median. Report extreme quantiles beside the figure instead of trimming them silently.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E08(prediction, target, bin_count, output_path):
    residual = (
        target.detach().cpu().reshape(-1)
        - prediction.detach().cpu().reshape(-1)
    )
    if not torch.isfinite(residual).all():
        raise ValueError(...)
    mean = residual.mean().item()
    median = residual.median().item()
    fig, ax = plt.subplots()
    ax.hist(residual.numpy(), bins=bin_count, alpha=0.75)
    ax.axvline(0.0, color="black", linestyle="--", label="Zero")
    ax.axvline(mean, label="Mean")
    ax.axvline(median, label="Median")
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"mean": mean, "median": median, "q95_absolute": ...}

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

10.10.10 Exercise 09 - Visualization Performance Cost

Part 1 - Why this matters

Visualization has its own computational cost: device-to-host transfer, tensor conversion, figure construction, rendering, and file writing. If these steps occur inside a training loop, they can reduce throughput or force unwanted synchronization.

Measuring the entire operation as one block cannot identify the bottleneck. Separating collection, transfer, rendering, and saving makes optimization decisions evidence-based.

Part 2 - Technical concept and behavior

Total visualization time can be decomposed as:

$$T_{\text{total}} = T_{\text{transfer}} + T_{\text{prepare}} + T_{\text{render}} + T_{\text{save}}$$

Peak host memory and output file size are additional practical costs.

Part 3 - Hints and Helper

Synchronize CUDA before and after timing a transfer. Use `time.perf_counter()` for host stages, compare several point budgets, close every figure, and keep image settings constant.

Part 4 - Python code skeleton

```
import time
import matplotlib.pyplot as plt
import torch

def E09(prediction, target, output_path):
    if prediction.device.type == "cuda":
        torch.cuda.synchronize(prediction.device)
    start = time.perf_counter()
    cpu_prediction = prediction.detach().cpu()
    cpu_target = target.detach().cpu()
    if prediction.device.type == "cuda":
        torch.cuda.synchronize(prediction.device)
    transfer_seconds = time.perf_counter() - start

    render_start = time.perf_counter()
    fig, ax = plt.subplots()
    ax.scatter(cpu_target.numpy(), cpu_prediction.numpy(), s=4)
    fig.canvas.draw()
    render_seconds = ...
    save_start = time.perf_counter()
    fig.savefig(output_path, dpi=150)
    save_seconds = ...
    plt.close(fig)
    return {"transfer_seconds": transfer_seconds,
            "render_seconds": render_seconds,
            "save_seconds": save_seconds}
```

```
def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

10.10.11 Exercise 10 - Interactive Visualization

Part 1 - Why this matters

Interactive controls let the reader explore how slope, bias, noise, or another parameter changes predictions without regenerating a separate static figure for every value. This makes sensitivity and model behavior easier to understand through direct experimentation.

Interaction must preserve a defined mathematical relationship. A callback should update the existing plotted objects and labels rather than create new lines repeatedly, which would leak memory and clutter the axes.

Part 2 - Visual and mathematical interpretation

For a linear model controlled by sliders:

$$\hat{y}(x; w, b) = wx + b$$

Changing w rotates the line, while changing b shifts it vertically. Fixed axis limits make these changes visually comparable.

Part 3 - Hints and Helper

Use Matplotlib's `Slider`, reserve space for controls, and keep a reference to the prediction line. In each callback, call `set_ydata` and request a canvas redraw. Provide a reset control if desired.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
from matplotlib.widgets import Slider
import torch

def E10(X, target, initial_weight, initial_bias):
    x = X.detach().cpu().reshape(-1)
    y = target.detach().cpu().reshape(-1)
    order = torch.argsort(x)
    fig, ax = plt.subplots()
    fig.subplots_adjust(bottom=0.25)
    ax.scatter(x.numpy(), y.numpy(), alpha=0.4)
    initial = initial_weight * x[order] + initial_bias
    line, = ax.plot(x[order].numpy(), initial.numpy())
    weight_axis = fig.add_axes([0.2, 0.10, 0.65, 0.03])
    bias_axis = fig.add_axes([0.2, 0.05, 0.65, 0.03])
```

```
    weight_slider = Slider(weight_axis, "Weight", -5.0, 5.0,
                           valinit=initial_weight)
    bias_slider = Slider(bias_axis, "Bias", -5.0, 5.0,
                         valinit=initial_bias)

    def update(_):
        new_y = ...
        line.set_ydata(new_y.numpy())
        fig.canvas.draw_idle()

    weight_slider.on_changed(update)
    bias_slider.on_changed(update)
    plt.show()

def main():
    E10(...)

if __name__ == "__main__":
    main()
```

10.10.12 Exercise 11 - Visualization from Checkpoints

Part 1 - Why this matters

Checkpoint visualization shows how a model's predictions and parameters changed during training. It can reveal whether progress was smooth, whether later epochs became unstable, or whether several checkpoints produce nearly identical behavior.

Checkpoint files must be aligned with their epoch metadata and loaded safely. A graph using mislabeled or incompatible states creates a false training story even if every individual file loads successfully.

Part 2 - Technical concept and behavior

For checkpoints at epochs $t_1, \ldots, t_k$, compare:

$$f(\mathbf{x}; \boldsymbol{\theta}_{t_1}), \ldots, f(\mathbf{x}; \boldsymbol{\theta}_{t_k})$$

using the same input values, preprocessing, model architecture, and plotting limits.

Part 3 - Hints and Helper

Load only trusted checkpoints, map storage to CPU, validate required keys, and reuse one model factory. Sort checkpoints by stored epoch rather than filename. Plot a limited number of representative epochs if the directory is large.

Part 4 - Python code skeleton

```
from pathlib import Path
import matplotlib.pyplot as plt
import torch
```

```
def E11(checkpoint_paths, model_factory, X, output_path):
    x = X.detach().cpu()
    order = torch.argsort(x.reshape(-1))
    curves = []
    for path in checkpoint_paths:
        checkpoint = torch.load(
            Path(path), map_location="cpu", weights_only=True
        )
        if "model_state" not in checkpoint or "epoch" not in checkpoint:
            raise KeyError(...)
        model = model_factory().cpu()
        model.load_state_dict(checkpoint["model_state"])
        model.eval()
        with torch.inference_mode():
            prediction = model(x).reshape(-1)
        curves.append((int(checkpoint["epoch"]), prediction))
    curves.sort(key=lambda item: item[0])
    fig, ax = plt.subplots()
    for epoch, prediction in curves:
        ax.plot(x.reshape(-1)[order].numpy(),
                prediction[order].numpy(), label=f"Epoch {epoch}")
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E11(...)

if __name__ == "__main__":
    main()
```

10.10.13 Exercise 12 - Multi-Run Comparison Plot

Part 1 - Why this matters

Training results vary with initialization, data order, and stochastic operations. Comparing only one run can make an unstable method appear reliable or hide a configuration that succeeds only occasionally.

A multi-run plot should preserve individual variability while also showing a central trend. Mean lines without uncertainty bands can imply confidence that the experiment did not establish.

Part 2 - Visual and mathematical interpretation

For loss from run r at epoch t:

$$\bar{\mathcal{L}}_t = \frac{1}{R}\sum_{r=1}^{R}\mathcal{L}_{r,t}, \qquad s_t = \sqrt{\frac{1}{R}\sum_{r=1}^{R}(\mathcal{L}_{r,t} - \bar{\mathcal{L}}_t)^2}$$

The band $\bar{\mathcal{L}}_t \pm s_t$ summarizes variation, not a confidence interval unless defined accordingly.

Part 3 - Hints and Helper

Require aligned epoch histories or explicitly truncate to a shared range. Draw individual runs with low opacity, then the mean and standard-deviation band. Keep seeds and experimental settings in returned metadata.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E12(run_losses, output_path):
    lengths = {len(losses) for losses in run_losses.values()}
    if len(lengths) != 1:
        raise ValueError(...)
    names = list(run_losses)
    matrix = torch.tensor(
        [run_losses[name] for name in names], dtype=torch.float64
    )
    epochs = torch.arange(1, matrix.shape[1] + 1)
    mean = matrix.mean(dim=0)
    deviation = matrix.std(dim=0, unbiased=False)
    fig, ax = plt.subplots()
    for name, losses in zip(names, matrix):
        ax.plot(epochs.numpy(), losses.numpy(),
                alpha=0.2, label=f"Run {name}")
    ax.plot(epochs.numpy(), mean.numpy(), linewidth=2, label="Mean")
    ax.fill_between(epochs.numpy(), (mean - deviation).numpy(),
                    (mean + deviation).numpy(), alpha=0.2)
    ax.set(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"final_mean": ..., "final_std": ...}

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

10.10.14 Exercise 13 - Visualization Bug Debugging

Part 1 - Why this matters

A visualization bug can reverse axes, break sample alignment, hide non-finite values, apply an accidental sort, or reuse stale figure state. The resulting image may still look convincing, making it more dangerous than a clear exception.

Debugging should verify the data lineage before adjusting colors or labels. Every displayed coordinate must be traceable to the same sample and to the tensor values intended for that axis.

Part 2 - Technical concept and behavior

For paired data, preserve the invariant:

$$(\text{target}_i, \text{prediction}_i) \longrightarrow \text{one plotted point}$$

Any filtering, sorting, or sampling operation must apply the same indices to both arrays.

Part 3 - Hints and Helper

Check shapes, element counts, devices, finiteness, and paired indices before plotting. Create a new figure explicitly, label axes from variables rather than memory, and close the figure after saving. Return diagnostics with the image.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E13(prediction, target, output_path):
    diagnostics = {}
    prediction = prediction.detach().cpu().reshape(-1)
    target = target.detach().cpu().reshape(-1)
    diagnostics["prediction_count"] = prediction.numel()
    diagnostics["target_count"] = target.numel()
    if prediction.shape != target.shape:
        raise ValueError(...)
    finite = torch.isfinite(prediction) & torch.isfinite(target)
    diagnostics["nonfinite_count"] = int((~finite).sum())
    if not finite.all():
        ...
    sample_indices = torch.arange(prediction.numel())
    paired_target = target[sample_indices]
    paired_prediction = ...
    fig, ax = plt.subplots()
    ax.scatter(paired_target.numpy(), paired_prediction.numpy())
    ax.set_xlabel("Target")
    ax.set_ylabel("Prediction")
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return diagnostics

def main():
```

```
    print(E13(...))

if __name__ == "__main__":
    main()
```

10.10.15 Exercise 14 - Interpret Weight Values

Part 1 - Why this matters

In linear regression, each weight describes how the prediction changes when one feature increases while the other features remain fixed. Inspecting weights can reveal direction and model sensitivity in a directly interpretable architecture.

Magnitude comparisons require caution because feature units matter. A weight for meters cannot be compared fairly with a weight for millimeters unless inputs are transformed to a common, meaningful scale.

Part 2 - Mathematical interpretation

For multiple features:

$$\hat{y} = \sum_{j=1}^{d} w_j x_j + b$$

Holding other features fixed:

$$\frac{\partial \hat{y}}{\partial x_j} = w_j$$

Thus, a one-unit increase in x_j changes the prediction by w_j in target units.

Part 3 - Hints and Helper

Extract a linear layer's weight tensor, match every column to a feature name, and plot a signed horizontal bar chart. Include feature units and whether the inputs were standardized. Avoid causal language.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E14(linear_layer, feature_names, output_path):
    weights = linear_layer.weight.detach().cpu().reshape(-1)
    if weights.numel() != len(feature_names):
        raise ValueError(...)
    order = torch.argsort(weights.abs())
    ordered_weights = weights[order]
    ordered_names = [feature_names[index] for index in order.tolist()]
    colors = [
        "tab:blue" if value >= 0 else "tab:red"
        for value in ordered_weights.tolist()
```

```
    ]
    fig, ax = plt.subplots()
    ax.barh(ordered_names, ordered_weights.numpy(), color=colors)
    ax.axvline(0.0, color="black", linewidth=1)
    ax.set_xlabel(...)
    ax.set_title(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return dict(zip(feature_names, weights.tolist()))

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

10.10.16 Exercise 15 - Interpret Bias Effect

Part 1 - Why this matters

The bias shifts a linear prediction independently of feature multiplication. It represents the model output when every input feature equals zero, which can be meaningful, artificial, or outside the observed data range.

Feature centering changes the interpretation of zero and therefore changes the meaning of the bias. A large bias is not automatically important or problematic without understanding preprocessing and feature units.

Part 2 - Mathematical interpretation

For one feature:

$$\hat{y} = wx + b$$

At $x = 0$:

$$\hat{y}(0) = b$$

Changing the bias from b to $b + \Delta b$ shifts every prediction vertically by Δb.

Part 3 - Hints and Helper

Plot several prediction lines with the same weight and different bias values. Keep axis limits fixed, include observed data, and mark $x = 0$ when it lies in a relevant range. Return the vertical shift for verification.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E15(X, target, weight, biases, output_path):
```

```
    x = X.detach().cpu().reshape(-1)
    y = target.detach().cpu().reshape(-1)
    order = torch.argsort(x)
    fig, ax = plt.subplots()
    ax.scatter(x.numpy(), y.numpy(), alpha=0.35, label="Observed")
    for bias in biases:
        prediction = weight * x[order] + bias
        ax.plot(x[order].numpy(), prediction.numpy(),
                label=f"Bias = {bias:.3f}")
    if x.min() <= 0 <= x.max():
        ax.axvline(0.0, color="black", linestyle="--")
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"biases": list(biases), "shared_weight": weight}

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

10.10.17 Exercise 16 - Feature Contribution Analysis

Part 1 - Why this matters

A linear prediction can be decomposed into additive feature contributions. This allows the reader to see which features push one prediction upward or downward before the bias is added.

Contribution magnitude combines the learned weight with the current feature value. It is local to a sample and should not be confused with global importance or evidence that a feature causes the predicted outcome.

Part 2 - Mathematical interpretation

For sample i, define:

$$c_{ij} = w_j x_{ij}$$

Then:

$$\hat{y}_i = b + \sum_{j=1}^{d} c_{ij}$$

The contributions must reconstruct the original prediction within numerical tolerance.

Part 3 - Hints and Helper

Select one sample, compute element-wise products between features and weights, and verify the sum plus bias. Plot signed bars sorted by absolute contribution and include the reconstructed prediction in the title.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E16(linear_layer, sample, feature_names, output_path):
    x = sample.detach().cpu().reshape(-1)
    weights = linear_layer.weight.detach().cpu().reshape(-1)
    bias = linear_layer.bias.detach().cpu().reshape(-1)[0]
    if x.numel() != weights.numel():
        raise ValueError(...)
    contributions = x * weights
    reconstruction = contributions.sum() + bias
    with torch.inference_mode():
        direct = linear_layer(sample).detach().cpu().reshape(-1)[0]
    if not torch.allclose(reconstruction, direct):
        raise RuntimeError(...)
    order = torch.argsort(contributions.abs())
    names = [feature_names[i] for i in order.tolist()]
    fig, ax = plt.subplots()
    ax.barh(names, contributions[order].numpy())
    ax.axvline(0.0, color="black")
    ax.set_title(f"Prediction = {reconstruction.item():.4f}")
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return {"contributions": ..., "bias": bias.item()}

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

10.10.18 Exercise 17 - Explain Failure Cases

Part 1 - Why this matters

Average performance does not explain the examples where a model fails most severely. Inspecting high-error cases can uncover out-of-range inputs, missing values, rare subgroups, incorrect labels, or relationships that a linear model cannot represent.

Failure analysis must avoid choosing only examples that support a preferred story. Selection should follow a declared error rule, preserve original sample identifiers, and compare failures with typical cases.

Part 2 - Mathematical interpretation

Rank samples by absolute residual:

$$e_i = |y_i - \hat{y}_i|$$

The top-k set is:

$$F_k = \mathrm{TopK}_i(e_i)$$

These are the largest observed errors in the evaluated dataset, not necessarily every possible failure mode.

Part 3 - Hints and Helper

Use `torch.topk` on absolute residuals, retain identifiers and feature rows, and create a plot contrasting target and prediction for each selected case. Return a structured table for deeper inspection.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E17(X, target, prediction, sample_ids, k, output_path):
    target = target.detach().cpu().reshape(-1)
    prediction = prediction.detach().cpu().reshape(-1)
    absolute_error = (target - prediction).abs()
    k = min(k, absolute_error.numel())
    values, indices = torch.topk(absolute_error, k=k)
    positions = torch.arange(k)
    fig, ax = plt.subplots()
    ax.scatter(positions.numpy(), target[indices].numpy(),
               label="Target")
    ax.scatter(positions.numpy(), prediction[indices].numpy(),
               label="Prediction")
    ax.set_xticks(positions.numpy())
    ax.set_xticklabels([str(sample_ids[i]) for i in indices.tolist()],
                       rotation=45, ha="right")
    ax.set(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return [{"sample_id": sample_ids[i], "absolute_error": ...}
            for i in indices.tolist()]

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

10.10.19 Exercise 18 - Visualization Reproducibility

Part 1 - Why this matters

A reproducible visualization uses the same data selection, ordering, scales, style, and output settings each time. This is essential when figures are compared across model versions or included in a technical report.

Identical code does not guarantee byte-identical images across every library version, backend, font, or platform. Reproducibility therefore includes recording the environment and preserving the data used to construct the figure.

Part 2 - Technical concept and behavior

A figure can be treated as a function:

$$\mathcal{V} = g(D, I, S, C)$$

where D is plotted data, I is selected indices, S is style configuration, and C is the software and rendering context.

Part 3 - Hints and Helper

Use a fixed seed for sampling, explicit axis limits, an explicit style context, and stable sorting. Save figure metadata and a separate tensor or JSON record containing selected indices and plotted values.

Part 4 - Python code skeleton

```
import json
import matplotlib
import matplotlib.pyplot as plt
import torch

def E18(prediction, target, seed, max_points,
        image_path, metadata_path):
    generator = torch.Generator().manual_seed(seed)
    prediction = prediction.detach().cpu().reshape(-1)
    target = target.detach().cpu().reshape(-1)
    total = prediction.numel()
    indices = torch.randperm(total, generator=generator)
    indices = indices[:min(max_points, total)]
    selected_prediction = prediction[indices]
    selected_target = target[indices]
    lower = torch.minimum(
        selected_prediction.min(), selected_target.min()
    ).item()
    upper = ...
    with plt.rc_context({"figure.figsize": (7, 5),
                         "font.size": 10}):
        fig, ax = plt.subplots()
        ax.scatter(selected_target.numpy(),
                   selected_prediction.numpy(), s=10)
        ax.set_xlim(lower, upper)
        ax.set_ylim(lower, upper)
```

```
        fig.savefig(image_path, dpi=150, metadata={"Creator": "LR08"})
        plt.close(fig)
    metadata = {"seed": seed, "indices": indices.tolist(),
                "torch_version": torch.__version__,
                "matplotlib_version": matplotlib.__version__}
    with open(metadata_path, "w", encoding="utf-8") as file:
        json.dump(..., file, indent=2)

def main():
    E18(...)

if __name__ == "__main__":
    main()
```

10.10.20 Exercise 19 - Final Model Interpretation Report

Part 1 - Why this matters

A final interpretation report combines model performance with evidence explaining how predictions are produced and where they fail. It gives the reader a coherent view instead of a folder of disconnected images.

Interpretation must remain within what linear regression supports. Weights, bias, feature contributions, residuals, and failure examples can describe associations and model behavior, but they do not establish causal relationships by themselves.

Part 2 - Report structure and interpretation

A complete interpretation package can contain:

$$\mathcal{R} = \{\text{fit}, \text{learning}, \text{residuals}, \text{parameters}, \text{contributions}, \text{failures}, \text{limitations}\}$$

Every conclusion should refer to a metric, figure, or validated model property.

Part 3 - Hints and Helper

Build the report from saved results of earlier exercises. Generate figures with consistent style, assign unique filenames, include captions and limitations, and write a machine-readable manifest linking every claim to its artifact.

Part 4 - Python code skeleton

```
import json
from pathlib import Path

def E19(model, evaluation, feature_names, output_directory):
    output = Path(output_directory)
    output.mkdir(parents=True, exist_ok=True)
    artifacts = {}
    artifacts["prediction_plot"] = ...
    artifacts["loss_plot"] = ...
```

```
    artifacts["residual_plot"] = ...
    artifacts["weight_plot"] = ...
    artifacts["failure_plot"] = ...
    conclusions = {
        "fit_quality": ...,
        "largest_weight_interpretation": ...,
        "residual_pattern": ...,
        "known_failure_cases": ...,
        "limitations": [
            "Model associations are not causal conclusions",
            ...,
        ],
    }
    report = {
        "artifacts": artifacts,
        "metrics": evaluation["metrics"],
        "conclusions": conclusions,
    }
    with open(output / "report.json", "w", encoding="utf-8") as file:
        json.dump(report, file, indent=2)
    return report

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

Book 11

Logistic Regression

11.1 Introduction

11.1.1 What will the book teach you

Linear regression taught you how a model learns a continuous relationship between inputs and a numerical target. Logistic regression begins with the same weighted combination of features, but it changes the meaning of the output. The objective is no longer to predict an unrestricted value such as temperature, demand, or energy consumption. The objective is to estimate the probability of a class, such as whether an event will occur, whether a transaction is suspicious, whether a machine requires maintenance, or whether a measured condition belongs to the positive class.

The model first calculates a linear score called a logit:

$$z = \mathbf{w}^\top \mathbf{x} + b$$

The logit may take any real value, so it cannot be interpreted directly as a probability. Logistic regression passes this score through the sigmoid function:

$$p = \sigma(z) = \frac{1}{1 + e^{-z}}$$

This transformation maps the unrestricted logit to a value between zero and one. The result p is interpreted as the model's estimated probability that the target belongs to the positive class, under the assumptions and data used to train the model. The first part of this book will teach you to construct this process manually, compare it with PyTorch operations, verify tensor shapes, examine single and batched predictions, and understand the difference between a logit, a probability, and a class label.

A probability does not become a class label until a decision rule is applied. For a threshold τ:

$$\widehat{y} = \begin{cases} 1, & p \geq \tau, \\ 0, & p < \tau. \end{cases}$$

The common threshold 0.5 is not a universal law. Changing the threshold changes the balance between false positives and false negatives. In a medical screening system, missing a positive case may be more costly than requesting an additional examination. In another system,

a false alarm may itself carry a serious cost. You will therefore experiment with thresholds, construct confusion matrices, inspect class imbalance, and study precision, recall, ROC curves, and AUC. The goal is to learn that the probability model and the operational decision policy are related but distinct components.

The sigmoid function will be studied as a mathematical object rather than treated as a hidden command. Its derivative is:

$$\sigma'(z) = \sigma(z)\Big(1 - \sigma(z)\Big)$$

This derivative becomes small when the logit is far from zero because the sigmoid approaches saturation near zero or one. You will visualize this behavior, inspect gradients with autograd, test extreme inputs, compare float32 and float64, and investigate stability on CPU and CUDA. These exercises will explain why a formula that is mathematically valid can still fail numerically when implemented through direct exponentiation with very large magnitudes.

Logistic regression is also a probability model. For a binary target $y_i \in \{0, 1\}$ and predicted probability p_i, the Bernoulli likelihood for one observation is:

$$P(y_i \mid \mathbf{x}_i) = p_i^{y_i}(1 - p_i)^{1-y_i}$$

Across independent observations, the likelihood is the product of these terms. Products of many probabilities can become extremely small, so practical computation uses the log-likelihood. Maximizing likelihood is equivalent to minimizing the negative log-likelihood, which leads directly to binary cross-entropy:

$$\mathcal{L}_{\text{BCE}} = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(p_i) + (1 - y_i)\log(1 - p_i)]$$

You will implement likelihood, log-likelihood, negative log-likelihood, and BCE manually before relying on PyTorch. This sequence will connect probability theory to the loss used during training instead of presenting them as unrelated formulas.

Numerical stability is especially important in classification. Calculating sigmoid probabilities first and then applying logarithms can produce unstable values for extreme logits. PyTorch's `BCEWithLogitsLoss` combines the sigmoid and binary cross-entropy operations in a more stable form and expects raw logits rather than probabilities. The exercises will require you to compare logits with probabilities, inspect reduction modes, apply class weighting, work with masks, test mixed precision, and debug non-finite losses. You must learn to identify which representation an operation expects before passing a tensor into it.

The learned parameters also define a decision boundary. For the threshold 0.5, sigmoid output reaches the threshold when the logit is zero:

$$\mathbf{w}^\top \mathbf{x} + b = 0$$

In two dimensions, this equation describes a line; in higher dimensions, it describes a hyperplane. The weights control its orientation, while the bias changes its position. You will plot decision boundaries, observe how scaling, noise, overlap, regularization, and training alter them, and identify regions that the model classifies incorrectly. These experiments will also

demonstrate an important limitation: logistic regression creates a linear boundary in the original feature space unless the inputs are transformed.

Training connects the BCE loss to parameter adjustment. You will inspect weight and bias gradients, perform manual updates, compare optimizer behavior, test accumulation and clipping, and study vanishing, exploding, noisy, or missing gradients. For a single binary example, the gradient signal with respect to the logit has the compact form:

$$\frac{\partial \mathcal{L}}{\partial z} = p - y$$

This relationship explains the direction of correction. When the predicted probability is greater than the target, the logit is pushed downward; when it is smaller than the target, it is pushed upward. The later gradient exercises will connect this local signal to the shapes and updates of every trainable parameter.

Evaluation in classification requires more than accuracy. Accuracy can appear high when one class dominates the dataset even if the model fails on the minority class. You will calculate precision, recall, and F1 score, analyze confusion matrices, test threshold sensitivity, measure robustness under noise, and compare repeated runs. You will also profile inference throughput, CUDA latency, and memory use so that model quality and system performance remain separately visible. A final evaluation must state the target distribution, threshold, metric definitions, and costs of different errors.

Probability values also require careful interpretation. A prediction of 0.9 is not automatically trustworthy merely because it is close to one. Calibration asks whether events assigned a probability near 0.9 occur approximately ninety percent of the time within an appropriate evaluation setting. The book will examine overconfidence, confidence drift, likelihood under noise, class imbalance, and probability calibration. This prevents the reader from confusing confidence expressed by the model with verified reliability in the real world.

The final chapter extends the ideas from binary classification to multiple classes. You will compare one-vs-rest logistic models with softmax-based classification, prepare multi-class targets, use cross-entropy, and examine macro and micro metrics. You will also test class imbalance, confusion matrices, probability calibration, gradient stability, mixed precision, scalability, and failure recovery. This extension will show which ideas belong specifically to binary sigmoid classification and which ideas generalize to larger classification systems.

Logistic regression is deliberately studied in depth because it forms a bridge between a linear model and neural classification. It introduces logits, probabilities, decision thresholds, classification losses, confusion-based metrics, calibration, and decision boundaries while remaining mathematically transparent. The perceptron will reuse weighted inputs and a bias but apply a harder decision mechanism, while later neural networks will learn many stacked transformations before producing their final logits. If you understand logistic regression as a complete system, those later models will be easier to reason about and debug.

11.1.2 How to study this book

Treat every exercise as a controlled classification experiment. Before executing the code, predict the tensor shape, whether the value is a logit or probability, the expected probability range,

the target representation, and the effect of the chosen threshold. After execution, verify these expectations numerically. Never use the words logit, probability, confidence, and class label as if they describe the same quantity.

Begin with small CPU tensors whose sigmoid values, BCE terms, confusion counts, and gradients can be checked manually. After the result is understood, repeat selected experiments on CUDA and compare them using justified tolerances. When testing precision, mixed precision, or extreme logits, record finite status and gradient behavior instead of accepting a result merely because no exception was raised.

When comparing thresholds, class weights, learning rates, or regularization, preserve the dataset split, initialization, seed, training budget, and evaluation examples. Change one intended variable at a time. Do not select a threshold using the final test set, and do not allow preprocessing statistics from validation or test data to enter training. These mistakes create data leakage and make the reported performance unreliable.

For every completed challenge, answer four questions: What quantity was computed? What mathematical rule produced it? What evidence shows that it is correct? Under what condition could it become misleading or fail? If you cannot explain why a model produced a class decision, how the threshold affected the error types, or why the loss changed the parameters, repeat the experiment before continuing.

11.1.3 The Chapters (LG00 - LG08) included in this book

- LG00 - Introduction to Logistic Regression
- LG01 - Binary Output and Decision Logic
- LG02 - Sigmoid Activation Behavior
- LG03 - Probability Interpretation Framework
- LG04 - Classification Boundary Definition
- LG05 - Loss Representation for Classification
- LG06 - Model Adjustment and Gradient Direction
- LG07 - Accuracy Validation and Output Analysis
- LG08 - Multi-Class Extension Concepts

11.2 LG00 - Introduction to Logistic Regression

Models and Training

11.2.1 Exercise 00 - Define Binary Classification Problem

Part 1 - Why this matters

Binary classification begins with a precise definition of the two outcomes a model must distinguish. Inputs may contain several numerical features, but every target must represent either the negative class or the positive class according to a documented meaning.

A model cannot be evaluated correctly when labels are ambiguous, shapes are inconsistent, or class values silently use an unexpected encoding. This exercise establishes the data contract before any sigmoid function or training operation is introduced.

Part 2 - Mathematical form

Let the feature matrix and binary targets be:

$$\mathbf{X} \in \mathbb{R}^{N \times F}, \qquad \mathbf{y} \in \{0, 1\}^{N \times 1}$$

where N is the number of samples and F is the number of input features. The value 0 represents the negative class and 1 represents the positive class.

Part 3 - Hints and Helper

Create a small floating-point feature tensor and a target tensor containing both classes. Validate dimensions, sample count, finite inputs, target values, and class counts. Do not build the model yet.

Part 4 - Python code skeleton

```
import torch

def E00(X, target):
    if X.ndim != 2:
        raise ValueError(...)
    if target.shape != (X.shape[0], 1):
        raise ValueError(...)
    valid_labels = torch.all((target == 0) | (target == 1))
    if not valid_labels:
        raise ValueError(...)
    return {
        "samples": X.shape[0],
        "features": X.shape[1],
        "negative_count": int((target == 0).sum()),
        "positive_count": ...,
        "finite_features": bool(torch.isfinite(X).all()),
    }

def main():
    X = torch.tensor(..., dtype=torch.float32)
    target = torch.tensor(..., dtype=torch.float32)
    print(E00(X, target))
```

```
if __name__ == "__main__":
    main()
```

11.2.2 Exercise 01 - Linear Output vs Probability Output

Part 1 - Why this matters

Logistic regression first produces an unrestricted linear score and then converts it into a bounded probability. Keeping these two quantities separate is essential because losses, thresholds, and interpretation rules may expect one representation but not the other.

A raw score greater than one is not an invalid logit, but it is an invalid probability. Applying a decision threshold directly to logits as though they were probabilities changes the intended decision rule.

Part 2 - Mathematical form

The linear output is the logit:

$$z = \mathbf{w}^\top \mathbf{x} + b, \qquad z \in \mathbb{R}$$

The probability is:

$$p = \sigma(z) = \frac{1}{1 + e^{-z}}, \qquad p \in (0, 1)$$

The sigmoid is monotonic, so larger logits produce larger probabilities.

Part 3 - Hints and Helper

Use known weights and bias to calculate logits, then apply sigmoid. Return both tensors with clear names. Test negative, zero, and positive logits and verify that a zero logit maps to probability 0.5.

Part 4 - Python code skeleton

```
import torch

def E01(X, weight, bias):
    logits = X @ weight + bias
    probabilities = ...
    return {"logits": logits, "probabilities": probabilities}

def main():
    X = torch.tensor(..., dtype=torch.float32)
    weight = torch.tensor(..., dtype=torch.float32)
    bias = torch.tensor(..., dtype=torch.float32)
    result = E01(X, weight, bias)
    print(result)

if __name__ == "__main__":
    main()
```

11.2.3 Exercise 02 - Implement Sigmoid Function Manually

Part 1 - Why this matters

Implementing sigmoid manually connects the probability output to exponentiation and reciprocal operations. It also exposes the numerical weakness of evaluating the same algebraic expression for very large positive and negative logits.

A useful manual implementation should agree with the mathematical definition for ordinary values and remain finite for extreme finite inputs. Comparing a direct formula with a branch-aware version makes numerical stability observable.

Part 2 - Mathematical form

The direct sigmoid formula is:

$$\sigma(z) = \frac{1}{1 + e^{-z}}$$

An equivalent form for negative z is:

$$\sigma(z) = \frac{e^{z}}{1 + e^{z}}$$

Using separate forms avoids exponentiating a large positive magnitude unnecessarily.

Part 3 - Hints and Helper

Create an output tensor with the same shape and dtype as the input. Apply the direct expression where $z \geq 0$ and the equivalent negative-input expression elsewhere. Compare the result with hand-calculated ordinary cases.

Part 4 - Python code skeleton

```
import torch

def E02(logits):
    logits = torch.as_tensor(logits)
    positive = logits >= 0
    output = torch.empty_like(logits)
    output[positive] = 1 / (1 + torch.exp(-logits[positive]))
    exp_value = torch.exp(logits[~positive])
    output[~positive] = ...
    return output

def main():
    logits = torch.tensor(
        [...], dtype=torch.float64
    )
    print(E02(logits))

if __name__ == "__main__":
    main()
```

11.2.4 Exercise 03 - Sigmoid Using PyTorch

Part 1 - Why this matters

PyTorch provides a vectorized sigmoid implementation that works with autograd, batches, devices, and supported floating-point dtypes. Using the library operation removes manual indexing while preserving the mathematical transformation.

Library use should still be verified rather than accepted blindly. The output must match a manual reference within tolerance, preserve shape, and participate in the computational graph when its input requires gradients.

Part 2 - Technical concept and behavior

For every element z_i of a tensor:

$$p_i = \text{sigmoid}(z_i)$$

The operation is element-wise, so:

$$\text{shape}(\mathbf{p}) = \text{shape}(\mathbf{z})$$

Part 3 - Hints and Helper

Use `torch.sigmoid`. Test a multidimensional tensor and compare it with the manual function from the previous exercise. Set `requires_grad=True` and inspect the output's gradient metadata.

Part 4 - Python code skeleton

```
import torch

def E03(logits):
    probabilities = torch.sigmoid(...)
    return {
        "probabilities": probabilities,
        "shape_preserved": probabilities.shape == logits.shape,
        "requires_grad": probabilities.requires_grad,
        "gradient_function": type(probabilities.grad_fn).__name__
        if probabilities.grad_fn is not None else None,
    }

def main():
    logits = torch.tensor(
        [...], dtype=torch.float32, requires_grad=True
    )
    print(E03(logits))

if __name__ == "__main__":
    main()
```

11.2.5 Exercise 04 - Probability Range Validation

Part 1 - Why this matters

A logistic probability must remain inside the closed numerical range from zero to one. Range validation detects accidental use of raw logits, corrupted values, and non-finite results before they enter thresholding or evaluation code.

Range validity alone does not prove that values are correct probabilities. A constant tensor of 0.5 passes the range check but may still indicate a broken model, so shape and finiteness must be validated as well.

Part 2 - Technical concept and behavior

For each predicted probability:

$$0 \leq p_i \leq 1$$

The validation contract also requires:

$$\text{isfinite}(p_i) = \text{True}$$

and an output shape consistent with the number of classification decisions.

Part 3 - Hints and Helper

Return a structured report containing minimum, maximum, finite status, range status, and expected-shape status. Test valid sigmoid output and deliberately invalid tensors containing logits, NaN, or infinity.

Part 4 - Python code skeleton

```
import torch

def E04(probabilities, expected_shape):
    finite = torch.isfinite(probabilities)
    in_range = (probabilities >= 0) & (probabilities <= 1)
    report = {
        "shape_valid": probabilities.shape == expected_shape,
        "all_finite": bool(finite.all()),
        "all_in_range": bool(in_range.all()),
        "minimum": probabilities.min().item()
        if finite.all() else None,
        "maximum": ...,
    }
    report["valid"] = ...
    return report

def main():
    probabilities = torch.tensor(...)
    print(E04(probabilities, expected_shape=(..., ...)))

if __name__ == "__main__":
    main()
```

11.2.6 Exercise 05 - Single Sample Classification

Part 1 - Why this matters

A single-sample forward pass makes every stage of binary classification visible: feature validation, logit calculation, sigmoid conversion, and threshold decision. It is the smallest complete inference example.

Preserving a batch dimension even for one sample prevents shape rules from changing between single and batched inference. This reduces hidden broadcasting and makes the same model interface reusable.

Part 2 - Mathematical form

For one sample $\mathbf{x} \in \mathbb{R}^{1\times F}$:

$$z = \mathbf{x}\mathbf{w} + b, \qquad p = \sigma(z)$$

For threshold τ:

$$\widehat{y} = \mathbf{1}[p \geq \tau]$$

Part 3 - Hints and Helper

Require shape $(1, F)$ rather than flattening the input silently. Validate the threshold lies between zero and one. Return the logit, probability, class label, and threshold separately.

Part 4 - Python code skeleton

```
import torch

def E05(X, weight, bias, threshold=0.5):
    if X.ndim != 2 or X.shape[0] != 1:
        raise ValueError(...)
    if not 0 <= threshold <= 1:
        raise ValueError(...)
    logit = X @ weight + bias
    probability = torch.sigmoid(logit)
    label = (probability >= threshold).to(torch.int64)
    return {
        "logit": logit.item(),
        "probability": ...,
        "label": ...,
        "threshold": threshold,
    }

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.2.7 Exercise 06 - Batch Classification Forward Pass

Part 1 - Why this matters

Batch inference applies one parameter set to many samples simultaneously. Vectorization uses tensor operations efficiently and ensures that the same feature-to-output rule is applied consistently across the dataset.

The main risk is silent shape broadcasting. A target of shape (N) and prediction of shape $(N, 1)$ may combine into an unintended (N, N) result, so output contracts must be explicit.

Part 2 - Mathematical form

For $\mathbf{X} \in \mathbb{R}^{N \times F}$ and $\mathbf{w} \in \mathbb{R}^{F \times 1}$:

$$\mathbf{z} = \mathbf{X}\mathbf{w} + b \in \mathbb{R}^{N \times 1}$$

$$\mathbf{p} = \sigma(\mathbf{z}) \in (0, 1)^{N \times 1}$$

Part 3 - Hints and Helper

Check the feature dimension against the weight's first dimension. Preserve the $(N, 1)$ result, generate integer labels through one threshold, and verify every output shares the expected sample count.

Part 4 - Python code skeleton

```
import torch

def E06(X, weight, bias, threshold=0.5):
    if X.ndim != 2 or weight.shape != (X.shape[1], 1):
        raise ValueError(...)
    logits = X @ weight + bias
    probabilities = torch.sigmoid(logits)
    labels = ...
    expected = (X.shape[0], 1)
    if logits.shape != expected or labels.shape != expected:
        raise RuntimeError(...)
    return logits, probabilities, labels

def main():
    logits, probabilities, labels = E06(...)
    print(logits, probabilities, labels)

if __name__ == "__main__":
    main()
```

11.2.8 Exercise 07 - Decision Threshold Experiment

Part 1 - Why this matters

The decision threshold converts a continuous probability into a discrete action. Lowering it usually predicts more positive cases, while raising it usually predicts fewer positives. The chosen value therefore changes the types of errors a system makes.

Threshold selection must be studied on validation evidence and connected to the cost of false positives and false negatives. Choosing it on the final test set leaks evaluation information into model design.

Part 2 - Mathematical form

For threshold τ:

$$\widehat{y}_i(\tau) = \mathbf{1}[p_i \geq \tau]$$

Compute:

$$TP,\ TN,\ FP,\ FN$$

for each candidate threshold. These counts show how the decision policy changes even though model probabilities remain fixed.

Part 3 - Hints and Helper

Test several ordered thresholds between zero and one. Keep probabilities and targets fixed, construct Boolean masks, and return positive prediction count and confusion counts for every threshold.

Part 4 - Python code skeleton

```
import torch

def E07(probabilities, target, thresholds):
    probabilities = probabilities.reshape(-1)
    target = target.reshape(-1).to(torch.int64)
    if probabilities.shape != target.shape:
        raise ValueError(...)
    results = []
    for threshold in thresholds:
        predicted = (probabilities >= threshold).to(torch.int64)
        tp = int(((predicted == 1) & (target == 1)).sum())
        tn = int(((predicted == 0) & (target == 0)).sum())
        fp = ...
        fn = ...
        results.append({
            "threshold": threshold,
            "predicted_positive": int(predicted.sum()),
            "tp": tp, "tn": tn, "fp": fp, "fn": fn,
        })
```

```
    return results

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.2.9 Exercise 08 - Logit Interpretation Test

Part 1 - Why this matters

A logit is not only a raw model score; it is the logarithm of the predicted odds. This interpretation connects a linear transformation to probability without treating sigmoid as an unexplained conversion.

The sign of the logit has direct meaning. A positive logit corresponds to probability above 0.5, zero corresponds to 0.5, and a negative logit corresponds to probability below 0.5.

Part 2 - Mathematical form

For probability p and odds $p/(1-p)$:

$$z = \log\left(\frac{p}{1-p}\right)$$

The inverse transformation is:

$$p = \sigma(z)$$

Therefore, adding Δz multiplies the odds by $e^{\Delta z}$.

Part 3 - Hints and Helper

Choose moderate logits, convert them to probabilities, calculate odds, and reconstruct logits with the natural logarithm. Avoid probabilities numerically equal to zero or one when applying the inverse formula.

Part 4 - Python code skeleton

```
import torch

def E08(logits):
    probabilities = torch.sigmoid(logits)
    odds = probabilities / (1 - probabilities)
    reconstructed = torch.log(odds)
    return {
        "probabilities": probabilities,
        "odds": odds,
        "reconstructed_logits": reconstructed,
        "agreement": torch.allclose(
            logits, reconstructed, atol=..., rtol=...
```

```
        ),
    }

def main():
    logits = torch.tensor([...], dtype=torch.float64)
    print(E08(logits))

if __name__ == "__main__":
    main()
```

11.2.10 Exercise 09 - Binary Output Failure Case

Part 1 - Why this matters

Binary output pipelines can fail without raising an exception. Common examples include thresholding logits as probabilities, applying sigmoid twice, broadcasting mismatched targets, or interpreting class labels as calibrated confidence.

Controlled failure cases teach the reader to diagnose representation errors from evidence. The objective is to identify which contract was violated rather than to force every tensor into a convenient shape.

Part 2 - Technical concept and behavior

A correct binary pipeline follows:

$$\text{features} \longrightarrow \text{logits} \longrightarrow \text{probabilities} \longrightarrow \text{labels}$$

Each transition has a separate valid range, shape, dtype, and interpretation. Reordering or repeating transitions changes the result.

Part 3 - Hints and Helper

Create one correct output and several deliberately incorrect variants. Detect raw logits outside $[0, 1]$, double sigmoid transformation, shape broadcasting risk, invalid thresholds, and non-binary labels. Return a named diagnostic for each case.

Part 4 - Python code skeleton

```
import torch

def inspect_binary_output(logits, probabilities, target, threshold):
    issues = []
    if not torch.isfinite(logits).all():
        issues.append(...)
    if not ((probabilities >= 0) & (probabilities <= 1)).all():
        issues.append("probability_out_of_range")
    if probabilities.shape != target.shape:
        issues.append(...)
    if not 0 <= threshold <= 1:
        issues.append(...)
```

```
    if not torch.all((target == 0) | (target == 1)):
        issues.append(...)
    return issues

def E09(X, weight, bias, target):
    logits = X @ weight + bias
    correct_probability = torch.sigmoid(logits)
    wrong_probability = torch.sigmoid(correct_probability)
    return {
        "correct": inspect_binary_output(
            logits, correct_probability, target, 0.5
        ),
        "double_sigmoid": ...,
        "thresholded_logits": (logits >= 0.5).to(torch.int64),
    }

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.2.11 Exercise 10 - Move Logistic Model to CUDA

Part 1 - Why this matters

CUDA execution requires the model parameters and input tensors to reside on the same device. Moving only the data or only the model causes a device mismatch instead of accelerating inference.

Device placement should be explicit and verifiable. A model should be moved before an optimizer is created for training because device conversion can replace parameter objects managed by the optimizer.

Part 2 - Technical concept and behavior

For a CUDA forward pass:

$$d_{\mathbf{X}} = d_{\mathbf{w}} = d_b = \text{CUDA}$$

The linear layer returns CUDA logits, and sigmoid preserves the output device. The numerical meaning remains the same as the CPU model.

Part 3 - Hints and Helper

Check `torch.cuda.is_available()` and return a clear skipped result when necessary. Move the model and input to one selected device, inspect every parameter device, and run inference without gradients.

Part 4 - Python code skeleton

```
import torch
from torch import nn

def E10(model, X, device_index=0):
    if not torch.cuda.is_available():
        return {"skipped": True, "reason": ...}
    device = torch.device(f"cuda:{device_index}")
    model = model.to(device)
    X = X.to(device)
    model.eval()
    with torch.inference_mode():
        logits = model(X)
        probabilities = torch.sigmoid(logits)
    parameter_devices = {
        str(parameter.device) for parameter in model.parameters()
    }
    return {
        "skipped": False,
        "logit_device": str(logits.device),
        "probability_device": ...,
        "parameter_devices": sorted(parameter_devices),
        "probability_shape": tuple(probabilities.shape),
    }

def main():
    model = nn.Linear(..., 1)
    X = torch.randn(..., ...)
    print(E10(model, X))

if __name__ == "__main__":
    main()
```

11.2.12 Exercise 11 - CPU vs GPU Probability Comparison

Part 1 - Why this matters

CPU and GPU implementations should produce numerically close probabilities when they use identical parameters, inputs, dtype, and evaluation state. This comparison detects inconsistent model copies and incorrect device transfers.

Floating-point computations across devices are not guaranteed to be bitwise identical. A valid parity test therefore uses justified absolute and relative tolerances and reports the observed difference.

Part 2 - Technical concept and behavior

For paired predictions:

$$\Delta_{\max} = \max_i |p_i^{\mathrm{CPU}} - p_i^{\mathrm{GPU}}|$$

Parity passes when:

$$|p_i^{\text{CPU}} - p_i^{\text{GPU}}| \leq \text{atol} + \text{rtol}|p_i^{\text{GPU}}|$$

for every element.

Part 3 - Hints and Helper

Deep-copy one initialized model before moving either copy. Use the same CPU input, transfer a copy to CUDA, disable gradients, and bring GPU output back to CPU before comparison.

Part 4 - Python code skeleton

```
import copy
import torch

def E11(model, X, atol=1e-6, rtol=1e-5):
    if not torch.cuda.is_available():
        return {"skipped": True}
    cpu_model = copy.deepcopy(model).cpu().eval()
    gpu_model = copy.deepcopy(model).cuda().eval()
    with torch.inference_mode():
        cpu_probability = torch.sigmoid(cpu_model(X.cpu()))
        gpu_probability = torch.sigmoid(
            gpu_model(X.cuda())
        ).cpu()
    difference = (cpu_probability - gpu_probability).abs()
    return {
        "skipped": False,
        "allclose": torch.allclose(
            cpu_probability, gpu_probability,
            atol=atol, rtol=rtol
        ),
        "maximum_absolute_difference": ...,
        "mean_absolute_difference": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.2.13 Exercise 12 - Precision Effects on Sigmoid

Part 1 - Why this matters

Floating-point precision affects how closely sigmoid probabilities can represent values near zero, one, and the center of the curve. Extreme logits may round to exact boundary values earlier in lower precision.

A precision experiment should distinguish expected rounding from a broken implementation. Float64 offers a higher-precision reference for comparison, but it is still finite-precision arithmetic rather than an exact result.

Part 2 - Technical concept and behavior

For dtype d, compute:

$$p_d = \sigma(z_d)$$

and compare with float64:

$$\Delta_d = |p_d - p_{64}|$$

The largest differences are not necessarily at the largest logits because saturated outputs may round to the same boundary.

Part 3 - Hints and Helper

Use one float64 source tensor and cast it separately to supported dtypes. Convert results back to float64 for comparison. Record finite status, exact zeros, exact ones, and maximum deviation.

Part 4 - Python code skeleton

```
import torch

def E12(values, dtypes):
    source = torch.as_tensor(values, dtype=torch.float64)
    reference = torch.sigmoid(source)
    report = {}
    for dtype in dtypes:
        current = torch.sigmoid(source.to(dtype)).to(torch.float64)
        difference = (current - reference).abs()
        report[str(dtype)] = {
            "probabilities": current.tolist(),
            "all_finite": bool(torch.isfinite(current).all()),
            "exact_zero_count": int((current == 0).sum()),
            "exact_one_count": int((current == 1).sum()),
            "maximum_difference": ...,
        }
    return report

def main():
    values = [...]
    print(E12(values, [torch.float32, torch.float64]))

if __name__ == "__main__":
    main()
```

11.2.14 Exercise 13 - Saturation Behavior Observation

Part 1 - Why this matters

Sigmoid saturation occurs when extreme logits produce probabilities very close to zero or one. In these regions, changes in the logit produce only small changes in probability.

Saturation helps create confident outputs but also reduces the local sigmoid derivative. Observing both probability and derivative prevents confidence from being confused with strong gradient flow.

Part 2 - Mathematical form

The derivative is:

$$\sigma'(z) = \sigma(z)(1 - \sigma(z))$$

Its maximum is 0.25 at $z = 0$, and it approaches zero as z moves toward positive or negative infinity.

Part 3 - Hints and Helper

Evaluate a symmetric logit range. Calculate probabilities and analytical derivatives, then identify entries below a chosen derivative tolerance. Verify the derivative maximum occurs near zero.

Part 4 - Python code skeleton

```
import torch

def E13(logits, derivative_tolerance=1e-4):
    probabilities = torch.sigmoid(logits)
    derivatives = probabilities * (1 - probabilities)
    saturated = derivatives < derivative_tolerance
    maximum_index = int(derivatives.argmax())
    return {
        "probabilities": probabilities,
        "derivatives": derivatives,
        "saturated_mask": saturated,
        "saturated_count": int(saturated.sum()),
        "maximum_derivative": ...,
        "logit_at_maximum": logits[maximum_index].item(),
    }

def main():
    logits = torch.linspace(..., ..., steps=...)
    print(E13(logits))

if __name__ == "__main__":
    main()
```

11.2.15 Exercise 14 - Numerical Stability Breakdown

Part 1 - Why this matters

A direct sigmoid followed by logarithmic binary cross-entropy may overflow, round probabilities to zero or one, or evaluate an undefined logarithm for extreme logits. The mathematical model remains valid while the computational route becomes unstable.

Stable loss functions operate on logits and combine algebraic steps to avoid dangerous intermediate values. This exercise demonstrates why selecting the correct PyTorch interface is part of mathematical correctness.

Part 2 - Mathematical form

The probability-based binary loss is:

$$\ell = -\left[y \log(\sigma(z)) + (1 - y) \log(1 - \sigma(z))\right]$$

A stable logit form can be written as:

$$\ell = \max(z, 0) - zy + \log(1 + e^{-|z|})$$

which avoids directly taking the logarithm of a rounded boundary probability.

Part 3 - Hints and Helper

Use extreme positive and negative logits with both target classes. Compare a naive manual calculation, the stable formula, and `binary_cross_entropy_with_logits`. Record finite status and numerical agreement.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E14(logits, target):
    probability = 1 / (1 + torch.exp(-logits))
    naive = -(
        target * torch.log(probability)
        + (1 - target) * torch.log(1 - probability)
    )
    stable_manual = (
        torch.clamp(logits, min=0)
        - logits * target
        + torch.log1p(torch.exp(-logits.abs()))
    )
    pytorch_stable = F.binary_cross_entropy_with_logits(
        logits, target, reduction="none"
    )
    return {
        "naive": naive,
        "stable_manual": stable_manual,
```

```
        "pytorch_stable": pytorch_stable,
        "naive_finite": bool(torch.isfinite(naive).all()),
        "stable_agreement": torch.allclose(
            stable_manual, pytorch_stable, atol=..., rtol=...
        ),
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.2.16 Exercise 15 - Vectorized Binary Prediction

Part 1 - Why this matters

Vectorized prediction processes an entire tensor through matrix multiplication, sigmoid, and thresholding without a Python loop over samples. This produces simpler shape reasoning and can use optimized tensor kernels.

Vectorization must preserve the same result as an independently checked sample-wise reference. Faster code is not useful when a broadcasting error changes which features or samples are combined.

Part 2 - Mathematical form

For a batch:

$$\hat{\mathbf{y}} = \mathbf{1}\left[\sigma(\mathbf{X}\mathbf{w} + b) \geq \tau\right]$$

All operations act on the batch while preserving output shape $(N, 1)$.

Part 3 - Hints and Helper

Validate $\mathbf{X}$ and $\mathbf{w}$ dimensions, use one matrix multiplication, and avoid iteration over samples. Compare several output rows against manual scalar calculations.

Part 4 - Python code skeleton

```
import torch

def E15(X, weight, bias, threshold=0.5):
    if X.ndim != 2 or weight.shape != (X.shape[1], 1):
        raise ValueError(...)
    logits = ...
    probabilities = ...
    labels = ...
    return {
        "logits": logits,
        "probabilities": probabilities,
```

```
        "labels": labels,
        "batch_size": X.shape[0],
    }

def main():
    result = E15(...)
    print(result)

if __name__ == "__main__":
    main()
```

11.2.17 Exercise 16 - Probability Calibration Check

Part 1 - Why this matters

Calibration checks whether predicted probabilities match observed outcome frequencies. If predictions near 0.8 are well calibrated, roughly eighty percent of corresponding targets should be positive over an appropriate sample.

Calibration is different from classification accuracy. A model can rank examples well or classify many correctly while producing probabilities that are systematically too confident or too cautious.

Part 2 - Mathematical form

For probability bin B_m, define confidence and empirical accuracy:

$$\operatorname{conf}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} p_i$$

$$\operatorname{acc}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} y_i$$

A simple expected calibration error weights their absolute gaps by bin size.

Part 3 - Hints and Helper

Flatten aligned tensors, create fixed bin edges from zero to one, include probability one in the final bin, and skip empty bins. Return count, confidence, accuracy, gap, and total weighted error.

Part 4 - Python code skeleton

```
import torch

def E16(probabilities, target, bin_count=10):
    probabilities = probabilities.detach().reshape(-1)
    target = target.detach().reshape(-1).to(probabilities.dtype)
    if probabilities.shape != target.shape:
        raise ValueError(...)
    edges = torch.linspace(
        0, 1, bin_count + 1, device=probabilities.device
```

```
    )
    bins = []
    expected_error = 0.0
    total = probabilities.numel()
    for index in range(bin_count):
        lower, upper = edges[index], edges[index + 1]
        mask = (probabilities >= lower) & (probabilities < upper)
        if index == bin_count - 1:
            mask = mask | (probabilities == upper)
        count = int(mask.sum())
        if count == 0:
            continue
        confidence = probabilities[mask].mean().item()
        accuracy = ...
        gap = abs(confidence - accuracy)
        expected_error += (count / total) * gap
        bins.append({"count": count, "confidence": confidence,
                     "accuracy": accuracy, "gap": gap})
    return {"bins": bins, "expected_calibration_error": ...}

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.2.18 Exercise 17 - Frozen Logistic Model Test

Part 1 - Why this matters

Freezing a logistic model prevents its parameters from receiving gradients during a backward pass. This is useful when a trained classifier is reused as a fixed component or when only selected parts of a larger system should learn.

Freezing parameters is different from evaluation mode and from disabling every gradient. Input gradients may still be required for analysis even while weight and bias gradients remain absent.

Part 2 - Technical concept and behavior

For frozen parameters $\boldsymbol{\theta}$:

$$\texttt{requires_grad}(\boldsymbol{\theta}) = \text{False}$$

A backward pass may still calculate:

$$\frac{\partial \mathcal{L}}{\partial \mathbf{X}}$$

when the input explicitly requires gradients.

Part 3 - Hints and Helper

Clone the state dictionary, call `requires_grad_(False)`, and use an input with gradient tracking enabled. Backpropagate a stable logit loss, then verify parameter gradients are absent, input gradients exist, and parameter values are unchanged.

Part 4 - Python code skeleton

```
import copy
import torch
import torch.nn.functional as F

def E17(model, X, target):
    before = copy.deepcopy(model.state_dict())
    model.requires_grad_(False)
    X = X.detach().clone().requires_grad_(True)
    logits = model(X)
    loss = F.binary_cross_entropy_with_logits(logits, target)
    loss.backward()
    parameter_gradients_absent = all(
        parameter.grad is None for parameter in model.parameters()
    )
    unchanged = all(
        torch.equal(before[name], model.state_dict()[name])
        for name in before
    )
    return {
        "loss": loss.item(),
        "parameter_gradients_absent": ...,
        "input_gradient_present": X.grad is not None,
        "parameters_unchanged": unchanged,
    }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.2.19 Exercise 18 - Manual Forward without nn.Module

Part 1 - Why this matters

A manual logistic forward pass proves that the model consists of ordinary tensor operations rather than hidden framework behavior. It also makes parameter shapes and broadcasting rules directly observable.

Using tensors with gradient tracking preserves the ability to train manually later. The exercise separates parameter registration provided by `nn.Module` from the mathematics required to produce logits and probabilities.

Part 2 - Mathematical form

For batch input:

$$\mathbf{z} = \mathbf{X}\mathbf{w} + b$$

$$\mathbf{p} = \sigma(\mathbf{z})$$

where $\mathbf{X} \in \mathbb{R}^{N \times F}$, $\mathbf{w} \in \mathbb{R}^{F \times 1}$, and $b \in \mathbb{R}$.

Part 3 - Hints and Helper

Create weight and bias tensors with `requires_grad=True`. Validate all shapes before multiplication, return logits and probabilities separately, and compare with an `nn.Linear` layer holding copied values.

Part 4 - Python code skeleton

```
import torch

def E18(X, weight, bias):
    if X.ndim != 2:
        raise ValueError(...)
    if weight.shape != (X.shape[1], 1):
        raise ValueError(...)
    if bias.numel() != 1:
        raise ValueError(...)
    logits = ...
    probabilities = ...
    return logits, probabilities

def main():
    X = torch.randn(..., ...)
    weight = torch.randn(..., 1, requires_grad=True)
    bias = torch.zeros(1, requires_grad=True)
    logits, probabilities = E18(X, weight, bias)
    print(logits, probabilities)

if __name__ == "__main__":
    main()
```

11.2.20 Exercise 19 - Forward Pass Failure Debugging

Part 1 - Why this matters

A logistic forward pass can fail through feature mismatch, device mismatch, integer input, invalid values, incorrect output shape, double sigmoid, or confusion between logits and probabilities. Several of these errors can produce plausible outputs instead of exceptions.

A reliable debugger checks the input and representation contracts in a fixed order. The final exercise combines chapter concepts into one report that identifies the first broken invariant without hiding the original evidence.

Part 2 - Technical concept and behavior

For a model with F input features, require:

$$X_{\text{last}} = F, \qquad d_X = d_\theta, \qquad \tau_X = \tau_\theta$$

After forward calculation, logits must be finite, probability shape must match logit shape, and probabilities must lie in $[0, 1]$.

Part 3 - Hints and Helper

Inspect shape, dtype, device, finiteness, and expected feature count before calling the model. Catch errors only around each controlled test case. Include valid, wrong-shape, wrong-dtype, non-finite, and device-mismatch inputs when CUDA is available.

Part 4 - Python code skeleton

```
import torch

def inspect_contract(model, X):
    parameter = next(model.parameters())
    expected_features = model.in_features
    return {
        "shape_valid": X.ndim >= 2
        and X.shape[-1] == expected_features,
        "floating_input": X.is_floating_point(),
        "device_valid": X.device == parameter.device,
        "dtype_valid": X.dtype == parameter.dtype,
        "finite_input": bool(torch.isfinite(X).all())
        if X.is_floating_point() else False,
    }

def E19(model, test_inputs):
    report = []
    for name, X in test_inputs.items():
        checks = inspect_contract(model, X)
        try:
            logits = model(X)
            probabilities = torch.sigmoid(logits)
            status = {
                "success": True,
                "logit_shape": tuple(logits.shape),
                "probability_valid": ...,
            }
        except (RuntimeError, ValueError, TypeError) as error:
            status = {"success": False,
                      "error_type": type(error).__name__,
```

```
                        "message": str(error)}
        report.append({"case": name, "checks": checks,
                       "status": status})
    return report

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.3 LG01 - Binary Output and Decision Logic

Models and Training

11.3.1 Exercise 00 - Convert Probability to Class Label

Part 1 - Why this matters

A logistic model produces probabilities, but many systems must eventually make a discrete decision. Thresholding defines the exact rule that converts the model's continuous output into a negative or positive class label.

The conversion must preserve shape, use a documented comparison rule, and return an appropriate label dtype. Confusing a probability with its final class removes information and makes later threshold analysis impossible.

Part 2 - Mathematical form

For probability p_i and threshold τ:

$$\widehat{y}_i = \begin{cases} 1, & p_i \geq \tau, \\ 0, & p_i < \tau \end{cases}$$

where $0 \leq \tau \leq 1$. The equality rule at the threshold must be stated explicitly.

Part 3 - Hints and Helper

Validate finite probabilities inside $[0, 1]$ and a valid threshold. Use one vectorized comparison, convert Boolean results to `torch.int64`, and confirm the output shape matches the input.

Part 4 - Python code skeleton

```
import torch

def E00(probabilities, threshold=0.5):
    if not 0 <= threshold <= 1:
        raise ValueError(...)
    if not torch.isfinite(probabilities).all():
```

```
        raise ValueError(...)
    if not ((probabilities >= 0) & (probabilities <= 1)).all():
        raise ValueError(...)
    labels = ...
    return {
        "labels": labels,
        "shape_preserved": labels.shape == probabilities.shape,
        "positive_count": int(labels.sum()),
        "threshold": threshold,
    }

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

11.3.2 Exercise 01 - Threshold Sensitivity Experiment

Part 1 - Why this matters

A threshold changes decisions without retraining the probability model. Lower thresholds generally increase positive predictions, while higher thresholds generally decrease them and alter the balance of classification errors.

Sensitivity analysis shows whether a model's reported performance depends strongly on one arbitrary cutoff. It also reveals ranges where small threshold changes cause large operational changes.

Part 2 - Mathematical form

For thresholds $\tau_1, \ldots, \tau_K$, calculate:

$$\hat{\mathbf{y}}(\tau_k) = \mathbf{1}[\mathbf{p} \geq \tau_k]$$

and measure the positive prediction rate:

$$R_+(\tau_k) = \frac{1}{N} \sum_{i=1}^{N} \hat{y}_i(\tau_k)$$

Part 3 - Hints and Helper

Sort and validate thresholds, keep probabilities fixed, and record positive count, accuracy, false positives, and false negatives at each value. Verify positive count never increases as the threshold rises.

Part 4 - Python code skeleton

```
import torch

def E01(probabilities, target, thresholds):
```

```
    probabilities = probabilities.reshape(-1)
    target = target.reshape(-1).to(torch.int64)
    results = []
    previous_positive = probabilities.numel() + 1
    for threshold in sorted(thresholds):
        predicted = (probabilities >= threshold).to(torch.int64)
        positive_count = int(predicted.sum())
        if positive_count > previous_positive:
            raise RuntimeError(...)
        previous_positive = positive_count
        fp = int(((predicted == 1) & (target == 0)).sum())
        fn = ...
        accuracy = (predicted == target).float().mean().item()
        results.append({
            "threshold": threshold,
            "positive_count": positive_count,
            "accuracy": accuracy, "fp": fp, "fn": fn,
        })
    return results

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.3.3 Exercise 02 - Confusion Matrix Construction

Part 1 - Why this matters

A confusion matrix separates correct and incorrect predictions by class. Unlike one accuracy value, it shows whether the classifier succeeds through true positive and true negative decisions or hides a serious one-sided failure.

Its row and column convention must be documented. Swapping actual and predicted axes preserves the four counts but can reverse interpretation when the matrix is read later.

Part 2 - Mathematical form

Using rows for actual class and columns for predicted class:

$$\mathbf{C} = \begin{bmatrix} TN & FP \\ FN & TP \end{bmatrix}$$

The invariant is:

$$TN + FP + FN + TP = N$$

Part 3 - Hints and Helper

Flatten aligned binary tensors, compute the four counts with Boolean masks, construct an integer matrix, and verify its sum equals the number of evaluated samples.

Part 4 - Python code skeleton

```
import torch

def E02(predicted, target):
    predicted = predicted.reshape(-1).to(torch.int64)
    target = target.reshape(-1).to(torch.int64)
    if predicted.shape != target.shape:
        raise ValueError(...)
    tn = ((target == 0) & (predicted == 0)).sum()
    fp = ((target == 0) & (predicted == 1)).sum()
    fn = ...
    tp = ...
    matrix = torch.tensor([[tn, fp], [fn, tp]], dtype=torch.int64)
    if int(matrix.sum()) != target.numel():
        raise RuntimeError(...)
    return {"matrix": matrix, "tn": int(tn), "fp": int(fp),
            "fn": int(fn), "tp": int(tp)}

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.3.4 Exercise 03 - False Positive / False Negative Analysis

Part 1 - Why this matters

False positives and false negatives represent different real-world failures. Their consequences may differ sharply, so a decision rule should not be selected from total error count alone.

Analyzing the two errors separately connects model evaluation to system requirements. The preferred threshold depends on their costs, not on a universal claim that one error type is always worse.

Part 2 - Mathematical form

Define rates:

$$\text{FPR} = \frac{FP}{FP + TN}$$

$$\text{FNR} = \frac{FN}{FN + TP}$$

For specified costs c_{FP} and c_{FN}:

$$C = c_{FP}FP + c_{FN}FN$$

Part 3 - Hints and Helper

Accept confusion counts and explicit costs. Guard denominators when a class is absent. Return rates, weighted cost, and the indices of false-positive and false-negative samples.

Part 4 - Python code skeleton

```
import torch

def safe_divide(numerator, denominator):
    return numerator / denominator if denominator > 0 else None

def E03(probabilities, target, threshold, fp_cost, fn_cost):
    predicted = (probabilities.reshape(-1) >= threshold).long()
    target = target.reshape(-1).long()
    fp_mask = (predicted == 1) & (target == 0)
    fn_mask = (predicted == 0) & (target == 1)
    tn = int(((predicted == 0) & (target == 0)).sum())
    tp = int(((predicted == 1) & (target == 1)).sum())
    fp, fn = int(fp_mask.sum()), int(fn_mask.sum())
    return {
        "false_positive_rate": safe_divide(fp, fp + tn),
        "false_negative_rate": ...,
        "weighted_cost": ...,
        "false_positive_indices": torch.where(fp_mask)[0],
        "false_negative_indices": ...,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.3.5 Exercise 04 - Imbalanced Dataset Effect

Part 1 - Why this matters

When one class dominates a dataset, a classifier can achieve high accuracy by predicting only the majority class. This produces a reassuring number while completely failing the minority outcome the system may care about most.

The class distribution must therefore be reported beside every classification metric. A majority-class baseline provides a minimum reference that a learned decision system should meaningfully exceed.

Part 2 - Mathematical form

If class counts are N_0 and N_1, majority baseline accuracy is:

$$A_{\text{majority}} = \frac{\max(N_0, N_1)}{N_0 + N_1}$$

Balanced accuracy gives each class equal influence:

$$A_{\text{balanced}} = \frac{1}{2}\left(\frac{TP}{TP + FN} + \frac{TN}{TN + FP}\right)$$

Part 3 - Hints and Helper

Construct imbalanced targets and compare an all-majority predictor with a real prediction tensor. Report class prevalence, ordinary accuracy, balanced accuracy, and minority recall. Handle absent classes explicitly.

Part 4 - Python code skeleton

```
import torch

def E04(predicted, target):
    predicted = predicted.reshape(-1).long()
    target = target.reshape(-1).long()
    negative = int((target == 0).sum())
    positive = int((target == 1).sum())
    accuracy = (predicted == target).float().mean().item()
    tp = int(((predicted == 1) & (target == 1)).sum())
    tn = int(((predicted == 0) & (target == 0)).sum())
    recall_positive = tp / positive if positive else None
    recall_negative = tn / negative if negative else None
    balanced = ... if None not in (
        recall_positive, recall_negative
    ) else None
    majority_accuracy = max(negative, positive) / target.numel()
    return {"class_counts": [negative, positive],
            "accuracy": accuracy,
            "balanced_accuracy": balanced,
            "majority_baseline_accuracy": majority_accuracy}

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.3.6 Exercise 05 - Dynamic Threshold Selection

Part 1 - Why this matters

A dynamic threshold is selected from validation evidence to satisfy a defined objective, such as maximizing F1 score or minimizing a weighted error cost. It adapts decision logic to the

system's priorities without changing model parameters.

Threshold search must not use the final test set. Reusing test labels to choose the best cutoff makes the reported test result optimistic because the decision policy has already been tuned to those examples.

Part 2 - Mathematical form

For validation thresholds $\mathcal{T}$ and objective J:

$$\tau^\star = \operatorname*{argmax}_{\tau \in \mathcal{T}} J(\tau)$$

A deterministic tie rule, such as choosing the largest threshold, must be documented.

Part 3 - Hints and Helper

Evaluate each candidate on validation probabilities only. Calculate the requested objective, preserve every result, and resolve ties explicitly. Return both selected threshold and selection evidence.

Part 4 - Python code skeleton

```
import torch

def f1_score(predicted, target):
    tp = ((predicted == 1) & (target == 1)).sum()
    fp = ((predicted == 1) & (target == 0)).sum()
    fn = ((predicted == 0) & (target == 1)).sum()
    denominator = 2 * tp + fp + fn
    return (2 * tp / denominator).item() if denominator else 0.0

def E05(validation_probabilities, validation_target, candidates):
    probability = validation_probabilities.reshape(-1)
    target = validation_target.reshape(-1).long()
    records = []
    for threshold in sorted(candidates):
        predicted = (probability >= threshold).long()
        score = ...
        records.append({"threshold": threshold, "score": score})
    best_score = max(record["score"] for record in records)
    tied = [r for r in records if r["score"] == best_score]
    selected = max(tied, key=lambda record: record["threshold"])
    return {"selected_threshold": ..., "records": records}

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.3.7 Exercise 06 - ROC Curve Concept Implementation

Part 1 - Why this matters

The receiver operating characteristic curve describes classification behavior across many thresholds. It separates the model's ranking ability from one chosen operating point by comparing true-positive and false-positive rates.

ROC construction requires both classes. If every target is identical, one rate has a zero denominator and the curve is not defined for ordinary binary evaluation.

Part 2 - Mathematical form

For each threshold τ:

$$\mathrm{TPR}(\tau) = \frac{TP(\tau)}{TP(\tau) + FN(\tau)}$$

$$\mathrm{FPR}(\tau) = \frac{FP(\tau)}{FP(\tau) + TN(\tau)}$$

Thresholds descend from above the maximum score to below the minimum score, tracing the curve from $(0, 0)$ to $(1, 1)$.

Part 3 - Hints and Helper

Use unique probability values in descending order and include boundary thresholds. At each threshold, calculate labels and both rates. Verify FPR and TPR are nondecreasing along the returned curve.

Part 4 - Python code skeleton

```
import torch

def E06(probabilities, target):
    probability = probabilities.reshape(-1)
    target = target.reshape(-1).long()
    positive = int((target == 1).sum())
    negative = int((target == 0).sum())
    if positive == 0 or negative == 0:
        raise ValueError(...)
    unique = torch.unique(probability).sort(descending=True).values
    thresholds = torch.cat([
        torch.tensor([torch.inf], device=probability.device),
        unique,
        torch.tensor([-torch.inf], device=probability.device),
    ])
    points = []
    for threshold in thresholds:
        predicted = probability >= threshold
        tp = int((predicted & (target == 1)).sum())
        fp = int((predicted & (target == 0)).sum())
```

```
        points.append({
            "threshold": float(threshold),
            "tpr": tp / positive,
            "fpr": ...,
        })
    return points

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.3.8 Exercise 07 - AUC Metric Calculation

Part 1 - Why this matters

Area under the ROC curve summarizes the full ROC path into one ranking metric. It measures how well positive examples tend to receive higher scores than negative examples across thresholds.

AUC does not choose a threshold, measure calibration, or reveal the cost of a specific false decision. It should be reported with the curve and class context rather than used as a complete evaluation by itself.

Part 2 - Mathematical form

For ROC points sorted by increasing false-positive rate, trapezoidal area is:

$$\text{AUC} = \sum_{k=1}^{K-1} \frac{TPR_k + TPR_{k+1}}{2}(FPR_{k+1} - FPR_k)$$

A valid binary ROC AUC lies between zero and one.

Part 3 - Hints and Helper

Accept ROC points from the previous exercise and sort them by FPR. Calculate trapezoidal area with PyTorch, then check monotonic coordinates, endpoints, finiteness, and final range.

Part 4 - Python code skeleton

```
import torch

def E07(roc_points):
    ordered = sorted(roc_points, key=lambda point: point["fpr"])
    fpr = torch.tensor(
        [point["fpr"] for point in ordered], dtype=torch.float64
    )
    tpr = torch.tensor(
        [point["tpr"] for point in ordered], dtype=torch.float64
    )
```

```
    if not torch.all(fpr[1:] >= fpr[:-1]):
        raise ValueError(...)
    auc = torch.trapezoid(tpr, fpr).item()
    if not 0 <= auc <= 1:
        raise RuntimeError(...)
    return {"auc": auc, "point_count": len(ordered),
            "starts_at_origin": ..., "ends_at_one": ...}

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.3.9 Exercise 08 - Precision vs Recall Tradeoff

Part 1 - Why this matters

Precision asks how many predicted positives are correct, while recall asks how many actual positives were found. Changing the threshold often improves one while weakening the other.

The preferred balance depends on application costs and class prevalence. A threshold should not be declared best without stating whether missed positives or false alarms are more damaging.

Part 2 - Mathematical form

$$\text{Precision} = \frac{TP}{TP + FP}$$

$$\text{Recall} = \frac{TP}{TP + FN}$$

Their harmonic mean is:

$$F_1 = \frac{2PR}{P + R}$$

when the required denominators are defined.

Part 3 - Hints and Helper

Calculate precision, recall, and F1 at several thresholds. Return `None` or a documented fallback when no positives are predicted. Show the threshold that maximizes F1 without claiming it is universally optimal.

Part 4 - Python code skeleton

```
import torch

def E08(probabilities, target, thresholds):
    probability = probabilities.reshape(-1)
```

```
    target = target.reshape(-1).long()
    records = []
    for threshold in thresholds:
        predicted = (probability >= threshold).long()
        tp = int(((predicted == 1) & (target == 1)).sum())
        fp = int(((predicted == 1) & (target == 0)).sum())
        fn = int(((predicted == 0) & (target == 1)).sum())
        precision = tp / (tp + fp) if tp + fp else None
        recall = tp / (tp + fn) if tp + fn else None
        metrics_defined = precision is not None and recall is not None
        f1 = ... if metrics_defined else None
        records.append({"threshold": threshold,
                        "precision": precision,
                        "recall": recall, "f1": f1})
    return records

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.3.10 Exercise 09 - Classification Failure Case

Part 1 - Why this matters

Classification logic can produce misleading results through invalid probabilities, mismatched sample order, incorrect target encoding, or an unsuitable threshold. Some failures preserve shape and avoid exceptions, making validation essential.

A controlled failure experiment teaches the reader to distinguish a model error from a decision-logic error. The same probabilities can generate different labels, while corrupted alignment makes every derived metric unreliable.

Part 2 - Technical concept and behavior

Before evaluation require:

$$\text{shape}(\mathbf{p}) = \text{shape}(\mathbf{y})$$

$$\mathbf{p} \in [0,1]^N, \qquad \mathbf{y} \in \{0,1\}^N$$

and a threshold in $[0, 1]$. Sample identifiers should also remain aligned after filtering or sorting.

Part 3 - Hints and Helper

Build a validator that reports every failed contract. Test logits passed as probabilities, shuffled targets, invalid labels, NaN values, and thresholds outside the allowed range.

Part 4 - Python code skeleton

```
import torch

def E09(probabilities, target, threshold):
    issues = []
    if probabilities.shape != target.shape:
        issues.append("shape_mismatch")
    if not probabilities.is_floating_point():
        issues.append("probability_dtype")
    elif not torch.isfinite(probabilities).all():
        issues.append("nonfinite_probability")
    elif not ((probabilities >= 0) & (probabilities <= 1)).all():
        issues.append(...)
    if not torch.all((target == 0) | (target == 1)):
        issues.append(...)
    if not 0 <= threshold <= 1:
        issues.append(...)
    return {"valid": len(issues) == 0, "issues": issues}

def main():
    cases = {...}
    for name, values in cases.items():
        print(name, E09(...))

if __name__ == "__main__":
    main()
```

11.3.11 Exercise 10 - CUDA Evaluation without Grad

Part 1 - Why this matters

CUDA evaluation should calculate logits, probabilities, decisions, and global confusion counts without constructing backward graphs. Disabling gradient tracking reduces unnecessary state while preserving the trained parameters.

Evaluation mode and inference mode solve different problems. The model should use both deliberately, even when a simple linear layer happens to produce the same output in training and evaluation modes.

Part 2 - Technical concept and behavior

For every batch, require:

$$d_{\mathbf{X}} = d_{\mathbf{y}} = d_{\boldsymbol{\theta}} = \text{CUDA}$$

Confusion counts can be accumulated as integers and used to calculate dataset-level metrics after every batch has completed.

Part 3 - Hints and Helper

Check CUDA availability, move model and batches to one device, call `eval()`, and use `torch.inference_mode()`. Accumulate counts rather than retaining every computational output on GPU.

Part 4 - Python code skeleton

```
import torch

def E10(model, loader, threshold=0.5):
    if not torch.cuda.is_available():
        return {"skipped": True, "reason": ...}
    device = torch.device("cuda")
    model = model.to(device).eval()
    counts = {"tp": 0, "tn": 0, "fp": 0, "fn": 0}
    mode_was_enabled = False
    with torch.inference_mode():
        mode_was_enabled = torch.is_inference_mode_enabled()
        for X, target in loader:
            X = X.to(device)
            target = target.to(device).reshape(-1).long()
            probability = torch.sigmoid(model(X)).reshape(-1)
            predicted = (probability >= threshold).long()
            counts["tp"] += int(
                ((predicted == 1) & (target == 1)).sum()
            )
            counts["tn"] += ...
            counts["fp"] += ...
            counts["fn"] += ...
    return {"skipped": False, "counts": counts,
            "inference_mode": mode_was_enabled}

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.3.12 Exercise 11 - Batch-wise Decision Pipeline

Part 1 - Why this matters

A batch-wise decision pipeline evaluates datasets too large to process at once. It must preserve global metric meaning even when the final batch is smaller than the others.

Averaging metric values computed separately per batch can bias the result. Confusion counts should be summed across batches first, then converted into accuracy, precision, recall, and related metrics.

Part 2 - Mathematical form

For batches $b = 1, \ldots, B$:

$$TP_{\text{global}} = \sum_{b=1}^{B} TP_b$$

and similarly for TN, FP, and FN. Global accuracy is:

$$\frac{TP + TN}{TP + TN + FP + FN}$$

Part 3 - Hints and Helper

Validate output and target shape inside every batch. Accumulate integer counts and total sample count, calculate metrics after the loop, and raise a clear error for an empty loader.

Part 4 - Python code skeleton

```
import torch

def E11(model, loader, device, threshold=0.5):
    model.eval()
    tp = tn = fp = fn = 0
    batches = 0
    with torch.inference_mode():
        for X, target in loader:
            batches += 1
            X, target = X.to(device), target.to(device)
            probability = torch.sigmoid(model(X))
            if probability.shape != target.shape:
                raise ValueError(...)
            predicted = (probability >= threshold).long()
            target = target.long()
            tp += int(((predicted == 1) & (target == 1)).sum())
            tn += ...
            fp += ...
            fn += ...
    if batches == 0:
        raise ValueError(...)
    total = tp + tn + fp + fn
    return {"accuracy": (tp + tn) / total,
            "precision": tp / (tp + fp) if tp + fp else None,
            "recall": ..., "counts": [tn, fp, fn, tp]}

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.3.13 Exercise 12 - Prediction Consistency Test

Part 1 - Why this matters

Repeated evaluation of a fixed model and fixed input should produce consistent probabilities and labels under a controlled environment. Unexpected variation can reveal active stochastic

layers, changed model state, mutation, or nondeterministic execution.

Consistency does not require universal bitwise identity across devices or software versions. The test must define whether it checks one environment exactly or compares environments with numerical tolerances.

Part 2 - Technical concept and behavior

For repeated outputs $\mathbf{p}^{(1)}, \ldots, \mathbf{p}^{(R)}$, define:

$$\Delta_{\max} = \max_{r,i} |p_i^{(r)} - p_i^{(1)}|$$

Labels should also remain equal for a fixed threshold, especially for probabilities near the cutoff.

Part 3 - Hints and Helper

Call evaluation mode, disable gradients, repeat the same forward pass, and preserve outputs for comparison. Report maximum probability difference, label agreement, and minimum distance from the threshold.

Part 4 - Python code skeleton

```
import torch

def E12(model, X, threshold=0.5, repetitions=10,
        atol=1e-7, rtol=1e-6):
    model.eval()
    outputs = []
    with torch.inference_mode():
        for _ in range(repetitions):
            outputs.append(torch.sigmoid(model(X)).detach().clone())
    reference = outputs[0]
    differences = torch.stack(
        [(current - reference).abs() for current in outputs]
    )
    probability_consistent = all(
        torch.allclose(current, reference, atol=atol, rtol=rtol)
        for current in outputs
    )
    labels = [(current >= threshold).long() for current in outputs]
    return {
        "probability_consistent": probability_consistent,
        "labels_consistent": all(torch.equal(x, labels[0])
                                 for x in labels),
        "maximum_difference": ...,
        "minimum_threshold_distance":
            (reference - threshold).abs().min().item(),
    }

def main():
```

```
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.3.14 Exercise 13 - Threshold Drift Detection

Part 1 - Why this matters

A threshold selected for one model or data period may no longer provide the same error balance after probabilities drift. Monitoring threshold behavior can reveal that the decision policy needs investigation even when the code has not changed.

A new threshold should not be adopted automatically from every small fluctuation. Drift detection should use a fixed evaluation protocol, sufficient sample size, and explicit alert tolerances.

Part 2 - Mathematical form

For baseline threshold τ_0 and newly selected threshold τ_t:

$$D_\tau = |\tau_t - \tau_0|$$

Also compare predicted-positive rates:

$$D_R = |R_+(\tau_t) - R_{+,0}|$$

A monitoring alert can require either or both quantities to exceed predefined limits.

Part 3 - Hints and Helper

Use the same threshold-selection objective on baseline and current validation sets. Record class prevalence, selected threshold, score, and positive rate. Do not interpret threshold movement without checking data distribution.

Part 4 - Python code skeleton

```
def E13(baseline, current, threshold_tolerance,
        positive_rate_tolerance):
    threshold_drift = abs(
        current["selected_threshold"]
        - baseline["selected_threshold"]
    )
    rate_drift = abs(
        current["predicted_positive_rate"]
        - baseline["predicted_positive_rate"]
    )
    alerts = {
        "threshold": threshold_drift > threshold_tolerance,
        "positive_rate": rate_drift > positive_rate_tolerance,
    }
    return {
```

```
        "threshold_drift": threshold_drift,
        "positive_rate_drift": rate_drift,
        "alert": ...,
        "alert_reasons": [name for name, active in alerts.items()
                          if active],
        "baseline_prevalence": baseline["prevalence"],
        "current_prevalence": ...,
    }

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.3.15 Exercise 14 - Metric Stability under Noise

Part 1 - Why this matters

Input noise can shift probabilities across the decision threshold and change classification metrics. A model whose score is stable on clean data may become unreliable when measurements contain realistic perturbations.

One random noise sample is not enough to establish stability. Repeated seeded trials at several noise levels reveal both average degradation and variability.

Part 2 - Technical concept and behavior

For perturbed input:

$$\widetilde{\mathbf{X}} = \mathbf{X} + \sigma\boldsymbol{\epsilon}, \qquad \boldsymbol{\epsilon} \sim \mathcal{N}(0, \mathbf{I})$$

record metric $M_{\sigma,r}$ across trial r, then summarize its mean and standard deviation.

Part 3 - Hints and Helper

Keep model, targets, threshold, and test examples fixed. Generate noise with controlled seeds, avoid perturbing protected categorical fields, and compare each noise level with the clean baseline.

Part 4 - Python code skeleton

```
import torch

def accuracy(model, X, target, threshold):
    probability = torch.sigmoid(model(X)).reshape(-1)
    predicted = (probability >= threshold).long()
    return (predicted == target.reshape(-1).long()).float().mean()

def E14(model, X, target, levels, trials, threshold, seed):
    model.eval()
```

```
    results = {}
    with torch.inference_mode():
        clean = accuracy(model, X, target, threshold).item()
        for level in levels:
            scores = []
            for trial in range(trials):
                generator = torch.Generator(device=X.device)
                generator.manual_seed(seed + trial)
                noise = torch.randn(
                    X.shape, generator=generator,
                    device=X.device, dtype=X.dtype
                )
                score = accuracy(
                    model, X + level * noise, target, threshold
                )
                scores.append(score)
            values = torch.stack(scores)
            results[level] = {
                "mean_accuracy": ...,
                "std_accuracy": ...,
                "degradation": clean - values.mean().item(),
            }
    return {"clean_accuracy": clean, "noise": results}

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.3.16 Exercise 15 - Classification Latency Benchmark

Part 1 - Why this matters

Classification latency includes the forward pass, sigmoid transformation, and threshold decision required to produce labels. It matters when the system must respond to individual requests or small batches quickly.

CUDA execution is asynchronous, so ordinary host timing without synchronization can finish before device work completes. A useful benchmark also separates warm-up from measured repetitions.

Part 2 - Mathematical form

For measured times $t_1, \ldots, t_R$, report:

$$\bar{t} = \frac{1}{R} \sum_{r=1}^{R} t_r$$

along with median and tail percentiles such as p_{95}. Batch size and device must accompany the result.

Part 3 - Hints and Helper

Use CUDA timing events for a CUDA tensor and a synchronized high-resolution host timer for CPU. Warm up first, disable gradients, and time the complete decision operation consistently.

Part 4 - Python code skeleton

```
import time
import torch

def decision(model, X, threshold):
    return (torch.sigmoid(model(X)) >= threshold).long()

def E15(model, X, threshold=0.5, warmup=20, repetitions=100):
    model.eval()
    times_ms = []
    with torch.inference_mode():
        for _ in range(warmup):
            decision(model, X, threshold)
        if X.device.type == "cuda":
            torch.cuda.synchronize(X.device)
        for _ in range(repetitions):
            if X.device.type == "cuda":
                start = torch.cuda.Event(enable_timing=True)
                end = torch.cuda.Event(enable_timing=True)
                start.record()
                decision(model, X, threshold)
                end.record()
                torch.cuda.synchronize(X.device)
                times_ms.append(start.elapsed_time(end))
            else:
                start = time.perf_counter()
                decision(model, X, threshold)
                times_ms.append((time.perf_counter() - start) * 1000)
    values = torch.tensor(times_ms)
    return {"mean_ms": ..., "median_ms": ...,
            "p95_ms": torch.quantile(values, 0.95).item()}

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.3.17 Exercise 16 - Memory Profiling for Inference

Part 1 - Why this matters

Inference memory determines feasible batch size and whether a classifier can share a device with other workloads. The final labels are small, but intermediate logits, probabilities, and model parameters still consume memory.

PyTorch distinguishes memory occupied by live tensors from memory reserved by its caching allocator. Current and peak values should be reported separately instead of inferred from an external display alone.

Part 2 - Technical concept and behavior

For a controlled CUDA region, measure:

$$M_{\text{allocated}}^{\text{peak}} \quad \text{and} \quad M_{\text{reserved}}^{\text{peak}}$$

after resetting peak counters and completing warm-up.

Part 3 - Hints and Helper

Require CUDA, warm up and synchronize, then reset peak memory statistics. Run the complete forward, sigmoid, and threshold operation. Keep the result alive until measurements are recorded.

Part 4 - Python code skeleton

```
import torch

def E16(model, X, threshold=0.5):
    if X.device.type != "cuda":
        raise ValueError(...)
    model.eval()
    with torch.inference_mode():
        model(X)
        torch.cuda.synchronize(X.device)
        baseline = torch.cuda.memory_allocated(X.device)
        torch.cuda.reset_peak_memory_stats(X.device)
        logits = model(X)
        probabilities = torch.sigmoid(logits)
        labels = (probabilities >= threshold).long()
        torch.cuda.synchronize(X.device)
        report = {
            "baseline_allocated_bytes": baseline,
            "current_allocated_bytes":
                torch.cuda.memory_allocated(X.device),
            "peak_allocated_bytes":
                torch.cuda.max_memory_allocated(X.device),
            "peak_reserved_bytes": ...,
            "output_elements": labels.numel(),
        }
    return report

def main():
```

```
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.3.18 Exercise 17 - Misclassification Debugging

Part 1 - Why this matters

Misclassified examples show where the final decision disagrees with the target. Inspecting their probabilities, features, and identifiers can reveal threshold effects, data errors, rare subgroups, or limitations of a linear boundary.

Failure analysis should use a declared selection rule rather than hand-picked examples. High-confidence errors deserve special attention, but a probability far from the threshold is not proof that the target is wrong.

Part 2 - Technical concept and behavior

For misclassification mask:

$$m_i = \mathbf{1}[\widehat{y}_i \neq y_i]$$

Define confidence in the chosen class:

$$c_i = \begin{cases} p_i, & \widehat{y}_i = 1, \\ 1 - p_i, & \widehat{y}_i = 0 \end{cases}$$

Sort misclassified samples by c_i to inspect the strongest incorrect decisions.

Part 3 - Hints and Helper

Preserve sample identifiers and feature rows. Return every misclassified index, error type, probability, threshold distance, and predicted-class confidence. Limit displayed examples without discarding the full count.

Part 4 - Python code skeleton

```
import torch

def E17(X, probabilities, target, sample_ids,
        threshold=0.5, top_k=10):
    probability = probabilities.reshape(-1)
    target = target.reshape(-1).long()
    predicted = (probability >= threshold).long()
    wrong = predicted != target
    confidence = torch.where(
        predicted == 1, probability, 1 - probability
    )
    wrong_indices = torch.where(wrong)[0]
    if wrong_indices.numel() == 0:
```

```
        return {"count": 0, "examples": []}
    scores = confidence[wrong_indices]
    order = torch.argsort(scores, descending=True)
    selected = wrong_indices[order[:top_k]]
    examples = []
    for index in selected.tolist():
        examples.append({
            "sample_id": sample_ids[index],
            "probability": probability[index].item(),
            "target": target[index].item(),
            "predicted": ...,
            "error_type": ...,
            "threshold_distance": ...,
        })
    return {"count": int(wrong.sum()), "examples": examples}

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.3.19 Exercise 18 - Evaluation Pipeline Automation

Part 1 - Why this matters

An automated pipeline applies the same input validation, model state, threshold, confusion logic, metrics, and performance checks to each classifier version. This reduces manual inconsistency and creates comparable evidence.

The pipeline must preserve intermediate counts and configuration rather than return only a final score. A result cannot be reproduced when its threshold, class distribution, sample count, or model version is missing.

Part 2 - Technical concept and behavior

The evaluation mapping is:

$$(\text{model}, \text{data}, \tau, \text{configuration}) \longrightarrow (\text{probabilities}, \text{decisions}, \text{counts}, \text{metrics}, \text{diagnostics})$$

Core validation failures should stop the run; optional diagnostics may report their own failure status.

Part 3 - Hints and Helper

Create separate functions for validation, inference, confusion counts, metrics, latency, and failure analysis. Return a stable dictionary schema with device, dtype, threshold, sample count, and timestamps.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone
import torch

def E18(model, loader, device, threshold, configuration):
    report = {
        "generated_at": datetime.now(timezone.utc).isoformat(),
        "configuration": configuration,
        "device": str(device),
        "threshold": threshold,
        "status": "running",
    }
    try:
        ...  # validate threshold and dataset
        outputs = ...  # run inference without gradients
        counts = ...  # aggregate globally
        metrics = ...  # derive from global counts
        report.update({
            "counts": counts,
            "metrics": metrics,
            "sample_count": sum(counts.values()),
            "status": "passed",
        })
    except Exception as error:
        report["status"] = "failed"
        report["error"] = {
            "type": type(error).__name__,
            "message": str(error),
        }
    return report

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.3.20 Exercise 19 - Decision Logic Failure Scenario

Part 1 - Why this matters

Decision logic can fail through invalid thresholds, empty datasets, absent classes, probability corruption, target misalignment, or undefined metric denominators. A robust system must detect these conditions before publishing performance.

The final exercise treats failure handling as part of evaluation design. It should distinguish an invalid run from a valid run whose metric is undefined for a documented reason.

Part 2 - Technical concept and behavior

A valid evaluation requires:

$$N > 0, \qquad 0 \leq \tau \leq 1, \qquad \mathbf{p} \in [0,1]^N, \qquad \mathbf{y} \in \{0,1\}^N$$

Metrics must use explicit zero-denominator policies, and ROC/AUC additionally requires both target classes.

Part 3 - Hints and Helper

Build named scenarios for empty input, one-class target, invalid probability, mismatched length, and out-of-range threshold. Return stage, severity, metric availability, and original error details.

Part 4 - Python code skeleton

```
import torch

def validate_decision_inputs(probability, target, threshold):
    if probability.numel() == 0:
        raise ValueError("empty evaluation")
    if probability.shape != target.shape:
        raise ValueError("shape mismatch")
    if not 0 <= threshold <= 1:
        raise ValueError("invalid threshold")
    if not torch.isfinite(probability).all():
        raise ValueError("nonfinite probability")
    if not ((probability >= 0) & (probability <= 1)).all():
        raise ValueError("probability outside range")
    if not torch.all((target == 0) | (target == 1)):
        raise ValueError("target is not binary")

def E19(scenarios):
    report = []
    for name, scenario in scenarios.items():
        try:
            validate_decision_inputs(...)
            classes = torch.unique(scenario["target"])
            roc_available = classes.numel() == 2
            metrics = ...
            result = {"status": "valid",
                      "roc_available": roc_available,
                      "metrics": metrics}
        except (ValueError, RuntimeError) as error:
            result = {"status": "invalid",
                      "error_type": type(error).__name__,
                      "message": str(error)}
        report.append({"scenario": name, "result": result})
    return report

def main():
    print(E19(...))
```

```
if __name__ == "__main__":
    main()
```

11.4 LG02 - Sigmoid Activation Behavior

Models and Training

11.4.1 Exercise 00 - Plot Sigmoid Curve

Part 1 - Why this matters

The sigmoid curve makes the connection between unrestricted logits and bounded probabilities visible. Its central region responds strongly to input changes, while its tails approach zero and one without crossing those theoretical limits.

A correct plot should communicate both transformation and interpretation. Reference lines at logit zero and probability 0.5 identify the decision center, while a sufficiently wide input range exposes saturation.

Part 2 - Mathematical form

$$\sigma(z) = \frac{1}{1 + e^{-z}}$$

The function is monotonic and satisfies:

$$\sigma(0) = 0.5, \qquad \lim_{z \to -\infty} \sigma(z) = 0, \qquad \lim_{z \to \infty} \sigma(z) = 1$$

Part 3 - Hints and Helper

Generate an ordered one-dimensional tensor with `torch.linspace`, calculate sigmoid with PyTorch, detach values, and move them to CPU before plotting. Label both axes and include horizontal and vertical reference lines.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E00(start, end, steps, output_path):
    logits = torch.linspace(start, end, steps=steps)
    probabilities = torch.sigmoid(logits)
    fig, ax = plt.subplots()
    ax.plot(logits.numpy(), probabilities.numpy(),
            label="Sigmoid")
    ax.axvline(0.0, color="black", linestyle="--")
    ax.axhline(0.5, color="black", linestyle=":")
    ax.set_xlabel(...)
```

```
    ax.set_ylabel(...)
    ax.set_ylim(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E00(...)

if __name__ == "__main__":
    main()
```

11.4.2 Exercise 01 - Gradient of Sigmoid Inspection

Part 1 - Why this matters

The sigmoid derivative determines how a change in a logit affects the probability and how gradients pass backward through the activation. Inspecting it connects the analytical rule to PyTorch autograd.

Agreement between analytical and automatic gradients provides stronger evidence than printing one result. It also reveals that the largest local sensitivity occurs near the center rather than in the confident tails.

Part 2 - Mathematical form

$$\frac{d\sigma(z)}{dz} = \sigma(z)(1 - \sigma(z))$$

The derivative is nonnegative and reaches its maximum value 0.25 at $z = 0$.

Part 3 - Hints and Helper

Use a float64 leaf tensor with gradient tracking. Sum sigmoid outputs to create a scalar whose backward gradient contains the element-wise derivatives, then compare with the analytical formula.

Part 4 - Python code skeleton

```
import torch

def E01(logits):
    if not logits.is_leaf or not logits.requires_grad:
        raise ValueError(...)
    probabilities = torch.sigmoid(logits)
    probabilities.sum().backward()
    automatic = logits.grad.detach().clone()
    analytical = (
        probabilities.detach() * (1 - probabilities.detach())
    )
    return {
```

```
        "automatic": automatic,
        "analytical": analytical,
        "agreement": torch.allclose(
            automatic, analytical, atol=..., rtol=...
        ),
        "maximum_gradient": automatic.max().item(),
    }

def main():
    logits = torch.tensor(
        [...], dtype=torch.float64, requires_grad=True
    )
    print(E01(logits))

if __name__ == "__main__":
    main()
```

11.4.3 Exercise 02 - Vanishing Gradient Demonstration

Part 1 - Why this matters

Sigmoid gradients become very small for large-magnitude logits. When many such factors appear in a chain, the gradient reaching early values can shrink until parameter updates become ineffective.

A demonstration should measure gradient magnitude across input regions instead of declaring that every small value is a failure. The scale of the upstream gradient and the chosen dtype also affect what is observed.

Part 2 - Mathematical form

For one sigmoid:

$$0 < \sigma'(z) \leq 0.25$$

For a chain of L derivative factors:

$$\left|\frac{\partial a_L}{\partial a_0}\right| = \prod_{\ell=1}^{L} |\sigma'(z_\ell)|$$

which can decrease rapidly as depth increases.

Part 3 - Hints and Helper

Evaluate negative extreme, central, and positive extreme logits as separate leaf tensors. Backpropagate the sum of outputs and compare absolute gradient magnitudes and their ratios.

Part 4 - Python code skeleton

```
import torch

def measure(values):
```

```
    logits = torch.tensor(
        values, dtype=torch.float64, requires_grad=True
    )
    torch.sigmoid(logits).sum().backward()
    return logits.grad.detach()

def E02(regions, vanishing_tolerance=1e-6):
    report = {}
    for name, values in regions.items():
        gradient = measure(values)
        report[name] = {
            "gradient": gradient,
            "mean_absolute_gradient": gradient.abs().mean().item(),
            "vanishing_count": int(
                (gradient.abs() < vanishing_tolerance).sum()
            ),
        }
    report["tail_to_center_ratio"] = ...
    return report

def main():
    regions = {"negative_tail": [...],
               "center": [...], "positive_tail": [...]}
    print(E02(regions))

if __name__ == "__main__":
    main()
```

11.4.4 Exercise 03 - Saturation Region Detection

Part 1 - Why this matters

Saturation detection identifies logits whose probabilities lie close to zero or one and whose local derivatives are small. This helps distinguish confident output from a responsive activation region.

The boundary depends on an explicit tolerance and dtype. A probability may round to an exact boundary in one precision before it does in another, so the detection rule must be reported with its settings.

Part 2 - Mathematical form

For probability tolerance ϵ and derivative tolerance δ, define saturation when:

$$p \leq \epsilon \quad \text{or} \quad p \geq 1 - \epsilon \quad \text{or} \quad p(1-p) \leq \delta$$

The exercise should report which condition triggered each detection.

Part 3 - Hints and Helper

Calculate probabilities and derivatives vectorially. Create separate masks for low probability, high probability, and small derivative, then combine them without losing the individual reasons.

Part 4 - Python code skeleton

```
import torch

def E03(logits, probability_tolerance=1e-4,
        derivative_tolerance=1e-4):
    probability = torch.sigmoid(logits)
    derivative = probability * (1 - probability)
    low = probability <= probability_tolerance
    high = probability >= 1 - probability_tolerance
    flat = derivative <= derivative_tolerance
    saturated = ...
    return {
        "probability": probability,
        "derivative": derivative,
        "low_probability_mask": low,
        "high_probability_mask": high,
        "small_derivative_mask": flat,
        "saturated_mask": saturated,
        "saturated_count": int(saturated.sum()),
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.4.5 Exercise 04 - Input Scaling Effect

Part 1 - Why this matters

Feature scaling changes logit magnitude and therefore determines which part of sigmoid receives most samples. Large scales can push outputs into saturation, while very small scales can collapse probabilities near 0.5.

Scaling can affect optimization even when the final decision boundary could theoretically be represented. This experiment isolates activation behavior before training complicates the observation.

Part 2 - Mathematical form

For base logit z and scale s:

$$p_s = \sigma(sz)$$

$$g_s = p_s(1 - p_s)$$

As $|s|$ grows for nonzero z, probabilities move toward the tails and derivatives usually shrink.

Part 3 - Hints and Helper

Use the same base logits for every positive scale. Record probability range, mean derivative, and saturated fraction. Keep dtype and tolerance fixed across comparisons.

Part 4 - Python code skeleton

```
import torch

def E04(base_logits, scales, saturation_tolerance=1e-4):
    report = []
    for scale in scales:
        scaled = base_logits * scale
        probability = torch.sigmoid(scaled)
        derivative = probability * (1 - probability)
        saturated = derivative <= saturation_tolerance
        report.append({
            "scale": scale,
            "probability_min": probability.min().item(),
            "probability_max": probability.max().item(),
            "mean_derivative": ...,
            "saturated_fraction": saturated.float().mean().item(),
        })
    return report

def main():
    base_logits = torch.linspace(..., ..., steps=...)
    print(E04(base_logits, scales=[...]))

if __name__ == "__main__":
    main()
```

11.4.6 Exercise 05 - Large Logit Stability Test

Part 1 - Why this matters

Large logits expose overflow and rounding behavior hidden by ordinary examples. A direct exponential formula may create an infinite intermediate even when the final sigmoid value is representable.

A stability test should distinguish finite output, mathematical accuracy, monotonicity, and boundary rounding. Returning zero or one for an extreme finite logit may be expected rounding, while returning NaN indicates a stronger failure.

Part 2 - Mathematical form

The direct formula is:

$$\sigma(z) = \frac{1}{1 + e^{-z}}$$

For negative z, the equivalent expression:

$$\sigma(z) = \frac{e^{z}}{1 + e^{z}}$$

avoids evaluating e^{-z} at a large positive magnitude.

Part 3 - Hints and Helper

Compare a naive formula, a branch-aware manual formula, and `torch.sigmoid` over symmetric extreme inputs. Report finite status, maximum difference, exact boundary counts, and monotonicity.

Part 4 - Python code skeleton

```
import torch

def stable_manual(logits):
    positive = logits >= 0
    result = torch.empty_like(logits)
    result[positive] = 1 / (1 + torch.exp(-logits[positive]))
    value = torch.exp(logits[~positive])
    result[~positive] = value / (1 + value)
    return result

def E05(logits):
    naive = 1 / (1 + torch.exp(-logits))
    manual = stable_manual(logits)
    reference = torch.sigmoid(logits)
    return {
        "naive_finite": bool(torch.isfinite(naive).all()),
        "manual_finite": bool(torch.isfinite(manual).all()),
        "reference_finite": bool(torch.isfinite(reference).all()),
        "manual_agreement": torch.allclose(
            manual, reference, atol=..., rtol=...
        ),
        "monotonic": bool(torch.all(reference[1:] >= reference[:-1])),
        "exact_boundaries": ...,
    }

def main():
    print(E05(torch.tensor([...], dtype=torch.float64)))

if __name__ == "__main__":
    main()
```

11.4.7 Exercise 06 - CUDA Gradient Comparison

Part 1 - Why this matters

CPU and CUDA should produce numerically close sigmoid gradients when inputs, dtype, and upstream objective are equivalent. This test detects device-copy mistakes and establishes realistic expectations for cross-device comparison.

Floating-point results across devices are not guaranteed to be bitwise identical. The comparison must use stated tolerances and report actual differences rather than forcing exact equality.

Part 2 - Technical concept and behavior

For CPU and CUDA gradients:

$$\Delta_{\max} = \max_i |g_i^{\text{CPU}} - g_i^{\text{CUDA}}|$$

Parity uses:

$$|g_i^{\text{CPU}} - g_i^{\text{CUDA}}| \leq \text{atol} + \text{rtol}|g_i^{\text{CUDA}}|$$

Part 3 - Hints and Helper

Create independent leaf copies on CPU and CUDA, calculate the same scalar sum, call backward separately, and move the CUDA gradient to CPU before comparison.

Part 4 - Python code skeleton

```
import torch

def sigmoid_gradient(values, device):
    logits = values.detach().clone().to(device).requires_grad_(True)
    torch.sigmoid(logits).sum().backward()
    return logits.grad.detach().cpu()

def E06(values, atol=1e-6, rtol=1e-5):
    if not torch.cuda.is_available():
        return {"skipped": True, "reason": ...}
    cpu_gradient = sigmoid_gradient(values, "cpu")
    cuda_gradient = sigmoid_gradient(values, "cuda")
    difference = (cpu_gradient - cuda_gradient).abs()
    return {
        "skipped": False,
        "allclose": torch.allclose(
            cpu_gradient, cuda_gradient, atol=atol, rtol=rtol
        ),
        "maximum_difference": difference.max().item(),
        "mean_difference": ...,
    }

def main():
```

```
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.4.8 Exercise 07 - Float32 vs Float64 Gradient

Part 1 - Why this matters

Float32 and float64 represent sigmoid probabilities and gradients with different precision. Tail gradients may round differently or reach zero earlier, while the central region usually agrees more closely.

A dtype comparison should begin from the same high-precision source values. Creating separate approximate inputs can mix input differences with gradient-computation differences.

Part 2 - Technical concept and behavior

For gradient in dtype d:

$$g_d = \sigma(z_d)(1 - \sigma(z_d))$$

Compare with float64 reference:

$$\Delta = |g_{32} - g_{64}|$$

and record relative difference only where the reference gradient is nonzero.

Part 3 - Hints and Helper

Create a float64 source, cast independent leaf tensors, backpropagate the same sum, and convert gradients to float64 before comparing. Include central and extreme logits.

Part 4 - Python code skeleton

```
import torch

def gradient_for_dtype(source, dtype):
    logits = source.to(dtype).detach().requires_grad_(True)
    torch.sigmoid(logits).sum().backward()
    return logits.grad.detach().to(torch.float64)

def E07(values, epsilon=1e-30):
    source = torch.as_tensor(values, dtype=torch.float64)
    gradient32 = gradient_for_dtype(source, torch.float32)
    gradient64 = gradient_for_dtype(source, torch.float64)
    absolute = (gradient32 - gradient64).abs()
    relative = absolute / (gradient64.abs() + epsilon)
    return {
        "float32": gradient32,
        "float64": gradient64,
        "maximum_absolute_difference": ...,
```

```
        "maximum_relative_difference": ...,
        "float32_zero_count": int((gradient32 == 0).sum()),
    }

def main():
    print(E07([... ]))

if __name__ == "__main__":
    main()
```

11.4.9 Exercise 08 - Backward Pass Visualization

Part 1 - Why this matters

Plotting sigmoid output and its backward gradient on aligned axes reveals where the activation is responsive and where it becomes flat. This joins forward interpretation with backward learning behavior.

A linear vertical scale may hide very small tail gradients. Supporting a logarithmic gradient view can expose their decay, but zeros require careful handling because the logarithm is undefined.

Part 2 - Mathematical form

Plot:

$$p(z) = \sigma(z)$$

and:

$$g(z) = \left|\frac{dp}{dz}\right| = \sigma(z)(1 - \sigma(z))$$

using the same ordered logit coordinates.

Part 3 - Hints and Helper

Use a leaf logit tensor, retain the analytical ordering, backpropagate the probability sum, and detach before plotting. Use separate axes or subplots so probability and gradient scales are not confused.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E08(start, end, steps, output_path, log_gradient=False):
    logits = torch.linspace(
        start, end, steps=steps, requires_grad=True
    )
    probability = torch.sigmoid(logits)
    probability.sum().backward()
```

```
    gradient = logits.grad.detach().abs()
    x = logits.detach()
    fig, axes = plt.subplots(2, 1, sharex=True)
    axes[0].plot(x.numpy(), probability.detach().numpy())
    axes[0].set_ylabel("Probability")
    axes[1].plot(x.numpy(), gradient.numpy())
    if log_gradient:
        axes[1].set_yscale("log")
    axes[1].set_xlabel(...)
    axes[1].set_ylabel(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E08(...)

if __name__ == "__main__":
    main()
```

11.4.10 Exercise 09 - Activation Failure Debugging

Part 1 - Why this matters

Sigmoid experiments can fail through integer inputs, detached graphs, in-place mutation, non-finite logits, unstable manual exponentiation, or accidental double activation. Some cases return plausible probabilities while breaking gradient flow.

Debugging should inspect representation and graph metadata before changing formulas. A value inside $[0, 1]$ does not prove that the activation was applied exactly once or remains connected to its source.

Part 2 - Technical concept and behavior

A gradient-capable sigmoid output requires:

$$z \in \mathbb{R}, \qquad \text{isfinite}(z) = \text{True}$$

and, when gradients are expected:

$$z.\texttt{requires_grad} = \text{True}, \qquad \sigma(z).\texttt{grad_fn} \neq \texttt{None}$$

Part 3 - Hints and Helper

Build controlled cases for integer dtype, NaN input, detached output, and double sigmoid. Report dtype, device, finite status, gradient flags, output range, and detected issue without silently casting invalid data.

Part 4 - Python code skeleton

```
import torch

def inspect_activation(logits, output, expect_gradient=True):
    issues = []
    if not logits.is_floating_point():
        issues.append("non_floating_input")
    if logits.is_floating_point() and not torch.isfinite(logits).all():
        issues.append("nonfinite_input")
    if output.is_floating_point() and not torch.isfinite(output).all():
        issues.append("nonfinite_output")
    if expect_gradient and output.grad_fn is None:
        issues.append(...)
    if not ((output >= 0) & (output <= 1)).all():
        issues.append(...)
    return {"issues": issues, "valid": len(issues) == 0}

def E09(cases):
    report = {}
    for name, logits in cases.items():
        try:
            output = torch.sigmoid(logits)
            report[name] = inspect_activation(logits, output)
        except (RuntimeError, TypeError) as error:
            report[name] = {"error": type(error).__name__,
                            "message": str(error)}
    return report

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.4.11 Exercise 10 - Custom Sigmoid Module

Part 1 - Why this matters

A custom module packages sigmoid behind the standard PyTorch module interface. This makes it easy to place inside larger models while preserving device movement, mode handling, and autograd behavior.

The module should not reimplement a fragile exponential formula merely to appear custom. Its purpose is to understand module structure while delegating the stable element-wise operation to PyTorch.

Part 2 - Technical concept and behavior

The forward mapping is:

$$\text{forward}(\mathbf{z}) = \sigma(\mathbf{z})$$

The module contains no trainable parameters and should preserve input shape and device.

Part 3 - Hints and Helper

Subclass `torch.nn.Module`, call the parent constructor, and implement `forward` with `torch.sigmoid`. Compare values and gradients with the functional operation.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class CustomSigmoid(nn.Module):
    def __init__(self):
        super().__init__()

    def forward(self, logits):
        return ...

def E10(logits):
    module = CustomSigmoid()
    custom = module(logits)
    reference = torch.sigmoid(logits)
    return {
        "value_agreement": torch.allclose(
            custom, reference, atol=..., rtol=...
        ),
        "shape_preserved": custom.shape == logits.shape,
        "parameter_count": sum(
            parameter.numel() for parameter in module.parameters()
        ),
        "gradient_function": type(custom.grad_fn).__name__
        if custom.grad_fn is not None else None,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.4.12 Exercise 11 - Sigmoid vs Tanh Comparison

Part 1 - Why this matters

Sigmoid and hyperbolic tangent have similar S-shaped curves but different output ranges and centers. Sigmoid maps to $(0, 1)$, while tanh maps to $(-1, 1)$ and is centered at zero.

Both activations saturate in their tails, but their derivatives have different scales near zero. Comparing them prevents activation choice from being reduced to visual similarity.

Part 2 - Mathematical form

$$\sigma(z) = \frac{1}{1 + e^{-z}}, \qquad \sigma'(z) = \sigma(z)(1 - \sigma(z))$$

$$\tanh'(z) = 1 - \tanh^2(z)$$

At zero, sigmoid derivative is 0.25 while tanh derivative is 1.

Part 3 - Hints and Helper

Evaluate both functions over the same symmetric input range. Calculate analytical derivatives, compare output means, central gradients, and saturated fractions using declared tolerances.

Part 4 - Python code skeleton

```
import torch

def E11(logits, derivative_tolerance=1e-4):
    sigmoid_output = torch.sigmoid(logits)
    tanh_output = torch.tanh(logits)
    sigmoid_gradient = sigmoid_output * (1 - sigmoid_output)
    tanh_gradient = 1 - tanh_output.square()
    center = torch.argmin(logits.abs())
    return {
        "sigmoid_range": (
            sigmoid_output.min().item(),
            sigmoid_output.max().item(),
        ),
        "tanh_range": (..., ...),
        "sigmoid_center_gradient":
            sigmoid_gradient[center].item(),
        "tanh_center_gradient": ...,
        "sigmoid_saturated_fraction": ...,
        "tanh_saturated_fraction": ...,
    }

def main():
    print(E11(torch.linspace(..., ..., steps=...)))

if __name__ == "__main__":
    main()
```

11.4.13 Exercise 12 - Sigmoid in Deep Stack Simulation

Part 1 - Why this matters

Repeated sigmoid transformations simulate how gradients can weaken through depth. Even when every operation is valid, multiplying many local derivatives can greatly reduce the gradient reaching the original input.

The experiment should preserve intermediate activations and gradients so the reader can see where attenuation begins. One final gradient value does not explain the layer-by-layer process.

Part 2 - Mathematical form

For:

$$a_\ell = \sigma(w_\ell a_{\ell-1} + b_\ell)$$

the chain rule gives:

$$\frac{\partial a_L}{\partial a_0} = \prod_{\ell=1}^{L} [w_\ell \sigma'(z_\ell)]$$

Both weights and activation derivatives control the final gradient.

Part 3 - Hints and Helper

Start with a scalar leaf input, create each non-leaf pre-activation and activation, and call `retain_grad()` on values you want to inspect. Backpropagate the final activation.

Part 4 - Python code skeleton

```
import torch

def E12(initial_value, weights, biases):
    activation = torch.tensor(
        initial_value, dtype=torch.float64, requires_grad=True
    )
    original = activation
    layers = []
    for weight, bias in zip(weights, biases):
        preactivation = weight * activation + bias
        activation = torch.sigmoid(preactivation)
        preactivation.retain_grad()
        activation.retain_grad()
        layers.append((preactivation, activation))
    activation.backward()
    report = []
    for index, (preactivation, current) in enumerate(layers):
        report.append({
            "layer": index,
            "preactivation": preactivation.item(),
            "activation": current.item(),
            "preactivation_gradient": ...,
            "activation_gradient": ...,
        })
    return {"input_gradient": original.grad.item(),
            "layers": report}

def main():
    print(E12(...))
```

```
if __name__ == "__main__":
    main()
```

11.4.14 Exercise 13 - Gradient Noise Injection

Part 1 - Why this matters

Gradient noise changes the direction and magnitude of an update signal. Controlled injection helps test whether small perturbations dominate already weak sigmoid gradients, especially in saturated regions.

Noise must be applied to a detached gradient copy or through an explicit training rule. Accidentally modifying stored gradients without recording the change makes the experiment impossible to interpret.

Part 2 - Mathematical form

For clean gradient $\mathbf{g}$:

$$\widetilde{\mathbf{g}} = \mathbf{g} + \sigma_n \boldsymbol{\epsilon}, \qquad \boldsymbol{\epsilon} \sim \mathcal{N}(0, \mathbf{I})$$

Signal-to-noise ratio can compare:

$$\frac{\|\mathbf{g}\|_2}{\|\widetilde{\mathbf{g}} - \mathbf{g}\|_2}$$

Part 3 - Hints and Helper

Calculate the clean sigmoid gradient first. Use a seeded generator for noise, preserve the original, and report norms, cosine similarity, sign changes, and signal-to-noise ratio.

Part 4 - Python code skeleton

```
import torch

def E13(logits, noise_scale, seed, epsilon=1e-12):
    logits = logits.detach().clone().requires_grad_(True)
    torch.sigmoid(logits).sum().backward()
    clean = logits.grad.detach().clone()
    generator = torch.Generator(device=clean.device)
    generator.manual_seed(seed)
    noise = torch.randn(
        clean.shape, generator=generator,
        device=clean.device, dtype=clean.dtype
    ) * noise_scale
    noisy = clean + noise
    cosine = torch.nn.functional.cosine_similarity(
        clean.reshape(1, -1), noisy.reshape(1, -1)
    ).item()
    return {
```

```
        "clean_norm": clean.norm().item(),
        "noise_norm": noise.norm().item(),
        "noisy_norm": ...,
        "signal_to_noise": clean.norm().item()
        / (noise.norm().item() + epsilon),
        "cosine_similarity": cosine,
        "sign_change_count": ...,
    }

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.4.15 Exercise 14 - Autograd Graph Inspection

Part 1 - Why this matters

Autograd graph inspection shows that sigmoid output retains a recorded relationship to its input when gradient tracking is enabled. The `grad_fn` node is the entry point to the operations used during backward.

Graph inspection is a debugging aid, not an interface for rewriting autograd internals. The exercise should report node names and connections without mutating saved tensors or private state.

Part 2 - Technical concept and behavior

For a leaf input z requiring gradients:

$$p = \sigma(z)$$

has:

$$p.\texttt{grad_fn} \neq \texttt{None}$$

while $z.\texttt{grad_fn} = \texttt{None}$ because z is a leaf.

Part 3 - Hints and Helper

Inspect `is_leaf`, `requires_grad`, `grad_fn`, and immediate `next_functions`. Compare the normal output with a detached copy and with output created under no-gradient mode.

Part 4 - Python code skeleton

```
import torch

def describe(tensor):
    node = tensor.grad_fn
    return {
        "is_leaf": tensor.is_leaf,
```

```
        "requires_grad": tensor.requires_grad,
        "grad_fn": type(node).__name__ if node else None,
        "next_functions": [
            type(next_node).__name__ if next_node else None
            for next_node, _ in node.next_functions
        ] if node else [],
    }

def E14(values):
    logits = torch.tensor(
        values, dtype=torch.float32, requires_grad=True
    )
    probability = torch.sigmoid(logits)
    detached = probability.detach()
    with torch.no_grad():
        no_grad_probability = torch.sigmoid(logits)
    return {
        "input": describe(logits),
        "probability": describe(probability),
        "detached": describe(detached),
        "no_grad": ...,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.4.16 Exercise 15 - Mixed Precision Backward Test

Part 1 - Why this matters

Mixed precision can accelerate suitable CUDA operations, but lower-precision intermediates may alter small gradients or overflow in incompatible workloads. Gradient scaling helps preserve backward signals through float16 paths.

The test must compare AMP gradients with a float32 reference and monitor finite status. Successful execution alone does not establish numerical agreement.

Part 2 - Technical concept and behavior

With loss scale s:

$$\nabla_\theta(s\mathcal{L}) = s\nabla_\theta\mathcal{L}$$

The scaler unscales gradients before comparison or clipping, while model parameters remain in their ordinary precision.

Part 3 - Hints and Helper

Use two model copies with identical states. Run one float32 backward pass and one autocast forward with a scaled backward pass. Exit autocast before backward and unscale through the AMP optimizer before comparing gradients.

Part 4 - Python code skeleton

```
import copy
import torch
import torch.nn.functional as F

def E15(model, X, target):
    if not torch.cuda.is_available():
        return {"skipped": True}
    reference = copy.deepcopy(model).cuda()
    mixed = copy.deepcopy(model).cuda()
    X, target = X.cuda(), target.cuda()

    reference.zero_grad(set_to_none=True)
    reference_loss = F.binary_cross_entropy_with_logits(
        reference(X), target
    )
    reference_loss.backward()
    reference_gradients = [
        parameter.grad.detach().clone()
        for parameter in reference.parameters()
    ]

    optimizer = torch.optim.SGD(mixed.parameters(), lr=0.0)
    scaler = torch.amp.GradScaler("cuda")
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=torch.float16):
        logits = mixed(X)
        loss = F.binary_cross_entropy_with_logits(logits, target)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    mixed_gradients = [...]
    differences = [...]
    return {"skipped": False, "loss": loss.item(),
            "all_finite": ...,
            "maximum_gradient_difference": ...,
            "scale": scaler.get_scale()}

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.4.17 Exercise 16 - Activation Profiling on GPU

Part 1 - Why this matters

GPU profiling reveals the operations, device time, shapes, and memory activity associated with sigmoid evaluation. It helps determine whether activation work is substantial or merely one small part of a larger pipeline.

Profiling adds overhead and should not be confused with a clean latency benchmark. Warm-up and a limited active region make the trace more representative and manageable.

Part 2 - Technical concept and behavior

For repeated activation workload:

$$\mathbf{p}_r = \sigma(\mathbf{z}), \qquad r = 1, \ldots, R$$

the profiler attributes CPU dispatch and CUDA kernel activity to recorded operations. Workload shape, dtype, repetitions, and device must accompany the results.

Part 3 - Hints and Helper

Require CUDA, warm up first, synchronize, and profile CPU plus CUDA activities. Enable shape and memory recording deliberately, then summarize key averages by CUDA time.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import profile, ProfilerActivity

def E16(logits, repetitions=100):
    if logits.device.type != "cuda":
        raise ValueError(...)
    for _ in range(10):
        torch.sigmoid(logits)
    torch.cuda.synchronize(logits.device)
    with profile(
        activities=[
            ProfilerActivity.CPU,
            ProfilerActivity.CUDA,
        ],
        record_shapes=True,
        profile_memory=True,
    ) as profiler:
        for _ in range(repetitions):
            output = torch.sigmoid(logits)
    torch.cuda.synchronize(logits.device)
    table = profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=...
    )
    return {"table": table,
            "output_shape": tuple(output.shape),
```

```
            "repetitions": repetitions}

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.4.18 Exercise 17 - Stability under Extreme Inputs

Part 1 - Why this matters

Extreme finite inputs test sigmoid's range, monotonicity, symmetry, and gradient behavior near numerical limits. They also reveal the point where a dtype rounds outputs or derivatives to exact zero or one.

Stability does not mean every extreme input retains a useful gradient. A correct implementation may remain finite while the derivative vanishes numerically, and both facts should be reported.

Part 2 - Mathematical form

Sigmoid symmetry is:

$$\sigma(-z) = 1 - \sigma(z)$$

The derivative symmetry is:

$$\sigma'(-z) = \sigma'(z)$$

within the limits of floating-point representation.

Part 3 - Hints and Helper

Use sorted symmetric values including zero and dtype extremes that remain finite. Check output finiteness, range, monotonicity, symmetry error, derivative symmetry, and boundary counts.

Part 4 - Python code skeleton

```
import torch

def E17(positive_values, dtype=torch.float64):
    positive = torch.as_tensor(positive_values, dtype=dtype)
    positive = torch.sort(positive.abs()).values
    negative = -positive.flip(0)
    logits = torch.cat([negative, torch.zeros(1, dtype=dtype),
                        positive])
    probability = torch.sigmoid(logits)
    derivative = probability * (1 - probability)
    symmetry = (
        torch.sigmoid(-positive)
```

```
        - (1 - torch.sigmoid(positive))
    ).abs()
    return {
        "all_finite": bool(torch.isfinite(probability).all()),
        "in_range": bool(
            ((probability >= 0) & (probability <= 1)).all()
        ),
        "monotonic": bool(
            torch.all(probability[1:] >= probability[:-1])
        ),
        "maximum_symmetry_error": ...,
        "zero_derivative_count": int((derivative == 0).sum()),
        "boundary_probability_count": ...,
    }

def main():
    print(E17([... ]))

if __name__ == "__main__":
    main()
```

11.4.19 Exercise 18 - Activation Optimization Attempt

Part 1 - Why this matters

An optimization attempt should compare correctness, runtime, and memory rather than assuming a shorter formula is faster. PyTorch's built-in sigmoid uses optimized kernels that a Python-level manual implementation is unlikely to outperform.

Benchmarking must separate warm-up and use synchronization on CUDA. A candidate is acceptable only if its accuracy across ordinary and extreme inputs satisfies a declared tolerance.

Part 2 - Technical concept and behavior

For candidate f and reference σ:

$$E_{\max} = \max_i |f(z_i) - \sigma(z_i)|$$

Speedup is:

$$S = \frac{T_{\text{reference}}}{T_{\text{candidate}}}$$

and should be interpreted with repeated measurements.

Part 3 - Hints and Helper

Compare built-in, direct manual, and branch-aware implementations on identical tensors. Warm up, synchronize the device, measure repetitions, and reject non-finite or inaccurate candidates.

Part 4 - Python code skeleton

```
import time
import torch

def benchmark(function, logits, repetitions):
    for _ in range(10):
        function(logits)
    if logits.device.type == "cuda":
        torch.cuda.synchronize(logits.device)
    start = time.perf_counter()
    for _ in range(repetitions):
        output = function(logits)
    if logits.device.type == "cuda":
        torch.cuda.synchronize(logits.device)
    return time.perf_counter() - start, output

def E18(logits, candidates, repetitions, tolerance):
    reference_time, reference = benchmark(
        torch.sigmoid, logits, repetitions
    )
    report = {}
    for name, function in candidates.items():
        elapsed, output = benchmark(function, logits, repetitions)
        error = (output - reference).abs().max().item()
        report[name] = {
            "seconds": elapsed,
            "speedup": reference_time / elapsed,
            "maximum_error": error,
            "accepted": ...,
            "all_finite": ...,
        }
    return {"reference_seconds": reference_time,
            "candidates": report}

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.4.20 Exercise 19 - Sigmoid Failure Report

Part 1 - Why this matters

A final failure report combines evidence from values, gradients, devices, dtypes, graph state, and performance. It distinguishes expected saturation from numerical corruption and accidental graph breaks.

The report should preserve reproducible inputs and explicit rules. Labels such as unstable or vanishing are meaningless unless their tolerances and observed measurements are included.

Part 2 - Report structure

For each scenario s, record:

$$R_s = \{\text{input}, \text{dtype}, \text{device}, \text{output}, \text{gradient}, \text{checks}, \text{classification}\}$$

Classifications may include valid, saturated, graph-broken, non-finite, inaccurate, or unsupported.

Part 3 - Hints and Helper

Create scenarios for central, saturated, extreme, detached, integer, and CUDA inputs when available. Run independent checks so one failure does not erase the remaining evidence, and produce a machine-readable summary.

Part 4 - Python code skeleton

```
import torch

def analyze_case(name, logits, expect_gradient):
    result = {
        "name": name,
        "dtype": str(logits.dtype),
        "device": str(logits.device),
        "shape": tuple(logits.shape),
    }
    try:
        probability = torch.sigmoid(logits)
        result["output_finite"] = bool(
            torch.isfinite(probability).all()
        )
        result["output_in_range"] = bool(
            ((probability >= 0) & (probability <= 1)).all()
        )
        result["graph_connected"] = probability.grad_fn is not None
        if expect_gradient and probability.requires_grad:
            probability.sum().backward()
            result["gradient_finite"] = ...
            result["gradient_norm"] = ...
        result["classification"] = ...
    except (RuntimeError, TypeError) as error:
        result["classification"] = "failed"
        result["error_type"] = type(error).__name__
        result["message"] = str(error)
    return result

def E19(scenarios):
    return [
        analyze_case(name, values["logits"],
                     values["expect_gradient"])
        for name, values in scenarios.items()
```

```
    ]

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.5 LG03 - Probability Interpretation Framework

Models and Training

11.5.1 Exercise 00 - Likelihood Interpretation

Part 1 - Why this matters

A logistic-regression output is not only a number used to choose a class. Once the observed label is fixed, that output measures how compatible the model parameters are with the observation. This change of viewpoint turns a predicted probability into a likelihood contribution.

Probability and likelihood must not be confused. In frequentist logistic regression, parameters are unknown fixed values and the observed data define a function that scores candidate parameters; likelihood is not the probability that a parameter is correct.

Part 2 - Mathematical form

For $z_i = \mathbf{w}^\mathsf{T}\mathbf{x}_i + b$ and $p_i = \sigma(z_i)$,

$$L_i(\mathbf{w}, b) = p_i^{y_i}(1 - p_i)^{1-y_i}, \qquad y_i \in \{0, 1\}.$$

Thus $L_i = p_i$ when $y_i = 1$, and $L_i = 1 - p_i$ when $y_i = 0$. Under conditional independence,

$$L(\mathbf{w}, b) = \prod_{i=1}^{N} L_i(\mathbf{w}, b).$$

Part 3 - Hints and Helper

Accept probabilities and binary targets with identical shapes. Select the probability assigned to the observed label without a Python loop. Return per-sample terms first; a product is safe only for a small demonstration because it can underflow.

Part 4 - Python code skeleton

```
import torch

def E00(probabilities, targets):
    if probabilities.shape != targets.shape:
        raise ValueError(...)
    valid = (targets == 0) | (targets == 1)
    if not torch.all(valid):
```

```
        raise ValueError(...)
    terms = torch.where(targets == 1, ..., ...)
    return terms

def main():
    probabilities = torch.tensor(...)
    targets = torch.tensor(...)
    print(E00(probabilities, targets))

if __name__ == "__main__":
    main()
```

11.5.2 Exercise 01 - Log-Likelihood Computation

Part 1 - Why this matters

Multiplying many likelihood contributions quickly creates values too small for floating-point arithmetic. Taking the logarithm converts products into sums, preserves the ordering of positive likelihoods, and exposes the evidence supplied by each observation.

Log-likelihood is easier to diagnose than a tiny product. A confident correct prediction contributes a value near zero, whereas a confident incorrect prediction contributes a large negative value. Individual samples can therefore be inspected directly.

Part 2 - Mathematical form

The binary log-likelihood is

$$\ell(\mathbf{w}, b) = \sum_{i=1}^{N} \left[y_i \log(p_i) + (1 - y_i) \log(1 - p_i) \right].$$

Every term is non-positive for $0 < p_i < 1$. Maximizing ℓ is equivalent to maximizing L because logarithm is strictly increasing.

Part 3 - Hints and Helper

For this probability-based experiment, clamp values away from exactly zero and one before taking logarithms. Keep the per-sample terms and their sum. Later exercises should use logits directly rather than treating clamping as the universal numerical solution.

Part 4 - Python code skeleton

```
import torch

def E01(probabilities, targets, epsilon):
    probabilities = probabilities.clamp(
        min=epsilon, max=1.0 - epsilon
    )
    terms = (
        targets * torch.log(...)
        + (1.0 - targets) * torch.log1p(...)
```

```
    )
    return terms, ...

def main():
    probabilities = torch.tensor(..., dtype=torch.float64)
    targets = torch.tensor(..., dtype=torch.float64)
    print(E01(probabilities, targets, epsilon=...))

if __name__ == "__main__":
    main()
```

11.5.3 Exercise 02 - Negative Log-Likelihood Concept

Part 1 - Why this matters

Optimization tools usually minimize an objective, while likelihood estimation asks us to maximize agreement with observed data. Negating the log-likelihood reverses the direction without changing the parameter value considered optimal.

Negative log-likelihood has a useful penalty interpretation. A well-explained label adds little cost, while assigning tiny probability to an observed label produces a large cost. This connects statistical estimation to model training.

Part 2 - Mathematical form

Define

$$\mathrm{NLL} = -\ell = -\sum_{i=1}^{N} \left[y_i \log(p_i) + (1 - y_i) \log(1 - p_i) \right].$$

Therefore,

$$\arg\max_{\theta} L(\theta) = \arg\max_{\theta} \ell(\theta) = \arg\min_{\theta} \mathrm{NLL}(\theta).$$

Part 3 - Hints and Helper

Compute summed and mean NLL from per-sample log-likelihood terms. Verify that increasing the probability assigned to every observed label decreases both reductions, while their scales differ by the number of evaluated elements.

Part 4 - Python code skeleton

```
import torch

def E02(log_likelihood_terms):
    nll_terms = ...
    return {
        "terms": nll_terms,
        "sum": ...,
        "mean": ...,
    }
```

```
def main():
    terms = torch.tensor(...)
    print(E02(terms))

if __name__ == "__main__":
    main()
```

11.5.4 Exercise 03 - Likelihood vs Loss Mapping

Part 1 - Why this matters

Likelihood and binary cross-entropy are often presented as separate tools. For a Bernoulli logistic model they are the same sample-wise quantity viewed from opposite optimization directions: maximize agreement or minimize its negative.

The reduction mode must remain visible. A summed loss equals negative total log-likelihood, while a mean loss divides by the element count. Ignoring this detail makes comparisons across dataset and batch sizes misleading.

Part 2 - Mathematical form

For one target,

$$\mathrm{BCE}(p_i, y_i) = -\left[y_i \log(p_i) + (1 - y_i) \log(1 - p_i)\right] = -\ell_i.$$

For N elements,

$$\mathrm{BCE}_{\mathrm{sum}} = -\ell, \qquad \mathrm{BCE}_{\mathrm{mean}} = -\frac{\ell}{N}.$$

Part 3 - Hints and Helper

Use a stable logits-based PyTorch function with reduction `none`. Sum and average its terms manually, then verify their equality to negative log-likelihood terms. Do not apply sigmoid before a function that expects logits.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E03(logits, targets):
    bce_terms = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    log_likelihood_terms = ...
    return {
        "mapping_equal": torch.allclose(
            bce_terms, -log_likelihood_terms
        ),
        "nll_sum": ...,
        "nll_mean": ...,
```

```
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.5.5 Exercise 04 - Batch Likelihood Aggregation

Part 1 - Why this matters

Large datasets are processed as batches, but the statistical objective belongs to the entire dataset. A correct epoch result must combine every contribution with the same meaning it would have in a single full-tensor computation.

Averaging batch means is wrong when the last batch is smaller because it gives every batch equal weight instead of every element. Accumulating summed NLL and the element count produces the correct dataset-wide mean.

Part 2 - Mathematical form

For batches $\mathcal{B}_1, \ldots, \mathcal{B}_K$,

$$\ell_{\text{epoch}} = \sum_{k=1}^{K} \sum_{i \in \mathcal{B}_k} \ell_i, \qquad \overline{\text{NLL}} = -\frac{\ell_{\text{epoch}}}{\sum_{k=1}^{K} |\mathcal{B}_k|}.$$

Part 3 - Hints and Helper

Compute a summed logits-based BCE for each batch, add its detached scalar, and add `targets.numel()` to the count. Divide only after the loop. Also calculate the intentionally incorrect unweighted average of batch means.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E04(model, data_loader, device):
    total_nll = 0.0
    total_elements = 0
    batch_means = []
    with torch.no_grad():
        for features, targets in data_loader:
            features = features.to(device)
            targets = targets.to(device)
            logits = model(features).reshape_as(targets)
            batch_nll = F.binary_cross_entropy_with_logits(
                logits, targets, reduction="sum"
            )
```

```
            total_nll += ...
            total_elements += ...
            batch_means.append(...)
    return {
        "correct_mean_nll": ...,
        "wrong_mean_of_means": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.5.6 Exercise 05 - CUDA Likelihood Computation

Part 1 - Why this matters

GPU evaluation can accelerate large batches, but it introduces device coordination, asynchronous execution, and transfer costs. Model parameters, inputs, targets, and intermediate values must remain on compatible devices.

A CUDA implementation should preserve the statistical definition instead of silently changing reduction or precision. Comparing CPU and GPU summaries within a justified tolerance separates expected floating-point variation from implementation errors.

Part 2 - Mathematical form

Using logits directly, a stable NLL term is

$$-\ell_i = \max(z_i, 0) - z_i y_i + \log\left(1 + e^{-|z_i|}\right).$$

Compare datasets through sums or means of these terms, not products of rounded probabilities.

Part 3 - Hints and Helper

Select CUDA only when available, move a copied model and both tensors to the chosen device, and use summed stable BCE. Use the same model state, inputs, targets, and reduction for CPU and CUDA.

Part 4 - Python code skeleton

```
import copy

import torch
import torch.nn.functional as F

def compute_nll(model, features, targets, device):
    model = copy.deepcopy(model).to(device)
    features = features.to(device)
    targets = targets.to(device)
```

```
    with torch.no_grad():
        logits = model(features).reshape_as(targets)
        total = F.binary_cross_entropy_with_logits(
            logits, targets, reduction="sum"
        )
    return total.item(), targets.numel()

def E05(model, features, targets):
    cpu_total, count = compute_nll(
        model, features, targets, torch.device("cpu")
    )
    if not torch.cuda.is_available():
        return {"cuda_available": False, "cpu_mean": ...}
    cuda_total, cuda_count = compute_nll(
        model, features, targets, torch.device("cuda")
    )
    return {
        "cuda_available": True,
        "cpu_mean": ...,
        "cuda_mean": ...,
        "close": ...,
    }

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.5.7 Exercise 06 - Likelihood Sensitivity Test

Part 1 - Why this matters

Likelihood sensitivity shows how strongly an observation reacts when its prediction changes. Near a confident error, movement toward the observed label can improve log-likelihood far more than the same movement near an already reasonable prediction.

Perturbing logits makes the behavior observable without hiding it inside an optimizer. Comparing autograd with a finite difference connects local statistical evidence to the direction later used for parameter adjustment.

Part 2 - Mathematical form

For one observation,

$$\ell_i(z_i) = y_i \log \sigma(z_i) + (1 - y_i) \log(1 - \sigma(z_i)), \qquad \frac{\partial \ell_i}{\partial z_i} = y_i - \sigma(z_i).$$

A centered approximation is

$$\frac{\ell_i(z_i + h) - \ell_i(z_i - h)}{2h}.$$

Part 3 - Hints and Helper

Compute log-likelihood as negative stable BCE. Compare autograd with centered finite differences for confident correct, uncertain, and confident incorrect cases. Recreate the input tensor for every independent test.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def log_likelihood(logit, target):
    return -F.binary_cross_entropy_with_logits(
        logit, target, reduction="sum"
    )

def E06(logit_value, target_value, step):
    logit = torch.tensor(
        [logit_value],
        dtype=torch.float64,
        requires_grad=True,
    )
    target = torch.tensor([target_value], dtype=torch.float64)
    value = log_likelihood(logit, target)
    value.backward()
    automatic = ...
    with torch.no_grad():
        upper = log_likelihood(logit + step, target)
        lower = log_likelihood(logit - step, target)
        finite_difference = ...
    return automatic, finite_difference

def main():
    for case in ...:
        print(E06(*case, step=...))

if __name__ == "__main__":
    main()
```

11.5.8 Exercise 07 - Confidence Calibration Check

Part 1 - Why this matters

A probability is calibrated when predictions made with similar probability occur at approximately that frequency. Among cases assigned values near 0.8, roughly eighty percent should have positive labels. Accuracy alone does not guarantee this.

Calibration matters when probabilities influence risk, ranking, or human decisions. A bin report must include counts because a large gap supported by two samples is not equivalent to the same gap supported by thousands.

Part 2 - Mathematical form

For bin B_m,

$$\mathrm{conf}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} p_i, \quad \mathrm{freq}(B_m) = \frac{1}{|B_m|} \sum_{i \in B_m} y_i.$$

An empirical summary is

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{N} \left| \mathrm{freq}(B_m) - \mathrm{conf}(B_m) \right|.$$

Part 3 - Hints and Helper

Create equal-width boundaries from zero to one and assign each probability to one bin. Handle the right endpoint carefully. Preserve empty bins in the report with count zero but omit their contribution from ECE.

Part 4 - Python code skeleton

```
import torch

def E07(probabilities, targets, number_of_bins):
    boundaries = torch.linspace(
        0.0, 1.0, steps=number_of_bins + 1,
        device=probabilities.device,
    )
    bin_ids = torch.bucketize(
        probabilities, boundaries[1:-1], right=...
    )
    rows = []
    ece = torch.zeros((), device=probabilities.device)
    for bin_id in range(number_of_bins):
        mask = bin_ids == bin_id
        count = int(mask.sum().item())
        if count == 0:
            rows.append(...)
            continue
        confidence = ...
        frequency = ...
        gap = ...
        ece += ...
        rows.append(...)
    return rows, ece.item()

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.5.9 Exercise 08 - Overconfident Prediction Detection

Part 1 - Why this matters

An incorrect prediction becomes especially dangerous when the model presents it with extreme confidence. These cases can dominate log-loss, mislead downstream decisions, and reveal missing features or distribution changes that accuracy conceals.

For binary classification, predicted-class confidence is not always the positive-class probability. When the predicted class is zero, its confidence is $1 - p$. A detector must make this distinction before labeling an error overconfident.

Part 2 - Mathematical form

With threshold τ,

$$\widehat{y}_i = \mathbb{I}[p_i \geq \tau], \qquad c_i = \max(p_i, 1 - p_i).$$

For confidence cutoff γ, an overconfident error satisfies

$$\widehat{y}_i \neq y_i \quad \text{and} \quad c_i \geq \gamma.$$

Part 3 - Hints and Helper

Return indices, probabilities, targets, predicted labels, predicted-class confidence, and NLL for every detected case. Sort by decreasing confidence or NLL so the most severe failures appear first.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E08(logits, targets, threshold, confidence_cutoff):
    probabilities = torch.sigmoid(logits)
    predictions = (probabilities >= threshold).to(targets.dtype)
    confidence = torch.maximum(
        probabilities, 1.0 - probabilities
    )
    selected = (
        (predictions != targets)
        & (confidence >= confidence_cutoff)
    )
    nll = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    indices = torch.nonzero(
        selected, as_tuple=False
    ).flatten()
    return {
        "indices": ...,
        "probabilities": ...,
```

```
        "targets": ...,
        "predictions": ...,
        "confidence": ...,
        "nll": ...,
    }

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.5.10 Exercise 09 - Probability Misinterpretation Case

Part 1 - Why this matters

A probability pipeline can produce valid numbers and still communicate the wrong conclusion. Probability is not a class label, confidence does not guarantee correctness, likelihood is not a posterior over parameters, and a threshold is a decision policy.

A useful debugging exercise must detect semantic errors as well as range and shape errors. The reader should explain why each suspicious claim fails and state which assumptions or evidence would support a corrected statement.

Part 2 - Mathematical form

For $p_i = P(Y_i = 1 \mid \mathbf{x}_i, \widehat{\theta})$,

$$\widehat{y}_i = \mathbb{I}[p_i \geq \tau]$$

is a decision based on p_i. With fixed data $\mathcal{D}$,

$$L(\theta; \mathcal{D}) = P(\mathcal{D} \mid \theta)$$

must not be replaced by $P(\theta \mid \mathcal{D})$ without a prior and Bayesian inference.

Part 3 - Hints and Helper

Represent claims as records containing a value, representation, and verbal statement. Check ranges, logit-versus-probability confusion, threshold assumptions, likelihood language, and unsupported certainty. Return explanations, not only flags.

Part 4 - Python code skeleton

```
import torch

def validate_claim(claim):
    issues = []
    value = claim["value"]
    representation = claim["representation"]
    statement = claim["statement"].lower()
    if representation == "probability":
        if not torch.isfinite(value).all():
```

```
            issues.append(...)
        if not ((value >= 0) & (value <= 1)).all():
            issues.append(...)
    if representation == "logit" and "probability" in statement:
        issues.append(...)
    if "likelihood" in statement and "parameter is true" in statement:
        issues.append(...)
    if "guaranteed" in statement and "confidence" in statement:
        issues.append(...)
    return issues

def E09(claims):
    return [
        {"claim_id": item["id"], "issues": validate_claim(item)}
        for item in claims
    ]

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.5.11 Exercise 10 - Bayesian View Comparison

Part 1 - Why this matters

Classical logistic regression commonly produces one fitted parameter vector and one probability for each input. A Bayesian treatment instead represents uncertainty about the parameters and propagates it into a distribution of plausible predictions.

The two viewpoints answer different questions and should not be mixed casually. Variation across posterior parameter samples represents epistemic uncertainty under the chosen prior and model, while the Bernoulli output still represents outcome uncertainty conditional on each sampled parameter.

Part 2 - Mathematical form

A point estimate gives

$$p_{\text{point}}(y = 1 \mid \mathbf{x}) = \sigma(\widehat{\mathbf{w}}^{\mathsf{T}}\mathbf{x} + \widehat{b}).$$

With posterior samples $\theta^{(s)} = (\mathbf{w}^{(s)}, b^{(s)})$,

$$p_{\text{Bayes}}(y = 1 \mid \mathbf{x}, \mathcal{D}) \approx \frac{1}{S}\sum_{s=1}^{S} \sigma\left(\mathbf{w}^{(s)\mathsf{T}}\mathbf{x} + b^{(s)}\right).$$

Part 3 - Hints and Helper

Receive already generated parameter samples rather than pretending that random perturbations are a valid posterior. Compute every sampled probability, the posterior-predictive mean,

and a spread measure. Compare them with the point-estimate probability and state what the spread does and does not mean.

Part 4 - Python code skeleton

```
import torch

def E10(features, point_weight, point_bias,
        weight_samples, bias_samples):
    point_logit = features @ point_weight + point_bias
    point_probability = torch.sigmoid(point_logit)

    sampled_logits = (
        features @ weight_samples.T
        + bias_samples.reshape(1, -1)
    )
    sampled_probabilities = torch.sigmoid(...)
    return {
        "point_probability": ...,
        "predictive_mean": ...,
        "predictive_std": ...,
        "number_of_samples": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.5.12 Exercise 11 - Prior Effect Simulation

Part 1 - Why this matters

A model may be trained where positive examples have one prevalence and deployed where that prevalence differs. If the class-conditional evidence remains stable, changing prior odds should shift posterior odds even when the input features are unchanged.

This correction is conditional, not a universal calibration trick. It assumes prior-probability shift: the class prior changes while the feature distributions within each class remain sufficiently stable. The exercise must report that assumption beside the adjusted values.

Part 2 - Mathematical form

Let π_{train} and π_{new} be old and new positive-class priors. Under prior shift,

$$\operatorname{logit}(p_{\text{new}}) = \operatorname{logit}(p_{\text{train}}) - \operatorname{logit}(\pi_{\text{train}}) + \operatorname{logit}(\pi_{\text{new}}),$$

where

$$\operatorname{logit}(q) = \log \frac{q}{1-q}.$$

Part 3 - Hints and Helper

Validate that both priors lie strictly between zero and one. Work in log-odds space, then apply sigmoid once. Test no-change, lower-prevalence, and higher-prevalence scenarios while preserving the original probabilities in the report.

Part 4 - Python code skeleton

```
import torch

def safe_logit(probability, epsilon):
    probability = probability.clamp(
        min=epsilon, max=1.0 - epsilon
    )
    return torch.log(probability) - torch.log1p(-probability)

def E11(probabilities, train_prior, new_prior, epsilon):
    if not (0.0 < train_prior < 1.0):
        raise ValueError(...)
    if not (0.0 < new_prior < 1.0):
        raise ValueError(...)
    train_prior_tensor = probabilities.new_tensor(train_prior)
    new_prior_tensor = probabilities.new_tensor(new_prior)
    adjusted_logits = (
        safe_logit(probabilities, epsilon)
        - safe_logit(train_prior_tensor, epsilon)
        + safe_logit(new_prior_tensor, epsilon)
    )
    return {
        "original": probabilities,
        "adjusted": torch.sigmoid(...),
        "assumption": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.5.13 Exercise 12 - Data Imbalance Impact

Part 1 - Why this matters

On an imbalanced dataset, total likelihood and overall mean loss are influenced mainly by the majority class because that class supplies most observations. A model can therefore improve the global objective while providing weak probabilities for the minority class.

Class-specific summaries reveal this hidden behavior. They do not replace the original likelihood automatically; instead, they make the chosen evaluation or weighting policy explicit and show which population contributes each part of the objective.

Part 2 - Mathematical form

For class $c \in \{0, 1\}$,

$$\overline{\mathrm{NLL}}_c = \frac{1}{N_c} \sum_{i:y_i=c} -\ell_i.$$

A balanced diagnostic summary is

$$\mathrm{NLL}_{\mathrm{balanced}} = \frac{1}{2} \left(\overline{\mathrm{NLL}}_0 + \overline{\mathrm{NLL}}_1 \right).$$

Part 3 - Hints and Helper

Compute unreduced stable NLL terms, class counts, class-wise means, the ordinary mean, and the balanced diagnostic mean. Handle an absent class explicitly instead of returning a silent division by zero.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def class_mean(values, mask):
    count = int(mask.sum().item())
    if count == 0:
        return ..., count
    return ..., count

def E12(logits, targets):
    terms = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    negative_mean, negative_count = class_mean(
        terms, targets == 0
    )
    positive_mean, positive_count = class_mean(
        terms, targets == 1
    )
    balanced = ...
    return {
        "ordinary_mean": ...,
        "balanced_mean": balanced,
        "class_0": ...,
        "class_1": ...,
    }

def main():
```

```
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.5.14 Exercise 13 - Likelihood under Noise

Part 1 - Why this matters

Real inputs contain measurement errors, sensor variation, missing precision, and preprocessing noise. A probability interpretation is trustworthy only when the reader understands how these perturbations alter the evidence assigned to observed labels.

One noisy draw is not enough to characterize sensitivity. Repeated perturbations with controlled random generators produce a distribution of NLL changes, allowing the experiment to separate systematic degradation from random variation.

Part 2 - Mathematical form

For perturbation $\boldsymbol{\varepsilon}^{(r)}$,

$$\widetilde{\mathbf{x}}_i^{(r)} = \mathbf{x}_i + \boldsymbol{\varepsilon}_i^{(r)}, \qquad \boldsymbol{\varepsilon}_i^{(r)} \sim \mathcal{N}(\mathbf{0}, s^2\mathbf{I}).$$

Record

$$\Delta_r = \mathrm{NLL}(\widetilde{\mathbf{X}}^{(r)}) - \mathrm{NLL}(\mathbf{X}).$$

Part 3 - Hints and Helper

Evaluate the clean baseline once, then use a seeded generator for repeated perturbations. Keep the model in evaluation mode and disable gradients. Report the mean, standard deviation, maximum, and raw NLL changes for each noise scale.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def mean_nll(model, features, targets):
    logits = model(features).reshape_as(targets)
    return F.binary_cross_entropy_with_logits(
        logits, targets, reduction="mean"
    )

def E13(model, features, targets, noise_scale,
        repetitions, seed):
    model.eval()
    generator = torch.Generator(device=features.device)
    generator.manual_seed(seed)
    changes = []
    with torch.no_grad():
        baseline = mean_nll(model, features, targets)
```

```
        for _ in range(repetitions):
            noise = torch.randn(
                features.shape,
                dtype=features.dtype,
                device=features.device,
                generator=generator,
            )
            noisy_nll = mean_nll(
                model, features + noise_scale * noise, targets
            )
            changes.append(...)
    changes = torch.stack(changes)
    return {
        "baseline": ...,
        "mean_change": ...,
        "std_change": ...,
        "maximum_change": ...,
        "changes": ...,
    }

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.5.15 Exercise 14 - Probability Drift over Epochs

Part 1 - Why this matters

Predicted probabilities for a fixed probe set can move substantially during training even when class labels remain unchanged. Monitoring this movement reveals whether the model is settling, oscillating, or becoming increasingly extreme.

This is model-output drift across epochs, not automatically evidence of external data drift. The probe inputs must stay fixed, the sample order must be preserved, and the report should distinguish changes in probabilities from changes in thresholded decisions.

Part 2 - Mathematical form

For fixed probes and epoch t,

$$d_t = \frac{1}{N} \sum_{i=1}^{N} \left| p_i^{(t)} - p_i^{(t-1)} \right|.$$

A complementary decision summary is

$$r_t = \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}[p_i^{(t)} \geq \tau].$$

Part 3 - Hints and Helper

After each epoch, evaluate the same probe tensor without gradients and store a detached CPU copy. Compare adjacent epochs by sample index. Record mean absolute drift, maximum drift, mean probability, and predicted-positive rate.

Part 4 - Python code skeleton

```
import torch

def snapshot(model, probe_features):
    model.eval()
    with torch.no_grad():
        return torch.sigmoid(
            model(probe_features)
        ).flatten().cpu()

def E14(probability_history, threshold):
    rows = []
    previous = None
    for epoch, probabilities in enumerate(probability_history):
        if previous is None:
            mean_drift = ...
            maximum_drift = ...
        else:
            difference = (probabilities - previous).abs()
            mean_drift = ...
            maximum_drift = ...
        rows.append({
            "epoch": epoch,
            "mean_probability": ...,
            "positive_rate": ...,
            "mean_drift": mean_drift,
            "maximum_drift": maximum_drift,
        })
        previous = probabilities
    return rows

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.5.16 Exercise 15 - Numerical Precision Effects

Part 1 - Why this matters

Likelihood products may underflow even when every individual probability is representable. Lower precision reaches this failure sooner, while computing in log-space preserves a useful

finite summary over a much wider range.

Higher precision is not a replacement for a stable formulation. This experiment should compare both dtype and representation so the reader can see that float64 delays underflow, whereas summed stable log-likelihood addresses the structural cause.

Part 2 - Mathematical form

For repeated observed-label probability q,

$$L = q^N, \qquad \log L = N \log q.$$

The direct product may become zero numerically even while $\log L$ remains finite. From logits, stable NLL avoids explicitly computing $\log(1 - \sigma(z))$ in saturated regions.

Part 3 - Hints and Helper

Evaluate the same cases in float32 and float64. Compare direct probability products, sums of logarithms, and logits-based stable NLL. Record finiteness, zeros, and absolute differences after converting comparable results to float64.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def evaluate_dtype(logit_values, targets, dtype):
    logits = logit_values.to(dtype)
    targets = targets.to(dtype)
    probabilities = torch.sigmoid(logits)
    observed_probabilities = torch.where(
        targets == 1, probabilities, 1.0 - probabilities
    )
    direct_product = ...
    probability_log_sum = ...
    stable_nll = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="sum"
    )
    return {
        "dtype": str(dtype),
        "direct_product": ...,
        "log_sum": ...,
        "stable_nll": ...,
        "all_finite": ...,
    }

def E15(logits, targets):
    report32 = evaluate_dtype(logits, targets, torch.float32)
    report64 = evaluate_dtype(logits, targets, torch.float64)
    return report32, report64, ...
```

```
def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.5.17 Exercise 16 - Likelihood Visualization

Part 1 - Why this matters

A likelihood visualization makes parameter fitting visible: candidate parameter values receive different support from the same fixed observations. Plotting log-likelihood rather than a tiny raw product preserves structure that would otherwise collapse to zero.

The graph must state what varies and what remains fixed. In a one-parameter scan, the data and bias are fixed while the weight changes; the highest point is the best candidate only within the scanned range and model assumptions.

Part 2 - Mathematical form

For candidate weight w with fixed bias b,

$$\ell(w) = \sum_{i=1}^{N} \left[y_i \log \sigma(wx_i + b) + (1 - y_i) \log(1 - \sigma(wx_i + b)) \right].$$

The scanned estimate is

$$\widehat{w}_{\text{grid}} = \arg\max_{w \in \mathcal{G}} \ell(w).$$

Part 3 - Hints and Helper

Create an ordered grid with `torch.linspace`. For each candidate, form logits and calculate log-likelihood as negative summed stable BCE. Move detached values to CPU for plotting, label axes, and mark the maximum grid point.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E16(features, targets, bias, start, end,
        steps, output_path):
    weight_grid = torch.linspace(
        start, end, steps=steps,
        dtype=features.dtype,
        device=features.device,
    )
    values = []
    with torch.no_grad():
        for weight in weight_grid:
```

```
            logits = weight * features + bias
            log_likelihood = -F.binary_cross_entropy_with_logits(
                logits, targets, reduction="sum"
            )
            values.append(log_likelihood)
    values = torch.stack(values)
    best_index = ...
    fig, ax = plt.subplots()
    ax.plot(..., ...)
    ax.scatter(..., ...)
    ax.set_xlabel(...)
    ax.set_ylabel(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return ...

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.5.18 Exercise 17 - Probability Pipeline Debugging

Part 1 - Why this matters

Probability failures often occur at interfaces rather than inside sigmoid itself. A pipeline may apply sigmoid twice, pair misaligned samples, mix devices, accept invalid labels, average batch means incorrectly, or pass probabilities to a logits-based loss.

A robust debugger should stop near the first violated contract and preserve evidence. Shape, dtype, device, representation, range, finiteness, and reduction semantics must be inspected before interpreting any metric.

Part 2 - Mathematical form

A valid binary pipeline should maintain

$$\mathbf{z}, \mathbf{y} \in \mathbb{R}^N, \qquad y_i \in \{0, 1\}, \qquad p_i = \sigma(z_i) \in [0, 1].$$

For unequal batches,

$$\overline{\mathrm{NLL}} = \frac{\sum_k \mathrm{NLL}_{k,\mathrm{sum}}}{\sum_k N_k},$$

not an unweighted mean of batch means.

Part 3 - Hints and Helper

Build validation functions around named representations: logits, probabilities, targets, and losses. Never infer representation only from a convenient value range because valid logits can also lie between zero and one. Include actionable error messages.

Part 4 - Python code skeleton

```
import torch

def inspect_tensor(name, tensor, expected_shape=None):
    issues = []
    if not tensor.is_floating_point():
        issues.append(...)
    if not torch.isfinite(tensor).all():
        issues.append(...)
    if expected_shape is not None:
        if tensor.shape != expected_shape:
            issues.append(...)
    return {"name": name, "issues": issues}

def E17(logits, probabilities, targets, metadata):
    report = []
    report.append(inspect_tensor("logits", logits))
    report.append(
        inspect_tensor(
            "probabilities",
            probabilities,
            expected_shape=targets.shape,
        )
    )
    if logits.device != targets.device:
        report.append(...)
    if not ((probabilities >= 0) & (probabilities <= 1)).all():
        report.append(...)
    if not torch.all((targets == 0) | (targets == 1)):
        report.append(...)
    if metadata["loss_input"] != "logits":
        report.append(...)
    if metadata["aggregation"] == "mean_of_batch_means":
        report.append(...)
    return report

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.5.19 Exercise 18 - Confidence Failure Detection

Part 1 - Why this matters

Confidence failures include more than high-confidence mistakes. A model can be systematically overconfident, underconfident, unstable under small perturbations, or extremely certain on inputs unlike those used for evaluation.

Detection rules should separate observed evidence from explanations. A high-confidence error is directly measurable, while its cause may involve data shift, label noise, leakage, or model misspecification and requires additional investigation.

Part 2 - Mathematical form

For predicted-class confidence c_i and correctness a_i,

$$c_i = \max(p_i, 1 - p_i), \qquad a_i = \mathbb{I}[\widehat{y}_i = y_i].$$

For a selected region S,

$$g_S = \frac{1}{|S|} \sum_{i \in S} c_i - \frac{1}{|S|} \sum_{i \in S} a_i.$$

A positive gap indicates empirical overconfidence in that region.

Part 3 - Hints and Helper

Combine high-confidence error detection with confidence-bin gaps and optional paired probabilities from perturbed inputs. Return sample-level evidence and aggregate counts. Use a minimum bin count so tiny groups are not promoted as strong conclusions.

Part 4 - Python code skeleton

```
import torch

def E18(probabilities, targets, threshold,
        confidence_cutoff, minimum_count):
    predictions = (probabilities >= threshold).to(targets.dtype)
    correctness = (predictions == targets).to(
        probabilities.dtype
    )
    confidence = torch.maximum(
        probabilities, 1.0 - probabilities
    )
    high_confidence = confidence >= confidence_cutoff
    high_confidence_errors = high_confidence & (
        correctness == 0
    )
    selected_count = int(high_confidence.sum().item())
    if selected_count >= minimum_count:
        regional_gap = (
            confidence[high_confidence].mean()
            - correctness[high_confidence].mean()
        )
    else:
        regional_gap = ...
    return {
        "error_indices": ...,
        "selected_count": selected_count,
        "regional_gap": ...,
        "evidence_strength": ...,
```

```
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.5.20 Exercise 19 - Final Probability Analysis Report

Part 1 - Why this matters

A final probability report should connect statistical fit, numerical stability, calibration, confidence failures, class imbalance, and output drift. No single number can establish that a probabilistic classifier is trustworthy.

The report must preserve assumptions and reproducibility details beside the measurements. Thresholds, binning rules, class counts, reduction modes, dtypes, devices, and any prior-shift assumption are part of the result rather than optional notes.

Part 2 - Mathematical form

A structured report may be represented as

$$R = \{\text{data}, \text{likelihood}, \text{calibration}, \text{confidence}, \text{drift}, \text{numerics}, \text{assumptions}, \text{status}\}.$$

A failure status should follow explicit checks, while unsupported sections should be marked unavailable rather than silently omitted.

Part 3 - Hints and Helper

Accept precomputed section results so this exercise focuses on integration rather than duplicating every earlier calculation. Validate required keys, convert tensors to serializable values, preserve warnings, and determine final status from declared rules.

Part 4 - Python code skeleton

```
import json

import torch

def serializable(value):
    if isinstance(value, torch.Tensor):
        if value.numel() == 1:
            return value.item()
        return value.detach().cpu().tolist()
    if isinstance(value, dict):
        return {key: serializable(item)
                for key, item in value.items()}
    if isinstance(value, list):
        return [serializable(item) for item in value]
```

```
    return value

def E19(sections, rules, output_path):
    required = {
        "data",
        "likelihood",
        "calibration",
        "confidence",
        "drift",
        "numerics",
        "assumptions",
    }
    missing = required - sections.keys()
    warnings = []
    if missing:
        warnings.append(...)
    if sections.get("calibration", {}).get("ece", 0.0) > \
            rules["maximum_ece"]:
        warnings.append(...)
    if sections.get("confidence", {}).get(
            "high_confidence_errors", 0
    ) > rules["maximum_high_confidence_errors"]:
        warnings.append(...)
    report = {
        "sections": serializable(sections),
        "warnings": warnings,
        "status": ...,
    }
    with open(output_path, "w", encoding="utf-8") as file:
        json.dump(report, file, indent=2)
    return report

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.6 LG04 - Classification Boundary Definition

Models and Training

11.6.1 Exercise 00 - Linear Decision Boundary Plot

Part 1 - Why this matters

A decision-boundary plot converts the algebra of logistic regression into a visible division of feature space. It shows where the model changes its predicted class and allows the reader to

compare that division with the actual distribution of labels.

The plotted line is determined by the learned parameters and the chosen probability threshold. It is not a line fitted independently for visualization, and it does not prove that the classes are truly separable.

Part 2 - Mathematical form

For two features,

$$z = w_1 x_1 + w_2 x_2 + b, \qquad p = \sigma(z).$$

At threshold $\tau = 0.5$, the boundary satisfies $z = 0$, so when $w_2 \neq 0$,

$$x_2 = -\frac{w_1 x_1 + b}{w_2}.$$

Points on opposite sides have logits with opposite signs.

Part 3 - Hints and Helper

Scatter the two classes with different colors. Generate ordered x_1 values across the observed range and calculate the matching x_2 values. Detect the special case $w_2 \approx 0$, where the boundary is vertical instead of dividing by a nearly zero value.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E00(features, targets, weight, bias, output_path):
    class_zero = targets == 0
    class_one = targets == 1
    fig, ax = plt.subplots()
    ax.scatter(..., ..., label="Class 0")
    ax.scatter(..., ..., label="Class 1")

    tolerance = ...
    if weight[1].abs() > tolerance:
        x_values = torch.linspace(
            features[:, 0].min(),
            features[:, 0].max(),
            steps=...,
        )
        y_values = ...
        ax.plot(x_values.cpu(), y_values.cpu(),
                label="Decision boundary")
    else:
        vertical_x = ...
        ax.axvline(vertical_x.item(),
                   label="Decision boundary")

    ax.set_xlabel(...)
```

```
    ax.set_ylabel(...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)

def main():
    E00(...)

if __name__ == "__main__":
    main()
```

11.6.2 Exercise 01 - Boundary Shift with Bias

Part 1 - Why this matters

The bias term controls where a linear boundary is positioned even when its orientation remains fixed. Changing only the bias translates the boundary parallel to itself and changes the baseline tendency to predict the positive class.

Observing several bias values prevents the intercept from being treated as an unimportant extra parameter. A large shift may change many classifications even though every feature weight remains exactly the same.

Part 2 - Mathematical form

For threshold 0.5, boundaries with fixed weight $\mathbf{w}$ and biases b_a, b_b satisfy

$$\mathbf{w}^\mathsf{T}\mathbf{x} + b_a = 0, \qquad \mathbf{w}^\mathsf{T}\mathbf{x} + b_b = 0.$$

Their perpendicular displacement is

$$d = \frac{|b_b - b_a|}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Plot several parallel boundaries on the same axes and label each bias. Calculate the theoretical perpendicular displacement relative to a reference bias. Reject an all-zero weight vector because it does not define a geometric hyperplane.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def boundary_values(x_values, weight, bias):
    if weight[1].abs() <= ...:
        raise ValueError(...)
    return ...

def E01(x_values, weight, biases, output_path):
```

```
    if torch.linalg.vector_norm(weight) <= ...:
        raise ValueError(...)
    reference_bias = biases[0]
    rows = []
    fig, ax = plt.subplots()
    for bias in biases:
        y_values = boundary_values(
            x_values, weight, bias
        )
        displacement = (
            torch.abs(bias - reference_bias)
            / torch.linalg.vector_norm(weight)
        )
        rows.append(...)
        ax.plot(..., ..., label=...)
    ax.legend()
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return rows

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.6.3 Exercise 02 - Multi-Feature Boundary Visualization

Part 1 - Why this matters

A logistic model with more than two features still has a linear decision boundary, but that boundary is a hyperplane that cannot be drawn directly on a two-dimensional page. A projection or slice is therefore required for visualization.

Every projection discards information. The reader must state whether the graph fixes unshown features, projects data and weights into a lower-dimensional basis, or displays only selected coordinates; otherwise the picture can misrepresent the original classifier.

Part 2 - Mathematical form

In d dimensions, the threshold-0.5 boundary is

$$\mathcal{H} = \left\{ \mathbf{x} \in \mathbb{R}^d : \mathbf{w}^\mathsf{T}\mathbf{x} + b = 0 \right\}.$$

For a projection basis $\mathbf{P} \in \mathbb{R}^{d\times 2}$ and reference point $\mathbf{x}_0$,

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{P}\mathbf{u}, \qquad (\mathbf{P}^\mathsf{T}\mathbf{w})^\mathsf{T}\mathbf{u} + \mathbf{w}^\mathsf{T}\mathbf{x}_0 + b = 0.$$

Part 3 - Hints and Helper

Require two orthonormal projection directions or verify them numerically. Project samples for the scatter plot, transform the weight into the same basis, and include the fixed reference point in the effective bias. Report how much input variance the chosen view preserves if available.

Part 4 - Python code skeleton

```
import matplotlib.pyplot as plt
import torch

def E02(features, targets, weight, bias,
        projection, reference, output_path):
    if projection.shape != (features.shape[1], 2):
        raise ValueError(...)
    gram = projection.T @ projection
    if not torch.allclose(
        gram,
        torch.eye(2, dtype=gram.dtype,
                  device=gram.device),
        atol=...,
    ):
        raise ValueError(...)

    coordinates = (
        features - reference
    ) @ projection
    projected_weight = projection.T @ weight
    effective_bias = weight @ reference + bias
    fig, ax = plt.subplots()
    ax.scatter(..., ..., c=targets.cpu())
    if projected_weight[1].abs() > ...:
        x_values = torch.linspace(..., ..., steps=...)
        y_values = ...
        ax.plot(..., ...)
    else:
        ax.axvline(...)
    fig.savefig(output_path, dpi=150, bbox_inches="tight")
    plt.close(fig)
    return ...

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.6.4 Exercise 03 - Boundary on CUDA Computation

Part 1 - Why this matters

A large decision surface may require millions of grid points, making vectorized GPU evaluation useful. The mathematical boundary is unchanged by the device, but tensor placement, synchronization, and memory allocation affect whether the experiment is correct and efficient.

CUDA should calculate the grid in batches when a full mesh would exceed available memory. The final plotting data can be transferred to CPU after computation; repeatedly moving small tensors during the inner loop can erase the performance benefit.

Part 2 - Mathematical form

For grid points $\mathbf{X}_{\text{grid}}$,

$$\mathbf{z} = \mathbf{X}_{\text{grid}}\mathbf{w} + b, \qquad \mathbf{p} = \sigma(\mathbf{z}).$$

The boundary contour for threshold τ is the level set

$$\mathbf{p} = \tau \quad \Longleftrightarrow \quad \mathbf{z} = \log \frac{\tau}{1-\tau}.$$

Part 3 - Hints and Helper

Choose CUDA only when available and create the grid directly on the selected device. Evaluate flattened grid points in chunks, concatenate results on that device, and transfer one final probability surface to CPU. Keep a CPU result for a numerical parity check.

Part 4 - Python code skeleton

```
import torch

def evaluate_grid(weight, bias, grid_points,
                  chunk_size):
    outputs = []
    with torch.no_grad():
        for start in range(0, grid_points.shape[0],
                           chunk_size):
            chunk = grid_points[
                start:start + chunk_size
            ]
            logits = chunk @ weight + bias
            outputs.append(torch.sigmoid(...))
    return torch.cat(outputs)

def E03(weight, bias, x_axis, y_axis, chunk_size):
    device = torch.device(
        "cuda" if torch.cuda.is_available() else "cpu"
    )
    grid_x, grid_y = torch.meshgrid(
        x_axis.to(device),
        y_axis.to(device),
        indexing="xy",
    )
    grid_points = torch.stack(
```

```
        [grid_x.flatten(), grid_y.flatten()],
        dim=1,
    )
    probabilities = evaluate_grid(
        weight.to(device),
        bias.to(device),
        grid_points,
        chunk_size,
    )
    return {
        "device": str(device),
        "shape": ...,
        "surface": ...,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.6.5 Exercise 04 - Margin Concept Experiment

Part 1 - Why this matters

The signed logit tells which side of the boundary contains a sample, but its magnitude depends on the scale of the weight vector. Dividing by the weight norm produces a geometric signed distance to the hyperplane.

Logistic regression does not maximize a hard margin in the same way as a support-vector machine. This experiment uses margin as an interpretation and robustness diagnostic, not as a claim that logistic regression learned a maximum-margin solution.

Part 2 - Mathematical form

For the threshold-0.5 hyperplane,

$$m_i = \frac{\mathbf{w}^\mathsf{T}\mathbf{x}_i + b}{\|\mathbf{w}\|_2}$$

is the signed geometric margin. A label-oriented margin is

$$\widetilde{m}_i = (2y_i - 1)m_i.$$

It is positive when the sample is correctly placed relative to the boundary.

Part 3 - Hints and Helper

Calculate logits, signed distance, and label-oriented margin. Compare samples with equal logits under rescaled weights and biases to see why normalization matters. Reject a zero-norm weight vector.

Part 4 - Python code skeleton

```
import torch

def E04(features, targets, weight, bias):
    weight_norm = torch.linalg.vector_norm(weight)
    if weight_norm <= ...:
        raise ValueError(...)
    logits = features @ weight + bias
    signed_distance = ...
    signed_labels = 2.0 * targets - 1.0
    label_margin = ...
    return {
        "logits": logits,
        "signed_distance": signed_distance,
        "label_margin": label_margin,
        "minimum_margin": ...,
        "median_margin": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.6.6 Exercise 05 - Overlapping Classes Scenario

Part 1 - Why this matters

Real classes often overlap, so no linear boundary can classify every sample correctly. In that situation the model represents a probability transition through the shared region rather than discovering a perfect separator.

Forcing the reader to inspect overlap prevents accuracy failures from being blamed automatically on code. The limitation may come from the available features, label noise, or an inappropriate linear assumption rather than from optimization.

Part 2 - Mathematical form

For class-conditional data distributions with shared support,

$$P(\mathbf{X} \in A \mid Y = 0) > 0, \qquad P(\mathbf{X} \in A \mid Y = 1) > 0$$

for some region A. Any deterministic classifier must then accept nonzero irreducible error within that representation. Logistic regression estimates

$$P(Y = 1 \mid \mathbf{x}) = \sigma(\mathbf{w}^{\mathsf{T}}\mathbf{x} + b).$$

Part 3 - Hints and Helper

Generate two clouds with adjustable separation and noise. Train or receive a fitted linear model, then report accuracy, NLL, and errors inside a chosen overlap region. Plot probabilities or a contour instead of pretending the boundary explains all uncertainty.

Part 4 - Python code skeleton

```
import torch

def generate_overlap(samples_per_class, separation,
                     noise_scale, generator):
    class_zero = ...
    class_one = ...
    features = torch.cat(
        [class_zero, class_one], dim=0
    )
    targets = torch.cat([
        torch.zeros(samples_per_class),
        torch.ones(samples_per_class),
    ])
    return features, targets

def E05(model, features, targets, threshold):
    with torch.no_grad():
        logits = model(features).flatten()
        probabilities = torch.sigmoid(logits)
        predictions = (
            probabilities >= threshold
        ).to(targets.dtype)
    error_mask = predictions != targets
    return {
        "accuracy": ...,
        "error_count": ...,
        "mean_probability_class_0": ...,
        "mean_probability_class_1": ...,
        "error_indices": ...,
    }

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.6.7 Exercise 06 - Noise Impact on Boundary

Part 1 - Why this matters

Noise in training features or labels can rotate and translate a learned boundary. The resulting change may be small in parameter space yet large near densely populated regions, where many predictions sit close to the decision surface.

A controlled experiment should separate input noise, label noise, and random training variation. Changing all three at once makes it impossible to attribute the observed boundary movement to a specific source.

Part 2 - Mathematical form

For clean parameters $(\mathbf{w}, b)$ and noisy-data parameters $(\widetilde{\mathbf{w}}, \widetilde{b})$, orientation change can be measured by

$$\alpha = \arccos\left(\frac{\mathbf{w}^{\mathsf{T}}\widetilde{\mathbf{w}}}{\|\mathbf{w}\|_2\|\widetilde{\mathbf{w}}\|_2}\right).$$

Prediction disagreement on probe points is

$$r = \frac{1}{N}\sum_i \mathbb{I}[\widehat{y}_i \neq \widetilde{y}_i].$$

Part 3 - Hints and Helper

Use the same initialization and training settings for clean and noisy datasets. Clamp the cosine value before `arccos` to protect against rounding. Compare angle, bias change, probability change, and decision disagreement on one fixed probe set.

Part 4 - Python code skeleton

```
import torch

def boundary_comparison(clean_weight, clean_bias,
                        noisy_weight, noisy_bias,
                        probe_features, threshold):
    denominator = (
        torch.linalg.vector_norm(clean_weight)
        * torch.linalg.vector_norm(noisy_weight)
    )
    if denominator <= ...:
        raise ValueError(...)
    cosine = (
        clean_weight @ noisy_weight / denominator
    ).clamp(-1.0, 1.0)
    angle = torch.arccos(cosine)

    clean_probabilities = torch.sigmoid(
        probe_features @ clean_weight + clean_bias
    )
    noisy_probabilities = torch.sigmoid(
        probe_features @ noisy_weight + noisy_bias
    )
    disagreement = (
        (clean_probabilities >= threshold)
        != (noisy_probabilities >= threshold)
    ).float().mean()
    return angle, disagreement, ...
```

```
def E06(...):
    return boundary_comparison(...)

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.6.8 Exercise 07 - Boundary Stability Test

Part 1 - Why this matters

A reliable boundary should not change unpredictably when training is repeated with small changes in sampling or initialization. Stability analysis measures whether the learned decision rule is supported consistently by the available data.

Parameter differences alone can be deceptive because scaling or correlated features may alter coefficients without changing many decisions. A useful test combines parameter statistics with probability and decision agreement on fixed reference inputs.

Part 2 - Mathematical form

For R trained models and probe $\mathbf{x}_i$, let

$$p_i^{(r)} = \sigma\left(\mathbf{w}^{(r)\mathsf{T}}\mathbf{x}_i + b^{(r)}\right).$$

Pointwise probability variability is

$$s_i = \mathrm{Std}_r\left(p_i^{(r)}\right),$$

and boundary instability can be summarized by prediction disagreement across runs.

Part 3 - Hints and Helper

Evaluate every model on the same ordered probe tensor. Stack probabilities with shape runs by samples, then compute per-sample standard deviation and the fraction of runs disagreeing with the majority label. Preserve seeds and model states in the report.

Part 4 - Python code skeleton

```
import torch

def E07(models, probe_features, threshold):
    probability_runs = []
    with torch.no_grad():
        for model in models:
            model.eval()
            logits = model(probe_features).flatten()
            probability_runs.append(torch.sigmoid(logits))
    probabilities = torch.stack(
```

```
        probability_runs, dim=0
    )
    predictions = probabilities >= threshold
    positive_votes = predictions.float().mean(dim=0)
    majority = positive_votes >= 0.5
    disagreement = (
        predictions != majority.unsqueeze(0)
    ).float().mean(dim=0)
    return {
        "mean_probability": ...,
        "probability_std": ...,
        "mean_disagreement": ...,
        "maximum_disagreement": ...,
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.6.9 Exercise 08 - Misclassified Region Detection

Part 1 - Why this matters

Listing individual mistakes is useful, but identifying regions where mistakes concentrate reveals structure. A cluster of errors may indicate overlap, missing nonlinear interactions, poor scaling, or a subgroup that the model does not represent well.

The region definition must be explicit and reproducible. Grid cells, geometric neighborhoods, or feature ranges can all be used, but the report must include support counts so a region with one error is not treated like a region with many observations.

Part 2 - Mathematical form

For region R_j, define

$$N_j = \sum_i \mathbb{I}[\mathbf{x}_i \in R_j], \qquad E_j = \sum_i \mathbb{I}[\mathbf{x}_i \in R_j \wedge \widehat{y}_i \neq y_i].$$

The regional error rate is

$$e_j = \frac{E_j}{N_j}$$

when $N_j > 0$.

Part 3 - Hints and Helper

Partition two selected features with fixed bin edges. Convert each sample to a cell index, accumulate support and error counts, and filter the final ranking by a minimum support. Return boundaries and counts with every region.

Part 4 - Python code skeleton

```
import torch

def E08(features, targets, probabilities,
        x_edges, y_edges, threshold,
        minimum_support):
    predictions = (
        probabilities >= threshold
    ).to(targets.dtype)
    errors = predictions != targets
    x_bins = torch.bucketize(
        features[:, 0], x_edges[1:-1]
    )
    y_bins = torch.bucketize(
        features[:, 1], y_edges[1:-1]
    )
    rows = []
    for x_bin in range(x_edges.numel() - 1):
        for y_bin in range(y_edges.numel() - 1):
            mask = (x_bins == x_bin) & (y_bins == y_bin)
            support = int(mask.sum().item())
            if support < minimum_support:
                continue
            error_count = int((errors & mask).sum().item())
            rows.append({
                "x_bin": x_bin,
                "y_bin": y_bin,
                "support": support,
                "error_count": error_count,
                "error_rate": ...,
            })
    return sorted(rows, key=..., reverse=True)

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.6.10 Exercise 09 - Boundary Failure Case

Part 1 - Why this matters

A boundary can fail because of invalid shapes, non-finite parameters, zero weights, device mismatches, extreme scaling, or a dataset that requires nonlinear structure. These failures require different responses and should not be collapsed into one generic error.

A diagnostic case should preserve the evidence that distinguishes computational failure from modeling failure. Valid code can still produce a poor boundary, while invalid tensors can prevent any meaningful boundary from being defined.

Part 2 - Mathematical form

A linear boundary exists geometrically when

$$\|\mathbf{w}\|_2 > 0 \quad \text{and} \quad \mathbf{w}, b \text{ are finite.}$$

Given valid parameters, model failure on evaluation data may be summarized by

$$\widehat{R} = \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}[\mathbb{I}[\mathbf{w}^{\mathsf{T}} \mathbf{x}_i + b \geq 0] \neq y_i].$$

Part 3 - Hints and Helper

Validate rank, feature count, dtype, device, and finiteness before calculating predictions. Classify results into invalid input, degenerate boundary, numerically risky, or valid but inaccurate. Do not use low accuracy as proof of a software bug.

Part 4 - Python code skeleton

```
import torch

def E09(features, targets, weight, bias,
        maximum_error_rate):
    issues = []
    if features.ndim != 2:
        issues.append(...)
    if weight.ndim != 1:
        issues.append(...)
    if features.shape[-1] != weight.numel():
        issues.append(...)
    if features.device != weight.device:
        issues.append(...)
    if not torch.isfinite(features).all():
        issues.append(...)
    if not torch.isfinite(weight).all():
        issues.append(...)
    if torch.linalg.vector_norm(weight) <= ...:
        issues.append(...)
    if issues:
        return {"status": ..., "issues": issues}

    logits = features @ weight + bias
    predictions = (logits >= 0).to(targets.dtype)
    error_rate = (predictions != targets).float().mean()
    return {
        "status": ...,
        "error_rate": error_rate.item(),
        "issues": ...,
    }
```

```
def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.6.11 Exercise 10 - High-Dimensional Boundary Projection

Part 1 - Why this matters

In high-dimensional data, the decision boundary is a hyperplane that cannot be inspected directly. Projection provides a controlled view of how samples and the learned normal vector relate inside a chosen two-dimensional subspace.

A projected boundary is not necessarily the complete classifier. Components of the weight vector outside the displayed subspace still affect logits unless the visualization uses a stated reference point or projects the full geometry carefully.

Part 2 - Mathematical form

Let $\mathbf{P} \in \mathbb{R}^{d \times 2}$ contain orthonormal directions and let

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{P}\mathbf{u}.$$

The boundary restricted to this affine plane is

$$(\mathbf{P}^\mathsf{T}\mathbf{w})^\mathsf{T}\mathbf{u} + \mathbf{w}^\mathsf{T}\mathbf{x}_0 + b = 0.$$

The fraction of weight energy visible in the plane is

$$q = \frac{\|\mathbf{P}^\mathsf{T}\mathbf{w}\|_2^2}{\|\mathbf{w}\|_2^2}.$$

Part 3 - Hints and Helper

Use an orthonormal projection such as two selected principal directions or a declared custom basis. Calculate the restricted boundary and visible weight-energy ratio. Warn when the projected weight is nearly zero because the chosen view cannot display the classifier orientation meaningfully.

Part 4 - Python code skeleton

```
import torch

def E10(features, weight, bias,
        projection, reference):
    if projection.shape != (features.shape[1], 2):
        raise ValueError(...)
    gram = projection.T @ projection
    identity = torch.eye(
        2, dtype=gram.dtype, device=gram.device
```

```
    )
    if not torch.allclose(gram, identity, atol=...):
        raise ValueError(...)

    coordinates = (
        features - reference
    ) @ projection
    projected_weight = projection.T @ weight
    effective_bias = weight @ reference + bias
    total_energy = weight.square().sum()
    visible_energy = projected_weight.square().sum()
    ratio = ...
    return {
        "coordinates": coordinates,
        "projected_weight": projected_weight,
        "effective_bias": effective_bias,
        "visible_weight_energy": ratio,
        "projection_is_informative": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.6.12 Exercise 11 - Boundary under Feature Scaling

Part 1 - Why this matters

Feature scaling changes the numerical coefficients used by a model. A boundary trained in standardized coordinates must be transformed back correctly before it can be interpreted in the original measurement units.

Comparing raw and standardized weights directly is misleading because each coefficient refers to a different unit. The transformed boundary should produce the same logits for corresponding inputs, aside from ordinary floating-point error.

Part 2 - Mathematical form

For element-wise standardization

$$\mathbf{x}' = \frac{\mathbf{x} - \boldsymbol{\mu}}{\boldsymbol{s}}, \qquad z = \mathbf{w}'^{\mathsf{T}}\mathbf{x}' + b',$$

the equivalent original-space parameters are

$$\mathbf{w} = \frac{\mathbf{w}'}{\boldsymbol{s}}, \qquad b = b' - \mathbf{w}'^{\mathsf{T}}\frac{\boldsymbol{\mu}}{\boldsymbol{s}}.$$

Part 3 - Hints and Helper

Require every scale value to be positive and nonzero. Convert standardized parameters to original units, then calculate logits by both routes on the same samples. Report maximum absolute discrepancy and prediction parity.

Part 4 - Python code skeleton

```
import torch

def original_space_parameters(
        scaled_weight, scaled_bias, mean, scale):
    if torch.any(scale <= 0):
        raise ValueError(...)
    original_weight = ...
    original_bias = ...
    return original_weight, original_bias

def E11(features, scaled_weight, scaled_bias,
        mean, scale, threshold):
    standardized = (features - mean) / scale
    scaled_logits = (
        standardized @ scaled_weight + scaled_bias
    )
    weight, bias = original_space_parameters(
        scaled_weight, scaled_bias, mean, scale
    )
    original_logits = features @ weight + bias
    discrepancy = (
        scaled_logits - original_logits
    ).abs()
    return {
        "original_weight": weight,
        "original_bias": bias,
        "maximum_logit_difference": ...,
        "prediction_parity": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.6.13 Exercise 12 - Regularization Effect on Boundary

Part 1 - Why this matters

Regularization changes the fitted coefficients and can alter both the orientation and confidence profile of a logistic model. Stronger L2 regularization usually discourages large weight

norms, but its exact geometric effect depends on feature scaling and data structure.

A smaller weight norm does not automatically mean a better boundary. The experiment must compare validation loss, decision agreement, coefficient norm, and probability behavior rather than selecting a model from geometry alone.

Part 2 - Mathematical form

For L2-regularized empirical loss,

$$J(\mathbf{w}, b) = \frac{1}{N}\sum_{i=1}^{N} \text{BCEWithLogits}(z_i, y_i) + \frac{\lambda}{2}\|\mathbf{w}\|_2^2.$$

For two fitted models, orientation difference is

$$\alpha = \arccos\left(\frac{\mathbf{w}_a^{\mathsf{T}}\mathbf{w}_b}{\|\mathbf{w}_a\|_2\|\mathbf{w}_b\|_2}\right).$$

Part 3 - Hints and Helper

Train independent models across declared regularization strengths using the same split and initialization policy. Do not regularize bias unless that is an explicit design choice. Compare norms, angle, validation NLL, and decisions on fixed probes.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def summarize_model(model, features, targets):
    with torch.no_grad():
        logits = model(features).flatten()
        nll = F.binary_cross_entropy_with_logits(
            logits, targets, reduction="mean"
        )
    weight = ...
    bias = ...
    return {
        "weight": weight,
        "bias": bias,
        "weight_norm": ...,
        "validation_nll": ...,
        "probabilities": torch.sigmoid(logits),
    }

def E12(models_by_strength, features, targets,
        threshold):
    summaries = {}
    for strength, model in models_by_strength.items():
        summaries[strength] = summarize_model(
```

```
            model, features, targets
        )
    reference = summaries[...]
    for strength, summary in summaries.items():
        denominator = (
            reference["weight_norm"]
            * summary["weight_norm"]
        )
        summary["angle_from_reference"] = ...
        summary["decision_disagreement"] = ...
    return summaries

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.6.14 Exercise 13 - Boundary Drift over Training

Part 1 - Why this matters

The boundary moves as gradient updates change weights and bias. Tracking this motion reveals whether training converges smoothly, oscillates, or continues changing geometry after the average loss appears nearly flat.

Parameter drift and prediction drift answer different questions. Coefficients may change in directions that have little effect on observed data, while a small parameter change can flip many samples concentrated near the boundary.

Part 2 - Mathematical form

Between epochs $t-1$ and t, define

$$\alpha_t = \arccos\left(\frac{\mathbf{w}^{(t-1)\mathsf{T}}\mathbf{w}^{(t)}}{\|\mathbf{w}^{(t-1)}\|_2\|\mathbf{w}^{(t)}\|_2}\right),$$

and probe disagreement

$$r_t = \frac{1}{N}\sum_i \mathbb{I}[\hat{y}_i^{(t)} \neq \hat{y}_i^{(t-1)}].$$

Part 3 - Hints and Helper

Save detached parameter snapshots and probabilities on one fixed probe set after every epoch. Compare adjacent snapshots, clamp cosine values before taking the angle, and handle zero-norm states explicitly. Plot drift beside loss instead of replacing loss.

Part 4 - Python code skeleton

```
import torch

def E13(snapshots, probe_features, threshold):
    rows = []
    previous = None
    for epoch, state in enumerate(snapshots):
        weight = state["weight"]
        bias = state["bias"]
        probabilities = torch.sigmoid(
            probe_features @ weight + bias
        )
        if previous is None:
            angle = ...
            disagreement = ...
            bias_change = ...
        else:
            denominator = (
                torch.linalg.vector_norm(previous["weight"])
                * torch.linalg.vector_norm(weight)
            )
            cosine = (
                previous["weight"] @ weight / denominator
            ).clamp(-1.0, 1.0)
            angle = torch.arccos(cosine)
            old_predictions = (
                previous["probabilities"] >= threshold
            )
            new_predictions = probabilities >= threshold
            disagreement = ...
            bias_change = ...
        rows.append({
            "epoch": epoch,
            "angle": ...,
            "bias_change": ...,
            "decision_disagreement": ...,
        })
        previous = {
            "weight": weight,
            "bias": bias,
            "probabilities": probabilities,
        }
    return rows

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.6.15 Exercise 14 - Boundary Sharpness Measurement

Part 1 - Why this matters

A geometric hyperplane has no thickness, but the probability transition around it can be gradual or steep. In logistic regression this transition sharpness is controlled by the weight norm when distance is measured in the same feature coordinate system.

Sharpness must be interpreted with feature scaling. Rescaling an input axis changes the numerical weight norm without necessarily changing the physical decision rule, so comparisons require a common representation or original-space transformation.

Part 2 - Mathematical form

For $p(\mathbf{x}) = \sigma(z)$ with $z = \mathbf{w}^\top \mathbf{x} + b$,

$$\nabla_{\mathbf{x}} p = p(1-p)\mathbf{w}.$$

At the threshold-0.5 boundary, $p = 0.5$, hence

$$\|\nabla_{\mathbf{x}} p\|_2 = \frac{1}{4}\|\mathbf{w}\|_2.$$

A transition from probabilities p_a to p_b along the unit normal has width

$$\Delta d = \frac{\operatorname{logit}(p_b) - \operatorname{logit}(p_a)}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Calculate boundary gradient magnitude and a declared probability-transition width, such as 0.1 to 0.9. Verify the analytical gradient against autograd at a constructed boundary point. Reject invalid probability limits and zero-norm weights.

Part 4 - Python code skeleton

```
import torch

def logit(probability):
    return torch.log(probability) - torch.log1p(
        -probability
    )

def E14(weight, lower_probability,
        upper_probability):
    weight_norm = torch.linalg.vector_norm(weight)
    if weight_norm <= ...:
        raise ValueError(...)
    if not (
        0.0 < lower_probability
        < upper_probability < 1.0
    ):
```

```
        raise ValueError(...)
    lower = weight.new_tensor(lower_probability)
    upper = weight.new_tensor(upper_probability)
    boundary_gradient_norm = ...
    transition_width = (
        logit(upper) - logit(lower)
    ) / weight_norm
    return {
        "weight_norm": ...,
        "boundary_gradient_norm": ...,
        "transition_width": ...,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.6.16 Exercise 15 - Visualization Performance Cost

Part 1 - Why this matters

Decision-surface plots can become expensive because a small grid-spacing reduction increases the number of evaluated points in two dimensions quadratically. High visual resolution may consume far more memory and time without improving interpretation.

A fair benchmark separates grid creation, model evaluation, device transfer, and rendering. Timing only the final plotting call hides the main computational cost, while CUDA timing without synchronization can report incomplete work.

Part 2 - Mathematical form

For a square grid with r points per axis,

$$N_{\text{grid}} = r^2.$$

If each point has d features using s bytes per value, the feature-grid storage alone is approximately

$$M = r^2 ds$$

bytes, excluding logits, probabilities, plotting copies, and framework overhead.

Part 3 - Hints and Helper

Benchmark several resolutions with warm-up runs. Synchronize CUDA before and after timed device work, record peak allocated memory when available, and use chunked evaluation. Return measurements without automatically generating every high-resolution figure.

Part 4 - Python code skeleton

```
import time

import torch

def synchronize(device):
    if device.type == "cuda":
        torch.cuda.synchronize(device)

def E15(model, bounds, resolutions,
        device, chunk_size):
    rows = []
    model = model.to(device).eval()
    for resolution in resolutions:
        synchronize(device)
        start = time.perf_counter()
        x_axis = torch.linspace(
            bounds[0], bounds[1],
            steps=resolution,
            device=device,
        )
        y_axis = torch.linspace(
            bounds[2], bounds[3],
            steps=resolution,
            device=device,
        )
        grid_x, grid_y = torch.meshgrid(
            x_axis, y_axis, indexing="xy"
        )
        points = torch.stack(
            [grid_x.flatten(), grid_y.flatten()],
            dim=1,
        )
        probabilities = []
        with torch.no_grad():
            for offset in range(
                0, points.shape[0], chunk_size
            ):
                probabilities.append(
                    torch.sigmoid(
                        model(
                            points[
                                offset:offset + chunk_size
                            ]
                        )
                    )
                )
        synchronize(device)
        elapsed = time.perf_counter() - start
```

```
        rows.append({
            "resolution": resolution,
            "grid_points": ...,
            "seconds": elapsed,
            "output_elements": ...,
        })
    return rows

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.6.17 Exercise 16 - Boundary Interpretation Report

Part 1 - Why this matters

A boundary interpretation should translate coefficients into geometry and decisions without claiming causation. It should state the feature units, scaling process, threshold, orientation, bias effect, and observed behavior on evaluation data.

Interpretation is incomplete when it lists coefficients alone. Correlated features, projection loss, class overlap, and sampling uncertainty can all limit what a coefficient or plotted line supports.

Part 2 - Mathematical form

At probability threshold τ, define

$$c_\tau = \operatorname{logit}(\tau).$$

The decision boundary is

$$\mathbf{w}^\mathsf{T}\mathbf{x} + b = c_\tau.$$

Holding all other features fixed, the coordinate crossing for feature j is

$$x_j = \frac{c_\tau - b - \sum_{k \neq j} w_k x_k}{w_j}, \qquad w_j \neq 0.$$

Part 3 - Hints and Helper

Create a structured report rather than free text only. Include model-space and original-space parameters when scaling was used, the threshold, coefficient units, probe-set error, margin statistics, projection limitations, and explicit cautions against causal interpretation.

Part 4 - Python code skeleton

```
import torch

def E16(feature_names, weight, bias, threshold,
```

```
        scaling, evaluation, limitations):
    threshold_tensor = weight.new_tensor(threshold)
    threshold_logit = torch.log(threshold_tensor) \
        - torch.log1p(-threshold_tensor)
    coefficients = []
    for name, value in zip(feature_names, weight):
        coefficients.append({
            "feature": name,
            "coefficient": value.item(),
            "direction": ...,
            "unit_interpretation": ...,
        })
    return {
        "threshold": threshold,
        "threshold_logit": threshold_logit.item(),
        "bias": bias.item(),
        "weight_norm": ...,
        "coefficients": coefficients,
        "scaling": scaling,
        "evaluation": evaluation,
        "limitations": limitations,
        "causal_claim": False,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.6.18 Exercise 17 - Decision Surface Debugging

Part 1 - Why this matters

A decision-surface plot can look plausible even when axes are reversed, features are scaled inconsistently, sigmoid is applied twice, grid points use the wrong order, or the contour threshold is interpreted in logit space incorrectly.

Debugging should compare a small number of manually chosen points with the plotted surface. Corner values, one known boundary point, and direct model calls provide stronger evidence than visual appearance alone.

Part 2 - Mathematical form

For a probability threshold τ,

$$p(\mathbf{x}) = \tau \quad \Longleftrightarrow \quad z(\mathbf{x}) = \operatorname{logit}(\tau).$$

A valid reshaped surface must preserve

$$S_{j,i} = p([x_i, y_j])$$

when the mesh uses `indexing="xy"`.

Part 3 - Hints and Helper

Validate axis ordering, grid shape, preprocessing, model device, output shape, and finite values. Select several flattened indices, reconstruct their coordinate pairs, and compare stored surface probabilities with independent model evaluations.

Part 4 - Python code skeleton

```
import torch

def E17(model, x_axis, y_axis, surface,
        preprocessing, device, tolerance):
    issues = []
    expected_shape = (
        y_axis.numel(), x_axis.numel()
    )
    if surface.shape != expected_shape:
        issues.append(...)
    if not torch.isfinite(surface).all():
        issues.append(...)

    grid_x, grid_y = torch.meshgrid(
        x_axis, y_axis, indexing="xy"
    )
    points = torch.stack(
        [grid_x.flatten(), grid_y.flatten()],
        dim=1,
    )
    selected_indices = torch.tensor(
        [...], dtype=torch.long
    )
    selected_points = points[selected_indices]
    transformed = preprocessing(selected_points)
    with torch.no_grad():
        direct = torch.sigmoid(
            model(transformed.to(device))
        ).flatten().cpu()
    stored = surface.flatten()[selected_indices].cpu()
    if not torch.allclose(
        direct, stored, atol=tolerance, rtol=...
    ):
        issues.append(...)
    return {
        "status": ...,
        "issues": issues,
        "checked_points": ...,
    }
```

```
def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.6.19 Exercise 18 - Boundary Robustness Test

Part 1 - Why this matters

Boundary robustness measures whether small, permitted input changes can alter decisions. Samples close to the hyperplane are naturally more vulnerable, while samples with large geometric margins require larger perturbations along the boundary normal.

Robustness is meaningful only under a declared perturbation model and feature scale. A Euclidean change of one unit can represent very different physical changes across features, so standardized and domain-constrained tests should be distinguished.

Part 2 - Mathematical form

For threshold logit c_τ, the geometric distance to the boundary is

$$d_i = \frac{\left|\mathbf{w}^\mathsf{T}\mathbf{x}_i + b - c_\tau\right|}{\|\mathbf{w}\|_2}.$$

The minimum unconstrained L2 perturbation that reaches the hyperplane is

$$\boldsymbol{\delta}_i = -\frac{\mathbf{w}^\mathsf{T}\mathbf{x}_i + b - c_\tau}{\|\mathbf{w}\|_2^2}\mathbf{w}.$$

Part 3 - Hints and Helper

Calculate analytical perturbations and verify that perturbed logits reach the threshold within tolerance. Compare distances with an allowed perturbation budget, but do not apply changes to immutable or categorical features unless the domain permits them.

Part 4 - Python code skeleton

```
import torch

def E18(features, weight, bias, threshold,
        perturbation_budget, tolerance):
    weight_norm = torch.linalg.vector_norm(weight)
    if weight_norm <= ...:
        raise ValueError(...)
    threshold_tensor = weight.new_tensor(threshold)
    threshold_logit = (
        torch.log(threshold_tensor)
        - torch.log1p(-threshold_tensor)
    )
```

```
    logits = features @ weight + bias
    offsets = logits - threshold_logit
    perturbations = (
        -offsets.unsqueeze(1)
        / weight_norm.square()
        * weight.unsqueeze(0)
    )
    boundary_logits = (
        (features + perturbations) @ weight + bias
    )
    verification_error = (
        boundary_logits - threshold_logit
    ).abs()
    return {
        "distance": ...,
        "vulnerable": ...,
        "perturbations": perturbations,
        "verified": ...,
        "maximum_verification_error": ...,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.6.20 Exercise 19 - Final Boundary Analysis

Part 1 - Why this matters

A final boundary analysis combines geometry, predictive behavior, stability, scaling, robustness, and visualization limitations. A visually attractive separator is not enough to establish that the model is accurate, stable, or suitable for deployment.

The report should preserve the evidence needed to reproduce every conclusion. Feature definitions, preprocessing state, threshold, model parameters, data split, seeds, projection basis, tolerances, and failure rules all belong beside the results.

Part 2 - Mathematical form

A structured analysis may be represented as

$$R = \{\text{definition}, \text{geometry}, \text{performance}, \text{stability}, \text{robustness}, \text{visualization}, \text{limitations}, \text{status}\}.$$

Status must follow declared checks rather than an informal impression of the boundary plot.

Part 3 - Hints and Helper

Accept results from earlier exercises, validate required sections, and convert tensors into serializable values. Add warnings for degenerate weights, excessive regional error, instability,

weak projection coverage, or robustness below the declared budget. Mark missing evidence explicitly.

Part 4 - Python code skeleton

```
import json

import torch

def serializable(value):
    if isinstance(value, torch.Tensor):
        if value.numel() == 1:
            return value.item()
        return value.detach().cpu().tolist()
    if isinstance(value, dict):
        return {
            key: serializable(item)
            for key, item in value.items()
        }
    if isinstance(value, list):
        return [serializable(item) for item in value]
    return value

def E19(sections, rules, output_path):
    required = {
        "definition",
        "geometry",
        "performance",
        "stability",
        "robustness",
        "visualization",
        "limitations",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if missing:
        warnings.append(...)
    if sections.get("geometry", {}).get(
        "weight_norm", 0.0
    ) <= rules["minimum_weight_norm"]:
        warnings.append(...)
    if sections.get("stability", {}).get(
        "mean_disagreement", 0.0
    ) > rules["maximum_disagreement"]:
        warnings.append(...)
    if sections.get("robustness", {}).get(
        "vulnerable_fraction", 0.0
    ) > rules["maximum_vulnerable_fraction"]:
        warnings.append(...)
```

```
    report = {
        "sections": serializable(sections),
        "missing_sections": missing,
        "warnings": warnings,
        "status": ...,
    }
    with open(output_path, "w", encoding="utf-8") as file:
        json.dump(report, file, indent=2)
    return report

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.7 LG05 - Loss Representation for Classification

Models and Training

11.7.1 Exercise 00 - Binary Cross Entropy Formula

Part 1 - Why this matters

Binary cross entropy measures how much probability a binary model assigns to the observed label. It penalizes confident mistakes strongly while giving small loss to confident correct predictions.

The formula is also the negative Bernoulli log-likelihood, so it connects classification training with maximum-likelihood estimation. The target must describe the same event as the predicted positive-class probability.

Part 2 - Mathematical form

$$\ell_i = -\left[y_i \log(p_i) + (1 - y_i) \log(1 - p_i)\right], \qquad y_i \in \{0, 1\}.$$

For N elements,

$$L_{\text{mean}} = \frac{1}{N} \sum_{i=1}^{N} \ell_i.$$

Part 3 - Hints and Helper

Implement the two target-dependent terms manually. Clamp only for this educational probability-space version, preserve unreduced terms, and compare their mean with PyTorch.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E00(probabilities, targets, epsilon):
    probabilities = probabilities.clamp(
        epsilon, 1.0 - epsilon
    )
    terms = -(
        targets * torch.log(...)
        + (1.0 - targets) * torch.log1p(...)
    )
    return terms, ...

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

11.7.2 Exercise 01 - BCE via PyTorch

Part 1 - Why this matters

PyTorch provides BCE operations with explicit input contracts. Selecting the correct function prevents duplicated sigmoid operations and improves numerical reliability.

The exercise should compare manual probability-space BCE with the library result while preserving shape and reduction choices. Agreement is meaningful only when both routes consume equivalent values.

Part 2 - Mathematical form

$$\text{BCELoss}(p, y) = -\left[y \log p + (1 - y) \log(1 - p)\right].$$

The input p must be a probability in $[0, 1]$.

Part 3 - Hints and Helper

Use `torch.nn.functional.binary_cross_entropy` with reduction `none`. Validate identical shapes and floating targets, then compare per-element values.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E01(probabilities, targets):
    if probabilities.shape != targets.shape:
        raise ValueError(...)
    terms = F.binary_cross_entropy(
```

```
        probabilities,
        targets,
        reduction="none",
    )
    return {
        "terms": terms,
        "mean": ...,
        "sum": ...,
    }

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.7.3 Exercise 02 - Logits vs Probabilities Loss

Part 1 - Why this matters

Logits and probabilities represent different stages of the model. Passing one representation to a function expecting the other may produce an error or, more dangerously, a plausible but incorrect loss.

A stable logits-based loss combines sigmoid and BCE internally. Probability-based BCE remains useful when probabilities are genuinely the input, but it should not be placed after an unnecessary second sigmoid.

Part 2 - Mathematical form

With $p = \sigma(z)$,

$$\text{BCEWithLogits}(z, y) = \text{BCE}(p, y).$$

The equality is mathematical; the logits formulation is numerically more stable.

Part 3 - Hints and Helper

Calculate both correct routes and one intentionally wrong double-sigmoid route. Report equality and the size of the semantic error.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E02(logits, targets):
    probabilities = torch.sigmoid(logits)
    from_logits = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    from_probabilities = F.binary_cross_entropy(
```

```
        probabilities, targets, reduction="none"
    )
    wrong_double_sigmoid = F.binary_cross_entropy(
        torch.sigmoid(probabilities),
        targets,
        reduction="none",
    )
    return {
        "correct_routes_equal": ...,
        "wrong_difference": ...,
    }

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.7.4 Exercise 03 - Numerical Stability (Log-Sum-Exp)

Part 1 - Why this matters

Extreme logits can round sigmoid outputs to exactly zero or one, making direct logarithms infinite. Stable loss computation avoids materializing those dangerous probability expressions.

This is a structural numerical issue, not merely a reason to increase precision. A log-sum-exp form remains useful over a much wider range than sigmoid followed by logarithm.

Part 2 - Mathematical form

A stable binary loss is

$$\ell(z, y) = \max(z, 0) - zy + \log(1 + e^{-|z|}).$$

This is algebraically equal to BCE but avoids unstable cancellation and overflow.

Part 3 - Hints and Helper

Implement the stable expression with torch.clamp and torch.log1p, then compare it with BCEWithLogitsLoss on extreme positive and negative logits.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E03(logits, targets):
    stable_manual = (
        torch.clamp(logits, min=0)
        - logits * targets
        + torch.log1p(torch.exp(-torch.abs(logits)))
```

```
    )
    reference = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    return stable_manual, reference, ...

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.7.5 Exercise 04 - BCE on CUDA

Part 1 - Why this matters

CUDA can accelerate BCE over large tensors, but inputs, targets, weights, and model outputs must share a compatible device. Transfer cost can dominate small evaluations.

The GPU result should preserve dtype and reduction semantics. CPU and CUDA values may differ slightly due to floating-point execution, so parity needs declared tolerances rather than exact equality.

Part 2 - Mathematical form

$$L_{\text{sum}} = \sum_{i=1}^{N} \text{BCEWithLogits}(z_i, y_i).$$

The device changes computation placement, not the objective definition.

Part 3 - Hints and Helper

Choose CUDA only when available, move both tensors, calculate a summed loss, and compare with the same CPU calculation. Return ordinary scalars after computation.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E04(logits, targets):
    cpu_loss = F.binary_cross_entropy_with_logits(
        logits.cpu(), targets.cpu(), reduction="sum"
    )
    if not torch.cuda.is_available():
        return {"cuda_available": False, "cpu": ...}
    cuda_loss = F.binary_cross_entropy_with_logits(
        logits.cuda(), targets.cuda(), reduction="sum"
    )
    return {
```

```
        "cuda_available": True,
        "cpu": ...,
        "cuda": ...,
        "close": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.7.6 Exercise 05 - Loss Gradient Inspection

Part 1 - Why this matters

The loss value describes model error, while its gradient describes how each logit should move to reduce that error. Inspecting gradients exposes confident mistakes and verifies graph connectivity.

For BCE with logits, the derivative has an especially clear interpretation: predicted probability minus target. Reduction changes its scale, so gradient comparisons must use the same reduction.

Part 2 - Mathematical form

$$\frac{\partial \ell_i}{\partial z_i} = \sigma(z_i) - y_i.$$

For mean reduction, the batch gradient is divided by the number of elements.

Part 3 - Hints and Helper

Create leaf logits with `requires_grad`, retain unreduced terms for inspection, backpropagate their mean, and compare `logits.grad` with the analytical expression.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E05(logit_values, targets):
    logits = logit_values.detach().clone()
    logits.requires_grad_(True)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="mean"
    )
    loss.backward()
    analytical = (
        torch.sigmoid(logits.detach()) - targets
    ) / targets.numel()
```

```
    return logits.grad, analytical, ...

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.7.7 Exercise 06 - Class Imbalance Weighting

Part 1 - Why this matters

When positives are rare, an unweighted mean can be dominated by negative examples. Weighting can change the training objective so positive errors contribute more strongly.

Weights encode a learning policy, not a correction that automatically creates calibrated probabilities. The report must record class counts, the chosen weight, and whether it applies to positive terms or all elements.

Part 2 - Mathematical form

With positive weight q,

$$\ell_i = -\left[q\, y_i \log \sigma(z_i) + (1 - y_i) \log(1 - \sigma(z_i))\right].$$

A common data-derived choice is $q = N_0/N_1$ when $N_1 > 0$.

Part 3 - Hints and Helper

Calculate class counts, reject an absent positive class, create `pos_weight` on the logits device, and compare class-wise contributions before and after weighting.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E06(logits, targets):
    negative_count = (targets == 0).sum()
    positive_count = (targets == 1).sum()
    if positive_count == 0:
        raise ValueError(...)
    positive_weight = (
        negative_count / positive_count
    ).to(logits.dtype)
    weighted = F.binary_cross_entropy_with_logits(
        logits,
        targets,
        pos_weight=positive_weight,
        reduction="none",
    )
```

```
    return positive_weight, weighted, ...

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.7.8 Exercise 07 - Loss Scaling Effect

Part 1 - Why this matters

Multiplying a loss scales its gradients even though it does not change which parameter minimizes the exact objective when the scale is positive and constant.

Loss scaling can be intentional for mixed precision or multi-objective balancing, but an unexplained factor changes optimization dynamics. Learning rate, clipping, and reported metrics must be interpreted accordingly.

Part 2 - Mathematical form

For constant $c > 0$,

$$L' = cL, \qquad \nabla_\theta L' = c\nabla_\theta L, \qquad \arg\min L' = \arg\min L.$$

Part 3 - Hints and Helper

Use identical cloned logits for several scales, run independent backward passes, and compare gradient norms and element-wise gradient ratios.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def gradient_for_scale(values, targets, scale):
    logits = values.detach().clone().requires_grad_(True)
    base = F.binary_cross_entropy_with_logits(
        logits, targets
    )
    scaled = scale * base
    scaled.backward()
    return scaled.detach(), logits.grad.detach()

def E07(values, targets, scales):
    return {
        scale: gradient_for_scale(
            values, targets, scale
        )
        for scale in scales
```

```
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.7.9 Exercise 08 - Loss Explosion Scenario

Part 1 - Why this matters

Very large loss can arise from extreme wrong logits, invalid learning rates, non-finite inputs, or corrupted targets. The magnitude is a symptom that needs classification, not proof of one specific bug.

Stable BCE prevents avoidable numerical failure, but it cannot make genuinely terrible predictions inexpensive. Monitoring logits, gradients, and finiteness distinguishes valid large penalties from NaN propagation.

Part 2 - Mathematical form

For $y = 1$ and $z \to -\infty$,

$$\ell(z, 1) \approx -z.$$

For $y = 0$ and $z \to +\infty$,

$$\ell(z, 0) \approx z.$$

Part 3 - Hints and Helper

Construct controlled extreme correct and incorrect cases. Record unreduced losses, maximum absolute logit, finite checks, and which samples exceed a declared warning threshold.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E08(logits, targets, warning_threshold):
    terms = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    return {
        "all_finite": ...,
        "maximum_loss": ...,
        "maximum_absolute_logit": ...,
        "warning_indices": ...,
    }

def main():
    print(E08(...))
```

```
if __name__ == "__main__":
    main()
```

11.7.10 Exercise 09 - Loss Debugging Case

Part 1 - Why this matters

Loss bugs commonly come from wrong shapes, integer targets, device mismatch, double sigmoid, invalid target ranges, or incorrect aggregation. Each failure requires a different explanation.

A debugger should validate contracts before calling the loss function and preserve actionable evidence. Broadcasting should never silently pair unrelated predictions and labels.

Part 2 - Mathematical form

A valid binary logits loss requires

$$\text{shape}(\mathbf{z}) = \text{shape}(\mathbf{y}), \qquad 0 \le y_i \le 1,$$

with compatible floating dtypes and devices.

Part 3 - Hints and Helper

Return a list of contract violations covering rank, shape, dtype, device, range, and finiteness. Accept an explicit representation label instead of guessing from value ranges.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E09(inputs, targets, representation):
    issues = []
    if inputs.shape != targets.shape:
        issues.append(...)
    if not inputs.is_floating_point():
        issues.append(...)
    if not targets.is_floating_point():
        issues.append(...)
    if inputs.device != targets.device:
        issues.append(...)
    if not torch.isfinite(inputs).all():
        issues.append(...)
    if not ((targets >= 0) & (targets <= 1)).all():
        issues.append(...)
    if representation != "logits":
        issues.append(...)
    return issues
```

```
def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.7.11 Exercise 10 - Custom BCE Loss Class

Part 1 - Why this matters

A custom loss module makes validation, weighting, and reduction policy reusable. It also teaches how PyTorch modules register configuration without hiding the mathematical objective.

Reimplementing a stable primitive manually is unnecessary for production use. The custom class should delegate numerical computation to BCEWithLogitsLoss while adding explicit project-level contracts.

Part 2 - Mathematical form

$$L = \text{reduce}\left(\text{BCEWithLogits}(\mathbf{z}, \mathbf{y}; q)\right).$$

The reduction is one of none, sum, or mean.

Part 3 - Hints and Helper

Subclass `nn.Module`, validate reduction in the constructor, register `pos_weight` as a buffer when supplied, and check shapes in `forward`.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

class CustomBCE(torch.nn.Module):
    def __init__(self, reduction="mean",
                 positive_weight=None):
        super().__init__()
        if reduction not in {"none", "mean", "sum"}:
            raise ValueError(...)
        self.reduction = reduction
        self.register_buffer(
            "positive_weight",
            positive_weight,
        )

    def forward(self, logits, targets):
        if logits.shape != targets.shape:
            raise ValueError(...)
        return F.binary_cross_entropy_with_logits(
            logits,
```

```
            targets,
            pos_weight=...,
            reduction=self.reduction,
        )

def E10(...):
    return CustomBCE(...)(...)

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.7.12 Exercise 11 - Masked Loss Computation

Part 1 - Why this matters

Some labels may be padded, missing, or intentionally excluded. Masking ensures these elements do not influence either the reported loss or the gradient.

Multiplying a mean loss by a mask after reduction is incorrect because excluded elements have already contributed. Mask unreduced terms first, then divide by the number or total weight of valid elements.

Part 2 - Mathematical form

For mask $m_i \in \{0, 1\}$,

$$L_{\text{masked}} = \frac{\sum_i m_i \ell_i}{\sum_i m_i}, \qquad \sum_i m_i > 0.$$

Part 3 - Hints and Helper

Calculate unreduced BCE, convert the mask to a compatible dtype, validate identical shapes, and reject an empty mask. Return valid count and masked sum as well as mean.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E11(logits, targets, mask):
    if not (
        logits.shape == targets.shape == mask.shape
    ):
        raise ValueError(...)
    terms = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    weights = mask.to(terms.dtype)
```

```
    valid_count = weights.sum()
    if valid_count <= 0:
        raise ValueError(...)
    masked_sum = ...
    return masked_sum / valid_count, ...

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.7.13 Exercise 12 - Reduction Mode Comparison

Part 1 - Why this matters

Reduction changes the numerical scale of both loss and gradients. The none, sum, and mean modes serve different purposes and must not be compared as if their values were interchangeable.

Dataset-wide means require element-weighted aggregation across batches. An average of batch means becomes biased when batch sizes differ.

Part 2 - Mathematical form

$$L_{\text{none}} = (\ell_1, \ldots, \ell_N), \quad L_{\text{sum}} = \sum_i \ell_i, \quad L_{\text{mean}} = \frac{1}{N} \sum_i \ell_i.$$

Part 3 - Hints and Helper

Compute unreduced terms once, derive sum and mean manually, and compare with all three PyTorch reductions. Verify the corresponding gradient scaling in a second experiment.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E12(logits, targets):
    none = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="none"
    )
    summed = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="sum"
    )
    mean = F.binary_cross_entropy_with_logits(
        logits, targets, reduction="mean"
    )
    return {
        "none": none,
```

```
        "sum_matches": ...,
        "mean_matches": ...,
        "element_count": ...,
    }

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.7.14 Exercise 13 - Mixed Precision Loss

Part 1 - Why this matters

Mixed precision can accelerate training and reduce memory, but extreme values and small gradients require careful dtype handling. Loss computation is often kept in a numerically suitable autocast path.

Gradient scaling protects small gradients from underflow; it does not change the intended optimizer update after unscaling. The experiment should run only on supported devices and include a full-precision reference.

Part 2 - Mathematical form

With scale s,

$$L' = sL, \qquad \nabla L' = s\nabla L.$$

After unscaling, the optimizer should receive the intended gradient ∇L.

Part 3 - Hints and Helper

Use torch.autocast with a device-appropriate dtype and GradScaler for CUDA training. Compare finite loss and gradients with float32; do not force CUDA when unavailable.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E13(model, features, targets, optimizer):
    device = features.device
    scaler = torch.amp.GradScaler(
        "cuda",
        enabled=device.type == "cuda",
    )
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(
        device_type=device.type,
        dtype=...,
        enabled=...,
```

```
    ):
        logits = model(features).reshape_as(targets)
        loss = F.binary_cross_entropy_with_logits(
            logits, targets
        )
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_finite = ...
    scaler.step(optimizer)
    scaler.update()
    return loss.detach(), gradient_finite

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.7.15 Exercise 14 - Loss Memory Profiling

Part 1 - Why this matters

Unreduced loss tensors, retained graphs, and large batches can consume substantial memory. Profiling reveals whether memory belongs to inputs, activations, loss terms, gradients, or accidental graph retention.

A meaningful measurement resets peak statistics, synchronizes device work, and compares the same workload across reduction modes. Allocated and reserved CUDA memory are different quantities.

Part 2 - Mathematical form

For N elements and dtype size s, an unreduced loss alone stores approximately

$$M_{\text{terms}} = Ns$$

bytes, excluding graph metadata and intermediate activations.

Part 3 - Hints and Helper

Profile none, sum, and mean with identical inputs. On CUDA reset peak statistics before each isolated run and synchronize before reading; on CPU provide tensor-byte estimates.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()
```

```
def E14(logits, targets, reduction):
    device = logits.device
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats(device)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=reduction
    )
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        peak = torch.cuda.max_memory_allocated(device)
    else:
        peak = ...
    return {
        "loss_shape": tuple(loss.shape),
        "loss_bytes": tensor_bytes(loss),
        "peak_bytes": peak,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.7.16 Exercise 15 - CPU vs GPU Loss Parity

Part 1 - Why this matters

CPU and GPU should implement the same objective, but operation ordering and hardware arithmetic can create small numerical differences. Exact bitwise equality is generally the wrong criterion.

Parity testing should preserve model state, dtype, shapes, weights, and reduction. Absolute and relative error should be reported together with declared tolerances.

Part 2 - Mathematical form

For results L_{cpu} and L_{gpu},

$$\Delta_{\text{abs}} = |L_{\text{cpu}} - L_{\text{gpu}}|, \qquad \Delta_{\text{rel}} = \frac{\Delta_{\text{abs}}}{|L_{\text{cpu}}| + \varepsilon}.$$

Part 3 - Hints and Helper

Use float64 comparison when supported for a strict reference and float32 for the practical path. Transfer the final GPU result to CPU once and report both errors.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E15(logits, targets, epsilon, atol, rtol):
    cpu = F.binary_cross_entropy_with_logits(
        logits.cpu(), targets.cpu(), reduction="sum"
    )
    if not torch.cuda.is_available():
        return {"cuda_available": False}
    gpu = F.binary_cross_entropy_with_logits(
        logits.cuda(), targets.cuda(), reduction="sum"
    ).cpu()
    difference = (cpu - gpu).abs()
    return {
        "cpu": cpu.item(),
        "gpu": gpu.item(),
        "absolute_error": ...,
        "relative_error": ...,
        "close": torch.allclose(
            cpu, gpu, atol=atol, rtol=rtol
        ),
    }

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.7.17 Exercise 16 - Loss Curve Logging

Part 1 - Why this matters

A loss curve exposes convergence, oscillation, divergence, and plateaus across training. Reliable logging uses one well-defined aggregation for every epoch.

Logging the final batch alone or averaging unequal batch means produces misleading curves. Training and validation losses should be labeled separately and calculated with consistent reductions.

Part 2 - Mathematical form

For epoch t,

$$\overline{L}_t = \frac{\sum_k L_{t,k,\mathrm{sum}}}{\sum_k N_{t,k}}.$$

Part 3 - Hints and Helper

Accumulate loss.item and element counts from summed batch losses. Store plain numbers after each epoch, include learning rate, and serialize without retaining computation graphs.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E16(model, data_loader, device):
    total_loss = 0.0
    total_elements = 0
    model.eval()
    with torch.no_grad():
        for features, targets in data_loader:
            features = features.to(device)
            targets = targets.to(device)
            logits = model(features).reshape_as(targets)
            loss = F.binary_cross_entropy_with_logits(
                logits, targets, reduction="sum"
            )
            total_loss += ...
            total_elements += ...
    return total_loss / total_elements

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.7.18 Exercise 17 - Loss Drift Detection

Part 1 - Why this matters

Loss may drift after data, preprocessing, model, or deployment conditions change. Comparing only a global mean can hide class-specific or subgroup-specific degradation.

A drift alert requires a reference distribution, a current window, minimum sample counts, and a declared threshold. Statistical change does not identify its cause automatically.

Part 2 - Mathematical form

For reference mean μ_0 and current mean μ_t,

$$d_t = \mu_t - \mu_0, \qquad r_t = \frac{\mu_t - \mu_0}{|\mu_0| + \varepsilon}.$$

Both absolute and relative changes provide context.

Part 3 - Hints and Helper

Store unreduced losses for reference and current windows. Compare mean, quantiles, class-wise means, and valid counts; require sustained violations before declaring drift.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E17(reference_losses, current_losses,
        absolute_limit, relative_limit, epsilon):
    reference_mean = reference_losses.mean()
    current_mean = current_losses.mean()
    absolute_change = current_mean - reference_mean
    relative_change = absolute_change / (
        reference_mean.abs() + epsilon
    )
    return {
        "absolute_change": ...,
        "relative_change": ...,
        "alert": ...,
        "reference_count": ...,
        "current_count": ...,
    }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.7.19 Exercise 18 - Failure Recovery Test

Part 1 - Why this matters

Training should detect non-finite loss before corrupting parameters. A recovery mechanism can skip an unsafe update, preserve diagnostics, and restore a known checkpoint when policy permits.

Recovery must not hide repeated failure. The system should count consecutive incidents, record inputs and optimizer state safely, and stop after a declared limit rather than continuing indefinitely.

Part 2 - Mathematical form

A safe update requires

$$L \in \mathbb{R}, \qquad \|\nabla_\theta L\|_2 < \infty.$$

If either condition fails, parameters must not be updated.

Part 3 - Hints and Helper

Snapshot parameters before the test step, check loss and every gradient for finiteness, and call optimizer.step only when all checks pass. Verify unchanged parameters after a rejected update.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E18(model, optimizer, logits, targets):
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    optimizer.zero_grad(set_to_none=True)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets
    )
    if not torch.isfinite(loss):
        return {"updated": False, "reason": ...}
    loss.backward()
    gradients_finite = all(
        parameter.grad is None
        or torch.isfinite(parameter.grad).all()
        for parameter in model.parameters()
    )
    if not gradients_finite:
        optimizer.zero_grad(set_to_none=True)
        return {"updated": False, "reason": ...}
    optimizer.step()
    return {
        "updated": True,
        "parameters_changed": ...,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.7.20 Exercise 19 - Final Loss Report

Part 1 - Why this matters

A final loss report should connect the loss definition, representation, reduction, weighting, numerical stability, gradients, device parity, memory, drift, and recovery behavior.

No isolated scalar can establish that a loss pipeline is correct. Reproducibility requires shapes, dtypes, devices, thresholds, class counts, masks, and tolerances beside the measurements.

Part 2 - Mathematical form

$$R = \{\text{contract}, \text{values}, \text{gradients}, \text{numerics}, \text{aggregation}, \text{resources}, \text{monitoring}, \text{status}\}.$$

Part 3 - Hints and Helper

Accept validated results from earlier exercises, mark missing sections, convert tensors to serializable values, and derive status from explicit rules instead of visual judgment.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E19(sections, rules):
    required = {
        "contract", "values", "gradients",
        "numerics", "aggregation",
        "resources", "monitoring",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if missing:
        warnings.append(...)
    if not sections.get(
        "numerics", {}
    ).get("all_finite", False):
        warnings.append(...)
    if sections.get(
        "monitoring", {}
    ).get("drift_alert", False):
        warnings.append(...)
    return {
        "sections": sections,
        "missing": missing,
        "warnings": warnings,
        "status": ...,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.8 LG06 - Model Adjustment and Gradient Direction

Models and Training

11.8.1 Exercise 00 - Backward Pass on BCE Loss

Part 1 - Why this matters

This experiment studies backward pass on bce loss inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E00(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,

11.8.2 Exercise 01 - Inspect Weight Gradients

Part 1 - Why this matters

This experiment studies inspect weight gradients inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E01(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }
```

```
def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.8.3 Exercise 02 - Inspect Bias Gradients

Part 1 - Why this matters

This experiment studies inspect bias gradients inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E02(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
```

```
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.8.4 Exercise 03 - Manual Gradient Update

Part 1 - Why this matters

This experiment studies manual gradient update inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E03(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
```

```
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.8.5 Exercise 04 - Learning Rate Sensitivity

Part 1 - Why this matters

This experiment studies learning rate sensitivity inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E04(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.8.6 Exercise 05 - Gradient Clipping in Classification

Part 1 - Why this matters

This experiment studies gradient clipping in classification inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E05(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.8.7 Exercise 06 - Gradient Noise Injection

Part 1 - Why this matters

This experiment studies gradient noise injection inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E06(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.8.8 Exercise 07 - Optimizer Step Comparison

Part 1 - Why this matters

This experiment studies optimizer step comparison inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices,

and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E07(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.8.9 Exercise 08 - CUDA Gradient Sync Check

Part 1 - Why this matters

This experiment studies cuda gradient sync check inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E08(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }
```

```
def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.8.10 Exercise 09 - Gradient Explosion Scenario

Part 1 - Why this matters

This experiment studies gradient explosion scenario inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E09(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
```

```
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.8.11 Exercise 10 - Gradient Vanishing Scenario

Part 1 - Why this matters

This experiment studies gradient vanishing scenario inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E10(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
```

```
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.8.12 Exercise 11 - Mixed Precision Backward

Part 1 - Why this matters

This experiment studies mixed precision backward inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E11(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.8.13 Exercise 12 - Frozen Layer Gradient Test

Part 1 - Why this matters

This experiment studies frozen layer gradient test inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E12(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.8.14 Exercise 13 - Gradient Accumulation

Part 1 - Why this matters

This experiment studies gradient accumulation inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E13(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.8.15 Exercise 14 - Backward Graph Retention

Part 1 - Why this matters

This experiment studies backward graph retention inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices,

and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E14(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.8.16 Exercise 15 - Gradient Memory Profiling

Part 1 - Why this matters

This experiment studies gradient memory profiling inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E15(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }
```

```
def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.8.17 Exercise 16 - Multi-Batch Gradient Behavior

Part 1 - Why this matters

This experiment studies multi-batch gradient behavior inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E16(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
```

```
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.8.18 Exercise 17 - Gradient Drift Detection

Part 1 - Why this matters

This experiment studies gradient drift detection inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E17(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
```

```
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.8.19 Exercise 18 - Debugging Gradient Failure

Part 1 - Why this matters

This experiment studies debugging gradient failure inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E18(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.8.20 Exercise 19 - End-to-End Gradient Report

Part 1 - Why this matters

This experiment studies end-to-end gradient report inside logistic-regression training. Gradients convert classification error into parameter movement, so their values, shapes, devices, and graph connections must be inspected rather than assumed.

A plausible loss does not guarantee a valid update. Accidental accumulation, detached tensors, non-finite values, incorrect scaling, and stale gradients can silently change learning, so the exercise records evidence before and after backward.

Part 2 - Mathematical form

For parameters θ and binary cross-entropy loss L,

$$\mathbf{g} = \nabla_\theta L, \qquad \theta_{t+1} = \theta_t - \eta \mathbf{g}.$$

The experiment must state its reduction, batch size, learning rate, and any transformation applied to $\mathbf{g}$.

Part 3 - Hints and Helper

Use `binary_cross_entropy_with_logits`, clear gradients at the declared point, and preserve detached parameter copies. Check shape, dtype, device, finiteness, gradient norm, and whether parameters changed. Complete the missing lines without hiding the behavior in a training utility.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def E19(model, features, targets, configuration):
    model.train()
    model.zero_grad(set_to_none=True)
    before = {
        name: parameter.detach().clone()
        for name, parameter in model.named_parameters()
    }
    logits = model(features).reshape_as(targets)
    loss = F.binary_cross_entropy_with_logits(
        logits, targets, reduction=...
    )
    ...
    return {
        "loss": ...,
        "gradient_norms": ...,
        "parameters_changed": ...,
        "all_finite": ...,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.9 LG07 - Accuracy Validation and Output Analysis

Models and Training

11.9.1 Exercise 00 - Accuracy Metric Implementation

Part 1 - Why this matters

Accuracy Metric Implementation turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}.$$

Part 3 - Hints and Helper

Convert probabilities to labels with a declared threshold, validate equal shapes, and return both count and ratio.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E00(probabilities, targets, threshold):
    predictions = (
        probabilities >= threshold
    ).to(targets.dtype)
    correct = predictions == targets
    return {
        "correct": ...,
        "total": ...,
        "accuracy": ...,
    }

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

11.9.2 Exercise 01 - Precision Metric

Part 1 - Why this matters

Precision Metric turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{Precision} = \frac{TP}{TP + FP}.$$

Part 3 - Hints and Helper

Define what happens when there are no predicted positives. Return the denominator and an undefined flag instead of silently hiding the case.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E01(predictions, targets, zero_division):
    true_positive = ((predictions == 1) & (targets == 1)).sum()
    false_positive = ((predictions == 1) & (targets == 0)).sum()
    denominator = true_positive + false_positive
    precision = ... if denominator > 0 else ...
    return true_positive, false_positive, precision

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.9.3 Exercise 02 - Recall Metric

Part 1 - Why this matters

Recall Metric turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{Recall} = \frac{TP}{TP + FN}.$$

Part 3 - Hints and Helper

Treat the positive class explicitly and handle a dataset containing no actual positives. Compare recall with precision on the same predictions.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E02(predictions, targets, zero_division):
    true_positive = ...
    false_negative = ...
    denominator = true_positive + false_negative
    recall = ... if denominator > 0 else ...
    return {
        "true_positive": ...,
        "false_negative": ...,
        "recall": recall,
    }

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.9.4 Exercise 03 - F1 Score Computation

Part 1 - Why this matters

F1 Score Computation turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$F_1 = \frac{2PR}{P+R} = \frac{2TP}{2TP+FP+FN}.$$

Part 3 - Hints and Helper

Compute F1 from confusion counts and independently from precision and recall. Verify equality and define the all-zero denominator policy.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E03(true_positive, false_positive,
        false_negative, zero_division):
    denominator = (
        2 * true_positive
        + false_positive
        + false_negative
    )
    f1_from_counts = ... if denominator > 0 else ...
    precision = ...
    recall = ...
    f1_from_metrics = ...
    return f1_from_counts, f1_from_metrics, ...

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.9.5 Exercise 04 - Evaluation without Grad

Part 1 - Why this matters

Evaluation without Grad turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\widehat{\mathbf{p}} = \sigma(f_\theta(\mathbf{X})), \qquad \nabla_\theta \widehat{\mathbf{p}} \text{ is not required during evaluation.}$$

Part 3 - Hints and Helper

Call `model.eval()` and use `torch.inference_mode()`. Confirm that outputs do not require gradients while leaving parameter `requires_grad` flags unchanged.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E04(model, data_loader, device):
    model.eval()
    total_correct = 0
    total_samples = 0
    with torch.inference_mode():
        for features, targets in data_loader:
            features = features.to(device)
            targets = targets.to(device)
            probabilities = torch.sigmoid(
                model(features).reshape_as(targets)
            )
            total_correct += ...
            total_samples += ...
    return total_correct / total_samples

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.9.6 Exercise 05 - GPU Evaluation Throughput

Part 1 - Why this matters

GPU Evaluation Throughput turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{Throughput} = \frac{N_{\text{samples}}}{T_{\text{seconds}}}.$$

Part 3 - Hints and Helper

Warm up the GPU, synchronize before and after the timed region, exclude one-time model transfer, and report batch size with throughput.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E05(model, batches, device):
    model = model.to(device).eval()
    ...
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    start = time.perf_counter()
    sample_count = 0
    with torch.inference_mode():
        for features in batches:
            output = model(features.to(device))
            sample_count += features.shape[0]
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - start
    return sample_count / elapsed, elapsed

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.9.7 Exercise 06 - Confusion Matrix Visualization

Part 1 - Why this matters

Confusion Matrix Visualization turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\mathbf{C} = \begin{bmatrix} TN & FP \\ FN & TP \end{bmatrix}.$$

Part 3 - Hints and Helper

Calculate the four cells manually, verify their sum equals the sample count, then plot a labeled two-by-two heatmap without swapping true and predicted axes.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E06(predictions, targets, output_path):
    matrix = torch.tensor([
        [..., ...],
        [..., ...],
    ])
    if matrix.sum() != targets.numel():
        raise RuntimeError(...)
    fig, ax = plt.subplots()
    image = ax.imshow(matrix.cpu(), cmap="Blues")
    ax.set_xlabel(...)
    ax.set_ylabel(...)
    ...
    fig.savefig(output_path, dpi=150,
                bbox_inches="tight")
    plt.close(fig)
    return matrix

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.9.8 Exercise 07 - Metric Stability under Noise

Part 1 - Why this matters

Metric Stability under Noise turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\Delta M_r = M(\mathbf{X} + \varepsilon_r) - M(\mathbf{X}), \qquad \varepsilon_r \sim \mathcal{N}(0, \sigma^2 I).$$

Part 3 - Hints and Helper

Use repeated seeded perturbations and fixed targets. Report mean, standard deviation, worst change, and class-specific metric changes.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E07(model, features, targets,
        noise_scale, repetitions, seed):
    generator = torch.Generator(
        device=features.device
    ).manual_seed(seed)
    baseline = ...
    results = []
    with torch.inference_mode():
        for _ in range(repetitions):
            noise = torch.randn(
                features.shape,
                generator=generator,
                device=features.device,
            )
            results.append(
                evaluate(model,
                         features + noise_scale * noise,
                         targets)
            )
    return baseline, summarize(...)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.9.9 Exercise 08 - Performance Scaling with Data Size

Part 1 - Why this matters

Performance Scaling with Data Size turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$T(N), \quad \frac{T(N)}{N}, \quad \text{Throughput}(N) = \frac{N}{T(N)}.$$

Part 3 - Hints and Helper

Benchmark increasing sample counts with identical dtype, device, and batch policy. Separate model execution from data generation and include warm-up.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E08(model, datasets, device, batch_size):
    rows = []
    model = model.to(device).eval()
    for sample_count, features in datasets.items():
        ...
        start = time.perf_counter()
        with torch.inference_mode():
            for batch in features.split(batch_size):
                model(batch.to(device))
        ...
        rows.append({
            "samples": sample_count,
            "seconds": ...,
            "throughput": ...,
        })
    return rows

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.9.10 Exercise 09 - Latency Profiling on CUDA

Part 1 - Why this matters

Latency Profiling on CUDA turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{Latency}_q = Q_q(t_1, \ldots, t_R),$$

where Q_q is a latency quantile.

Part 3 - Hints and Helper

Use CUDA events or explicit synchronization, perform warm-up, and report median and tail percentiles rather than only the arithmetic mean.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E09(model, sample, repetitions):
    if not torch.cuda.is_available():
        return {"cuda_available": False}
    model = model.cuda().eval()
    sample = sample.cuda()
    timings = []
    with torch.inference_mode():
        for _ in range(...):
            model(sample)
        for _ in range(repetitions):
            start = torch.cuda.Event(enable_timing=True)
            end = torch.cuda.Event(enable_timing=True)
            start.record()
            model(sample)
            end.record()
            torch.cuda.synchronize()
            timings.append(start.elapsed_time(end))
    values = torch.tensor(timings)
    return {"median_ms": ..., "p95_ms": ...}

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.9.11 Exercise 10 - Memory Usage Profiling

Part 1 - Why this matters

Memory Usage Profiling turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$M_{\text{peak}} = \max_t M_{\text{allocated}}(t).$$

Part 3 - Hints and Helper

Reset CUDA peak statistics immediately before the measured workload. Report allocated and reserved memory separately and state that external allocations may be invisible.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E10(model, features, device):
    if device.type != "cuda":
        return {"tensor_bytes": ...}
    model = model.to(device).eval()
    features = features.to(device)
    torch.cuda.reset_peak_memory_stats(device)
    with torch.inference_mode():
        output = model(features)
    torch.cuda.synchronize(device)
    return {
        "peak_allocated": ...,
        "peak_reserved": ...,
        "output_bytes": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.9.12 Exercise 11 - Error Distribution Analysis

Part 1 - Why this matters

Error Distribution Analysis turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$e_i = y_i - p_i, \qquad \mathcal{E} = \{e_1, \ldots, e_N\}.$$

Part 3 - Hints and Helper

Analyze errors by target class, predicted class, confidence, and feature subgroup. Return quantiles and severe-error indices, not only a histogram.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E11(probabilities, targets):
    residuals = targets - probabilities
    absolute_errors = residuals.abs()
    quantiles = torch.quantile(
        absolute_errors,
        torch.tensor(
            [...],
            device=absolute_errors.device,
        ),
    )
    return {
        "quantiles": ...,
        "class_0_mean": ...,
        "class_1_mean": ...,
        "largest_error_indices": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.9.13 Exercise 12 - Threshold Sensitivity Analysis

Part 1 - Why this matters

Threshold Sensitivity Analysis turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\widehat{y}_i(\tau) = \mathbb{I}[p_i \geq \tau], \qquad M = M(\tau).$$

Part 3 - Hints and Helper

Sweep ordered thresholds over zero to one and recompute confusion counts and metrics. Select a threshold only from a declared objective and validation data.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E12(probabilities, targets, thresholds):
    rows = []
    for threshold in thresholds:
        predictions = (
            probabilities >= threshold
        ).to(targets.dtype)
        counts = confusion_counts(
            predictions, targets
        )
        rows.append({
            "threshold": ...,
            "accuracy": ...,
            "precision": ...,
            "recall": ...,
            "f1": ...,
        })
    return rows

def main():
    print(E12(...))
```

```
if __name__ == "__main__":
    main()
```

11.9.14 Exercise 13 - Metric Regression Detection

Part 1 - Why this matters

Metric Regression Detection turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\Delta M = M_{\text{candidate}} - M_{\text{reference}}.$$

Part 3 - Hints and Helper

Compare the same frozen evaluation dataset, threshold, preprocessing, and metric definitions. Support one-sided tolerances and minimum sample size.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E13(reference, candidate, tolerances):
    regressions = []
    for metric, reference_value in reference.items():
        candidate_value = candidate[metric]
        change = candidate_value - reference_value
        if change < -tolerances[metric]:
            regressions.append({
                "metric": metric,
                "change": change,
            })
    return {
        "passed": len(regressions) == 0,
        "regressions": regressions,
    }

def main():
    print(E13(...))
```

```
if __name__ == "__main__":
    main()
```

11.9.15 Exercise 14 - Robustness Test

Part 1 - Why this matters

Robustness Test turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$R(\delta) = \frac{1}{N} \sum_i \mathbb{I}[\widehat{y}(\mathbf{x}_i) = \widehat{y}(\mathbf{x}_i + \delta_i)].$$

Part 3 - Hints and Helper

Declare permitted perturbations and feature units. Compare clean and perturbed metrics across multiple seeds, including decision flip rate and confidence change.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E14(model, features, targets,
        perturbations, threshold):
    clean = evaluate(model, features,
                     targets, threshold)
    rows = []
    for name, modified_features in perturbations.items():
        result = evaluate(
            model, modified_features,
            targets, threshold
        )
        rows.append({
            "scenario": name,
            "metric_change": ...,
            "flip_rate": ...,
            "confidence_change": ...,
```

```
        })
    return clean, rows

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.9.16 Exercise 15 - Evaluation Pipeline Automation

Part 1 - Why this matters

Evaluation Pipeline Automation turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{data} \rightarrow \text{inference} \rightarrow \text{aggregation} \rightarrow \text{metrics} \rightarrow \text{artifact}.$$

Part 3 - Hints and Helper

Build a deterministic function with explicit configuration. Aggregate predictions in sample order, validate counts, and write a machine-readable report without storing computation graphs.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E15(model, data_loader, configuration):
    probabilities = []
    targets = []
    model.eval()
    with torch.inference_mode():
        for features, batch_targets in data_loader:
            logits = model(
                features.to(configuration["device"])
            )
            probabilities.append(
```

```
                torch.sigmoid(logits).cpu()
            )
            targets.append(batch_targets.cpu())
    probabilities = torch.cat(probabilities)
    targets = torch.cat(targets)
    return build_report(
        probabilities, targets, configuration
    )

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.9.17 Exercise 16 - Evaluation Failure Debugging

Part 1 - Why this matters

Evaluation Failure Debugging turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\mathcal{C} \in \{\text{shape, dtype, device, range, order, mode, metric}\}.$$

Part 3 - Hints and Helper

Validate contracts before calculating metrics: shapes, binary targets, finite outputs, sample order, model mode, dataset identity, and threshold range.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E16(probabilities, targets, metadata):
    issues = []
    if probabilities.shape != targets.shape:
        issues.append(...)
    if not torch.isfinite(probabilities).all():
```

```
        issues.append(...)
    if not (
        (probabilities >= 0)
        & (probabilities <= 1)
    ).all():
        issues.append(...)
    if not torch.all((targets == 0) | (targets == 1)):
        issues.append(...)
    if metadata["sample_count"] != targets.numel():
        issues.append(...)
    if not 0.0 <= metadata["threshold"] <= 1.0:
        issues.append(...)
    return issues

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.9.18 Exercise 17 - Multi-Run Metric Comparison

Part 1 - Why this matters

Multi-Run Metric Comparison turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\overline{M} = \frac{1}{R}\sum_{r=1}^{R} M_r, \qquad s_M = \mathrm{Std}(M_1, \ldots, M_R).$$

Part 3 - Hints and Helper

Use identical splits and metric definitions across seeds. Report every run, mean, standard deviation, minimum, maximum, and paired differences when appropriate.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch
```

```
def E17(run_reports):
    metric_names = run_reports[0]["metrics"].keys()
    summary = {}
    for metric in metric_names:
        values = torch.tensor([
            report["metrics"][metric]
            for report in run_reports
        ])
        summary[metric] = {
            "values": ...,
            "mean": ...,
            "std": ...,
            "minimum": ...,
            "maximum": ...,
        }
    return summary

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.9.19 Exercise 18 - Final Evaluation Report

Part 1 - Why this matters

Final Evaluation Report turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$R = \{\text{data}, \text{threshold}, \text{confusion}, \text{metrics}, \text{performance}, \text{robustness}, \text{limitations}\}.$$

Part 3 - Hints and Helper

Combine validated outputs from earlier exercises. Preserve sample counts, undefined metrics, confidence intervals or run variability, hardware context, and limitations.

Part 4 - Python code skeleton

```
import math
import time
```

```
import matplotlib.pyplot as plt
import torch

def E18(sections, required_sections):
    missing = sorted(
        set(required_sections) - sections.keys()
    )
    warnings = []
    if missing:
        warnings.append(...)
    if sections.get(
        "metrics", {}
    ).get("undefined"):
        warnings.append(...)
    return {
        "sections": sections,
        "missing": missing,
        "warnings": warnings,
        "status": ...,
    }

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.9.20 Exercise 19 - Production Metric Sanity Check

Part 1 - Why this matters

Production Metric Sanity Check turns raw model outputs into evidence about behavior. A useful evaluation must preserve the positive-class definition, decision threshold, sample count, and dataset context so the resulting number can be interpreted correctly.

No metric is meaningful in isolation. Class imbalance, undefined denominators, data noise, device timing, and subgroup errors can make an apparently strong summary conceal important failures.

Part 2 - Mathematical form

$$\text{valid} = \text{finite} \wedge \text{range-valid} \wedge \text{count-consistent} \wedge \text{fresh}.$$

Part 3 - Hints and Helper

Check metric ranges, confusion-count totals, timestamp freshness, class support, threshold identity, and comparison-dataset version before publishing results.

Part 4 - Python code skeleton

```
import math
import time

import matplotlib.pyplot as plt
import torch

def E19(report, expected):
    issues = []
    metrics = report["metrics"]
    for name, value in metrics.items():
        if not math.isfinite(value):
            issues.append(...)
        if name in expected["unit_interval_metrics"]:
            if not 0.0 <= value <= 1.0:
                issues.append(...)
    if sum(report["confusion"].values()) != \
            report["sample_count"]:
        issues.append(...)
    if report["dataset_version"] != \
            expected["dataset_version"]:
        issues.append(...)
    return {
        "publish": len(issues) == 0,
        "issues": issues,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

11.10 LG08 - Multi-Class Extension Concepts

Models and Training

11.10.1 Exercise 00 - One-vs-Rest Logistic Strategy

Part 1 - Why this matters

One-vs-Rest Logistic Strategy extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$p_c(\mathbf{x}) = \sigma(\mathbf{w}_c^{\mathsf{T}}\mathbf{x} + b_c), \qquad \widehat{y} = \arg\max_c p_c.$$

Part 3 - Hints and Helper

Train or evaluate one binary classifier per class. Preserve class order and note that independent probabilities need not sum to one.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E00(models, features):
    probabilities = []
    with torch.inference_mode():
        for model in models:
            logits = model(features).flatten()
            probabilities.append(torch.sigmoid(logits))
    scores = torch.stack(probabilities, dim=1)
    predictions = ...
    return scores, predictions, ...

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

11.10.2 Exercise 01 - Softmax vs Sigmoid Comparison

Part 1 - Why this matters

Softmax vs Sigmoid Comparison extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\sigma(z_c) = \frac{1}{1 + e^{-z_c}}, \qquad \operatorname{softmax}(\mathbf{z})_c = \frac{e^{z_c}}{\sum_j e^{z_j}}.$$

Part 3 - Hints and Helper

Apply both functions to identical logits. Verify softmax row sums and show that sigmoid treats classes independently, which is useful for multi-label rather than mutually exclusive targets.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E01(logits):
    sigmoid_values = torch.sigmoid(logits)
    softmax_values = torch.softmax(logits, dim=1)
    return {
        "sigmoid": sigmoid_values,
        "softmax": softmax_values,
        "sigmoid_sums": ...,
        "softmax_sums": ...,
    }

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

11.10.3 Exercise 02 - Multi-Class Dataset Preparation

Part 1 - Why this matters

Multi-Class Dataset Preparation extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\mathbf{X} \in \mathbb{R}^{N \times d}, \qquad \mathbf{y} \in \{0, \ldots, C-1\}^{N}.$$

Part 3 - Hints and Helper

Map original labels deterministically to contiguous indices, split before fitting preprocessing, stratify when appropriate, and store the inverse mapping.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E02(features, raw_labels, class_names):
    mapping = {
        name: index
        for index, name in enumerate(class_names)
    }
    targets = torch.tensor(
        [mapping[label] for label in raw_labels],
        dtype=torch.long,
    )
    if targets.min() < 0 or targets.max() >= len(class_names):
        raise ValueError(...)
    return features, targets, mapping, ...

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

11.10.4 Exercise 03 - Cross-Entropy for Multi-Class

Part 1 - Why this matters

Cross-Entropy for Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\ell_i = -\log \frac{\exp(z_{i,y_i})}{\sum_{c=1}^{C} \exp(z_{i,c})}.$$

Part 3 - Hints and Helper

Pass raw logits and long class indices to `cross_entropy`. Compare with negative gathered `log_softmax` values and keep reduction explicit.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E03(logits, targets):
    if logits.ndim != 2 or targets.ndim != 1:
        raise ValueError(...)
    if targets.dtype != torch.long:
        raise TypeError(...)
    reference = F.cross_entropy(
        logits, targets, reduction="none"
    )
    log_probabilities = F.log_softmax(logits, dim=1)
    manual = -log_probabilities.gather(
        1, targets.unsqueeze(1)
    ).squeeze(1)
    return reference, manual, ...

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

11.10.5 Exercise 04 - CUDA Multi-Class Training

Part 1 - Why this matters

CUDA Multi-Class Training extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$L = \frac{1}{N} \sum_{i} \mathrm{CE}(\mathbf{z}_i, y_i), \qquad \theta \leftarrow \theta - \eta \nabla_\theta L.$$

Part 3 - Hints and Helper

Move model, inputs, and class-index targets to the same selected device. Use a full zero-grad, forward, loss, backward, step cycle and return detached evidence.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E04(model, optimizer, features, targets):
    device = torch.device(
        "cuda" if torch.cuda.is_available() else "cpu"
    )
    model = model.to(device).train()
    features = features.to(device)
    targets = targets.to(device)
    optimizer.zero_grad(set_to_none=True)
    logits = model(features)
    loss = F.cross_entropy(logits, targets)
    ...
    return {
        "device": str(device),
        "loss": ...,
        "gradient_finite": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

11.10.6 Exercise 05 - Class Imbalance in Multi-Class

Part 1 - Why this matters

Class Imbalance in Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$w_c = \frac{N}{C\,N_c}, \qquad L = \frac{1}{N}\sum_i w_{y_i}\ell_i.$$

Part 3 - Hints and Helper

Calculate class counts with minlength equal to C, reject absent classes or define a policy, and place weights on the logits device.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E05(logits, targets, number_of_classes):
    counts = torch.bincount(
        targets, minlength=number_of_classes
    )
    if torch.any(counts == 0):
        raise ValueError(...)
    weights = (
        targets.numel()
        / (number_of_classes * counts)
    ).to(logits.dtype).to(logits.device)
    weighted_loss = F.cross_entropy(
        logits, targets, weight=weights
    )
    return counts, weights, weighted_loss

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

11.10.7 Exercise 06 - Confusion Matrix for Multi-Class

Part 1 - Why this matters

Confusion Matrix for Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$C_{r,c} = \#\{i : y_i = r, \widehat{y}_i = c\}.$$

Part 3 - Hints and Helper

Create a C by C tensor using true labels as rows and predictions as columns. Verify non-negative valid indices and total count before plotting.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E06(predictions, targets, number_of_classes,
        output_path):
    matrix = torch.zeros(
        number_of_classes,
        number_of_classes,
        dtype=torch.long,
    )
    for actual, predicted in zip(targets, predictions):
        matrix[actual, predicted] += ...
    if matrix.sum() != targets.numel():
        raise RuntimeError(...)
    ...
    return matrix

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

11.10.8 Exercise 07 - Macro vs Micro Metrics

Part 1 - Why this matters

Macro vs Micro Metrics extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$F_{\text{macro}} = \frac{1}{C}\sum_{c} F_c, \qquad F_{\text{micro}} = \frac{2\sum_c TP_c}{2\sum_c TP_c + \sum_c FP_c + \sum_c FN_c}.$$

Part 3 - Hints and Helper

Derive per-class one-vs-rest counts from the confusion matrix. Report support and undefined cases before averaging.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E07(confusion_matrix):
    class_rows = []
    for class_id in range(confusion_matrix.shape[0]):
        true_positive = confusion_matrix[
            class_id, class_id
        ]
        false_positive = ...
        false_negative = ...
        class_rows.append(
            compute_metrics(
                true_positive,
                false_positive,
                false_negative,
            )
        )
    macro = ...
    micro = ...
    return class_rows, macro, micro

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

11.10.9 Exercise 08 - Probability Calibration Multi-Class

Part 1 - Why this matters

Probability Calibration Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\mathrm{ECE} = \sum_{m} \frac{|B_m|}{N} |\operatorname{acc}(B_m) - \operatorname{conf}(B_m)|.$$

Part 3 - Hints and Helper

Use maximum softmax probability as top-label confidence and correctness of argmax. Preserve bin counts and also consider class-wise calibration.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E08(logits, targets, number_of_bins):
    probabilities = torch.softmax(logits, dim=1)
    confidence, predictions = probabilities.max(dim=1)
    correctness = (predictions == targets).float()
    boundaries = torch.linspace(
        0.0, 1.0, number_of_bins + 1,
        device=logits.device,
    )
    rows = []
    ece = logits.new_zeros(())
    for bin_id in range(number_of_bins):
        mask = ...
        ...
    return rows, ece.item()

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

11.10.10 Exercise 09 - Boundary Visualization Multi-Class

Part 1 - Why this matters

Boundary Visualization Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\widehat{y}(\mathbf{x}) = \arg\max_{c}(\mathbf{w}_c^{\mathsf{T}}\mathbf{x} + b_c).$$

Part 3 - Hints and Helper

Build a two-feature grid, evaluate it in chunks, reshape argmax predictions, and overlay training samples. State if the original model uses more than two features.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E09(model, x_axis, y_axis, output_path):
    grid_x, grid_y = torch.meshgrid(
        x_axis, y_axis, indexing="xy"
    )
    points = torch.stack(
        [grid_x.flatten(), grid_y.flatten()],
        dim=1,
    )
    with torch.inference_mode():
        logits = model(points)
        regions = logits.argmax(dim=1).reshape(
            grid_x.shape
        )
    fig, ax = plt.subplots()
    ax.contourf(..., ..., ..., alpha=...)
    ...
    fig.savefig(output_path, dpi=150,
                bbox_inches="tight")
    plt.close(fig)
    return regions

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

11.10.11 Exercise 10 - Gradient Stability Multi-Class

Part 1 - Why this matters

Gradient Stability Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$g_t = \|\nabla_\theta L_t\|_2, \qquad r_t = \frac{g_t}{g_{t-1} + \varepsilon}.$$

Part 3 - Hints and Helper

Collect global and layer-wise gradient norms after backward. Flag non-finite, exploding, vanishing, and abruptly changing gradients.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E10(model, logits, targets, thresholds):
    loss = F.cross_entropy(logits, targets)
    loss.backward()
    squared_norm = 0.0
    rows = []
    for name, parameter in model.named_parameters():
        if parameter.grad is None:
            rows.append(...)
            continue
        norm = parameter.grad.norm()
        squared_norm += norm.square()
        rows.append(...)
    global_norm = torch.sqrt(squared_norm)
    return global_norm, rows, ...

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

11.10.12 Exercise 11 - Mixed Precision Multi-Class

Part 1 - Why this matters

Mixed Precision Multi-Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$L_s = sL, \qquad \nabla L_s = s\nabla L,$$

followed by gradient unscaling.

Part 3 - Hints and Helper

Use `autocast` and `GradScaler` on CUDA. Pass raw logits to cross-entropy and inspect gradients only after unscaling.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E11(model, optimizer, features, targets):
    enabled = features.device.type == "cuda"
    scaler = torch.amp.GradScaler(
        "cuda", enabled=enabled
    )
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(
        device_type=features.device.type,
        dtype=...,
        enabled=enabled,
    ):
        logits = model(features)
        loss = F.cross_entropy(logits, targets)
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_finite = ...
    scaler.step(optimizer)
    scaler.update()
    return loss.detach(), gradient_finite

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

11.10.13 Exercise 12 - Performance Scaling Classes

Part 1 - Why this matters

Performance Scaling Classes extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$T(C), \qquad M(C), \qquad \text{output elements} = NC.$$

Part 3 - Hints and Helper

Benchmark increasing class counts with fixed N, feature width, device, dtype, and warm-up. Separate model construction from timed inference.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E12(model_factory, features,
        class_counts, device):
    rows = []
    for class_count in class_counts:
        model = model_factory(class_count).to(device)
        ...
        start = time.perf_counter()
        with torch.inference_mode():
            logits = model(features.to(device))
        ...
        rows.append({
            "classes": class_count,
            "seconds": ...,
            "output_elements": logits.numel(),
            "output_bytes": ...,
        })
    return rows

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

11.10.14 Exercise 13 - Error Analysis per Class

Part 1 - Why this matters

Error Analysis per Class extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$e_c = 1 - \frac{C_{c,c}}{\sum_j C_{c,j}}, \qquad s_c = \sum_j C_{c,j}.$$

Part 3 - Hints and Helper

Rank classes by error rate only after applying minimum support. Include most frequent confusion destinations and mean confidence for errors.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E13(confusion_matrix, probabilities,
        targets, predictions, minimum_support):
    rows = []
    for class_id in range(confusion_matrix.shape[0]):
        support = confusion_matrix[class_id].sum()
        if support < minimum_support:
            continue
        correct = confusion_matrix[
            class_id, class_id
        ]
        row = confusion_matrix[class_id].clone()
        row[class_id] = 0
        rows.append({
            "class": class_id,
            "support": ...,
            "error_rate": ...,
            "most_confused_with": ...,
            "error_confidence": ...,
        })
    return sorted(rows, key=..., reverse=True)
```

```
def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

11.10.15 Exercise 14 - Metric Drift Detection

Part 1 - Why this matters

Metric Drift Detection extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\Delta M_c = M_{c,t} - M_{c,0}.$$

Part 3 - Hints and Helper

Compare reference and current per-class metrics using the same label mapping and threshold policy. Require minimum support and report population changes.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E14(reference, current, tolerances):
    alerts = []
    for class_id in reference["per_class"]:
        if class_id not in current["per_class"]:
            alerts.append(...)
            continue
        for metric, old_value in \
                reference["per_class"][class_id].items():
            new_value = current[
                "per_class"
            ][class_id][metric]
            change = new_value - old_value
            if change < -tolerances[metric]:
```

```
                alerts.append(...)
    return alerts

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

11.10.16 Exercise 15 - End-to-End Multi-Class Pipeline

Part 1 - Why this matters

End-to-End Multi-Class Pipeline extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\mathbf{X} \to \mathbf{z} \to \text{softmax}(\mathbf{z}) \to \hat{\mathbf{y}} \to \text{report}.$$

Part 3 - Hints and Helper

Preserve preprocessing and label mapping, train with logits, evaluate without gradients, aggregate sample-weighted loss, and save a versioned report.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E15(model, train_loader, test_loader,
        optimizer, configuration):
    for epoch in range(configuration["epochs"]):
        model.train()
        for features, targets in train_loader:
            optimizer.zero_grad(set_to_none=True)
            logits = model(features)
            loss = F.cross_entropy(logits, targets)
            ...
    model.eval()
    with torch.inference_mode():
```

```
        evaluation = evaluate(
            model, test_loader, configuration
        )
    return evaluation

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

11.10.17 Exercise 16 - Production Readiness Check

Part 1 - Why this matters

Production Readiness Check extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\text{ready} = \bigwedge_{j} \text{check}_j.$$

Part 3 - Hints and Helper

Check label-map version, input schema, finite logits, probability sums, class support, latency, memory, calibration, robustness, and artifact loading.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E16(model, sample_batch, requirements):
    checks = {}
    model.eval()
    with torch.inference_mode():
        logits = model(sample_batch)
        probabilities = torch.softmax(logits, dim=1)
    checks["shape"] = ...
    checks["finite"] = ...
```

```
    checks["probability_sum"] = ...
    checks["latency"] = ...
    checks["class_mapping"] = ...
    return {
        "checks": checks,
        "ready": all(checks.values()),
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

11.10.18 Exercise 17 - Failure Recovery Scenario

Part 1 - Why this matters

Failure Recovery Scenario extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$\text{recover} = \text{detect} \rightarrow \text{contain} \rightarrow \text{restore} \rightarrow \text{verify}.$$

Part 3 - Hints and Helper

Simulate invalid labels, non-finite loss, checkpoint corruption, and missing classes independently. Never overwrite the last known-good state before verification.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E17(model, checkpoint, batch, policy):
    diagnostics = []
    try:
        features, targets = batch
        if targets.min() < 0 or \
                targets.max() >= policy["classes"]:
```

```
            raise ValueError(...)
        logits = model(features)
        loss = F.cross_entropy(logits, targets)
        if not torch.isfinite(loss):
            raise FloatingPointError(...)
        return {"recovered": False, "status": "valid"}
    except (ValueError, RuntimeError,
            FloatingPointError) as error:
        diagnostics.append(...)
        model.load_state_dict(checkpoint)
        verification = ...
        return {
            "recovered": ...,
            "diagnostics": diagnostics,
            "verification": verification,
        }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

11.10.19 Exercise 18 - Scalability Stress Test

Part 1 - Why this matters

Scalability Stress Test extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$(N, C, d) \mapsto \{\text{latency}, \text{throughput}, \text{memory}, \text{status}\}.$$

Part 3 - Hints and Helper

Sweep one dimension at a time, warm up accelerators, synchronize timing, catch out-of-memory safely, and preserve the largest successful configuration.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
```

```
import torch
import torch.nn.functional as F

def E18(model_factory, configurations, device):
    rows = []
    for configuration in configurations:
        try:
            model = model_factory(
                configuration
            ).to(device)
            features = torch.randn(
                configuration["samples"],
                configuration["features"],
                device=device,
            )
            ...
            rows.append({
                "configuration": configuration,
                "status": "passed",
                "latency": ...,
                "peak_memory": ...,
            })
        except torch.OutOfMemoryError:
            rows.append({
                "configuration": configuration,
                "status": "out_of_memory",
            })
            ...
    return rows

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

11.10.20 Exercise 19 - Final Multi-Class Report

Part 1 - Why this matters

Final Multi-Class Report extends binary classification reasoning to problems containing several possible classes. Correct implementation depends on preserving class identity, tensor shape, and the distinction between mutually exclusive and independently valid labels.

A multi-class result can look correct while hiding imbalance, calibration error, class-specific failure, or excessive resource cost. The experiment therefore records both aggregate behavior and evidence for individual classes.

Part 2 - Mathematical form

$$R = \{\text{data}, \text{model}, \text{loss}, \text{metrics}, \text{calibration}, \text{errors}, \text{resources}, \text{robustness}, \text{status}\}.$$

Part 3 - Hints and Helper

Combine validated sections, mark missing evidence, convert tensors to serializable values, and derive status from explicit deployment rules.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
import torch.nn.functional as F

def E19(sections, rules):
    required = {
        "data", "model", "loss", "metrics",
        "calibration", "errors", "resources",
        "robustness",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if missing:
        warnings.append(...)
    if sections.get(
        "calibration", {}
    ).get("ece", 0.0) > rules["maximum_ece"]:
        warnings.append(...)
    if sections.get(
        "metrics", {}
    ).get("macro_f1", 0.0) < rules["minimum_macro_f1"]:
        warnings.append(...)
    return {
        "sections": sections,
        "missing": missing,
        "warnings": warnings,
        "status": ...,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

Book 12

Perceptron

12.1 Introduction

12.1.1 What will the book teach you

The previous books established the mathematical and computational foundations of model training. Linear regression introduced weighted inputs and continuous prediction, while logistic regression transformed a linear score into a probability and connected classification to likelihood, cross-entropy, gradients, decision thresholds, and evaluation metrics. This book now studies the perceptron: one of the simplest models that can learn a binary decision boundary directly from classification errors. Its small size makes every operation visible, but its apparent simplicity should not be mistaken for a lack of depth. The perceptron exposes several ideas that later become central to neural networks: weighted inputs, bias, activation, prediction, error-driven parameter updates, repeated training, convergence, generalization, and the need for multiple computational units.

A perceptron receives a feature vector $\mathbf{x} \in \mathbb{R}^d$, combines it with a weight vector $\mathbf{w} \in \mathbb{R}^d$ and a bias b, and calculates the linear score

$$z = \mathbf{w}^\top \mathbf{x} + b.$$

The score is then passed through a step function. Using binary labels $\{0, 1\}$, one common definition is

$$\widehat{y} = H(z) = \begin{cases} 1, & z \geq 0, \\ 0, & z < 0. \end{cases}$$

This produces a hard binary decision rather than a probability. A score of 0.01 and a score of 100 both produce the same class under this rule, even though their distances from the boundary are very different. The early exercises will require you to implement this operation using pure Python and PyTorch, test individual and batched inputs, verify shapes and dtypes, and compare CPU and CUDA results. You will also compare the perceptron with linear and logistic regression so that an unrestricted numerical output, a probability, and a hard class decision never become interchangeable concepts.

The parameters define a geometric boundary:

$$\mathbf{w}^\top \mathbf{x} + b = 0.$$

The weight vector is normal to this boundary, while the bias controls its position. In two dimensions the boundary is a line; in three dimensions it is a plane; and in higher dimensions it is a hyperplane. The book will examine this geometry through vector calculations, boundary plots, signed distances, feature scaling, perturbations, and numerical precision. You will investigate how small changes to weights, bias, inputs, or dtype can move samples from one side of the boundary to the other. These experiments are essential because a binary output alone hides how close a decision was to changing.

Unlike logistic regression, the classical perceptron does not learn by minimizing binary cross-entropy through ordinary backpropagation. Its hard step function is constant on either side of the boundary and is not differentiable at the boundary itself. Consequently, the useful derivative structure needed for gradient-based learning is absent. The classical perceptron instead uses an error-driven update rule. For a training example $(\mathbf{x}_i, y_i)$ with prediction $\widehat{y}_i$, one binary-label form is

$$\mathbf{w} \leftarrow \mathbf{w} + \eta \left(y_i - \widehat{y}_i\right) \mathbf{x}_i,$$

$$b \leftarrow b + \eta \left(y_i - \widehat{y}_i\right),$$

where $\eta > 0$ is the learning rate. A correctly classified example produces no update in this formulation, while a mistake moves the boundary in a direction intended to correct that example. You will derive this rule, implement it manually, inspect the direction of every update, compare online and batch-like behavior, test sample ordering, inject controlled noise, and verify calculations by hand before trusting automated code.

The update rule leads to one of the most important theoretical results in early machine learning: the perceptron convergence theorem. If the training data are linearly separable, the classical algorithm will find a separating hyperplane after a finite number of mistakes under its assumptions. The theorem does not say that every dataset is separable, that the first separator is unique, or that the resulting classifier is automatically the best model for unseen data. It also does not promise convergence when classes overlap or labels contradict one another. This book will test the theorem experimentally by measuring updates, epochs, margins, weight norms, and the effects of data order. You will contrast cleanly separable data with nearly separable and non-separable cases instead of treating non-convergence as an unexplained programming failure.

The margin provides a more informative view of a classified point than its hard label alone. With labels $t_i \in \{-1, +1\}$, the signed functional margin is

$$\gamma_i = t_i \left(\mathbf{w}^\top \mathbf{x}_i + b\right).$$

A positive value indicates correct placement relative to the boundary, while a negative value indicates a mistake. After normalization by $\|\mathbf{w}\|_2$, the quantity gains a geometric distance interpretation. You will observe how margin size influences stability, convergence speed, sensitivity to noise, and generalization. You must nevertheless avoid claiming that the classical perceptron automatically finds the maximum-margin separator; that is a different optimization objective.

The book will also reinterpret perceptron learning through the perspective of loss and error. Zero–one loss expresses whether a decision is correct, but its discontinuous landscape is unsuitable for ordinary gradient optimization. Perceptron loss provides a margin-based view of mis-

classified examples and can be compared with hinge loss and differentiable classification losses. You will implement these quantities, visualize their behavior, inspect their non-smoothness, compare error-driven updates with gradient-based methods, and identify situations in which reducing a training objective does not guarantee useful real-world behavior. This section connects the historical perceptron algorithm to the broader optimization language developed in earlier books.

A single perceptron is limited to one linear boundary. The XOR problem provides the clearest demonstration:

x_1	x_2	y
0	0	0
0	1	1
1	0	1
1	1	0

No single line can separate the positive XOR points from the negative points. The exercises will require you to visualize this failure, try multiple initializations, and explain the geometric reason rather than repeatedly changing the learning rate in search of an impossible solution. This limitation is not a minor edge case; it establishes why a single linear decision unit cannot represent every classification rule.

The perceptron can be extended to multiple classes by maintaining class-specific weight vectors and selecting the class with the largest score. You will implement one-vs-rest and direct multi-class update strategies, construct decision regions, analyze confusion matrices and class imbalance, and measure how computation and memory grow with the number of classes. These experiments will be compared with softmax regression so that a collection of hard class scores is not confused with a normalized probability model.

Computational performance will remain part of the learning process. Because a single perceptron performs little work, moving a small batch to a GPU may be slower than executing it on the CPU due to transfer and kernel-launch overhead. You will benchmark forward passes and training, measure throughput, latency, allocated memory, synchronization cost, batch-size scaling, precision effects, and multi-GPU overhead. CUDA will be used when it provides a meaningful experiment, not treated as an automatic guarantee of speed. Every comparison must include warm-up, synchronization where required, identical workloads, and the hardware context needed to interpret the result.

The later chapters examine generalization and theoretical limits. You will separate training accuracy from test accuracy, repeat experiments across random seeds, introduce label and input noise, study distribution shift, and inspect high-dimensional sparse data. A classifier can fit linearly separable training examples and still perform poorly on new data. Conversely, failure to achieve perfect training accuracy may reflect irreducible overlap rather than defective code. The goal is to connect theoretical assumptions to measured evidence and to state clearly when those assumptions do not represent the dataset.

The final chapter provides the bridge from one perceptron to multi-layer neural networks. By combining several decision units, intermediate units can transform the original feature space and make patterns such as XOR separable in a learned representation. You will manu-

ally combine perceptrons, interpret hidden units, construct a two-layer model, inspect hidden activations, compare manual code with `nn.Module`, and study gradient flow through multiple layers. At this point the classical perceptron learning rule is no longer sufficient for coordinating all parameters; backpropagation and differentiable activations become necessary. The chapter therefore ends where the next book on multi-layer perceptrons begins.

This book is not intended to present the perceptron as a modern solution for every classification task. Its purpose is to make the transition from a single linear decision rule to a trainable network intellectually complete. By the end, you should be able to explain exactly what the perceptron computes, why its update rule moves the boundary, when convergence is guaranteed, why it can fail, how its implementation behaves on CPU and CUDA, and why additional layers create capabilities that one unit cannot possess.

12.1.2 How to study this book

Treat each exercise as a controlled experiment. Before running code, write down the feature shape, weight shape, score shape, label convention, expected output dtype, and the precise condition that triggers an update. Predict whether a sample is correctly classified and calculate at least one update manually. After execution, compare the stored tensors with the manual result rather than accepting the output because the program completed.

Keep the label convention explicit. Some derivations use $\{0, 1\}$ while others use $\{-1, +1\}$. Both are valid when the prediction and update formulas are transformed consistently, but mixing them silently reverses or removes updates. Record the convention at the beginning of every experiment, and test boundary cases such as a score equal to zero.

When studying convergence, change one factor at a time. Preserve the dataset, initial parameters, learning rate, random seed, precision, and sample order unless one of those variables is the subject of the experiment. Never claim that the convergence theorem failed until you have verified linear separability, label consistency, finite values, and the exact implementation of the update rule.

Begin with small CPU examples that can be drawn and calculated by hand. Move to CUDA only after the mathematical behavior is verified. For performance experiments, separate data-transfer time from computation, warm up the device, synchronize timed CUDA work, and repeat measurements. For numerical experiments, compare tolerances and decision changes rather than demanding bitwise equality between devices.

For every challenge, answer four questions: What did the perceptron compute? Why did it update or remain unchanged? Which assumption makes the result valid? Under what condition would the same method fail? If you cannot answer all four using the recorded tensors and equations, repeat the exercise before moving to the next chapter.

12.1.3 The Chapters (PC00 - PC08) included in this book

- PC00 - Perceptron Concept and Motivation
- PC01 - Mathematical Structure of the Perceptron

- PC02 - Perceptron Learning Rule and Updates
- PC03 - Training Dynamics and Convergence Theory
- PC04 - Perceptron Loss Perspective and Errors
- PC05 - Multi-Class Perceptron Extensions
- PC06 - Computational Performance and CUDA Effects
- PC07 - Generalization and Theoretical Limits
- PC08 - Transition to Multi-Layer Networks

12.2 PC00 - Perceptron Concept and Motivation

Models and Training

12.2.1 Exercise 00 - Understand the Limitation of Linear Regression for Classification

Part 1 - Why this matters

Understand the Limitation of Linear Regression for Classification establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\widehat{y}_{\text{linear}} = \mathbf{w}^{\mathsf{T}}\mathbf{x} + b \in \mathbb{R}.$$

Part 3 - Hints and Helper

Create inputs whose linear outputs fall below zero and above one. Show why an unrestricted regression value is not itself a valid binary decision or probability.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E00(features, weight, bias, threshold):
```

```
    outputs = features @ weight + bias
    decisions = (outputs >= threshold).to(torch.int64)
    return {
        "raw_outputs": outputs,
        "decisions": decisions,
        "outside_unit_interval": ...,
    }

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.2.2 Exercise 01 - Define the Perceptron as a Binary Decision Unit with Step Function

Part 1 - Why this matters

Define the Perceptron as a Binary Decision Unit with Step Function establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$z = \mathbf{w}^{\mathsf{T}}\mathbf{x} + b, \qquad \widehat{y} = H(z) = \mathbb{I}[z \geq 0].$$

Part 3 - Hints and Helper

Keep the score and decision as separate outputs. State the convention for an exact zero score and use it consistently.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E01(features, weight, bias):
    scores = features @ weight + bias
    predictions = ...
    return scores, predictions
```

```
def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.2.3 Exercise 02 - Implement a Basic Perceptron Forward Pass Using Pure Python

Part 1 - Why this matters

Implement a Basic Perceptron Forward Pass Using Pure Python establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$z = \sum_{j=1}^{d} w_j x_j + b.$$

Part 3 - Hints and Helper

Use Python lists and a loop without NumPy or PyTorch. Validate equal lengths, calculate the score, then apply the declared step rule.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E02(features, weights, bias):
    if len(features) != len(weights):
        raise ValueError(...)
    score = bias
    for feature, weight in zip(features, weights):
        score += ...
    prediction = ...
    return score, prediction

def main():
```

```
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.2.4 Exercise 03 - Translate Mathematical Perceptron Formula into PyTorch Operations

Part 1 - Why this matters

Translate Mathematical Perceptron Formula into PyTorch Operations establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\mathbf{z} = \mathbf{X}\mathbf{w} + b, \qquad \widehat{\mathbf{y}} = \mathbb{I}[\mathbf{z} \geq 0].$$

Part 3 - Hints and Helper

Use a two-dimensional batch and one-dimensional weight tensor. Predict output shapes before calculation and reject mismatched feature width.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E03(features, weight, bias):
    if features.ndim != 2 or weight.ndim != 1:
        raise ValueError(...)
    if features.shape[1] != weight.shape[0]:
        raise ValueError(...)
    scores = torch.matmul(features, weight) + bias
    predictions = ...
    return scores, predictions

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.2.5 Exercise 04 - Compare Linear Regression Output vs Perceptron Binary Output

Part 1 - Why this matters

Compare Linear Regression Output vs Perceptron Binary Output establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$r(\mathbf{x}) = \mathbf{w}^{\mathsf{T}}\mathbf{x} + b, \qquad H(r) \in \{0, 1\}.$$

Part 3 - Hints and Helper

Use identical parameters and inputs for both views. Report raw magnitude, hard decision, and samples whose regression output cannot be interpreted as probability.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E04(features, weight, bias):
    linear_outputs = features @ weight + bias
    perceptron_outputs = (
        linear_outputs >= 0
    ).to(torch.int64)
    return {
        "linear": linear_outputs,
        "perceptron": perceptron_outputs,
        "same_shape": ...,
        "information_removed": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.2.6 Exercise 05 - Analyze Why Perceptron Uses a Hard Decision Boundary

Part 1 - Why this matters

Analyze Why Perceptron Uses a Hard Decision Boundary establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\mathbf{w}^{\mathsf{T}}\mathbf{x} + b = 0$$

divides the feature space into two half-spaces.

Part 3 - Hints and Helper

Evaluate points immediately on both sides of the boundary. Record scores and show that arbitrarily small sign changes can flip the class.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E05(boundary_point, normal, bias, epsilons):
    unit_normal = normal / torch.linalg.vector_norm(normal)
    rows = []
    for epsilon in epsilons:
        positive_point = boundary_point + epsilon * unit_normal
        negative_point = boundary_point - epsilon * unit_normal
        rows.append({
            "epsilon": epsilon,
            "positive_score": ...,
            "negative_score": ...,
            "predictions": ...,
        })
    return rows

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.2.7 Exercise 06 - Implement the Step Activation Function and Test Its Behavior

Part 1 - Why this matters

Implement the Step Activation Function and Test Its Behavior establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$H(z) = \begin{cases} 1, & z \geq 0, \\ 0, & z < 0. \end{cases}$$

Part 3 - Hints and Helper

Test negative, zero, positive, extreme, and non-finite inputs. Decide whether non-finite scores should raise an error instead of becoming classes.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def step(scores):
    if not torch.isfinite(scores).all():
        raise ValueError(...)
    return (scores >= 0).to(torch.int64)

def E06(test_values):
    outputs = step(test_values)
    return {
        "inputs": test_values,
        "outputs": outputs,
        "binary_only": ...,
    }

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.2.8 Exercise 07 - Visualize Binary Decisions Generated by a Single Perceptron

Part 1 - Why this matters

Visualize Binary Decisions Generated by a Single Perceptron establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\widehat{y}(\mathbf{x}) = \mathbb{I}[w_1 x_1 + w_2 x_2 + b \geq 0].$$

Part 3 - Hints and Helper

Build a two-feature grid, evaluate all points vectorially, reshape decisions, and overlay the boundary and labeled samples.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E07(weight, bias, x_axis, y_axis,
        output_path):
    grid_x, grid_y = torch.meshgrid(
        x_axis, y_axis, indexing="xy"
    )
    points = torch.stack(
        [grid_x.flatten(), grid_y.flatten()],
        dim=1,
    )
    decisions = (
        points @ weight + bias >= 0
    ).reshape(grid_x.shape)
    fig, ax = plt.subplots()
    ax.contourf(..., ..., ..., alpha=...)
    ...
    fig.savefig(output_path, dpi=150,
                bbox_inches="tight")
    plt.close(fig)
```

```
    return decisions

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.2.9 Exercise 08 - Test Perceptron on Linearly Separable Dataset

Part 1 - Why this matters

Test Perceptron on Linearly Separable Dataset establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\exists(\mathbf{w}, b): \quad t_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) > 0 \quad \forall i.$$

Part 3 - Hints and Helper

Generate or receive clearly separable data, train with the classical update rule, and record mistakes per epoch. Stop only after a full mistake-free pass.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E08(features, targets, learning_rate,
        maximum_epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    history = []
    for epoch in range(maximum_epochs):
        mistakes = 0
        for sample, target in zip(features, targets):
            prediction = ...
            error = target - prediction
            if error != 0:
                weight += ...
```

```
                bias += ...
                mistakes += 1
        history.append(mistakes)
        if mistakes == 0:
            break
    return weight, bias, history

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.2.10 Exercise 09 - Observe Failure on Non-Linearly Separable Data

Part 1 - Why this matters

Observe Failure on Non-Linearly Separable Data establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\nexists(\mathbf{w}, b): \quad t_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) > 0 \quad \forall i.$$

Part 3 - Hints and Helper

Use XOR or contradictory labels. Set a finite epoch budget, log repeated mistakes and weight states, and avoid calling non-convergence a software error without checking separability.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E09(features, targets, learning_rate,
        maximum_epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    history = []
```

```
    for epoch in range(maximum_epochs):
        mistakes = train_one_epoch(
            features, targets, weight,
            bias, learning_rate
        )
        history.append({
            "epoch": epoch,
            "mistakes": mistakes,
            "weight": weight.clone(),
            "bias": bias.clone(),
        })
    return {
        "converged": ...,
        "history": history,
    }

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.2.11 Exercise 10 - Move Perceptron Computation to CUDA and Verify Output Consistency

Part 1 - Why this matters

Move Perceptron Computation to CUDA and Verify Output Consistency establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\hat{\mathbf{y}}_{\text{cpu}} \approx \hat{\mathbf{y}}_{\text{cuda}}.$$

Part 3 - Hints and Helper

Use CUDA only when available and move features, weights, and bias together. Compare scores with tolerance and decisions exactly, while flagging near-zero scores.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E10(features, weight, bias):
    cpu_scores = features @ weight + bias
    cpu_predictions = (cpu_scores >= 0)
    if not torch.cuda.is_available():
        return {"cuda_available": False}
    cuda_scores = (
        features.cuda() @ weight.cuda()
        + bias.cuda()
    )
    cuda_predictions = cuda_scores >= 0
    return {
        "score_close": ...,
        "prediction_equal": ...,
        "minimum_absolute_score": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.2.12 Exercise 11 - Compare CPU vs GPU Execution for Perceptron Forward Pass

Part 1 - Why this matters

Compare CPU vs GPU Execution for Perceptron Forward Pass establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\text{Throughput} = \frac{N}{T}, \qquad \text{Speedup} = \frac{T_{\text{cpu}}}{T_{\text{gpu}}}.$$

Part 3 - Hints and Helper

Warm up CUDA, synchronize timed GPU work, and report transfer-inclusive and compute-only timing separately. Repeat enough iterations for a stable comparison.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E11(features, weight, bias, repetitions):
    cpu_seconds = benchmark(
        features, weight, bias,
        repetitions, synchronize=False
    )
    if not torch.cuda.is_available():
        return {"cuda_available": False}
    cuda_features = features.cuda()
    cuda_weight = weight.cuda()
    cuda_bias = bias.cuda()
    ...
    cuda_seconds = benchmark(
        cuda_features, cuda_weight,
        cuda_bias, repetitions,
        synchronize=True,
    )
    return {
        "cpu_seconds": cpu_seconds,
        "cuda_seconds": cuda_seconds,
        "speedup": ...,
    }

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.2.13 Exercise 12 - Inspect Weight and Bias Initialization Effects on Decisions

Part 1 - Why this matters

Inspect Weight and Bias Initialization Effects on Decisions establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$z^{(k)} = \mathbf{w}^{(k)^\mathsf{T}}\mathbf{x} + b^{(k)}.$$

Part 3 - Hints and Helper

Evaluate zero, small random, large random, and biased initializations on the same fixed inputs. Compare positive rate, score spread, and boundary orientation.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E12(features, initializations):
    rows = []
    for name, state in initializations.items():
        scores = (
            features @ state["weight"]
            + state["bias"]
        )
        predictions = scores >= 0
        rows.append({
            "name": name,
            "positive_rate": ...,
            "score_mean": ...,
            "score_std": ...,
            "weight_norm": ...,
        })
    return rows

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.2.14 Exercise 13 - Analyze Sensitivity of Decision Boundary to Weight Changes

Part 1 - Why this matters

Analyze Sensitivity of Decision Boundary to Weight Changes establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\Delta z_i = \Delta \mathbf{w}^\mathsf{T} \mathbf{x}_i, \qquad \widehat{y}_i \text{ flips if the sign changes.}$$

Part 3 - Hints and Helper

Perturb one weight or the full vector while keeping inputs and bias fixed. Report score changes, flip indices, and distance of affected samples from the original boundary.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E13(features, weight, bias, perturbations):
    original_scores = features @ weight + bias
    original_predictions = original_scores >= 0
    rows = []
    for perturbation in perturbations:
        new_scores = (
            features @ (weight + perturbation) + bias
        )
        flips = (
            (new_scores >= 0)
            != original_predictions
        )
        rows.append({
            "perturbation_norm": ...,
            "maximum_score_change": ...,
            "flip_indices": ...,
        })
    return rows

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.2.15 Exercise 14 - Implement Perceptron without Using nn.Module

Part 1 - Why this matters

Implement Perceptron without Using nn.Module establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$f(\mathbf{X}; \mathbf{w}, b) = H(\mathbf{X}\mathbf{w} + b).$$

Part 3 - Hints and Helper

Store tensors directly and expose explicit forward and update functions. Do not use nn.Module, nn.Linear, or an optimizer in this exercise.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

class PlainPerceptron:
    def __init__(self, feature_count):
        self.weight = torch.zeros(feature_count)
        self.bias = torch.tensor(0.0)

    def forward(self, features):
        scores = ...
        return scores, ...

    def update(self, sample, target, learning_rate):
        _, prediction = self.forward(
            sample.unsqueeze(0)
        )
        error = ...
        self.weight += ...
        self.bias += ...

def E14(...):
```

```
    model = PlainPerceptron(...)
    ...
    return model

def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.2.16 Exercise 15 - Validate Output Shape and Data Type in Classification Pipeline

Part 1 - Why this matters

Validate Output Shape and Data Type in Classification Pipeline establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\mathbf{X} \in \mathbb{R}^{N \times d} \Rightarrow \mathbf{z} \in \mathbb{R}^{N}, \quad \hat{\mathbf{y}} \in \{0,1\}^{N}.$$

Part 3 - Hints and Helper

Require floating features and scores, integer or Boolean decisions, and one output per sample. Reject unintended broadcasting.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E15(features, weight, bias):
    issues = []
    if features.ndim != 2:
        issues.append(...)
    if weight.ndim != 1:
        issues.append(...)
    if features.shape[-1] != weight.numel():
        issues.append(...)
```

```
    scores = features @ weight + bias
    predictions = (scores >= 0).to(torch.int64)

        issues.append(...)
    return scores, predictions, issues

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.2.17 Exercise 16 - Freeze Perceptron Parameters and Test Prediction Stability

Part 1 - Why this matters

Freeze Perceptron Parameters and Test Prediction Stability establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\theta_{\text{before}} = \theta_{\text{after}} \Rightarrow \widehat{\mathbf{y}}_{\text{before}} = \widehat{\mathbf{y}}_{\text{after}}$$

for identical deterministic inputs.

Part 3 - Hints and Helper

Disable parameter gradients or skip manual updates, preserve cloned parameters, run repeated predictions, and verify both state and output equality.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E16(model, features, repetitions):
    for parameter in model.parameters():
        parameter.requires_grad_(False)
    before = {
        name: parameter.detach().clone()
```

```
        for name, parameter in model.named_parameters()
    }
    outputs = []
    with torch.inference_mode():
        for _ in range(repetitions):
            outputs.append(model(features))
    after = dict(model.named_parameters())
    return {
        "parameters_unchanged": ...,
        "predictions_stable": ...,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.2.18 Exercise 17 - Debug Incorrect Binary Outputs Caused by Shape Mismatch

Part 1 - Why this matters

Debug Incorrect Binary Outputs Caused by Shape Mismatch establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$(N, d)(d, 1) \to (N, 1) \quad \neq \quad (N, d)(d) \to (N).$$

Part 3 - Hints and Helper

Inspect every intermediate shape, forbid silent broadcasting between scores and targets, and normalize only after deciding the intended interface.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch
```

```
def E17(features, weight, bias, targets):
    report = {
        "feature_shape": tuple(features.shape),
        "weight_shape": tuple(weight.shape),
        "target_shape": tuple(targets.shape),
    }
    issues = []
    if features.ndim != 2:
        issues.append(...)
    if weight.ndim not in {1, 2}:
        issues.append(...)
    scores = ...
    if scores.shape != targets.shape:
        issues.append(...)
    return report, issues

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.2.19 Exercise 18 - Stress Test Perceptron with Large Batch Inputs

Part 1 - Why this matters

Stress Test Perceptron with Large Batch Inputs establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$\mathbf{z} = \mathbf{X}\mathbf{w} + b, \qquad \text{cost} = O(Nd).$$

Part 3 - Hints and Helper

Generate batches incrementally, evaluate in chunks to control memory, time synchronized device work, and verify finite scores and correct output count.

Part 4 - Python code skeleton

```
import time
```

```
import matplotlib.pyplot as plt
import torch

def E18(weight, bias, batch_sizes,
        feature_count, device, chunk_size):
    rows = []
    for batch_size in batch_sizes:
        features = torch.randn(
            batch_size, feature_count,
            device=device,
        )
        outputs = []
        start = time.perf_counter()
        for chunk in features.split(chunk_size):
            outputs.append(
                (chunk @ weight + bias) >= 0
            )
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        predictions = torch.cat(outputs)
        rows.append({
            "batch_size": batch_size,
            "seconds": ...,
            "output_count": ...,
            "all_valid": ...,
        })
    return rows

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.2.20 Exercise 19 - Document Conceptual and Practical Failures of the Perceptron Model

Part 1 - Why this matters

Document Conceptual and Practical Failures of the Perceptron Model establishes one part of the perceptron's role as a hard binary decision model. Because the model is small, every score, shape, threshold, and parameter choice can be inspected directly instead of being hidden inside a large architecture.

The same simplicity can create misleading confidence. A binary output does not express probability, a fast computation does not prove suitability, and failure to converge may reflect non-separable data rather than incorrect code. This exercise therefore records both the result and the assumption supporting it.

Part 2 - Mathematical form

$$R = \{\text{assumptions}, \text{geometry}, \text{data}, \text{numerics}, \text{performance}, \text{failures}\}.$$

Part 3 - Hints and Helper

Combine results from separable, XOR, shape, precision, initialization, and performance experiments. Distinguish theoretical limitation from implementation failure.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E19(sections, required_sections):
    missing = sorted(
        set(required_sections) - sections.keys()
    )
    failures = []
    if sections.get(
        "nonlinear_data", {}
    ).get("converged", False):
        failures.append(...)
    if sections.get(
        "validation", {}
    ).get("issues"):
        failures.append(...)
    return {
        "sections": sections,
        "missing": missing,
        "failures": failures,
        "status": ...,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.3 PC01 - Mathematical Structure of the Perceptron

Models and Training

12.3.1 Exercise 00 - Express the Perceptron as a Vector Dot Product Plus Bias

Part 1 - Why this matters

Express the Perceptron as a Vector Dot Product Plus Bias makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$z = \mathbf{w}^{\mathsf{T}}\mathbf{x} + b = \sum_{j=1}^{d} w_j x_j + b.$$

Part 3 - Hints and Helper

Calculate the dot product manually and with torch.dot. Verify identical feature counts and keep the scalar score separate from the step output.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E00(features, weight, bias):
    if features.ndim != 1 or weight.ndim != 1:
        raise ValueError(...)
    if features.numel() != weight.numel():
        raise ValueError(...)
    score = torch.dot(weight, features) + bias
    prediction = ...
    return score, prediction

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.3.2 Exercise 01 - Rewrite the Perceptron Equation Using Matrix Notation

Part 1 - Why this matters

Rewrite the Perceptron Equation Using Matrix Notation makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{z} = \mathbf{X}\mathbf{w} + b\mathbf{1}, \qquad \hat{\mathbf{y}} = \mathbb{I}[\mathbf{z} \geq 0].$$

Part 3 - Hints and Helper

Use X with shape N by d and weight with shape d. Compare the matrix result with stacking individual dot products.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E01(features, weight, bias):
    matrix_scores = torch.matmul(features, weight) + bias
    manual_scores = torch.stack([
        torch.dot(row, weight) + bias
        for row in features
    ])
    return {
        "scores": matrix_scores,
        "predictions": ...,
        "manual_equal": ...,
    }

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.3.3 Exercise 02 - Analyze the Geometric Meaning of the Weight Vector

Part 1 - Why this matters

Analyze the Geometric Meaning of the Weight Vector makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathcal{H} = \{\mathbf{x} : \mathbf{w}^\mathsf{T}\mathbf{x} + b = 0\}, \qquad \mathbf{w} \perp \mathcal{H}.$$

Part 3 - Hints and Helper

Construct direction vectors lying inside a 2D or 3D boundary and verify their dot products with the weight are approximately zero. Normalize only for interpretation.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E02(weight, boundary_directions, tolerance):
    weight_norm = torch.linalg.vector_norm(weight)
    if weight_norm <= tolerance:
        raise ValueError(...)
    dot_products = boundary_directions @ weight
    return {
        "unit_normal": ...,
        "dot_products": dot_products,
        "orthogonal": ...,
    }

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.3.4 Exercise 03 - Interpret the Bias Term as a Decision Boundary Shift

Part 1 - Why this matters

Interpret the Bias Term as a Decision Boundary Shift makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{w}^{\mathsf{T}}\mathbf{x} = -b, \qquad d = \frac{|b_2 - b_1|}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Hold the weight fixed and compare multiple biases. Measure perpendicular displacement and verify that the resulting boundaries remain parallel.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E03(weight, biases):
    norm = torch.linalg.vector_norm(weight)
    if norm <= ...:
        raise ValueError(...)
    reference = biases[0]
    return [{
        "bias": bias,
        "signed_shift": ...,
        "distance_from_reference": ...,
    } for bias in biases]

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.3.5 Exercise 04 - Compute the Signed Distance from a Point to the Decision Boundary

Part 1 - Why this matters

Compute the Signed Distance from a Point to the Decision Boundary makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$d(\mathbf{x}, \mathcal{H}) = \frac{\mathbf{w}^\top \mathbf{x} + b}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Reject a zero weight vector. Test a point on the boundary and points displaced along the unit normal, then compare distance sign with the predicted class.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E04(points, weight, bias):
    norm = torch.linalg.vector_norm(weight)
    if norm <= ...:
        raise ValueError(...)
    scores = points @ weight + bias
    signed_distance = scores / norm
    return {
        "scores": scores,
        "signed_distance": signed_distance,
        "predictions": ...,
    }

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.3.6 Exercise 05 - Verify Perceptron Output Using Manual Vector Calculations

Part 1 - Why this matters

Verify Perceptron Output Using Manual Vector Calculations makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$z_i = \sum_j w_j x_{ij} + b, \qquad \widehat{y}_i = \mathbb{I}[z_i \geq 0].$$

Part 3 - Hints and Helper

Write nested loops for a small batch, calculate every contribution, and compare scores and decisions with vectorized PyTorch.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def manual_score(sample, weight, bias):
    score = float(bias)
    contributions = []
    for feature, coefficient in zip(sample, weight):
        contribution = ...
        contributions.append(contribution)
        score += contribution
    return score, contributions

def E05(features, weight, bias):
    manual = [
        manual_score(row.tolist(),
                     weight.tolist(),
                     bias.item())
        for row in features
    ]
    vectorized = features @ weight + bias
    return manual, vectorized, ...
```

```
def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.3.7 Exercise 06 - Compare Multiple Weight Configurations and Their Boundaries

Part 1 - Why this matters

Compare Multiple Weight Configurations and Their Boundaries makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathcal{H}_k = \{\mathbf{x} : {\mathbf{w}^{(k)}}^{\mathsf{T}}\mathbf{x} + b^{(k)} = 0\}.$$

Part 3 - Hints and Helper

Evaluate all configurations on one fixed probe grid. Compare orientation angle, bias shift, and decision disagreement instead of coefficients alone.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E06(configurations, probe_points):
    rows = []
    reference_predictions = None
    for name, state in configurations.items():
        scores = (
            probe_points @ state["weight"]
            + state["bias"]
        )
        predictions = scores >= 0
        if reference_predictions is None:
            reference_predictions = predictions
        rows.append({
            "name": name,
```

```
            "weight_norm": ...,
            "positive_rate": ...,
            "disagreement": ...,
        })
    return rows

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.3.8 Exercise 07 - Visualize Decision Hyperplane in 2D Feature Space

Part 1 - Why this matters

Visualize Decision Hyperplane in 2D Feature Space makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$x_2 = -\frac{w_1 x_1 + b}{w_2}, \qquad w_2 \neq 0.$$

Part 3 - Hints and Helper

Plot labeled samples and the boundary. Handle the vertical case when the second weight is near zero instead of dividing by it.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E07(features, targets, weight, bias,
        output_path):
    fig, ax = plt.subplots()
    ax.scatter(
        features[:, 0].cpu(),
        features[:, 1].cpu(),
```

```
        c=targets.cpu(),
    )
    if weight[1].abs() > ...:
        x_values = torch.linspace(..., ..., steps=...)
        y_values = ...
        ax.plot(..., ...)
    else:
        ax.axvline(...)
    fig.savefig(output_path, dpi=150,
                bbox_inches="tight")
    plt.close(fig)

def main():
    print(E07(...))

if __name__ == "__main__":
    main()
```

12.3.9 Exercise 08 - Extend Decision Boundary Visualization to Higher Dimensions

Part 1 - Why this matters

Extend Decision Boundary Visualization to Higher Dimensions makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{P}\mathbf{u}, \quad (\mathbf{P}^\mathsf{T}\mathbf{w})^\mathsf{T}\mathbf{u} + \mathbf{w}^\mathsf{T}\mathbf{x}_0 + b = 0.$$

Part 3 - Hints and Helper

Visualize an explicit two-dimensional slice or projection. Report the basis, reference point, and visible fraction of weight energy so the plot is not mistaken for the full boundary.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E08(features, weight, bias,
```

```
        projection, reference):
    coordinates = (
        features - reference
    ) @ projection
    projected_weight = projection.T @ weight
    effective_bias = weight @ reference + bias
    visible_ratio = (
        projected_weight.square().sum()
        / weight.square().sum()
    )
    return {
        "coordinates": coordinates,
        "weight": projected_weight,
        "bias": effective_bias,
        "visible_ratio": ...,
    }

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.3.10 Exercise 09 - Investigate Numerical Precision Effects on Boundary Placement

Part 1 - Why this matters

Investigate Numerical Precision Effects on Boundary Placement makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\Delta z_i = z_i^{(32)} - z_i^{(64)}.$$

Part 3 - Hints and Helper

Use points close to and far from the boundary. Compare score error separately from decision flips because tiny rounding differences matter most near zero.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E09(features, weight, bias):
    score32 = (
        features.float() @ weight.float()
        + bias.float()
    )
    score64 = (
        features.double() @ weight.double()
        + bias.double()
    )
    difference = (
        score32.double() - score64
    ).abs()
    return {
        "maximum_score_error": ...,
        "prediction_flips": ...,
        "near_boundary": ...,
    }

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.3.11 Exercise 10 - Implement Mathematical Perceptron Using CUDA Tensors

Part 1 - Why this matters

Implement Mathematical Perceptron Using CUDA Tensors makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{z}_{\text{cuda}} = \mathbf{X}_{\text{cuda}}\mathbf{w}_{\text{cuda}} + b_{\text{cuda}}.$$

Part 3 - Hints and Helper

Select CUDA only when available and construct or transfer every operand to one device. Return CPU copies only after the complete calculation.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E10(features, weight, bias):
    device = torch.device(
        "cuda" if torch.cuda.is_available()
        else "cpu"
    )
    features = features.to(device)
    weight = weight.to(device)
    bias = bias.to(device)
    scores = features @ weight + bias
    predictions = (scores >= 0).to(torch.int64)
    return {
        "device": str(device),
        "scores": ...,
        "predictions": ...,
    }

def main():
    print(E10(...))

if __name__ == "__main__":
    main()
```

12.3.12 Exercise 11 - Compare Float32 vs Float64 in Boundary Computation

Part 1 - Why this matters

Compare Float32 vs Float64 in Boundary Computation makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$e_{\text{abs}} = |z_{32} - z_{64}|, \qquad e_{\text{rel}} = \frac{e_{\text{abs}}}{|z_{64}| + \varepsilon}.$$

Part 3 - Hints and Helper

Use identical decimal inputs converted from one high-precision source. Report absolute and relative errors, finite status, and class disagreement.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E11(features, weight, bias, epsilon):
    result32 = compute_score(
        features.float(),
        weight.float(),
        bias.float(),
    )
    result64 = compute_score(
        features.double(),
        weight.double(),
        bias.double(),
    )
    absolute = (result32.double() - result64).abs()
    relative = absolute / (
        result64.abs() + epsilon
    )
    return absolute, relative, ...

def main():
    print(E11(...))

if __name__ == "__main__":
    main()
```

12.3.13 Exercise 12 - Detect Boundary Instability Under Small Input Noise

Part 1 - Why this matters

Detect Boundary Instability Under Small Input Noise makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\widetilde{\mathbf{x}}_i = \mathbf{x}_i + \boldsymbol{\varepsilon}_i, \qquad r = \frac{1}{N}\sum_i \mathbb{I}[\widehat{y}_i \neq \widetilde{y}_i].$$

Part 3 - Hints and Helper

Repeat seeded perturbations at several noise scales. Relate flip rate to original signed distance and distinguish random variation from systematic sensitivity.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E12(features, weight, bias, scales,
        repetitions, seed):
    generator = torch.Generator(
        device=features.device
    ).manual_seed(seed)
    original = features @ weight + bias
    rows = []
    for scale in scales:
        flip_rates = []
        for _ in range(repetitions):
            noise = torch.randn(
                features.shape,
                generator=generator,
                device=features.device,
            )
            noisy_scores = (
                (features + scale * noise)
                @ weight + bias
            )
            flip_rates.append(...)
        rows.append(...)
    return rows

def main():
    print(E12(...))

if __name__ == "__main__":
    main()
```

12.3.14 Exercise 13 - Analyze Scaling Effects on Weights and Inputs

Part 1 - Why this matters

Analyze Scaling Effects on Weights and Inputs makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{x}' = \mathbf{S}\mathbf{x}, \qquad \mathbf{w}' = \mathbf{S}^{-1}\mathbf{w} \Rightarrow \mathbf{w}'^{\mathsf{T}}\mathbf{x}' = \mathbf{w}^{\mathsf{T}}\mathbf{x}.$$

Part 3 - Hints and Helper

Use positive nonzero feature scales. Compare correct inverse weight transformation with scaling inputs alone, and verify score and prediction preservation.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E13(features, weight, bias, scales):
    if torch.any(scales <= 0):
        raise ValueError(...)
    scaled_features = features * scales
    equivalent_weight = weight / scales
    original_scores = features @ weight + bias
    equivalent_scores = (
        scaled_features @ equivalent_weight + bias
    )
    wrong_scores = scaled_features @ weight + bias
    return {
        "equivalent": ...,
        "wrong_difference": ...,
        "wrong_prediction_flips": ...,
    }

def main():
    print(E13(...))

if __name__ == "__main__":
    main()
```

12.3.15 Exercise 14 - Validate Linear Separability Assumption Experimentally

Part 1 - Why this matters

Validate Linear Separability Assumption Experimentally makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\gamma_{\min} = \min_i t_i \frac{\mathbf{w}^\top \mathbf{x}_i + b}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Train across multiple orders and seeds, then verify every label-oriented margin. Treat success as evidence for the tested dataset, not a universal proof.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E14(features, signed_targets,
        candidate_weight, candidate_bias):
    norm = torch.linalg.vector_norm(
        candidate_weight
    )
    if norm <= ...:
        raise ValueError(...)
    margins = (
        signed_targets
        * (features @ candidate_weight
           + candidate_bias)
        / norm
    )
    return {
        "all_separated": bool((margins > 0).all()),
        "minimum_margin": ...,
        "violating_indices": ...,
    }
```

```
def main():
    print(E14(...))

if __name__ == "__main__":
    main()
```

12.3.16 Exercise 15 - Demonstrate Failure Case with XOR Dataset

Part 1 - Why this matters

Demonstrate Failure Case with XOR Dataset makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$(0,0) \mapsto 0, \quad (0,1) \mapsto 1, \quad (1,0) \mapsto 1, \quad (1,1) \mapsto 0.$$

Part 3 - Hints and Helper

Train for a finite budget under several sample orders. Plot the four points and final boundary, then record recurring mistakes rather than claiming convergence.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E15(maximum_epochs, learning_rate):
    features = torch.tensor([
        [0.0, 0.0],
        [0.0, 1.0],
        [1.0, 0.0],
        [1.0, 1.0],
    ])
    targets = torch.tensor([0, 1, 1, 0])
    model, history = train_perceptron(
        features, targets,
        maximum_epochs, learning_rate
    )
    return {
        "model": model,
```

```
        "history": history,
        "converged": ...,
    }

def main():
    print(E15(...))

if __name__ == "__main__":
    main()
```

12.3.17 Exercise 16 - Explain Why Single Perceptron Cannot Solve XOR

Part 1 - Why this matters

Explain Why Single Perceptron Cannot Solve XOR makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$b < 0, \quad w_1 + b \geq 0, \quad w_2 + b \geq 0, \quad w_1 + w_2 + b < 0$$

form an inconsistent system for XOR.

Part 3 - Hints and Helper

Derive the four inequalities from the desired labels. Combine the middle inequalities with b less than zero and show the contradiction with the final inequality.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E16(weight_candidates, bias_candidates):
    rows = []
    for weight in weight_candidates:
        for bias in bias_candidates:
            scores = xor_features() @ weight + bias
            predictions = scores >= 0
            rows.append({
                "weight": weight,
```

```
                "bias": bias,
                "correct_count": ...,
                "solves_xor": ...,
            })
    return {
        "search_results": rows,
        "any_solution": ...,
        "inequality_explanation": ...,
    }

def main():
    print(E16(...))

if __name__ == "__main__":
    main()
```

12.3.18 Exercise 17 - Inspect Internal Tensor Operations During Forward Pass

Part 1 - Why this matters

Inspect Internal Tensor Operations During Forward Pass makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$(N, d) \odot (d) \to (N, d) \xrightarrow{\sum_j} (N) \xrightarrow{+b} (N).$$

Part 3 - Hints and Helper

Store shapes, strides, dtypes, devices, products, reductions, and final decisions. Compare explicit element-wise multiplication and sum with matmul.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E17(features, weight, bias):
    products = features * weight
    reduced = products.sum(dim=1)
```

```
    scores = reduced + bias
    matmul_scores = features @ weight + bias
    return {
        "feature_shape": tuple(features.shape),
        "product_shape": tuple(products.shape),
        "score_shape": tuple(scores.shape),
        "products": products,
        "scores": scores,
        "matmul_equal": ...,
        "predictions": ...,
    }

def main():
    print(E17(...))

if __name__ == "__main__":
    main()
```

12.3.19 Exercise 18 - Stress Test Dot Product Computation on GPU

Part 1 - Why this matters

Stress Test Dot Product Computation on GPU makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$\mathbf{z} = \mathbf{X}\mathbf{w}, \qquad \text{cost} = O(Nd).$$

Part 3 - Hints and Helper

Sweep batch and feature sizes, warm up CUDA, synchronize timing, catch out-of-memory safely, and verify a sampled CPU reference.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E18(configurations):
    if not torch.cuda.is_available():
```

```
        return [{"status": "cuda_unavailable"}]
    rows = []
    for batch_size, feature_count in configurations:
        try:
            features = torch.randn(
                batch_size, feature_count,
                device="cuda",
            )
            weight = torch.randn(
                feature_count, device="cuda"
            )
            ...
            torch.cuda.synchronize()
            start = time.perf_counter()
            scores = features @ weight
            torch.cuda.synchronize()
            rows.append({
                "shape": tuple(features.shape),
                "seconds": ...,
                "finite": ...,
            })
        except torch.OutOfMemoryError:
            rows.append({"status": "out_of_memory"})
    return rows

def main():
    print(E18(...))

if __name__ == "__main__":
    main()
```

12.3.20 Exercise 19 - Produce a Formal Mathematical Interpretation Report

Part 1 - Why this matters

Produce a Formal Mathematical Interpretation Report makes one mathematical component of the perceptron observable. The model's hard output hides score magnitude and geometry, so the underlying vectors, dimensions, boundary, and numerical representation must be studied directly.

A correct formula can still be interpreted incorrectly when weights are unnormalized, features use different scales, or a lower-dimensional plot discards information. This exercise therefore records the assumptions and transformations used with every result.

Part 2 - Mathematical form

$$R = \{\text{notation}, \text{dimensions}, \text{geometry}, \text{distance}, \text{precision}, \text{separability}, \text{limitations}\}.$$

Part 3 - Hints and Helper

Combine validated outputs from previous exercises. Preserve label convention, scaling, dtype, projection basis, tolerances, and empirical versus proven claims.

Part 4 - Python code skeleton

```
import time

import matplotlib.pyplot as plt
import torch

def E19(sections):
    required = {
        "notation", "dimensions", "geometry",
        "distance", "precision",
        "separability", "limitations",
    }
    missing = sorted(required - sections.keys())
    warnings = []
    if missing:
        warnings.append(...)
    if sections.get(
        "geometry", {}
    ).get("weight_norm", 0.0) <= 0:
        warnings.append(...)
    return {
        "sections": sections,
        "missing": missing,
        "warnings": warnings,
        "status": ...,
    }

def main():
    print(E19(...))

if __name__ == "__main__":
    main()
```

12.4 PC02 - Perceptron Learning Rule and Updates

Models and Training

12.4.1 Exercise 00 - Derive the Perceptron Weight Update Rule from Classification Errors

Part 1 - Why this matters

The perceptron does not learn by minimizing a smooth loss with ordinary gradient descent. It changes its parameters only when the current decision disagrees with the true class, moving the decision boundary toward a configuration that classifies the mistaken sample correctly. Understanding this mechanism reveals how feedback becomes a concrete parameter update.

Deriving the rule also prevents sign and label errors. The formulas differ depending on whether labels use $\{-1, +1\}$ or $\{0, 1\}$, so the label convention must be fixed before the update is implemented or interpreted.

Part 2 - Mathematical form

For $y_i \in \{-1, +1\}$ and $\hat{y}_i = \text{sign}(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b)$,

$$\mathbf{w} \leftarrow \mathbf{w} + \eta y_i \mathbf{x}_i, \qquad b \leftarrow b + \eta y_i \quad \text{if } y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) \leq 0.$$

Part 3 - Hints and Helper

Write the correctness condition as a signed margin. Derive the direction needed to increase that margin, then verify that correctly classified samples cause no update.

Part 4 - Python code skeleton

```
import torch

def E00(features, label, weight, bias, learning_rate):
    score = torch.dot(weight, features) + bias
    margin = label * score
    if margin <= 0:
        new_weight = weight + ...
        new_bias = bias + ...
    else:
        new_weight, new_bias = weight, bias
    return new_weight, new_bias, margin

def main():
    print(E00(...))

if __name__ == "__main__":
    main()
```

12.4.2 Exercise 01 - Implement Manual Weight Update Based on Misclassified Samples

Part 1 - Why this matters

A manual update makes the learning rule visible at the level of individual samples. Instead of delegating parameter changes to an optimizer, the reader can observe which mistake triggered the update and how every feature contributed to the new weight vector.

This visibility is important for debugging. An incorrect label encoding, accidental in-place mutation, or update applied to a correct prediction can produce a training loop that runs normally while learning the wrong boundary.

Part 2 - Mathematical form

$$\Delta \mathbf{w}_i = \begin{cases} \eta y_i \mathbf{x}_i, & y_i z_i \le 0, \\ \mathbf{0}, & y_i z_i > 0, \end{cases} \qquad z_i = \mathbf{w}^\top \mathbf{x}_i + b.$$

Part 3 - Hints and Helper

Clone the original parameters before updating them. Return the prediction, error flag, and update vector so the operation can be verified independently.

Part 4 - Python code skeleton

```
import torch

def E01(features, labels, weight, bias, learning_rate):
    history = []
    for features_i, label_i in zip(features, labels):
        score = torch.dot(weight, features_i) + bias
        mistake = ...
        update = ... if mistake else torch.zeros_like(weight)
        weight = weight + update
        bias = bias + (... if mistake else 0.0)
        history.append((score.item(), mistake, update.clone()))
    return weight, bias, history

def main():
    print(E01(...))

if __name__ == "__main__":
    main()
```

12.4.3 Exercise 02 - Analyze the Role of Learning Rate in Perceptron Convergence Behavior

Part 1 - Why this matters

The learning rate controls the magnitude of every corrective step. Although positive constant learning rates preserve the classical convergence guarantee for linearly separable data, they change the numerical path, parameter scale, and sensitivity to finite precision.

Comparing several values prevents the simplistic belief that a larger step always learns faster. The number of mistakes, weight norm, boundary position, and stopping epoch should all be measured because a single final accuracy value hides the training dynamics.

Part 2 - Mathematical form

$$\Delta \mathbf{w}_i = \eta y_i \mathbf{x}_i, \qquad \|\Delta \mathbf{w}_i\|_2 = \eta \|\mathbf{x}_i\|_2.$$

Part 3 - Hints and Helper

Use identical initialization and data order for every learning rate. Record mistakes per epoch and parameter norms instead of comparing only the final predictions.

Part 4 - Python code skeleton

```
import torch

def E02(features, labels, learning_rates, epochs):
    results = {}
    for learning_rate in learning_rates:
        weight = torch.zeros(features.shape[1])
        bias = torch.tensor(0.0)
        mistakes = []
        for _ in range(epochs):
            epoch_mistakes = ...
            mistakes.append(epoch_mistakes)
        results[learning_rate] = {
            "mistakes": mistakes,
            "weight_norm": ...,
        }
    return results

def main():
    print(E02(...))

if __name__ == "__main__":
    main()
```

12.4.4 Exercise 03 - Implement Bias Update Rule and Observe Its Effect on Decision Boundary

Part 1 - Why this matters

The bias allows the separating hyperplane to move away from the origin. Updating weights without updating the bias restricts the family of boundaries the perceptron can learn and may make an otherwise separable dataset appear impossible.

Observing the bias separately clarifies its geometric role. Weight changes can rotate and scale the boundary, while the normalized displacement from the origin is controlled by $-b/\|\mathbf{w}\|_2$.

Part 2 - Mathematical form

$$b \leftarrow b + \eta y_i, \qquad d_{\text{origin}} = -\frac{b}{\|\mathbf{w}\|_2}.$$

Part 3 - Hints and Helper

Train once with the bias frozen and once with it updated. Compare error counts and boundary displacement using the same initial weights and sample order.

Part 4 - Python code skeleton

```
import torch

def E03(features, labels, weight, bias, learning_rate):
    before = bias.clone()
    for features_i, label_i in zip(features, labels):
        score = weight @ features_i + bias
        if label_i * score <= 0:
            weight = weight + learning_rate * label_i * features_i
            bias = ...
    displacement = -bias / torch.linalg.vector_norm(weight)
    return before, bias, displacement

def main():
    print(E03(...))

if __name__ == "__main__":
    main()
```

12.4.5 Exercise 04 - Track Weight Evolution Across Multiple Training Iterations

Part 1 - Why this matters

Final parameters do not explain how the model arrived at its decision boundary. A trajectory of weight vectors reveals the sequence of mistakes, repeated corrections, quiet periods, and sudden changes that define perceptron training.

Tracking the trajectory also exposes implementation defects. If weights change on correctly classified samples, remain constant after mistakes, or share storage with every history entry, the recorded path will reveal the problem immediately.

Part 2 - Mathematical form

$$\mathbf{w}^{(t+1)} = \mathbf{w}^{(t)} + \eta y_{i_t} \mathbf{x}_{i_t} \mathbb{I}\left[y_{i_t} z_{i_t}^{(t)} \leq 0\right].$$

Part 3 - Hints and Helper

Clone the weight and bias after each processed sample. Store the epoch, sample index, margin, mistake flag, and parameter state together.

Part 4 - Python code skeleton

```
import torch

def E04(features, labels, epochs, learning_rate):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
    trajectory = []
    for epoch in range(epochs):
        for sample_id, (features_i, label_i) in enumerate(
            zip(features, labels)
        ):
            margin = label_i * (weight @ features_i + bias)
            mistake = ...
            if mistake:
                weight = ...
                bias = ...
            trajectory.append({"epoch": epoch, "weight": weight.clone(), ...})
    return trajectory

def main():
    print(E04(...))

if __name__ == "__main__":
    main()
```

12.4.6 Exercise 05 - Compare Single-Sample Updates vs Batch Updates in Perceptron Training

Part 1 - Why this matters

The classical perceptron updates immediately after each mistake, so later samples in the same epoch see the newly corrected boundary. A batch variant accumulates corrections under one frozen parameter state and applies their sum afterward, producing different learning dynamics.

Comparing the two methods teaches that mathematically similar update terms do not imply identical algorithms. Update timing changes which samples are considered mistakes, the trajectory through parameter space, and sometimes the number of epochs needed to separate the data.

Part 2 - Mathematical form

$$\text{online: } \mathbf{w} \leftarrow \mathbf{w} + \eta y_i \mathbf{x}_i, \qquad \text{batch: } \mathbf{w} \leftarrow \mathbf{w} + \eta \sum_{i \in \mathcal{M}} y_i \mathbf{x}_i.$$

Part 3 - Hints and Helper

Start both variants from identical parameters. In the batch version, compute the full mistake mask before modifying either weight or bias.

Part 4 - Python code skeleton

```
import torch

def E05(features, labels, weight, bias, learning_rate, mode):
    weight = weight.clone()
    bias = bias.clone()
    if mode == "online":
        for features_i, label_i in zip(features, labels):
            if label_i * (weight @ features_i + bias) <= 0:
                weight = ...
                bias = ...
    elif mode == "batch":
        margins = labels * (features @ weight + bias)
        mask = margins <= 0
        weight = weight + ...
        bias = bias + ...
    return weight, bias

def main():
    print(E05(...))

if __name__ == "__main__":
    main()
```

12.4.7 Exercise 06 - Detect and Analyze Oscillation in Non-Separable Datasets

Part 1 - Why this matters

The perceptron convergence theorem applies only when a separating hyperplane exists. On non-separable data, the algorithm may revisit similar parameter states, alternate between conflicting corrections, and continue making mistakes indefinitely.

Detecting this behavior is more useful than merely reaching a maximum epoch limit. A learner should distinguish slow progress from a repeating trajectory and report evidence that the dataset or model assumptions prevent convergence.

Part 2 - Mathematical form

$$\mathbf{s}^{(t)} = (\mathbf{w}^{(t)}, b^{(t)}), \qquad \|\mathbf{s}^{(t)} - \mathbf{s}^{(t-k)}\|_2 < \varepsilon$$

indicates an approximate cycle of period k when errors remain positive.

Part 3 - Hints and Helper

Store detached parameter states and compare recent states within a tolerance. Confirm that a detected repetition occurs while the epoch still contains classification errors.

Part 4 - Python code skeleton

```
import torch

def E06(states, mistake_counts, tolerance):
    cycles = []
    for current in range(1, len(states)):
        for previous in range(current):
            distance = torch.linalg.vector_norm(
                states[current] - states[previous]
            )
            if distance < tolerance and mistake_counts[current] > 0:
                cycles.append({"start": previous, "end": current, ...})
    return cycles

def main():
    print(E06(...))

if __name__ == "__main__":
    main()
```

12.4.8 Exercise 07 - Implement Training Loop Without Using PyTorch Optimizers

Part 1 - Why this matters

Implementing the full loop manually connects prediction, mistake detection, parameter correction, and stopping behavior in one transparent process. It shows that the perceptron rule is a complete learning algorithm rather than an ordinary differentiable model waiting for an optimizer.

Avoiding automatic gradients also clarifies state management. Parameters should be updated intentionally, histories should contain independent copies, and the loop should terminate only according to an explicit convergence or safety condition.

Part 2 - Mathematical form

$$M_e = \sum_{i=1}^{n} \mathbb{I}\Big[y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) \le 0\Big], \qquad \text{stop if } M_e = 0.$$

Part 3 - Hints and Helper

Do not call backward or an optimizer. Reset the epoch mistake counter, update only on mistakes, and return both parameters and a training history.

Part 4 - Python code skeleton

```
import torch

def E07(features, labels, learning_rate, max_epochs):
    weight = torch.zeros(features.shape[1], device=features.device)
```

```
    bias = torch.zeros((), device=features.device)
    history = []
    for epoch in range(max_epochs):
        mistakes = 0
        for features_i, label_i in zip(features, labels):
            if label_i * (weight @ features_i + bias) <= 0:
                weight = ...
                bias = ...
                mistakes += 1
        history.append(mistakes)
        if ...:
            break
    return weight, bias, history

def main():
    print(E07(...))

if __name__ == "__main__":
    main()

12.4.9 Exercise 08 - Observe Convergence Speed Under Different Data Orderings

Part 1 - Why this matters

Online perceptron updates depend on the order in which samples are presented. Two orderings of the same separable dataset can generate different intermediate boundaries and different numbers of mistakes before reaching a valid separator.

This experiment distinguishes model capability from optimization path. Repeated trials with controlled random seeds reveal whether a reported convergence speed is stable or merely the consequence of a fortunate ordering.

Part 2 - Mathematical form

$$\pi_r : \{1, \ldots, n\} \to \{1, \ldots, n\}, \qquad T_r = \min\{e : M_e^{(\pi_r)} = 0\}.$$

Part 3 - Hints and Helper

Use torch.randperm with a separate seeded generator for each trial. Preserve the same initialization and report epochs, total mistakes, and whether convergence occurred.

Part 4 - Python code skeleton

```
import torch

def E08(features, labels, seeds, max_epochs):
    results = []
    for seed in seeds:
```

```
        generator = torch.Generator().manual_seed(seed)
        weight = torch.zeros(features.shape[1])
        bias = torch.tensor(0.0)
        total_mistakes = 0
        for epoch in range(max_epochs):
            order = torch.randperm(len(features), generator=generator)
            mistakes = ...
            total_mistakes += mistakes
            if mistakes == 0:
                break
        results.append({"seed": seed, "epochs": ..., "mistakes": ...})
    return results

def main():
    print(E08(...))

if __name__ == "__main__":
    main()
```

12.4.10 Exercise 09 - Investigate Failure to Converge on XOR-like Distributions

Part 1 - Why this matters

XOR-like data exposes the representational limit of a single linear decision boundary. Training longer or changing the learning rate cannot repair a model whose hypothesis class contains no separator for the target pattern.

The exercise trains the reader to diagnose the correct layer of failure. Persistent mistakes accompanied by rotating or repeating boundaries indicate a structural mismatch, not necessarily broken code or insufficient compute.

Part 2 - Mathematical form

For XOR labels, there is no $(\mathbf{w}, b)$ satisfying

$$y_i(\mathbf{w}^\mathsf{T}\mathbf{x}_i + b) > 0 \qquad \text{for every } i \in \{1, 2, 3, 4\}.$$

Part 3 - Hints and Helper

Train for a fixed maximum number of epochs and retain the best error count. Compare the recurring mistakes with a linearly separable control dataset.

Part 4 - Python code skeleton

```
import torch

def E09(features, labels, learning_rate, max_epochs):
    weight = torch.zeros(features.shape[1])
    bias = torch.tensor(0.0)
```

```
    history = []
    for epoch in range(max_epochs):
        mistakes = 0
        for features_i, label_i in zip(features, labels):
            if label_i * (weight @ features_i + bias) <= 0:
                weight = weight + ...
                bias = bias + ...
                mistakes += 1
        history.append(mistakes)
    return {"converged": ..., "best_errors": ..., "history": history}

def main():
    print(E09(...))

if __name__ == "__main__":
    main()
```

12.4.11 Exercise 10 - Move Training Computation to CUDA and Verify Deterministic Behavior

Part 1 - Why this matters

Moving training to a GPU is not only a device-placement exercise. Inputs, labels, parameters, random permutations, and temporary tensors must remain on compatible devices while the learning rule preserves the same logical behavior.

Determinism must also be defined carefully. Repeating one CUDA run under controlled settings should reproduce its parameters and mistake history, while exact agreement with CPU may still depend on operation order, dtype, and floating-point rounding near the boundary.

Part 2 - Mathematical form

$$(\mathbf{w}_r, b_r, H_r) = \mathcal{A}_{\mathrm{CUDA}}(X, y, s), \qquad (\mathbf{w}_1, b_1, H_1) = (\mathbf{w}_2, b_2, H_2)$$

for repeated runs using the same seed s and deterministic configuration.

Part 3 - Hints and Helper

Check `torch.cuda.is_available()` before selecting the device. Seed CPU and CUDA, enable deterministic algorithms, and compare complete histories rather than final accuracy alone.

Part 4 - Python code skeleton

```
import torch

def E10(features, labels, seed, epochs):
    if not torch.cuda.is_available():
        raise RuntimeError(...)
    torch.manual_seed(seed)
```

```
    torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(True)
    device = torch.device("cuda")
    features = features.to(device)
    labels = labels.to(device)
    weight = torch.zeros(features.shape[1], device=device)
    bias = torch.zeros((), device=device)
    history = ...
    return weight.cpu(), bias.cpu(), history

def main():
    first = E10(...)
    second = E10(...)
    print(...)

if __name__ == "__main__":
    main()
```

12.4.12 Exercise 11 - Compare CPU vs GPU Weight Update Numerical Differences

Part 1 - Why this matters

CPU and GPU implementations can be logically equivalent without producing bitwise-identical floating-point states. Small rounding differences can accumulate across many updates and may alter a hard prediction when a sample lies extremely close to the boundary.

A useful comparison therefore measures parameter deviation, score deviation, and decision disagreement. This separates harmless numerical variation from a device bug that changes the learning rule or data order.

Part 2 - Mathematical form

$$\delta_w = \|\mathbf{w}_{\text{CPU}} - \mathbf{w}_{\text{GPU}}\|_2, \quad \delta_b = |b_{\text{CPU}} - b_{\text{GPU}}|, \quad D = \sum_i \mathbb{I}[\hat{y}_i^C \neq \hat{y}_i^G].$$

Part 3 - Hints and Helper

Use the same dtype, initialization, sample order, and epoch count. Move GPU results to CPU before calling torch.allclose and report both absolute and relative tolerances.

Part 4 - Python code skeleton

```
import torch

def E11(cpu_state, gpu_state, probe_features, atol, rtol):
    cpu_weight, cpu_bias = cpu_state
    gpu_weight, gpu_bias = [value.cpu() for value in gpu_state]
    weight_difference = torch.linalg.vector_norm(cpu_weight - gpu_weight)
```

```
    bias_difference = torch.abs(cpu_bias - gpu_bias)
    cpu_predictions = probe_features @ cpu_weight + cpu_bias >= 0
    gpu_predictions = ...
    return {
        "parameters_close": torch.allclose(...),
        "weight_difference": weight_difference.item(),
