Create controlled failure modes: train without positional information, corrupt the target shift, omit source padding in cross-attention, choose a maximum output length shorter than the reference, and evaluate while dropout remains active. For each failure, predict its signature. A positionless model should struggle especially with reversal; wrong shifting may yield suspiciously easy training; padding leakage creates length-dependent errors; an inadequate token budget causes systematic truncation. Store the first mismatching position and the model confidence there instead of recording only a zero exact-match score.

Part 2 - Mathematical form and reasoning

For copy, $g(x_1, \ldots, x_S) = (x_1, \ldots, x_S)$; for reverse,

$$g(x_1, \ldots, x_S) = (x_S, \ldots, x_1).$$

Token accuracy and exact match are

$$\mathrm{Acc}_{\mathrm{token}} = \frac{\sum_{b,t} m_{b,t} \mathbf{1}[\hat{y}_{b,t} = y_{b,t}]}{\sum_{b,t} m_{b,t}},$$

$$\mathrm{EM} = \frac{1}{B} \sum_{b} \mathbf{1}[\hat{y}_b = y_b],$$

where comparison ends consistently at EOS and excludes padding. Exact match is strict: one early error can shift the remainder. Therefore report first-error position and length-conditioned results alongside it.

Part 3 - Hints, controls, and evidence

Start with short fixed-length sequences and overfit one batch. Progress to variable lengths only after exact match reaches one. Use separate random-number generators for training and evaluation. Ensure content tokens never collide with special IDs. Decode one token at a time using the exact same source mask as training. Compare teacher-forced predictions and autoregressive predictions for the same example to localize exposure effects. Plot loss, token accuracy, exact match, EOS rate, and accuracy by length. The strongest evidence includes one successful run, each intentional failure, a root-cause explanation, and a regression assertion that detects it.

Part 4 - Python code skeleton

```
import torch

def make_reverse_batch(batch_size, minimum_length, maximum_length,
                       vocabulary_size, bos_id, eos_id, padding_id, device):
    lengths = torch.randint(
        minimum_length, maximum_length + 1, (batch_size,), device=device
    )
    source = torch.full(
        (batch_size, maximum_length), padding_id, device=device
    )
```

```
    target = torch.full(
        (batch_size, maximum_length + 2), padding_id, device=device
    )
    target[:, 0] = bos_id
    for row in range(batch_size):
        length = int(lengths[row].item())
        tokens = torch.randint(3, vocabulary_size, (length,), device=device)
        source[row, :length] = tokens
        target[row, 1:length + 1] = tokens.flip(0)
        target[row, length + 1] = eos_id
    return source, target, lengths

def exact_match(predictions, references, eos_id, padding_id):
    matched = 0
    for row in range(predictions.size(0)):
        predicted_list = []
        reference_list = []
        for token in predictions[row].tolist():
            if token == eos_id:
                break
            if token != padding_id:
                predicted_list.append(token)
        for token in references[row].tolist():
            if token == eos_id:
                break
            if token != padding_id:
                reference_list.append(token)
        if predicted_list == reference_list:
            matched += 1
    return matched / predictions.size(0)

def E04(model, optimizer, source, full_target, padding_id):
    model.train()
    optimizer.zero_grad(set_to_none=True)
    loss, _, _ = model.training_objective(source, full_target, padding_id)
    loss.backward()
    optimizer.step()
    return float(loss.item())
```

Part 5 - The Philosophy Behind the Exercise

Synthetic tasks remove excuses. Their simplicity does not make them trivial; it makes them scientifically sharp. When the correct transformation is known exactly, failure becomes information about the pipeline rather than a debate about the data. Mastery begins by demanding that a complex system prove itself on a world whose laws we fully control.

17.9.6 Exercise 05

Exercise Title: Debug Seq2Seq Alignment Bugs Caused by Wrong Target Shifting or Incorrect Mask Broadcasting

Part 1 - Why this matters

Alignment bugs are among the most expensive seq2seq errors because they often produce legal shapes, finite gradients, and decreasing loss. If decoder input and label both contain the current token, the network learns an identity leak. If labels are shifted twice, predictions are judged against the wrong future. If a source mask broadcasts across target queries incorrectly, only particular batch sizes or sequence lengths may fail. This exercise creates an explicit alignment audit that runs before long training.

Build a batch with unique, easily recognized IDs rather than natural text. Print every row as source, full target, decoder input, label, source-valid mask, target-valid mask, and loss-valid positions. Verify these relations element by element, not merely by comparing shapes. The decoder input must begin with BOS; labels must end at EOS; no label at position t may appear as the decoder input at that same position unless it also genuinely occurred earlier. Count exactly how many tokens contribute to loss.

For mask broadcasting, construct attention scores with $B > 1$, $H > 1$, $T \neq S$, and a different padding pattern per row. Expand a semantic source visibility mask explicitly to $(B, 1, T, S)$ and compare it with the broadcast result used by the implementation. Inject common wrong shapes such as $(B, S, 1)$ or (S, B) and confirm the audit rejects them even when an operation happens to broadcast. Then run one optimization step on the correct and corrupted targets; the point is to see why loss magnitude alone cannot certify alignment.

Part 2 - Mathematical form and reasoning

Correct shifting requires

$$D_{b,t} = Y^{\text{full}}_{b,t}, \qquad L_{b,t} = Y^{\text{full}}_{b,t+1},$$

for $0 \leq t < T - 1$. Thus D and L have identical shapes but different temporal meanings. For source-valid mask $P \in \{0, 1\}^{B \times S}$, the desired cross-attention blocked mask is

$$M_{b,h,t,s} = \neg P_{b,s}, \qquad M \in \{0, 1\}^{B \times H \times T \times S}.$$

It is constant across heads and target queries but varies across batch and source position. A broadcast is correct only if it is equivalent to this full semantic tensor.

Part 3 - Hints, controls, and evidence

Keep BOS, EOS, PAD, and content ID ranges disjoint. Assert `decoder_ids[:, 1:] == labels[:, :-1]` only over positions where that relation is defined by the full target. Compare label count with the sum of the loss mask. In the mask test, materialize the expanded tensor once for auditing; efficiency is irrelevant at this size. Test batch-row isolation by changing padding in one row and checking other rows remain identical. Save the failing indices and expected versus observed token or visibility value. Include a known wrong shift and a transposed-mask injection so the audit itself is tested.

Part 4 - Python code skeleton

```
import torch

def build_shifted_targets(full_target, padding_id):
    decoder_ids = full_target[:, :-1].contiguous()
    labels = full_target[:, 1:].contiguous()
    loss_mask = labels.ne(padding_id)
    if decoder_ids.shape != labels.shape:
        raise AssertionError("decoder inputs and labels must align in shape")
    return decoder_ids, labels, loss_mask

def audit_shift(full_target, decoder_ids, labels):
    expected_decoder = full_target[:, :-1]
    expected_labels = full_target[:, 1:]
    if not torch.equal(decoder_ids, expected_decoder):
        wrong = (decoder_ids != expected_decoder).nonzero()
        raise AssertionError("wrong decoder shift at " + str(wrong.tolist()))
    if not torch.equal(labels, expected_labels):
        wrong = (labels != expected_labels).nonzero()
        raise AssertionError("wrong label shift at " + str(wrong.tolist()))

def audit_cross_mask(source_valid, heads, target_length):
    batch_size, source_length = source_valid.shape
    broadcast_mask = (~source_valid)[:, None, None, :]
    expanded = broadcast_mask.expand(
        batch_size, heads, target_length, source_length
    )
    for batch_index in range(batch_size):
        for target_index in range(target_length):
            observed = expanded[batch_index, 0, target_index]
            expected = ~source_valid[batch_index]
            if not torch.equal(observed, expected):
                raise AssertionError("cross-mask semantic mismatch")
    return broadcast_mask

def E05(full_target, source_valid, padding_id, heads):
    decoder_ids, labels, loss_mask = build_shifted_targets(
        full_target, padding_id
    )
    audit_shift(full_target, decoder_ids, labels)
    cross_mask = audit_cross_mask(source_valid, heads, decoder_ids.size(1))
    return decoder_ids, labels, loss_mask, cross_mask
```

Part 5 - The Philosophy Behind the Exercise

Alignment is an agreement between time, data, and supervision. Equal tensor dimensions can conceal a disagreement among all three. The discipline here is to prove meaning before optimization: which fact is available, which fact is predicted, and which positions may influence the decision. Learning cannot redeem a contradiction in the definition of the task.

17.9.7 Exercise 06

Exercise Title: Implement Attention Visualization for Cross-Attention and Interpret Which Source Tokens Drive Outputs

Part 1 - Why this matters

Cross-attention matrices expose how every decoder query distributes retrieval weight over source positions. On copy and reverse tasks, expected alignment is known, so visualization can reveal transposition, padding leakage, diffuse retrieval, repeated focus, or off-by-one target labeling. On natural language, the pattern can suggest alignments and head specialization. Yet attention is an internal routing weight, not guaranteed proof that a source token caused the final output. This exercise combines visualization with interventions.

Capture weights from every decoder layer and head in evaluation mode. Preserve shape (L, B, H, T, S) and attach the actual source tokens and predicted target tokens to the axes. Remove padded target rows and source columns only after checking their weights. Plot individual heads, mean-over-heads, and optionally rollups across layers; never average first and then claim all heads behaved the same. Normalize colors consistently across compared examples.

For a reverse task, target position zero should usually focus near the last source content position, then move backward. Quantify this rather than judging only the image: calculate peak source index, attention entropy, mass on the known aligned position, padding mass, and monotonic direction. Then intervene on a high-attention source token and a low-attention token. Measure the change in the chosen target logit. A head can have visually sharp weights but little causal effect after value projection, residual mixing, or later layers; state this limitation in the interpretation.

Part 2 - Mathematical form and reasoning

For layer ℓ and head h, cross-attention is

$$A_{t,s}^{(\ell,h)} = p(s \mid q_t), \qquad \sum_{s \in \mathcal{V}_x} A_{t,s}^{(\ell,h)} = 1.$$

Attention entropy is

$$H_t^{(\ell,h)} = -\sum_{s \in \mathcal{V}_x} A_{t,s}^{(\ell,h)} \log(A_{t,s}^{(\ell,h)} + \varepsilon).$$

For known alignment $a(t)$, alignment mass is $A_{t,a(t)}$. A simple token intervention effect for target logit $z_{t,v}$ is

$$\Delta_s = |z_{t,v}(x) - z_{t,v}(x_{s \leftarrow x'})|.$$

Attention weight and intervention effect answer different questions and should be reported together rather than equated.

Part 3 - Hints, controls, and evidence

Disable dropout, use a fixed checkpoint, and request weights before any head averaging. Verify axis labels with unique token IDs. Use the same color scale when comparing heads or checkpoints. Never let padding occupy plotted columns without a visible marker. For each target token, store predicted ID, reference ID, confidence, peak source position, aligned-position

mass, and entropy. Compare correct predictions with first-error positions. Run source-token replacement and source-token masking interventions while keeping the target prefix unchanged. Include examples where visualization is informative and where it is ambiguous; interpretation quality includes acknowledging uncertainty.

Part 4 - Python code skeleton

```
import torch

def cross_attention_statistics(weights, source_valid, alignment=None):
    visible = source_valid[:, None, None, :]
    valid_weights = weights.masked_fill(~visible, 0.0)
    padding_mass = weights.masked_fill(visible, 0.0).sum(dim=-1)
    probabilities = valid_weights.float().clamp_min(1e-12)
    entropy = -(probabilities * probabilities.log()).sum(dim=-1)
    peak_position = valid_weights.argmax(dim=-1)
    result = {
        "padding_mass_max": float(padding_mass.max().item()),
        "entropy": entropy.detach().cpu(),
        "peak_position": peak_position.detach().cpu(),
    }
    if alignment is not None:
        gather_index = alignment[:, None, :, None]
        gather_index = gather_index.expand(
            -1, weights.size(1), -1, 1
        )
        aligned_mass = valid_weights.gather(-1, gather_index).squeeze(-1)
        result["aligned_mass"] = aligned_mass.detach().cpu()
    return result

@torch.inference_mode()
def source_intervention(model, source_ids, decoder_ids, source_mask,
                        source_position, replacement_id):
    baseline_logits, baseline_weights = model.inspect(
        source_ids, decoder_ids, source_mask
    )
    changed = source_ids.clone()
    changed[:, source_position] = replacement_id
    changed_logits, changed_weights = model.inspect(
        changed, decoder_ids, source_mask
    )
    effect = (baseline_logits - changed_logits).abs().max(dim=-1).values
    return baseline_weights, changed_weights, effect

def E06(weights, source_valid, alignment):
    return cross_attention_statistics(weights, source_valid, alignment)
```

Part 5 - The Philosophy Behind the Exercise

Visualization is a question-generating instrument, not a verdict. It helps us see where the model routes information, then experiments test whether that route matters to the decision. The responsible interpretation of a complex model combines visibility with intervention and treats an attractive pattern as the beginning of explanation, never its end.

17.9.8 Exercise 07

Exercise Title: Compare Greedy vs Beam Search for Seq2Seq and Show When Beam Search Helps and When It Hurts

Part 1 - Why this matters

Greedy decoding chooses the most probable next token and discards every other continuation. Beam search preserves several partial hypotheses and may recover a better complete sequence when the locally best token leads to a poor future. This is especially relevant in conditional generation because source evidence can support several early target formulations. Yet beam search optimizes model score, not human usefulness, and wider beams can amplify length bias, generic phrasing, repetition, or model miscalibration.

Implement greedy and beam decoding over the same trained seq2seq model. Encode the source once, reuse memory for every hypothesis, and keep per-beam target tokens, cumulative log probability, completion state, and decoder cache if available. Finished beams must not generate ordinary tokens. When beams are reordered, every layer's cached state must be reordered identically. Begin with a hand-defined probability tree where greedy is provably suboptimal, then use the copy or reverse model where exact correctness is known.

Compare beam widths one, two, four, and eight. Beam width one must equal greedy under identical tie-breaking. Report raw log probability, normalized score, exact match, length, EOS rate, repetition, diversity among returned candidates, and latency. Include examples where beam search corrects an early greedy choice and where it selects a shorter or blander output despite a wider search. The conclusion should identify which failure belongs to search, which belongs to the model distribution, and which arises from the scoring objective.

Part 2 - Mathematical form and reasoning

For a partial hypothesis $y_{1:t}$,

$$s(y_{1:t}) = \sum_{i=1}^{t} \log p_\theta(y_i \mid y_{<i}, x).$$

At each step beam search forms all allowed one-token extensions and retains the top B_w by search score. Because each log probability is nonpositive, raw score tends to favor short completed sequences. A later exercise introduces length penalty; here report raw scores so this bias is visible. Search error exists when a better model-scored sequence was pruned. Model error exists when the highest-scored sequence is not the desired answer.

Part 3 - Hints, controls, and evidence

Use log-softmax to avoid multiplying small probabilities. Define deterministic tie-breaking. Keep completed and active hypotheses conceptually separate. Apply minimum length, EOS, and maximum length identically across methods. Verify beam one equals greedy token for token and that every beam shares the same encoder memory without recomputing it. If batched

beams are used, test cache reordering against a slow full-prefix reference. Evidence includes the hand-computed tree, beam frontier at every step, ranked final hypotheses, task metrics, and latency. Do not claim that beam search improves quality from one favorable example.

Part 4 - Python code skeleton

```
import torch

@torch.inference_mode()
def seq2seq_beam_search(model, source_ids, source_mask, bos_id, eos_id,
                        beam_width, maximum_tokens):
    model.eval()
    memory = model.encode(source_ids, source_mask)
    initial = torch.tensor([[bos_id]], device=source_ids.device)
    beams = [{"tokens": initial, "score": 0.0, "finished": False}]

    for step in range(maximum_tokens):
        candidates = []
        for beam in beams:
            if beam["finished"]:
                candidates.append(beam)
                continue
            logits = model.decode(beam["tokens"], memory, source_mask)
            log_probabilities = torch.log_softmax(logits[:, -1, :], dim=-1)
            values, indices = torch.topk(
                log_probabilities, beam_width, dim=-1
            )
            for candidate_index in range(beam_width):
                token = indices[:, candidate_index:candidate_index + 1]
                candidate_tokens = torch.cat((beam["tokens"], token), dim=1)
                token_score = float(values[0, candidate_index].item())
                candidates.append({
                    "tokens": candidate_tokens,
                    "score": beam["score"] + token_score,
                    "finished": int(token.item()) == eos_id,
                })
        def raw_score(candidate):
            return candidate["score"]
        candidates.sort(key=raw_score, reverse=True)
        beams = candidates[:beam_width]
        all_finished = True
        for beam in beams:
            if not beam["finished"]:
                all_finished = False
        if all_finished:
            break
    return beams

def E07(model, source_ids, source_mask, bos_id, eos_id):
```

```
    return seq2seq_beam_search(
        model, source_ids, source_mask, bos_id, eos_id, 4, 64
    )
```

Part 5 - The Philosophy Behind the Exercise

Search cannot create knowledge that the model did not assign probability to, and it cannot know that our scoring rule misrepresents value. Beam search is a method for delaying commitment within a declared objective. Wider deliberation is useful only when the objective deserves to be pursued more thoroughly.

17.9.9 Exercise 08

Exercise Title: Implement Length Penalty in Beam Search and Show Its Effect on Too-Short Output Bias

Part 1 - Why this matters

Cumulative log probability becomes more negative whenever another token is added. Consequently, raw beam score can prefer a short hypothesis that emits EOS early even when a longer output better represents the source. Length penalty changes ranking so sequences of different lengths can be compared under a declared normalization. It does not repair missing source information or poor probabilities; it changes the search objective and can overshoot into verbosity.

Extend the previous beam search while preserving raw cumulative log probability for audit. Rank hypotheses using a separate normalized score. Compare no penalty with several strengths on sources of different reference lengths. Record output length, length ratio, EOS rate, exact match or task metric, raw score, normalized score, and latency. Show at least one case in which the penalty rescues a truncated output and one where excessive normalization keeps an unnecessary continuation alive.

Be precise about which length is counted. Exclude the source, usually exclude BOS, and state whether EOS counts. Apply the same convention during intermediate pruning and final ranking. Do not normalize unfinished and finished beams under different undocumented rules. A minimum-length constraint is not a length penalty: it prohibits EOS before a threshold, whereas a penalty continuously changes preferences among allowed hypotheses.

Part 2 - Mathematical form and reasoning

A simple normalized score is

$$s_\alpha(y) = \frac{s(y)}{|y|^\alpha},$$

where $s(y)$ is cumulative log probability and $\alpha \geq 0$. Because $s(y)$ is negative, dividing by a larger positive denominator makes longer sequences less severely penalized. Another common form is

$$\mathrm{lp}_\alpha(|y|) = \left(\frac{5 + |y|}{6}\right)^\alpha, \qquad s_\alpha(y) = \frac{s(y)}{\mathrm{lp}_\alpha(|y|)}.$$

The choice is part of the experiment. At $\alpha = 0$, ranking reduces exactly to raw beam score.

Part 3 - Hints, controls, and evidence

Implement the scoring function independently and unit-test it on hand-written hypotheses. Ensure an alpha of zero preserves ordering. Log raw and normalized scores together so the ranking change is explainable. Use matched beam width, maximum length, and prompts. Report length histograms, not only averages, and stratify by source length. Inspect early EOS probability at the step where an unpenalized beam terminates. Tune on validation data and evaluate once on held- out data; choosing alpha from test BLEU is leakage. Evidence must show the score calculation for at least one ranking reversal.

Part 4 - Python code skeleton

```
def generated_length(tokens, bos_id, eos_id):
    count = 0
    token_values = tokens[0].tolist()
    for token in token_values:
        if token == bos_id:
            continue
        count += 1
        if token == eos_id:
            break
    return max(count, 1)

def length_penalty(length, alpha):
    return ((5.0 + float(length)) / 6.0) ** alpha

def normalized_beam_score(beam, bos_id, eos_id, alpha):
    length = generated_length(beam["tokens"], bos_id, eos_id)
    penalty = length_penalty(length, alpha)
    return beam["raw_score"] / penalty

def rank_beams(beams, bos_id, eos_id, alpha):
    scored = []
    for beam in beams:
        copied = dict(beam)
        copied["normalized_score"] = normalized_beam_score(
            beam, bos_id, eos_id, alpha
        )
        scored.append(copied)
    def score_value(item):
        return item["normalized_score"]
    scored.sort(key=score_value, reverse=True)
    return scored

def E08(beams, bos_id, eos_id):
    results = {}
    for alpha in (0.0, 0.4, 0.8, 1.2):
        results[alpha] = rank_beams(beams, bos_id, eos_id, alpha)
    return results
```

Part 5 - The Philosophy Behind the Exercise

Every decoding score contains a theory of what a good sequence is. Length penalty makes one hidden preference visible and adjustable. Its deeper lesson is that inference is not neutral: once competing sequences must be ranked, an engineering choice becomes a value judgment expressed in mathematics.

17.9.10 Exercise 09

Exercise Title: Build a Seq2Seq Evaluation Pipeline Using BLEU Conceptually and Explain What BLEU Measures and Misses

Part 1 - Why this matters

BLEU evaluates overlap between generated and reference sequences using modified n-gram precision and a penalty for outputs that are too short. It is useful for reproducible corpus-level comparison, especially in translation-like tasks, but it does not directly measure truth, semantic equivalence, discourse quality, or usefulness. A fluent paraphrase may receive a low score; a harmful or incorrect sentence can share many n-grams and score well. This exercise builds the metric transparently and surrounds it with complementary evidence.

Normalize, tokenize, and detokenize predictions and references under a frozen policy. Keep special tokens and padding out of the metric. Implement clipped n-gram counts: a prediction cannot receive more credit for an n-gram than the maximum count present in its references. Aggregate counts over the corpus before taking the geometric mean. Handle zero counts with an explicit smoothing policy and report that policy. Apply the brevity penalty using total candidate and effective reference lengths.

Evaluate the same outputs with BLEU, exact match for synthetic tasks, token accuracy, length ratio, EOS success, repetition, and a small error taxonomy. Construct counterexamples: identical meaning with different wording, repeated high-overlap fragments, correct words in wrong order, and a short output that matches a common prefix. Explain how BLEU responds. Do not use sentence BLEU as if it had the stability of a sufficiently large corpus score, and do not compare numbers produced by different tokenization or smoothing conventions.

Part 2 - Mathematical form and reasoning

Modified precision for order n is

$$p_n = \frac{\sum_{g \in G_n(\hat{Y})} \min(c_{\hat{Y}}(g), \max_r c_{Y^{(r)}}(g))}{\sum_{g \in G_n(\hat{Y})} c_{\hat{Y}}(g)}.$$

For candidate corpus length c and effective reference length r, brevity penalty is

$$\mathrm{BP} = \begin{cases} 1, & c > r, \\ \exp(1 - r/c), & c \le r. \end{cases}$$

Then

$$\mathrm{BLEU} = \mathrm{BP} \exp\left(\sum_{n=1}^{N} w_n \log p_n \right).$$

The geometric mean requires performance across orders; a zero precision can collapse the unsmoothed score.

Part 3 - Hints, controls, and evidence

Unit-test n-gram extraction and clipping on lists short enough to count by hand. Preserve case and punctuation policy in the report. Use multiple references when the task genuinely permits multiple valid expressions. Bootstrap the evaluation set or report variation across subsets to avoid treating a small score difference as certainty. Store per-example outputs for error analysis but compute corpus BLEU from aggregated counts. Compare against a trusted metric implementation only after the manual version passes. Evidence should contain manual examples, corpus counts for every n, brevity penalty, final score, and the complementary metrics that reveal BLEU's blind spots.

Part 4 - Python code skeleton

```
import math
from collections import Counter

def extract_ngrams(tokens, order):
    counts = Counter()
    final_start = len(tokens) - order
    for start in range(final_start + 1):
        ngram = tuple(tokens[start:start + order])
        counts[ngram] += 1
    return counts

def clipped_counts(candidate, references, order):
    candidate_counts = extract_ngrams(candidate, order)
    maximum_reference_counts = Counter()
    for reference in references:
        reference_counts = extract_ngrams(reference, order)
        for ngram, count in reference_counts.items():
            previous = maximum_reference_counts[ngram]
            if count > previous:
                maximum_reference_counts[ngram] = count
    clipped = 0
    total = 0
    for ngram, count in candidate_counts.items():
        clipped += min(count, maximum_reference_counts[ngram])
        total += count
    return clipped, total

def brevity_penalty(candidate_length, reference_length):
    if candidate_length == 0:
        return 0.0
    if candidate_length > reference_length:
        return 1.0
    return math.exp(1.0 - reference_length / candidate_length)
```

```
def E09(candidate, references):
    precisions = []
    for order in range(1, 5):
        clipped, total = clipped_counts(candidate, references, order)
        precisions.append((clipped + 1.0) / (total + 1.0))
    reference_length = len(references[0])
    log_precision_sum = 0.0
    for value in precisions:
        log_precision_sum += math.log(value)
    score = brevity_penalty(len(candidate), reference_length)
    score *= math.exp(log_precision_sum / 4.0)
    return score, precisions
```

Replace the single-reference length rule with a documented closest-reference rule when multiple references are used at corpus scale.

Part 5 - The Philosophy Behind the Exercise

A metric is a compressed question. BLEU asks whether local pieces of generated language resemble reference pieces while discouraging extreme brevity. It does not ask whether the answer is true or sufficient. Scientific evaluation begins when we understand the question a number answers and refuse to make it testify about questions it was never designed to address.

17.9.11 Exercise 10

Exercise Title: Run Full Seq2Seq Training on CUDA and Benchmark Runtime, Memory, and Throughput for Different Sequence Lengths

Part 1 - Why this matters

Seq2seq cost depends on two lengths rather than one. Encoder self-attention scales with source length, decoder self-attention with target length, and cross- attention with their product. A benchmark that varies only batch size cannot explain which component exhausts memory or reduces throughput. Furthermore, asynchronous CUDA execution makes ordinary wall timing misleading unless device work is synchronized at measurement boundaries.

Move model, source IDs, target IDs, masks, labels, and any positional buffers to one CUDA device. Use pinned host memory and nonblocking transfers only after verifying the input pipeline can benefit. Separate data wait and transfer, forward, loss, backward, optimizer, and generation phases. Warm up kernels and allocator state, then measure a steady window. Record valid source tokens and valid target tokens rather than padded tensor elements, because padding can inflate apparent throughput.

Build a grid over source lengths, target lengths, and batch sizes. Change one axis at a time, and include both uniform-length and mixed-length batches. Record steps per second, valid target tokens per second, examples per second, peak allocated memory, reserved memory, and out-of-memory boundary. For inference, separate encoder time, decoder prefill, and per-token autoregressive decode. Synchronize around timings but remove unnecessary synchronization from the real training loop. Compare CPU only on configurations for which it is meaningful, and state hardware and software versions.

Part 2 - Mathematical form and reasoning

Ignoring constants and feed-forward work, attention score complexity is

$$\mathcal{O}(BS^2d) + \mathcal{O}(BT^2d) + \mathcal{O}(BSTd).$$

The three terms correspond to encoder self-attention, decoder self-attention, and cross-attention. Useful target throughput is

$$\tau_y = \frac{\sum_{i \in \text{measured steps}} N_{y,\text{valid}}^{(i)}}{t_{\text{measured}}}.$$

Padding efficiency is $\eta = N_{\text{valid}}/N_{\text{padded}}$. Report it with throughput so a faster batch is not credited merely for processing more pads.

Part 3 - Hints, controls, and evidence

Use identical model weights, precision, optimizer, and number of measured steps across comparable configurations. Reset peak memory immediately before the measured region. Exclude compilation and first allocation from steady-state numbers but report startup separately. Use CUDA events for GPU regions and a synchronized wall timer for end-to-end latency. Detect nonfinite loss and skip no batches silently. Record the exact configuration that produces OOM and the largest safe setting. Validate that increasing padding lowers useful-token efficiency even if raw tensor throughput looks stable. Evidence is a table and scaling curves, followed by a bottleneck explanation grounded in profiles.

Part 4 - Python code skeleton

```
import time
import torch

def timed_training_step(model, optimizer, batch, loss_function, device):
    source = batch["source"].to(device, non_blocking=True)
    decoder = batch["decoder"].to(device, non_blocking=True)

    torch.cuda.reset_peak_memory_stats(device)
    total_seconds = 0.0
    total_tokens = 0
    losses = []
    for batch in batches:
        loss, seconds, valid_tokens = timed_training_step(
            model, optimizer, batch, loss_function, device
        )
        losses.append(loss)
        total_seconds += seconds
        total_tokens += valid_tokens
    return {
        "mean_loss": sum(losses) / len(losses),
        "valid_tokens_per_second": total_tokens / total_seconds,
        "peak_allocated_bytes": torch.cuda.max_memory_allocated(device),
        "peak_reserved_bytes": torch.cuda.max_memory_reserved(device),
    }

def E10(model, optimizer, batches, loss_function):
    device = torch.device("cuda:0")
    model.to(device)
    return benchmark_configuration(
        model, optimizer, batches, loss_function, device
    )
```

Part 5 - The Philosophy Behind the Exercise

Performance is a property of a workload, not a device label. The GPU accelerates specific tensor structures under specific sizes and data conditions. Honest benchmarking reveals the geometry of cost: which length creates the burden, which work is useful, and where speed is being reported for computation the task never needed.

17.9.12 Exercise 11

Exercise Title: Implement Mixed Precision Seq2Seq Training and Identify Instability Cases in Cross-Attention Softmax

Part 1 - Why this matters

Mixed precision can reduce activation memory and accelerate matrix operations, allowing larger batches or sequences. Seq2seq Transformers also contain fragile operations: large query-key scores, masked softmax, normalization, exponentials, and small gradients. A run that is faster but occasionally emits NaNs, changes mask semantics, or silently skips many optimizer steps is not a successful optimization.

Build a float32 reference and an automatic mixed-precision run from identical weights and batches. Use autocast for supported compute and gradient scaling when float16 requires it. Keep attention logits and softmax in float32 in the scratch implementation, then cast normalized weights back to the value dtype. Apply masks before softmax with a representable value appropriate to the dtype, and explicitly reject fully masked rows. Log scaler value, skipped steps, nonfinite gradients, attention-score range, maximum cross-attention probability, entropy, loss difference, and output parity.

Stress source and target length, weight scale, learning rate, and mask sparsity. Construct extreme query and key tensors to reproduce overflow in a naive float16 softmax, then prove stable float32 softmax prevents it. Compare bfloat16 where supported because its exponent range differs from float16. Evaluate generated sequences as well as training loss: small logit changes can alter an early token and create a large autoregressive divergence.

Part 2 - Mathematical form and reasoning

The stable softmax uses

$$\operatorname{softmax}(z)_i = \frac{\exp(z_i - m)}{\sum_j \exp(z_j - m)}, \qquad m = \max_j z_j.$$

Subtracting m prevents positive exponential overflow, but masked values, nonfinite dot products, and insufficient accumulation precision still require care. Gradient scaling computes

$$\nabla_\theta(s\mathcal{L}) = s\nabla_\theta\mathcal{L}$$

in the backward pass and unscales before clipping or updating. If nonfinite gradients are found, the optimizer step is skipped and the scale is reduced.

Part 3 - Hints, controls, and evidence

Confirm the accelerator supports the selected dtype. Keep one fixed batch for step-level parity and a longer run for stability. Unscale before gradient norm measurement and clipping. Never call gradient clipping on scaled gradients. Monitor each attention layer separately to identify the first nonfinite tensor. Use identical masks and seeds; dropout complicates exact comparison, so begin in evaluation mode. Report speed, peak memory, final quality, skipped-step count, and the largest safe sequence or score range. Demonstrate at least one injected failure and its correction rather than reporting only a stable default.

Part 4 - Python code skeleton

```
import torch

def stable_attention_softmax(scores, blocked_mask):
    if blocked_mask.shape[-1] != scores.shape[-1]:
        raise ValueError("mask must address the key sequence axis")
    masked_scores = scores.float().masked_fill(blocked_mask, float("-inf"))
    fully_blocked = blocked_mask.all(dim=-1)
    if bool(fully_blocked.any()):
        raise ValueError("attention contains a fully blocked query row")
    probabilities = torch.softmax(masked_scores, dim=-1)
    if not bool(torch.isfinite(probabilities).all()):
```

```
        raise FloatingPointError("nonfinite attention probabilities")
    return probabilities.to(scores.dtype)

def mixed_precision_step(model, optimizer, scaler, batch, loss_function,
                         device, autocast_dtype):
    optimizer.zero_grad(set_to_none=True)
    with torch.autocast(device_type="cuda", dtype=autocast_dtype):
        logits = model.forward_batch(batch, device)
        labels = batch["labels"].to(device, non_blocking=True)
        loss = loss_function(
            logits.reshape(-1, logits.size(-1)), labels.reshape(-1)
        )
    if not bool(torch.isfinite(loss)):
        raise FloatingPointError("nonfinite mixed-precision loss")
    scaler.scale(loss).backward()
    scaler.unscale_(optimizer)
    gradient_norm = torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)
    previous_scale = scaler.get_scale()
    scaler.step(optimizer)
    scaler.update()
    new_scale = scaler.get_scale()
    skipped = new_scale < previous_scale
    return float(loss.item()), float(gradient_norm), skipped, new_scale

def E11(model, optimizer, batch, loss_function):
    device = torch.device("cuda:0")
    scaler = torch.amp.GradScaler("cuda")
    return mixed_precision_step(
        model, optimizer, scaler, batch, loss_function,
        device, torch.float16
    )
```

Part 5 - The Philosophy Behind the Exercise

Precision is a budget for representing distinctions. Mixed precision spends that budget selectively to gain speed and capacity. The correct question is not whether half precision runs, but whether every discarded numerical distinction is irrelevant to learning and generation. Optimization becomes trustworthy only when its approximation is bounded by evidence.

17.9.13 Exercise 12

Exercise Title: Implement Label Smoothing for Seq2Seq and Measure Its Effect on Generalization and Calibration

Part 1 - Why this matters

One-hot cross-entropy demands that all target probability move to one vocabulary item. In tasks with limited data, annotation ambiguity, or several acceptable phrases, this can encourage excessive confidence and brittle generalization. Label smoothing assigns most probability to the reference token and a small amount to alternatives. It can improve validation performance

and calibration, but too much smoothing weakens the learning signal and may harm exact tasks such as copying.

Implement the loss manually before using a built-in option. Exclude padding positions completely. Decide whether smoothing mass is spread across all classes or only non-reference classes, and state the convention. If PAD should never be generated, decide whether it belongs to the smoothed support; do not let an accidental vocabulary convention teach probability for padding. Compare the manual result with a trusted implementation on a small tensor.

Train matched models with several smoothing values using identical seeds, updates, and data. Measure training negative log-likelihood, validation NLL, token accuracy, exact match or BLEU, confidence, entropy, expected calibration error, and reliability diagrams. A smoothed training objective is not directly comparable to unsmoothed NLL, so evaluate all models with the same unsmoothed metric. Inspect correct and incorrect token confidence separately and test distribution shift or mild label noise.

Part 2 - Mathematical form and reasoning

For vocabulary size V, reference class y, and smoothing ε, one non-reference convention is

$$q_k = \begin{cases} 1-\varepsilon, & k = y, \\ \varepsilon/(V-1), & k \neq y. \end{cases}$$

The loss is

$$\mathcal{L}_{\mathrm{LS}} = -\sum_{k=1}^{V} q_k \log p_k.$$

Calibration compares confidence with empirical accuracy. For confidence bins B_m, expected calibration error is

$$\mathrm{ECE} = \sum_m \frac{|B_m|}{N} |\operatorname{acc}(B_m) - \operatorname{conf}(B_m)|.$$

Lower ECE is useful only alongside task quality; a uniformly uncertain model may be calibrated yet unhelpful.

Part 3 - Hints, controls, and evidence

Unit-test epsilon zero against ordinary cross-entropy. Verify each constructed target distribution sums to one and has no negative entry. Apply the valid-token mask before reduction and divide by the exact valid count. Keep validation scoring unsmoothed. Use sufficiently populated calibration bins and report bin counts. Compare confidence at the first autoregressive error, because exposure can amplify overconfidence. Evidence includes loss parity tests, quality and calibration tables, reliability data, and a clear choice of epsilon based only on validation results.

Part 4 - Python code skeleton

```
import torch

def label_smoothed_loss(logits, labels, padding_id, epsilon):
```

```
    vocabulary_size = logits.size(-1)
    flat_logits = logits.reshape(-1, vocabulary_size).float()
    flat_labels = labels.reshape(-1)
    valid = flat_labels.ne(padding_id)
    valid_logits = flat_logits[valid]
    valid_labels = flat_labels[valid]
    log_probabilities = torch.log_softmax(valid_logits, dim=-1)

    reference_log_probability = log_probabilities.gather(
        1, valid_labels[:, None]
    ).squeeze(1)
    total_log_probability = log_probabilities.sum(dim=-1)
    nonreference_log_probability = total_log_probability
    nonreference_log_probability = (
        nonreference_log_probability - reference_log_probability
    )
    reference_loss = -(1.0 - epsilon) * reference_log_probability
    nonreference_loss = -epsilon * nonreference_log_probability
    nonreference_loss = nonreference_loss / (vocabulary_size - 1)
    return (reference_loss + nonreference_loss).mean()

def calibration_bins(probabilities, labels, padding_id, number_of_bins):
    confidence, prediction = probabilities.max(dim=-1)
    valid = labels.ne(padding_id)
    confidence = confidence[valid]
    correct = prediction[valid].eq(labels[valid])
    rows = []
    for bin_index in range(number_of_bins):
        lower = bin_index / number_of_bins
        upper = (bin_index + 1) / number_of_bins
        members = (confidence > lower) & (confidence <= upper)
        count = int(members.sum().item())
        if count > 0:
            rows.append((count, float(confidence[members].mean().item()),
                         float(correct[members].float().mean().item())))
    return rows

def E12(logits, labels, padding_id):
    return label_smoothed_loss(logits, labels, padding_id, epsilon=0.1)
```

Part 5 - The Philosophy Behind the Exercise

Certainty is not the same as knowledge. Label smoothing asks the learner to reserve a small space for alternatives, but that humility must match the task. In an exact symbolic transformation, ambiguity may be artificial; in language, it may be honest. Regularization is strongest when it expresses a defensible belief about the world rather than a fashionable default.

17.9.14 Exercise 13

Exercise Title: Implement Scheduled Sampling Conceptually and Compare It Against Teacher Forcing for Exposure Bias

Part 1 - Why this matters

Teacher forcing conditions every training prediction on a correct target prefix, while inference conditions later predictions on the model's earlier choices. This mismatch is exposure bias: the model is rarely trained to recover from the states created by its own mistakes. Scheduled sampling sometimes replaces a reference decoder input with a model-generated token during training. It exposes the model to its own trajectory, but changes the objective, reduces parallelism, and can propagate low-quality early predictions.

Implement a controlled autoregressive training loop on a small seq2seq task. At target step t, compute logits from the current mixed prefix, select or sample a model token, and use a Bernoulli decision to choose between that token and the reference token for the next input. Never replace BOS. Do not overwrite the label: supervision still asks for the reference next token. Detach selected discrete tokens so the code does not imply a differentiable path through the sampling decision.

Compare constant teacher forcing with linear or inverse-sigmoid schedules. Log the realized model-token fraction, not only the requested probability. Measure teacher-forced validation loss, autoregressive exact match or BLEU, recovery after an injected wrong token, training time, and variance across seeds. Begin scheduled sampling only after the model has learned basic alignment; otherwise the decoder may train mostly on meaningless prefixes. Discuss the method's objective inconsistency rather than presenting it as a universal correction.

Part 2 - Mathematical form and reasoning

Let $r_t \sim \text{Bernoulli}(\rho_e)$ at epoch e. The next decoder input is

$$\widetilde{y}_t = \begin{cases} y_t, & r_t = 0, \\ \widehat{y}_t, & r_t = 1, \end{cases}$$

where $\widehat{y}_t$ is chosen from the model distribution conditioned on the mixed prefix. A linear schedule might be

$$\rho_e = \min(\rho_{\max}, \max(0, (e - e_0)\Delta\rho)).$$

Because the distribution of training prefixes now depends on the current model, the expected objective differs from maximum likelihood under clean data.

Part 3 - Hints, controls, and evidence

Use an explicit seeded generator for Bernoulli decisions and token sampling. Apply decisions only to active non-padding rows. Decide whether EOS-completed rows receive PAD or EOS thereafter. Compare greedy replacement with sampled replacement. Match update count and compute budget when possible, and report the extra sequential cost. Test recovery by forcing one incorrect decoder token at a known position and measuring whether later outputs realign. Record schedule, realized replacement rate, loss, autoregressive quality, and seed variation. Include a case where scheduled sampling harms performance; negative evidence is important for selecting rather than merely demonstrating the technique.

Part 4 - Python code skeleton

```
import torch

def scheduled_sampling_probability(epoch, start_epoch, increment, maximum):
    if epoch < start_epoch:
        return 0.0
    value = (epoch - start_epoch) * increment
    return min(maximum, value)

def build_mixed_decoder_input(model, memory, source_mask, full_target,
                              replacement_probability, generator):
    decoder = full_target[:, :1]
    target_steps = full_target.size(1) - 1
    decisions = []
    for step in range(target_steps - 1):
        logits = model.decode(decoder, memory, source_mask)
        model_token = logits[:, -1, :].argmax(dim=-1).detach()
        reference_token = full_target[:, step + 1]
        random_values = torch.rand(
            reference_token.shape, device=reference_token.device,
            generator=generator
        )
        use_model = random_values < replacement_probability
        chosen = torch.where(use_model, model_token, reference_token)
        decoder = torch.cat((decoder, chosen[:, None]), dim=1)
        decisions.append(use_model)
    return decoder, decisions

def E13(model, source_ids, source_mask, full_target, epoch, generator):
    model.train()
    memory = model.encode(source_ids, source_mask)
    probability = scheduled_sampling_probability(
        epoch, start_epoch=5, increment=0.05, maximum=0.5
    )
    decoder, decisions = build_mixed_decoder_input(
        model, memory, source_mask, full_target, probability, generator
    )
    return decoder, decisions, probability
```

Part 5 - The Philosophy Behind the Exercise

Training creates the world in which a model learns to act. Teacher forcing gives perfect history; inference gives consequences. Scheduled sampling asks whether practice should contain some of those consequences. Its philosophical warning is equally important: realism introduced without control can become noise, and exposure to failure is useful only when the learner has a path to recovery.

17.9.15 Exercise 14

Exercise Title: Profile GPU Kernels and Identify Whether Encoder or Decoder Dominates Cost for Your Task

Part 1 - Why this matters

An encoder-decoder model has several computational phases whose dominance changes with workload. A long source and short target may make the encoder largest; long teacher-forced targets add decoder self-attention and cross- attention; autoregressive generation repeatedly invokes the decoder while the encoder normally runs once. Optimizing the architecture without measuring the actual phase can accelerate a component that contributes little to user-visible latency.

Instrument encoder forward, decoder self-attention, cross-attention, decoder feed-forward layers, loss, backward, optimizer, encoder prefill, and each generation step. Use named profiler ranges and collect CPU and CUDA activity, shapes, memory, kernel counts, and call stacks for a short representative window. Profile training and inference separately. Detailed profiling adds overhead, so use it for attribution and use lightweight CUDA-event timing for final performance numbers.

Repeat across source-target length pairs, batch sizes, and teacher-forced versus autoregressive modes. Aggregate kernel time by phase rather than listing only the largest individual matrix multiplication. Identify CPU gaps, synchronization, padding waste, repeated encoder computation, and small decoder kernels. Make one targeted change, such as bucketing lengths, reusing encoder memory, compiling a block, or increasing generation batch size, then re-profile and report end-to- end improvement. A faster isolated kernel is not evidence of a faster service.

Part 2 - Mathematical form and reasoning

Total training time can be decomposed as

$$t_{\text{train}} = t_{\text{data}} + t_{\text{enc}} + t_{\text{dec,self}} + t_{\text{cross}} + t_{\text{FFN}} + t_{\text{loss}} + t_{\text{backward}} + t_{\text{optimizer}} + t_{\text{sync}} - t_{\text{overlap}}.$$

Autoregressive inference is approximately

$$t_{\text{request}} = t_{\text{encode}} + t_{\text{start}} + \sum_{u=1}^{U} t_{\text{decode}}(u) + t_{\text{control}}.$$

The phase share $r_i = t_i / t_{\text{request}}$ identifies the dominant non-overlapped cost. The sum also shows why decoder work can dominate even when one decoder step is cheaper than encoding.

Part 3 - Hints, controls, and evidence

Warm up before profiling, keep the measured schedule short, and avoid printing inside it. Synchronize only at deliberate measurement boundaries. Label phases with `record_function`; otherwise kernels from encoder and decoder may be indistinguishable. Use a fixed batch and repeat profiles for stability. Report both self CUDA time and total CUDA time, plus kernel launch counts and peak memory. Confirm encoder memory is computed once during generation. If the CPU is the bottleneck, GPU kernel percentages alone are incomplete. Evidence is a phase table before and after one intervention, with unchanged output parity and quality metrics.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import ProfilerActivity, profile, record_function

def profiled_seq2seq_step(model, batch, optimizer, loss_function, device):
    source = batch["source"].to(device)
    decoder = batch["decoder"].to(device)
    labels = batch["labels"].to(device)
    source_mask = batch["source_mask"].to(device)
    optimizer.zero_grad(set_to_none=True)

    with record_function("encoder"):
        memory = model.encode(source, source_mask)
    with record_function("decoder"):
        logits = model.decode(decoder, memory, source_mask)
    with record_function("loss"):
        loss = loss_function(
            logits.reshape(-1, logits.size(-1)), labels.reshape(-1)
        )
    with record_function("backward"):
        loss.backward()
    with record_function("optimizer"):
        optimizer.step()
    return loss

def E14(model, batch, optimizer, loss_function):
    device = torch.device("cuda:0")
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    with profile(
        activities=activities, record_shapes=True, profile_memory=True
    ) as profiler:
        loss = profiled_seq2seq_step(
            model, batch, optimizer, loss_function, device
        )
    table = profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=30
    )
    return float(loss.item()), table
```

Part 5 - The Philosophy Behind the Exercise

Profiling disciplines attention in the human sense: it directs effort toward the part of reality that controls the outcome. Architecture diagrams distribute visual importance evenly; execution does not. Optimization begins when measured time, memory, and dependency replace intuition as the map of the system.

17.9.16 Exercise 15

Exercise Title: Implement Checkpointing and Resume for Seq2Seq Training and Verify State Consistency

Part 1 - Why this matters

A checkpoint is a promise that interrupted training can continue with the same meaning. Saving model weights alone permits fine-tuning, but it does not resume an optimizer trajectory. Adam moments, scheduler position, gradient scaler, completed epoch and batch, random-number states, sampler order, configuration, tokenizer identity, and data split all influence the next update. Losing one can create a silent branch in the experiment while the program prints "resumed."

Define a versioned checkpoint schema. Save model, optimizer, scheduler, scaler, global update, epoch, batch position or sampler state, Python and PyTorch RNG states, CUDA RNG states, model/data/tokenizer configuration, validation history, and the best-checkpoint criterion. Write to a temporary path and atomically rename only after serialization succeeds. Store a checksum and reject corrupt or incompatible files before mutating live objects. Never load untrusted pickle- based checkpoints.

Prove exact continuation with a fork test. Train a deterministic tiny seq2seq model for K updates and save. Branch A continues for M updates without interruption. Branch B starts from a fresh process or fresh objects, restores, and consumes the same next batches for M updates. Compare learning rates, losses, scaler values, model parameters, optimizer tensors, scheduler state, and generated outputs after every step. If exact equality is unsupported on the chosen CUDA path, document the deterministic limits and use justified numerical tolerances rather than claiming exactness.

Part 2 - Mathematical form and reasoning

Training state is more than parameters:

$$S_k = (\theta_k, O_k, R_k, G_k, \mathcal{R}_k, D_k, C),$$

where O is optimizer state, R scheduler state, G gradient-scaler state, $\mathcal{R}$ random state, D data progress, and C immutable configuration. A correct resume satisfies

$$U(S_k, B_{k+1}) = S_{k+1}$$

for uninterrupted and restored executions under the same batch B_{k+1}. Measure maximum parameter error and compare discrete outputs because a small numeric deviation may later alter decoding.

Part 3 - Hints, controls, and evidence

Construct the model and optimizer before loading their states, then move optimizer tensors to the intended device if required. Restore RNG after object initialization that consumes randomness. Validate vocabulary size, special IDs, architecture, and scheduler definition before continuing. Save at a clear boundary after an optimizer step, and define whether the recorded batch is last completed or next to consume. Test missing file, truncated file, mismatched configuration, CPU load of CUDA checkpoint, and scaler absence. Evidence includes schema, checksum, fork-test traces, maximum state differences, and an intentional incomplete-checkpoint failure.

Part 4 - Python code skeleton

```
import os
import random
import torch

def capture_training_state(model, optimizer, scheduler, scaler,
                           epoch, global_step, configuration):
    cuda_random_state = None
    if torch.cuda.is_available():
        cuda_random_state = torch.cuda.get_rng_state_all()
    state = {

    return checkpoint_path
```

Part 5 - The Philosophy Behind the Exercise

Reproducibility is continuity of causes. A checkpoint preserves not only what the model became, but the forces positioned to change it next. Resuming weights without momentum, randomness, and data position creates a new history wearing the old experiment's name. Honest recovery preserves identity or clearly marks the branch.

17.9.17 Exercise 16

Exercise Title: Export Seq2Seq Model and Validate Inference Parity and Deployment Constraints

Part 1 - Why this matters

Seq2seq export has more state and shape variation than a single forward graph. The encoder consumes a variable source and creates reusable memory. The decoder consumes a growing target, source mask, positions, and possibly a per-layer cache. Generation adds beam management, EOS rules, and sampling outside the neural network. Exporting one teacher-forced forward pass does not prove that autoregressive inference or cached beam search can be deployed correctly.

Define explicit export boundaries. An encoder graph maps source IDs and source validity to memory. A decoder graph maps target tokens, encoder memory, source validity, positions, and optional past state to logits and new state. Flatten nested caches in a documented layer/key/value order if the export runtime does not support the native structure. Declare dynamic batch, source length, target length, and cache length axes. Keep tokenization, beam search, and stopping in a tested host controller unless their export semantics are equally clear.

Validate native and exported executions across several source-target length pairs, padding patterns, batches, and precision modes. Compare encoder memory, decoder logits, cache tensors, greedy tokens, and complete short sequences. Tracing can freeze shape-dependent Python logic, ONNX backends may lower masks or attention operators differently, and dynamic cache shapes may be unsupported. Record limitations rather than hiding them behind one successful example. Benchmark export time, runtime initialization, encoder latency, decoder prefill, per-token decode, end-to-end generation, model size, and memory.

Part 2 - Mathematical form and reasoning

The two deployment contracts are

$$f_{\text{enc}}(X, M_x) \to H,$$

$$f_{\text{dec}}(Y, H, M_x, P, K_{<t}) \to (Z, K_{\le t}).$$

For native output Z and exported output $\widehat{Z}$, report

$$e_{\max} = \max_i |Z_i - \widehat{Z}_i|, \qquad e_{\text{rel}} = \frac{\|Z - \widehat{Z}\|_2}{\|Z\|_2 + \varepsilon}.$$

Also compare $\arg\max Z$ and complete decoded tokens. Numerical closeness does not guarantee sequence equality when two logits are nearly tied.

Part 3 - Hints, controls, and evidence

Use evaluation mode and inference mode. Freeze checkpoint, tokenizer, special IDs, masks, and stopping policy. Export small wrappers with only tensor inputs and outputs. Make causal and source masks explicit and test non-square lengths. Test all-padding rejection and at least one mixed-length batch. Warm each runtime before timing and synchronize device work. Save the first divergent step and tensor, not only the final different sentence. Evidence includes an interface schema, dynamic-axis table, parity matrix, supported/unsupported configuration list, latency breakdown, and a deterministic generation trace.

Part 4 - Python code skeleton

```
import time
import torch
from torch import nn

class EncoderExport(nn.Module):
    def __init__(self, model):
        super().__init__()
        self.model = model

    def forward(self, source_ids, source_mask):
        return self.model.encode(source_ids, source_mask)

class DecoderExport(nn.Module):
    def __init__(self, model):
        super().__init__()
        self.model = model

    def forward(self, decoder_ids, memory, source_mask):
        return self.model.decode(decoder_ids, memory, source_mask)

def parity(reference, candidate, absolute_tolerance, relative_tolerance):
    difference = (reference - candidate).abs()
    maximum_error = float(difference.max().item())
    close = torch.allclose(
        reference, candidate,
        atol=absolute_tolerance, rtol=relative_tolerance
    )
    same_token = torch.equal(reference.argmax(-1), candidate.argmax(-1))
    return close, same_token, maximum_error

@torch.inference_mode()
def E16(model, source_ids, source_mask, decoder_ids):
    model.eval()
    encoder = EncoderExport(model)
    decoder = DecoderExport(model)
```

```
encoder_example = (source_ids, source_mask)
traced_encoder = torch.jit.trace(encoder, encoder_example, strict=False)
native_memory = encoder(source_ids, source_mask)
exported_memory = traced_encoder(source_ids, source_mask)
memory_result = parity(native_memory, exported_memory, 1e-5, 1e-4)

decoder_example = (decoder_ids, native_memory, source_mask)
traced_decoder = torch.jit.trace(decoder, decoder_example, strict=False)
native_logits = decoder(decoder_ids, native_memory, source_mask)
exported_logits = traced_decoder(
    decoder_ids, exported_memory, source_mask
)
logit_result = parity(native_logits, exported_logits, 1e-5, 1e-4)
return memory_result, logit_result
```

Extend this reference with separate cached-decode exports and validate cache ordering before using it in beam search.

Part 5 - The Philosophy Behind the Exercise

Export moves computation across an institutional boundary: a new runtime, hardware stack, and control system become responsible for the model's meaning. Serialization transfers bytes; validation transfers trust. A deployable model is one whose conditional behavior survives that transfer under the shapes and states the real world will present.

17.9.18 Exercise 17

Exercise Title: Stress Test Seq2Seq Generation for Long Source Inputs and Detect Memory and Latency Failure Conditions

Part 1 - Why this matters

Long-source seq2seq inference can fail before the requested target becomes long. Encoder self-attention materializes relationships among source positions; cross-attention compares every decoder query with the source; encoder memory is retained throughout generation; and beam search duplicates decoder state across hypotheses. A short benchmark can hide nonlinear latency, out-of-memory events, mask allocation mistakes, positional limits, and timeouts that appear only near the deployment boundary.

Construct a stress matrix over source length, generated target length, batch, beam width, precision, and padding ratio. Increase one dimension at a time from a verified baseline. Log encoder latency, first-token latency, per-token decoder latency, total request latency, useful throughput, encoder-memory bytes, decoder- cache bytes, peak allocated and reserved CUDA memory, and output correctness. Record the last successful and first failed configuration. Treat OOM, NaN, timeout, violated mask parity, excessive latency, and wrong termination as distinct failure conditions.

Repeat identical requests after releasing request-local tensors. Expected memory for encoder representation remains proportional to source length during one request; retained growth across completed equal-size requests indicates a leak or lingering reference. Reserved allocator memory may stay high without being a leak, so compare allocated memory and live tensor ownership

at equal checkpoints. Test a source exceeding learned positional capacity and reject it cleanly or apply a documented extension strategy. If chunking or truncation is introduced, measure its effect on output meaning; bounded compute is not free when relevant source evidence is discarded.

Part 2 - Mathematical form and reasoning

Approximate dominant attention storage includes

$$M_{\text{scores}} \propto BH(S^2 + T^2 + ST)s,$$

where s is bytes per scalar. Encoder memory itself is approximately

$$M_H = BSds.$$

With beam width W, decoder-side states may scale with BW, while encoder memory may be shared or physically repeated depending on implementation. Define the latency failure boundary by a service objective $t_{p95} > t_{\max}$ and the memory boundary by peak allocated memory approaching the device budget with a declared safety margin.

Part 3 - Hints, controls, and evidence

Run under inference mode and start with greedy decoding. Warm up, synchronize measurements, and avoid storing full logits or attention maps in the stress loop. Save scalar summaries on CPU. Assert source-mask length, positional bounds, finite encoder memory, cache growth, EOS state, and maximum output length at every checkpoint. Test both dense valid sources and heavy padding because equal tensor length can contain different useful work. Repeat trials to distinguish allocator reuse from drift. If a configuration fails, capture the exception, input dimensions, memory just before failure, and minimal reproducer. Evidence is a scaling surface and a declared safe operating envelope, not one maximum.

Part 4 - Python code skeleton

```
import gc
import time
import torch

@torch.inference_mode()
def stress_one_request(model, source_ids, source_mask, bos_id,
                       maximum_new_tokens, device):
    model.eval()
    torch.cuda.reset_peak_memory_stats(device)
    torch.cuda.synchronize(device)
    request_start = time.perf_counter()

    encoder_start = torch.cuda.Event(enable_timing=True)
    encoder_end = torch.cuda.Event(enable_timing=True)
    encoder_start.record()
    memory = model.encode(source_ids, source_mask)
    encoder_end.record()
    torch.cuda.synchronize(device)
```

```
    generated = torch.full(
        (source_ids.size(0), 1), bos_id,
        dtype=torch.long, device=device
    )
    token_latencies = []
    for step in range(maximum_new_tokens):
        step_start = torch.cuda.Event(enable_timing=True)
        step_end = torch.cuda.Event(enable_timing=True)
        step_start.record()
        logits = model.decode(generated, memory, source_mask)
        next_token = logits[:, -1, :].argmax(dim=-1, keepdim=True)
        generated = torch.cat((generated, next_token), dim=1)
        step_end.record()
        torch.cuda.synchronize(device)
        token_latencies.append(step_start.elapsed_time(step_end))

    request_seconds = time.perf_counter() - request_start
    return {
        "source_length": source_ids.size(1),
        "output_length": generated.size(1) - 1,
        "encoder_ms": encoder_start.elapsed_time(encoder_end),
        "token_ms": token_latencies,
        "request_seconds": request_seconds,
        "peak_allocated": torch.cuda.max_memory_allocated(device),
        "peak_reserved": torch.cuda.max_memory_reserved(device),
    }

def release_request():
    gc.collect()
    if torch.cuda.is_available():
        torch.cuda.synchronize()

def E17(model, source_ids, source_mask, bos_id):
    return stress_one_request(
        model, source_ids, source_mask, bos_id, 128, source_ids.device
    )
```

Add EOS and cached decoding after the uncached reference passes; retain both so cache speedups cannot conceal semantic disagreement.

Part 5 - The Philosophy Behind the Exercise

Scale is where assumptions become physical. A mathematically valid architecture must still live within finite memory, time, and positional contracts. Stress testing does not ask how far the system can be pushed once; it discovers the region in which behavior remains correct, predictable, and recoverable.

17.9.19 Exercise 18

Exercise Title: Build a Full Seq2Seq Debugging Checklist Covering Masks, Shifts, Alignment, and Decoding Settings

Part 1 - Why this matters

Seq2seq failures cross boundaries. A tokenizer can change special IDs; a collate function can shift targets incorrectly; an encoder mask can hide valid source tokens; a decoder causal mask can leak the answer; cross-attention can broadcast one row's padding across another; beam search can reorder tokens without reordering cache; and EOS policy can truncate useful content. Fluent output and decreasing loss are compatible with several of these defects. The solution is an executable, dependency-ordered audit.

Start with artifact identity and raw examples. Verify dataset split, tokenizer fingerprint, vocabulary sizes, PAD/BOS/EOS IDs, source IDs, full targets, and lengths. Next verify shifted decoder inputs and labels, valid-token loss count, source padding, target padding, causal visibility, and batch-row isolation. Then verify encoder memory, cross-attention source dependence, finite logits, gradient reachability, and tiny-batch overfitting. Only after these contracts pass should autoregressive generation, beam scoring, length penalty, stopping, mixed precision, export, and performance be debugged.

Every checklist item must specify an invariant, test input, assertion, captured evidence, and known fault injection. For example, future-target intervention must not change earlier logits; padded-source intervention must not change valid outputs; valid-source intervention should change a conditioned output; beam one must equal greedy; batched generation must match independent generation under the same policy; resumed training must match uninterrupted continuation. A line that says "inspect masks" is advice, not protection.

Part 2 - Mathematical form and reasoning

Represent the pipeline as contracts

$$(X, Y) \xrightarrow{\mathcal{D}} (I_x, I_y, L, M_x, M_y) \xrightarrow{\mathcal{E}} H \xrightarrow{\mathcal{R}} Z \xrightarrow{\mathcal{G}} \widehat{Y} \xrightarrow{\mathcal{V}} R.$$

Data preparation $\mathcal{D}$, encoding $\mathcal{E}$, decoder retrieval $\mathcal{R}$, generation $\mathcal{G}$, and evaluation $\mathcal{V}$ each own invariants. Diagnose the earliest violated contract. Examples include

$$Z_{\le t}(Y_{>t}) = Z_{\le t}(Y'_{>t}), \qquad Z(X_{\text{pad}}) = Z(X'_{\text{pad}}),$$

and cached/full-prefix logit parity at every generated step.

Part 3 - Hints, controls, and evidence

Run greedy float32 evaluation first to remove sampling and precision variables. Use unique IDs and non-square source/target lengths. Include batch one and many, left and right padding if supported, source length one, early EOS, no EOS, maximum length, near-tied logits, and fully invalid inputs that must be rejected. Log first divergence, mask slices, positions, top logits, attention mass, cache shapes, stop reason, RNG state, and configuration. Do not relax tolerances until the error scale and decision effect are understood. Require every regression test to fail when its associated known bug is injected.

Part 4 - Python code skeleton

```
class Seq2SeqAudit:
    def __init__(self):
        self.records = []

    def require(self, name, condition, details):
        passed = bool(condition)
        record = {"name": name, "passed": passed, "details": details}
        self.records.append(record)
        if not passed:
            raise AssertionError(str(record))

def audit_shift(full_target, decoder_ids, labels, audit):
    audit.require(
        "decoder shift",
        (decoder_ids == full_target[:, :-1]).all(),
        {"decoder_shape": tuple(decoder_ids.shape)},
    )
    audit.require(
        "label shift",
        (labels == full_target[:, 1:]).all(),
        {"label_shape": tuple(labels.shape)},
    )

def audit_cross_weights(weights, source_valid, audit):
    visible = source_valid[:, None, None, :]
    padding_mass = weights.masked_fill(visible, 0.0).sum(dim=-1)
    row_sum = weights.masked_fill(~visible, 0.0).sum(dim=-1)
    audit.require(
        "zero source padding mass",
        padding_mass.max() < 1e-6,
        {"maximum_padding_mass": float(padding_mass.max().item())},
    )
    audit.require(
        "cross-attention normalized",
        (row_sum - 1.0).abs().max() < 1e-5,
        {"maximum_row_error": float((row_sum - 1.0).abs().max().item())},
    )

def audit_decoder_equivalence(greedy_tokens, beam_one_tokens, audit):
    audit.require(
        "beam width one equals greedy",
        (greedy_tokens == beam_one_tokens).all(),
        {"shape": tuple(greedy_tokens.shape)},
    )

def E18(full_target, decoder_ids, labels, weights, source_valid,
        greedy_tokens, beam_one_tokens):
    audit = Seq2SeqAudit()
```

```
    audit_shift(full_target, decoder_ids, labels, audit)
    audit_cross_weights(weights, source_valid, audit)
    audit_decoder_equivalence(greedy_tokens, beam_one_tokens, audit)
    return audit.records
```

Extend the registry with causal intervention, padded-source invariance, gradient checks, resume parity, mixed-precision finiteness, export parity, and stress limits. Keep each failure record independently reproducible.

Part 5 - The Philosophy Behind the Exercise

Debugging is the search for the first broken agreement. Complex pipelines tempt us to inspect the final symptom, but causality flows from data contracts through visibility, representation, decisions, and control. An executable checklist turns institutional memory into a system that can object when an old mistake returns.

17.9.20 Exercise 19

Exercise Title: Produce a Complete Seq2Seq Transformer Engineering Report Covering Training, Decoding, and Failure Analysis

Part 1 - Why this matters

The final report must make the entire seq2seq system reproducible and reviewable. It is not a list of successful metrics. It connects data alignment, masks, encoder memory, cross-attention, optimization, teacher forcing, autoregressive decoding, search policy, numerical precision, hardware behavior, export, and failure recovery. Another engineer should be able to reproduce the model, understand why each default was chosen, and recognize when the evidence no longer applies.

Record experiment identity first: code version, environment, hardware, dataset and split fingerprints, tokenizer version, special-token IDs, normalization, model dimensions, parameter count, initialization, seed controls, precision, optimizer, schedule, batch construction, checkpoint, and resume history. Report training and validation loss, token accuracy, exact match or BLEU, calibration, gradient norms, throughput, and peak memory. Include tiny-task overfitting and mask intervention results as correctness evidence.

Treat decoding as its own controlled study. Compare greedy, beam widths, length penalties, and relevant sampling policies on matched inputs. Report raw and normalized sequence scores, length, EOS success, repetition, exact match or BLEU, latency, and memory. Include cross-attention diagnostics without claiming they are complete explanations. Document mixed-precision differences, encoder and decoder profile shares, resume parity, export parity, and the long-source safe operating envelope. Preserve failed experiments with symptom, reproduction, root cause, correction, regression test, and remaining risk. End with defaults, exceptions, limitations, and measurable triggers for revisiting decisions.

Part 2 - Mathematical form and reasoning

Model fit is summarized by conditional negative log-likelihood

$$\mathcal{L}_{\mathrm{NLL}} = -\frac{1}{N}\sum_{b,t} \log p_\theta(y_{b,t} \mid y_{b,<t}, x_b),$$

but engineering selection is multi-objective. For configuration c, define

$$R(c) = (Q_c, C_c, L_c, M_c, T_c, F_c),$$

where Q is task quality, C calibration, L latency, M memory, T throughput, and F failure rate. Do not collapse this vector into one number without justified weights. Report variation across seeds, examples, and length buckets. A production limit is a measured boundary with a failure criterion, not the largest input that survived once.

Part 3 - Hints, controls, and evidence

Use a fixed schema and link every claim to a table, plot, trace, sample, or test. Separate observations, interpretations, and recommendations. State tokenization, metric implementation, smoothing, beam scoring, timing boundary, warm-up, hardware, padding efficiency, and exclusions. Select qualitative examples by a predeclared rule such as first failure per length bucket, not by attractiveness. Validate that recommendations cite evidence and that generation has explicit maximum length and stop policy. Include unknowns honestly. A negative result can prevent repeated waste and therefore belongs in the permanent report.

Part 4 - Python code skeleton

```
import json
from pathlib import Path

REQUIRED_SECTIONS = (
    "experiment_identity",

)

def validate_report(report):
    errors = []
    for section in REQUIRED_SECTIONS:
        if section not in report:
            errors.append("missing section: " + section)
    identity = report.get("experiment_identity", {})
    required_identity = (
        "code_version", "checkpoint_hash", "dataset_hash",
        "tokenizer_hash", "seed", "device"
    )
```

```
    for field in required_identity:
        if field not in identity:
            errors.append("missing identity field: " + field)
    defaults = report.get("recommended_defaults", {})
    for field in ("beam_width", "length_penalty", "maximum_tokens",
                  "evidence_ids"):
        if field not in defaults:
            errors.append("missing decoding default: " + field)
    failures = report.get("failure_registry", [])
    for index in range(len(failures)):
        failure = failures[index]
        required = ("symptom", "reproduction", "root_cause",
                    "fix", "regression_test")
        for field in required:
            if field not in failure:
                message = "failure " + str(index) + " missing " + field
                errors.append(message)
    if errors:
        raise ValueError("\n".join(errors))

def save_report(report, output_path):
    validate_report(report)
    path = Path(output_path)
    path.parent.mkdir(parents=True, exist_ok=True)
    with path.open("w", encoding="utf-8") as handle:
        json.dump(report, handle, indent=2, sort_keys=True)

def E19(report):
    output_path = "reports/trf07_seq2seq_engineering_report.json"
    save_report(report, output_path)
    return output_path
```

Generate human-readable tables from the same structured record so narrative and machine-verifiable evidence cannot silently diverge.

Part 5 - The Philosophy Behind the Exercise

An engineering report transfers responsibility. It preserves what was tested, what failed, why a decision was made, and what future observation should change that decision. The final achievement is not merely conditional generation; it is a chain of evidence strong enough that another researcher can inherit the system without inheriting its hidden assumptions.

17.10 TRF08

Chapter Title: Efficiency, Long Context, and Production Readiness
Specialization: Applied AI and Deployment

17.10.1 Exercise 00

Exercise Title: Explain Why Attention Is $O(\text{seq}^2)$ and Identify When Long Context Becomes Impossible on Your GPU

Part 1 - Why this matters

Long context is not obtained by changing one maximum-length constant. Standard self-attention compares every query position with every key position. Doubling sequence length therefore creates four times as many pairwise scores, before accounting for gradients, saved activations, masks, temporary buffers, and the rest of the Transformer. A configuration can be mathematically valid yet physically impossible on a particular GPU. The useful skill is to predict that boundary, measure it safely, and explain which allocation reaches it first.

Start from tensor shapes rather than asymptotic notation. For batch B, heads H, sequence length L, and head width d_h, queries, keys, and values occupy linear memory in L, while the score and probability tensors have shape (B, H, L, L). During training, autograd may retain inputs or intermediates for the backward pass. Optimized kernels may avoid materializing the full probability matrix, whereas a naive implementation does not. Consequently, $O(L^2)$ describes scaling, not the exact byte total.

Build an analytic estimator that separately reports parameters, gradients, optimizer state, Q/K/V tensors, attention scores, probabilities, other layer activations, and a safety margin. Then measure peak allocated and reserved CUDA memory for increasing lengths using a fixed model, batch, dtype, and mode. Increase gradually and catch out-of-memory errors without crashing the whole experiment. Record the largest successful length and first failure for forward inference, cached decoding, and training; they have different memory profiles. Do not report the failure point as a universal model limit without hardware, kernel, precision, batch, layer count, and free-memory context.

Part 2 - Mathematical form and reasoning

Score construction for one layer is

$$S = \frac{QK^\top}{\sqrt{d_h}}, \qquad S \in \mathbb{R}^{B\times H\times L\times L}.$$

Its element count is BHL^2 and its storage is approximately

$$M_S = BHL^2 s,$$

where s is bytes per scalar. Materializing scores and probabilities requires about $2BHL^2 s$ before backward storage and temporary workspace. Attention matrix multiplications require on the order of $BHL^2 d_h$ operations. If usable GPU memory is M_{usable} and non-attention allocations consume $M_0(L)$, the naive feasibility condition is

$$M_0(L) + cBHL^2 s \le M_{\text{usable}},$$

where c must be measured for the implementation and execution mode.

Part 3 - Hints, controls, and evidence

Query free and total memory immediately before each isolated trial. Warm up at a small length, reset peak statistics, synchronize, and delete trial-local tensors after measurement.

Compare forward-only, backward, and optimizer-step peaks. Repeat for float32 and float16 or bfloat16, but do not infer quality from memory. Use binary search only after a safe coarse sweep brackets the boundary. Distinguish allocated memory from reserved allocator memory. Include a prediction-versus- measurement table, relative estimator error, first OOM configuration, and the exact safety margin you would enforce in production.

Part 4 - Python code skeleton

```
import gc
import torch

def attention_matrix_bytes(batch_size, heads, length, dtype,
                           materialized_matrices):
    bytes_per_value = torch.empty((), dtype=dtype).element_size()
    values = batch_size * heads * length * length
    return values * bytes_per_value * materialized_matrices

```

Part 5 - The Philosophy Behind the Exercise

Asymptotic notation is a warning about growth, not a substitute for measurement. Engineering begins when the warning is translated into bytes, kernels, safety margins, and failure boundaries on a real machine. Long context is therefore not merely a model feature; it is a contract between mathematical ambition and finite physical resources.

17.10.2 Exercise 01

Exercise Title: Implement Flash-Attention Conceptually and Compare Memory Use Against Standard Attention on Toy Example

Part 1 - Why this matters

Standard attention is often described only by its arithmetic, but performance is also controlled by movement between GPU memory and fast on-chip storage. A naive implementation writes the complete score matrix, reads it for softmax, writes probabilities, and reads them again to mix values. Flash-style attention tiles queries, keys, and values, performs more work while data is local, and avoids storing the full $L \times L$ probability matrix. It computes exact attention up to floating-point ordering; it is not sparse or approximate attention.

Implement a pedagogical blockwise reference using online softmax. Process one query block against successive key/value blocks. Maintain for every query row the running maximum, running exponential denominator, and running weighted value accumulator. When a new key block contains a larger score, rescale earlier sums before merging. Apply causal or padding masks inside each tile using global indices. This Python reference will not be faster than fused kernels; its goal is to prove the recurrence and the fact that global normalization can be constructed without the global score matrix.

Compare blockwise output and gradients with naive float64 attention on small tensors, then test float32 and reduced precision with realistic tolerances. Use PyTorch's scaled dot-product attention as the optimized execution path when its backend is available. Measure peak CUDA memory and latency across lengths, but separate the slow pedagogical loop from the fused implementation. Verify dropout semantics and deterministic limitations. If attention weights are requested, the memory advantage may disappear because the full matrix must be returned.

Part 2 - Mathematical form and reasoning

For one query row, suppose processed blocks have running maximum m, normalizer ℓ, and unnormalized output accumulator o. For a new score block s,

$$m' = \max(m, \max s),$$

$$\ell' = e^{m-m'}\ell + \sum_j e^{s_j - m'},$$

$$o' = e^{m-m'}o + \sum_j e^{s_j - m'} v_j.$$

After the last block, the attention output is o/ℓ. The rescaling term $e^{m-m'}$ preserves contributions from earlier blocks under the new stable maximum. Working storage scales with tile sizes rather than L^2, while total attention arithmetic remains quadratic for dense attention.

Part 3 - Hints, controls, and evidence

Start with batch one, head one, no dropout, and no mask. Add padding, then causal mask. Use global query and key offsets when constructing tile visibility. Handle fully masked query rows explicitly. Compare output, loss, and Q/K/V gradients against the naive formula. Record maximum absolute and relative error. For CUDA benchmarks, warm up, synchronize, reset peak memory, and report which scaled- dot-product backend was selected. Compare lengths large enough to expose memory movement, and note compilation or kernel-selection effects. Evidence must show the online recurrence manually for at least two key blocks.

Part 4 - Python code skeleton

```
import math
import torch

def blockwise_attention(queries, keys, values, key_block_size):
    batch_size, heads, query_length, head_width = queries.shape
    running_maximum = torch.full(
        (batch_size, heads, query_length, 1), float("-inf"),
        dtype=torch.float64, device=queries.device
    )
    running_sum = torch.zeros_like(running_maximum)
    running_output = torch.zeros(
        batch_size, heads, query_length, head_width,
        dtype=torch.float64, device=queries.device
    )
    query_values = queries.to(torch.float64)
    for start in range(0, keys.size(2), key_block_size):
        end = min(start + key_block_size, keys.size(2))
        key_block = keys[:, :, start:end, :].to(torch.float64)
        value_block = values[:, :, start:end, :].to(torch.float64)
        scores = torch.matmul(query_values, key_block.transpose(-2, -1))
        scores = scores / math.sqrt(head_width)

        block_maximum = scores.max(dim=-1, keepdim=True).values
        new_maximum = torch.maximum(running_maximum, block_maximum)
        old_scale = torch.exp(running_maximum - new_maximum)
```

```
        block_exponentials = torch.exp(scores - new_maximum)
        running_sum = old_scale * running_sum
        block_sum = block_exponentials.sum(dim=-1, keepdim=True)
        running_sum = running_sum + block_sum
        running_output = old_scale * running_output
        running_output = running_output + torch.matmul(
            block_exponentials, value_block
        )
        running_maximum = new_maximum
    return (running_output / running_sum).to(queries.dtype)

def E01(queries, keys, values):
    blockwise = blockwise_attention(queries, keys, values, 64)
    naive_scores = torch.matmul(queries, keys.transpose(-2, -1))
    naive_scores = naive_scores / math.sqrt(queries.size(-1))
    naive = torch.matmul(torch.softmax(naive_scores, dim=-1), values)
    assert torch.allclose(blockwise, naive, atol=1e-5, rtol=1e-4)
    return blockwise
```

Part 5 - The Philosophy Behind the Exercise

An algorithm is not only a count of operations; it is a schedule for where information lives while those operations occur. Flash attention changes the schedule while preserving the mathematical answer. Its lesson is that major efficiency gains can come from respecting the memory hierarchy rather than weakening the model's computation.

17.10.3 Exercise 02

Exercise Title: Implement Sliding Window Attention Conceptually and Show How It Reduces Cost While Preserving Local Context

Part 1 - Why this matters

Many sequence relationships are local: nearby tokens often contain the most immediate syntactic or temporal evidence. Sliding-window attention limits each query to a neighborhood instead of all positions. With fixed window width, its score count grows linearly with sequence length, enabling longer inputs. The tradeoff is structural, not merely numerical: information outside the window cannot be retrieved directly, and distant dependencies require propagation through layers or special global mechanisms.

Implement a transparent reference that builds a Boolean visibility matrix from global query and key indices. Support bidirectional windows for encoders and a causal backward-looking window for decoders. Apply padding after window visibility. Compare output with full attention at positions whose full-attention weights are known to be local. Then construct a task where the first token must affect the last token beyond the window and show failure or slower multi-layer propagation.

Measure score elements, peak memory, runtime, and task quality for several window sizes and sequence lengths. A dense masked implementation still materializes L^2 scores and therefore demonstrates semantics but not the true memory benefit; a production implementation needs

sparse or block-local kernels. State this difference explicitly. Test boundary positions, sequences shorter than the window, padding, and causal leakage. Consider periodic global tokens or dilated patterns only as separately measured architectural changes.

Part 2 - Mathematical form and reasoning

For a bidirectional radius w, position i may attend to

$$\mathcal{N}(i) = \{j : |i - j| \leq w\}.$$

For causal local attention,

$$\mathcal{N}_{\text{causal}}(i) = \{j : 0 \leq i - j < w\}.$$

The number of visible pairs is at most $L(2w+1)$ bidirectionally or Lw causally, rather than L^2. Dense masked computation remains $O(L^2)$ in storage unless the kernel avoids constructing blocked entries. After D layers, the theoretical receptive field of a simple causal window can grow to roughly Dw positions, though information quality may degrade through repeated mixing.

Part 3 - Hints, controls, and evidence

Use unique position-coded values to verify which keys contribute. Print the mask for a tiny sequence and inspect first, middle, and last rows. Confirm future positions are blocked in causal mode. Change a token outside the window and assert the current layer's output is invariant; change one inside and expect an effect. Distinguish window radius from total window width in configuration. Benchmark a genuinely local kernel separately from the dense teaching version. Report accuracy by dependency distance, memory, latency, and the smallest window that preserves the task's required context.

Part 4 - Python code skeleton

```
import math
import torch

def sliding_visibility(length, window_size, causal, device):
    query_position = torch.arange(length, device=device)[:, None]
    key_position = torch.arange(length, device=device)[None, :]
    if causal:
        distance = query_position - key_position
        visible = (distance >= 0) & (distance < window_size)
    else:
        radius = window_size // 2
        visible = (query_position - key_position).abs() <= radius
    return visible

def dense_reference_window_attention(queries, keys, values,
                                     window_size, causal):
    length = queries.size(-2)
    visible = sliding_visibility(
        length, window_size, causal, queries.device
    )
```

```
    scores = torch.matmul(queries, keys.transpose(-2, -1))
    scores = scores / math.sqrt(queries.size(-1))
    scores = scores.masked_fill(~visible, float("-inf"))
    probabilities = torch.softmax(scores.float(), dim=-1).to(scores.dtype)
    output = torch.matmul(probabilities, values)
    return output, probabilities, visible

def E02(queries, keys, values):
    output, probabilities, visible = dense_reference_window_attention(
        queries, keys, values, window_size=8, causal=True
    )
    blocked_mass = probabilities.masked_fill(visible, 0.0).abs().max()
    assert blocked_mass.item() == 0.0
    return output, visible
```

Part 5 - The Philosophy Behind the Exercise

Efficiency sometimes comes from refusing to represent every possible relationship. A sliding window asserts that locality is valuable enough to be an inductive bias. The gain is honest only when the excluded relationships are named and tested. Scarcity becomes architecture when we decide deliberately which information is allowed to remain reachable.

17.10.4 Exercise 03

Exercise Title: Implement KV Cache Properly and Measure Latency Reduction for Autoregressive Inference

Part 1 - Why this matters

Without a key/value cache, autoregressive generation repeatedly recomputes keys and values for the entire prefix at every token. The result is correct but wasteful: history that has not changed is projected again and again. A KV cache stores each layer's past keys and values, so decode processes only new tokens. This changes inference from a stateless full-prefix call into a stateful protocol, introducing new correctness obligations for positions, masks, batches, beams, devices, and cache ownership.

Implement prefill and decode as explicit phases. Prefill consumes the prompt, produces first next-token logits, and initializes per-layer key/value tensors. Decode accepts one new token, calculates its projections, appends them along the sequence axis, attends over valid history, and returns updated state. Assert cache shape (B, H, T, d_h) at every layer and exact growth by the number of new tokens. Position IDs for cached decode must begin at the previous logical length, not restart from zero.

Establish token-by-token parity against full-prefix recomputation in evaluation mode. Compare logits before comparing chosen tokens; greedy sequence equality can hide compensating errors. Test batch reordering, beam expansion, finished rows, mixed prompt lengths, and cache reset between requests. Measure prompt prefill time, first-token latency, steady decode latency, tokens per second, and cache bytes. Benchmark several output lengths because cache overhead may not pay off for extremely short generations or tiny models.

Part 2 - Mathematical form and reasoning

At layer ℓ and step t, cache update is

$$K_{1:t}^{(\ell)} = \mathrm{concat}(K_{1:t-1}^{(\ell)}, K_t^{(\ell)}), \qquad V_{1:t}^{(\ell)} = \mathrm{concat}(V_{1:t-1}^{(\ell)}, V_t^{(\ell)}).$$

Cache storage for L_n layers is approximately

$$M_{\mathrm{KV}} = 2L_nBHTd_hs.$$

Full-prefix decoding repeatedly projects $O(T)$ tokens per step, whereas cached decode projects only the new block. Dense attention of the new query still reads the growing key history, so cache does not make context cost constant.

Part 3 - Hints, controls, and evidence

Begin with batch one and greedy decoding. Disable dropout and control dtype. Capture maximum absolute logit difference per layer and step. Verify cache length, batch, head, head width, device, and dtype. Test prompt prefill with more than one token and decode blocks larger than one. For beams, reorder every cache tensor with the same parent-beam indices used for token sequences. Never reuse cache across unrelated requests. Time after warm-up with CUDA events and synchronized boundaries. Report speedup versus generation length and the memory cost per additional token. Preserve the slow uncached implementation as an oracle.

Part 4 - Python code skeleton

```
import torch

def cache_bytes(past_key_values):
    total = 0
    for layer_cache in past_key_values:
        key, value = layer_cache
        total += key.numel() * key.element_size()
        total += value.numel() * value.element_size()
    return total

@torch.inference_mode()
def cached_greedy(model, prompt_ids, maximum_new_tokens):
    model.eval()
    output = model(input_ids=prompt_ids, use_cache=True)
    cache = output.past_key_values
    next_token = output.logits[:, -1, :].argmax(dim=-1, keepdim=True)
    generated = [next_token]
    expected_length = prompt_ids.size(1)

    for step in range(maximum_new_tokens - 1):
        output = model(
            input_ids=next_token,
            past_key_values=cache,
            use_cache=True,
        )
```

```
        cache = output.past_key_values
        expected_length += 1
        for layer_index in range(len(cache)):
            key, value = cache[layer_index]
            if key.shape != value.shape:
                raise AssertionError("key/value shape mismatch")
            if key.size(-2) != expected_length:
                raise AssertionError("cache length mismatch")
        next_token = output.logits[:, -1, :].argmax(dim=-1, keepdim=True)
        generated.append(next_token)
    return torch.cat(generated, dim=1), cache_bytes(cache)

def E03(model, prompt_ids):
    tokens, bytes_used = cached_greedy(model, prompt_ids, 64)
    return {"tokens": tokens, "cache_bytes": bytes_used}
```

Add an uncached trace and compare logits at every step before trusting the reported latency improvement.

Part 5 - The Philosophy Behind the Exercise

Caching is the preservation of valid work. It gains speed by declaring that the past computation still means the same thing. That declaration creates responsibility: identity, position, order, and ownership must remain intact. Efficiency is trustworthy only while remembered computation remains correctly attached to the history that produced it.

17.10.5 Exercise 04

Exercise Title: Implement Quantization Conceptually and Compare Accuracy Drop vs Speed Gain for Transformer Inference

Part 1 - Why this matters

Quantization represents weights or activations with fewer bits. It can reduce model size, memory bandwidth, and sometimes latency, which is valuable when a Transformer is limited by moving weights rather than arithmetic. But converting numbers to int8 does not automatically accelerate inference: the hardware and runtime need optimized kernels, quantize/dequantize overhead must be amortized, and small or unsupported operators may fall back to slower paths. Quality loss depends on value distribution, calibration data, granularity, and sensitive layers.

Implement symmetric weight-only quantization for a linear layer as a transparent reference. Calculate a scale from maximum absolute weight, map weights to the integer range, clamp, round, and reconstruct floating weights for comparison. This fake-quantized reference demonstrates error but not true integer-kernel speed. Then use a supported dynamic or weight-only quantization backend for real latency measurement. State whether activations remain floating point and whether scales are per-tensor, per-channel, or per-group.

Compare layer outputs, logits, greedy tokens, perplexity or task accuracy, model bytes, peak memory, and latency across representative prompts and lengths. Identify sensitive components by quantizing embeddings, attention projections, FFN layers, normalization, and output

head separately. Calibration data must represent production distributions; otherwise activation ranges can fail on rare inputs. Include extreme values and distribution shift. Report where quality degradation first appears and whether mixed precision, selective exclusion, or finer quantization granularity repairs it.

Part 2 - Mathematical form and reasoning

For symmetric signed b-bit quantization, integer range is $[-q_{\max}, q_{\max}]$ with $q_{\max} = 2^{b-1} - 1$. For tensor W,

$$s = \frac{\max |W|}{q_{\max}}, \qquad Q = \text{clamp}\left(operatornameround(W/s), -q_{\max}, q_{\max}\right),$$

$$\widehat{W} = sQ.$$

Quantization error is $E = W - \widehat{W}$. A single outlier increases s and reduces resolution for ordinary values; per-channel scales can reduce this effect at the cost of more metadata and implementation complexity.

Part 3 - Hints, controls, and evidence

Handle the all-zero tensor without dividing by zero. Use float32 as reference and identical inputs. Measure weight error by maximum, mean absolute, and relative norms. Test per-tensor and per-output-channel scales. Separate fake quantization from true backend execution in every table. Warm up and synchronize latency tests, include batch and sequence length, and report p50 and p95. Check that serialized size and runtime memory actually improve. Stratify quality by input length and rarity. Evidence must support a deployment choice, including a case where quantization is rejected because the tradeoff is unfavorable.

Part 4 - Python code skeleton

```
import torch

def symmetric_quantize(weight, bits, per_output_channel):
    integer_maximum = 2 ** (bits - 1) - 1
    if per_output_channel:
        maximum = weight.abs().amax(dim=1, keepdim=True)
    else:
        maximum = weight.abs().amax()
    scale = maximum / integer_maximum
    scale = torch.where(scale == 0, torch.ones_like(scale), scale)
    quantized = torch.round(weight / scale)
    quantized = torch.clamp(quantized, -integer_maximum, integer_maximum)
    return quantized.to(torch.int8), scale

def dequantize(quantized, scale):
    return quantized.float() * scale

def quantized_linear_reference(inputs, weight, bias, bits=8):
    quantized, scale = symmetric_quantize(
        weight, bits, per_output_channel=True
```

```
    )
    reconstructed = dequantize(quantized, scale)
    output = torch.nn.functional.linear(inputs.float(), reconstructed, bias)
    return output, quantized, scale

def E04(inputs, linear_layer):
    reference = linear_layer(inputs.float())
    candidate, quantized, scale = quantized_linear_reference(
        inputs, linear_layer.weight.detach(), linear_layer.bias, bits=8
    )
    error = (reference - candidate).abs()
    return {
        "maximum_output_error": float(error.max().item()),
        "mean_output_error": float(error.mean().item()),
        "quantized_weight": quantized,
        "scale": scale,
    }
```

Part 5 - The Philosophy Behind the Exercise

Quantization asks which numerical distinctions the model truly needs. Fewer bits can expose redundancy and make intelligence cheaper to move, but every removed distinction is an approximation. The ethical engineering position is neither "smaller is always better" nor "precision is sacred"; it is to measure what the system forgets and decide whether that loss is acceptable for its purpose.

17.10.6 Exercise 05

Exercise Title: Benchmark Inference Under float32 float16 and int8 and Build a Performance Tradeoff Table

Part 1 - Why this matters

Precision selection is a system decision involving quality, memory, kernel availability, hardware, batch size, and workload phase. Float16 often accelerates matrix multiplication on suitable GPUs and halves tensor storage, but sensitive softmax or normalization paths may need float32 accumulation. Int8 can reduce weight bandwidth further, yet unsupported operations, conversion overhead, or small batches may eliminate the speed benefit. A fair benchmark must use the same model semantics and distinguish prefill from decode.

Prepare three validated variants from one checkpoint: float32 reference, float16 or autocast inference, and a true int8 backend configuration. Record exactly which tensors and operators use each dtype. Use identical tokenized prompts, masks, stopping policy, maximum output length, and deterministic greedy decoding for parity. Evaluate several prompt lengths, generation lengths, and batch sizes. Warm up every variant independently and exclude conversion, quantization calibration, compilation, and runtime initialization from steady- state latency while reporting those startup costs separately.

Build a tradeoff table containing serialized model size, resident memory, peak allocated memory, first-token latency, steady per-token latency, throughput, p50/p95/p99 request latency, maximum logit error, greedy token agreement, perplexity or task metric, failure count, and energy proxy if available. Repeat measurements and report variation. A variant is not production-ready merely because average latency improves: rare NaNs, tail spikes, or quality collapse on long inputs can dominate operational value.

Part 2 - Mathematical form and reasoning

For reference logits Z and candidate $\widehat{Z}$, report

$$e_{\max} = \max_i |Z_i - \widehat{Z}_i|, \qquad e_{\mathrm{rel}} = \frac{\|Z - \widehat{Z}\|_2}{\|Z\|_2 + \varepsilon}.$$

Token agreement is

$$A_{\mathrm{token}} = \frac{1}{N} \sum_i \mathbf{1}[\arg\max Z_i = \arg\max \widehat{Z}_i].$$

For latency samples sorted increasingly, percentile p is an empirical order statistic. Report sample count and measurement boundary. Speedup is t_{32}/t_q, but must be paired with quality difference and memory reduction.

Part 3 - Hints, controls, and evidence

Run each variant in evaluation and inference modes. Reset peak memory and synchronize around timings. Randomize or rotate variant order to reduce thermal and background bias. Keep tokenization outside model timing unless measuring end-to-end service latency. Test ordinary, extreme-logit, long-context, rare- token, and distribution-shift inputs. Verify int8 is actually using integer or weight-only kernels rather than dequantizing the whole model before compute. Report unsupported layers and fallbacks. Select a deployment precision only after applying explicit quality, failure-rate, memory, and tail-latency gates.

Part 4 - Python code skeleton

```
import statistics
import time
import torch

def synchronized_call(function, argument, device):
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    started = time.perf_counter()
    output = function(argument)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    return output, time.perf_counter() - started

def benchmark_variant(name, generate_function, prompts, device):
    for warmup_index in range(10):
        generate_function(prompts[0])
    latencies = []
```

```
    outputs = []
    if device.type == "cuda":
        torch.cuda.reset_peak_memory_stats(device)
    for prompt in prompts:
        output, seconds = synchronized_call(
            generate_function, prompt, device
        )
        outputs.append(output)
        latencies.append(seconds)
    ordered = sorted(latencies)
    p50_index = int(0.50 * (len(ordered) - 1))
    p95_index = int(0.95 * (len(ordered) - 1))
    peak = 0
    if device.type == "cuda":
        peak = torch.cuda.max_memory_allocated(device)
    return {
        "name": name,
        "mean_seconds": statistics.mean(latencies),
        "p50_seconds": ordered[p50_index],
        "p95_seconds": ordered[p95_index],
        "peak_allocated_bytes": peak,
        "outputs": outputs,
    }

def E05(variants, prompts, device):
    rows = []
    for name, generate_function in variants.items():
        row = benchmark_variant(
            name, generate_function, prompts, device
        )
        rows.append(row)
    return rows
```

Part 5 - The Philosophy Behind the Exercise

A dtype is a compressed representation of the model's numerical world. The right precision is not the smallest one that executes; it is the least costly representation that preserves the decisions and reliability the task requires. A tradeoff table makes that judgment visible instead of letting speed silently define success.

17.10.7 Exercise 06

Exercise Title: Implement torch.compile and Measure Speedups and Compilation Overhead for Transformer Models

Part 1 - Why this matters

`torch.compile` can capture PyTorch execution, specialize graphs, fuse operations, and reduce Python and kernel-launch overhead. Transformer speedup depends on graph structure, shapes, dynamic control flow, backend, and workload. The first calls may be much slower

because compilation occurs, and new sequence lengths or branches may trigger recompilation. Reporting only a warmed fixed- shape result can therefore misrepresent a variable-length production service.

Compile a copied evaluation model or a stable inference wrapper while preserving an eager reference. Test a fixed-shape workload first, then a realistic shape distribution. Record initial compile latency, number of warm-up calls, graph breaks, recompilations, steady latency, throughput, peak memory, and output parity. Test encoder prefill and one-token decode separately; Python sampling and stopping logic may remain outside the compiled graph. Do not compile an entire request loop blindly when its changing sequence tensors cause a new graph every step.

Compare default, reduce-overhead, and maximum-autotune modes only when the backend supports them and budgets are matched. Use length bucketing or dynamic shapes as explicit strategies and measure their effect. Validate logits and generated tokens across batches, masks, lengths, and dtypes. Compilation may alter floating-point operation ordering, so establish tolerances and investigate decision-changing differences. Include a break-even calculation: how many requests are required before steady-state savings repay compilation cost.

Part 2 - Mathematical form and reasoning

If eager latency is t_e, compiled steady latency is t_c, and one-time compile cost is C, total times for N calls are

$$T_e(N) = Nt_e, \qquad T_c(N) = C + Nt_c.$$

Compilation breaks even when

$$N > \frac{C}{t_e - t_c},$$

provided $t_c < t_e$. Recompilations add costs C_j for encountered shape or control-flow guards, so production amortization depends on the input distribution, not one benchmark shape.

Part 3 - Hints, controls, and evidence

Freeze the checkpoint, evaluation mode, precision, and inputs. Warm eager and compiled variants separately. Synchronize CUDA around wall timing. Separate first call, subsequent compilation calls, and steady samples. Enable compiler diagnostics to count graph breaks and guard failures without placing verbose logging inside final timing. Test common and rare lengths, batch changes, mask patterns, and cache state shapes. Save the smallest input causing recompile or parity failure. Evidence includes compile cost, break-even request count, steady-state percentiles, memory, graph count, and a recommendation about shape bucketing or eager fallback.

Part 4 - Python code skeleton

```
import time
import torch

def synchronized_seconds(function, arguments, device):
    if device.type == "cuda":
```

```
        torch.cuda.synchronize(device)
    started = time.perf_counter()
    output = function(*arguments)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    return output, time.perf_counter() - started

@torch.inference_mode()
def benchmark_compile(model, example_batches, device):
    model.eval()
    compiled_model = torch.compile(model, mode="reduce-overhead")
    eager_times = []
    compiled_times = []
    parity = []

    for batch in example_batches:
        arguments = (batch["input_ids"], batch["attention_mask"])
        eager_output, eager_seconds = synchronized_seconds(
            model, arguments, device
        )
        compiled_output, compiled_seconds = synchronized_seconds(
            compiled_model, arguments, device
        )
        eager_times.append(eager_seconds)
        compiled_times.append(compiled_seconds)
        close = torch.allclose(
            eager_output, compiled_output, atol=1e-5, rtol=1e-4
        )
        same_token = torch.equal(
            eager_output.argmax(-1), compiled_output.argmax(-1)
        )
        parity.append({"close": close, "same_token": same_token})
    return eager_times, compiled_times, parity

def E06(model, batches):
    device = next(model.parameters()).device
    return benchmark_compile(model, batches, device)
```

The first compiled timing contains compilation. Preserve it, then collect a separate repeated steady window for every shape bucket.

Part 5 - The Philosophy Behind the Exercise

Compilation converts generality into specialized execution. It is powerful because it assumes something about future shapes and control flow. The engineer must measure whether reality honors that assumption often enough to repay its cost. Speed is not only how fast a graph runs; it includes the price of deciding which graph the world requires.

17.10.8 Exercise 07

Exercise Title: Profile GPU Utilization and Identify Bottlenecks in Attention, FFN, and Data Transfer During Inference

Part 1 - Why this matters

Low GPU utilization is a symptom, not a diagnosis. In Transformer inference, the device may wait for host-to-device transfers, tokenization, Python generation logic, synchronization, dynamic batching, or small sequential decode kernels. At other times the GPU is busy but memory bandwidth, attention, FFN matrix multiplication, or cache movement limits throughput. A global utilization percentage cannot tell these cases apart.

Profile a representative service path and mark preprocessing, transfer, prefill attention, prefill FFN, decode attention, decode FFN, logits processing, sampling, cache update, and stopping. Collect CPU and CUDA activities, shapes, memory, kernel launch count, and self versus total time. Separate prefill from decode: prefill often has larger parallel matrix operations, while single-token decode can be bandwidth- or launch-bound. Profile batch one and realistic dynamic batches.

Calculate phase shares and locate idle gaps on the timeline. Vary prompt length, generation length, batch, vocabulary size, and cache length one at a time. If transfer dominates, test pinned memory, nonblocking copies, and overlap. If attention dominates long prefill, test an optimized attention kernel. If FFN dominates, compilation, quantization, or batching may help. If CPU control dominates decode, reduce per-token synchronizations and tensor-to-Python conversions. Apply one change, verify output parity, and re-profile end to end.

Part 2 - Mathematical form and reasoning

End-to-end request latency can be decomposed as

$$t = t_{\text{queue}} + t_{\text{preprocess}} + t_{\text{transfer}} + t_{\text{prefill}} + \sum_{u=1}^{U} (t_{\text{attention,u}} + t_{\text{FFN,u}} + t_{\text{control,u}}) - t_{\text{overlap}}.$$

Phase fraction is $r_i = t_i/t$. Arithmetic intensity, approximately FLOPs per byte transferred, helps distinguish compute-bound from bandwidth-bound kernels. Optimization priority belongs to the largest non-overlapped component that can be changed without violating quality or latency objectives.

Part 3 - Hints, controls, and evidence

Warm up before profiling and profile a short steady window because collection changes timing. Avoid printing inside the measured region. Use named ranges and NVTX or profiler annotations to retain semantic phases. Synchronize only at measurement boundaries and search for accidental `item()` calls that force synchronization. Record GPU utilization, memory bandwidth indicators, kernel time, CPU gaps, and request percentiles. Use a lightweight benchmark for the final performance result. Evidence includes a timeline screenshot or table, phase attribution, bottleneck hypothesis, one controlled intervention, parity results, and measured end-to-end improvement.

Part 4 - Python code skeleton

```
import torch
from torch.profiler import ProfilerActivity, profile, record_function

@torch.inference_mode()
def instrumented_request(model, tokenizer, text, device, maximum_tokens):
    model.eval()
    with record_function("cpu_preprocess"):
        encoded = tokenizer(text, return_tensors="pt")
    with record_function("host_to_device"):
        input_ids = encoded["input_ids"].to(device, non_blocking=True)
        attention_mask = encoded["attention_mask"].to(
            device, non_blocking=True
        )
    with record_function("prefill"):
        output = model(
            input_ids=input_ids,
            attention_mask=attention_mask,
            use_cache=True,
        )
    cache = output.past_key_values
    token = output.logits[:, -1, :].argmax(dim=-1, keepdim=True)
    for step in range(maximum_tokens - 1):
        with record_function("decode_model"):
            output = model(
                input_ids=token, past_key_values=cache, use_cache=True
            )
        with record_function("decode_selection"):
            token = output.logits[:, -1, :].argmax(dim=-1, keepdim=True)
        with record_function("cache_update"):
            cache = output.past_key_values
    return token

def E07(model, tokenizer, text):
    device = torch.device("cuda:0")
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    with profile(
        activities=activities, record_shapes=True, profile_memory=True
    ) as profiler:
        instrumented_request(model, tokenizer, text, device, 32)
    return profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=40
    )
```

Add attention- and FFN-specific ranges inside the model or use module hooks so the aggregate decode range can be attributed to its internal sublayers.

Part 5 - The Philosophy Behind the Exercise

Optimization is disciplined attention directed at the system itself. Aggregate utilization tempts us to blame the most visible component. Profiling reconstructs the dependency chain

and asks what the request is actually waiting for. The fastest engineering path begins by refusing to optimize a story before measuring the mechanism.

17.10.9 Exercise 08

Exercise Title: Build a Production Inference Wrapper that Handles Batching, Padding, Stop Tokens, and Errors Correctly

Part 1 - Why this matters

A production wrapper converts untrusted, variable requests into a controlled model execution. It owns validation, tokenization, length limits, batching, padding, masks, decoding policy, stopping, output decoding, timeouts, and error classification. A correct model behind a weak wrapper can leak padding into attention, mix request state, ignore EOS, exhaust memory, or return partially corrupt output as success.

Define a request schema with text or token IDs, maximum new tokens, allowed decoding options, stop-token sequences, and request identifier. Reject empty or oversized inputs, invalid parameter ranges, unsupported dtypes, and unknown special IDs before GPU work. Tokenize with a fixed version and preserve original lengths. Batch compatible requests by model version and decoding policy. Apply a documented padding side, construct masks, and select logits from each prompt's last valid position rather than the last padded column.

Maintain per-row generated tokens, finished state, stop reason, and cache. Finished rows must remain finished and must not contaminate active rows. Match multi-token stop sequences at token level, resolve precedence among EOS, custom stop, maximum length, cancellation, and timeout, and specify whether matched tokens are returned. Decode each row only through its logical endpoint. Return structured success or typed error information without exposing internal stack traces. Test batched results against independent requests and inject tokenizer, OOM, nonfinite-logit, timeout, malformed-input, and partial-batch failures.

Part 2 - Mathematical form and reasoning

For request b, active state evolves as

$$a_{b,t+1} = a_{b,t} \wedge \neg(\mathrm{EOS}_{b,t} \vee \mathrm{STOP}_{b,t} \vee \mathrm{LIMIT}_{b,t} \vee \mathrm{CANCEL}_{b,t}).$$

Monotonicity requires $a_{b,t+1} \leq a_{b,t}$. With right-padded prompt logits $Z \in \mathbb{R}^{B\times L\times V}$ and valid length ℓ_b, initial next- token logits are $Z_{b,\ell_b-1,:}$, not necessarily $Z_{b,L-1,:}$. Batching is correct when each row equals independent execution under matched deterministic settings.

Part 3 - Hints, controls, and evidence

Separate pure validation and token processing from GPU execution. Assign maximum prompt, output, batch-token, and wall-time budgets. Use one explicit policy for padding and position IDs. Keep request IDs attached through sorting and batching. Never recover from OOM by silently truncating content; return a declared error or apply an authorized fallback. Test variable prompt lengths, empty stop patterns, overlapping stops, EOS inside a custom stop, all rows finishing at different steps, and one invalid request in a batch. Evidence includes schema, state transition tests, independent-versus-batch parity, error matrix, and latency under representative batching.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import torch

@dataclass
class GenerationRequest:
    request_id: str
    text: str
    maximum_new_tokens: int
    temperature: float

def validate_request(request, maximum_prompt_characters, maximum_new_tokens):
    if not isinstance(request.text, str) or len(request.text) == 0:
        raise ValueError("text must be a non-empty string")
    if len(request.text) > maximum_prompt_characters:
        raise ValueError("prompt exceeds character budget")
    if request.maximum_new_tokens < 1:
        raise ValueError("maximum_new_tokens must be positive")
    if request.maximum_new_tokens > maximum_new_tokens:
        raise ValueError("requested output exceeds service limit")
    if request.temperature <= 0.0:
        raise ValueError("temperature must be positive")

def last_valid_logits(logits, attention_mask):
    lengths = attention_mask.sum(dim=1)
    rows = torch.arange(logits.size(0), device=logits.device)
    columns = lengths - 1
    return logits[rows, columns, :]

def update_finished(selected, finished, eos_id):
    current_eos = selected.eq(eos_id)
    updated = finished | current_eos
    if bool((finished & (~updated)).any()):
        raise AssertionError("finished state revived")
    return updated

class InferenceWrapper:
    def __init__(self, model, tokenizer, device, eos_id):
        self.model = model.eval()
        self.tokenizer = tokenizer
        self.device = device
        self.eos_id = eos_id

    @torch.inference_mode()
    def generate_batch(self, requests):
        for request in requests:
            validate_request(request, 20000, 512)
        texts = []
        for request in requests:
```

```
            texts.append(request.text)
        batch = self.tokenizer(texts, padding=True, return_tensors="pt")
        input_ids = batch["input_ids"].to(self.device)
        attention_mask = batch["attention_mask"].to(self.device)
        output = self.model(
            input_ids=input_ids, attention_mask=attention_mask
        )
        return last_valid_logits(output.logits, attention_mask)

def E08(wrapper, requests):
    return wrapper.generate_batch(requests)
```

Extend the wrapper with explicit cache, stop-sequence matching, timeout checks, and typed result objects while preserving the same invariants.

Part 5 - The Philosophy Behind the Exercise

The wrapper is where mathematical capability meets public responsibility. It decides which requests the model is allowed to see, how resources are shared, and when computation must stop. Production readiness begins when these decisions become explicit contracts rather than accidental consequences of tensor code.

17.10.10 Exercise 09

Exercise Title: Implement Monitoring for Drift and Confidence and Detect Distribution Shift in Production Text Streams

Part 1 - Why this matters

A deployed model encounters language, topics, lengths, token distributions, and user behavior that differ from its evaluation set. Inputs can drift gradually or change suddenly after a product event. Output confidence can shift even when ground-truth labels are delayed or unavailable. Monitoring must detect these changes without treating every natural fluctuation as an incident and without collecting raw sensitive text unnecessarily.

Define a versioned reference window from approved evaluation or early production traffic. Extract privacy-conscious aggregate features: prompt length, generated length, unknown or rare-token rate, token-frequency sketch, language or domain category when authorized, average negative log probability, entropy, maximum probability, EOS rate, refusal or error rate, repetition, latency, and memory. Keep operational and model-quality signals connected by model, tokenizer, decoding policy, and deployment version.

Compare recent windows with the reference using several detectors. Useful choices include population stability index, Jensen–Shannon divergence, Wasserstein distance for scalar features, and classifier-based shift tests. Confidence is not correctness; validate its relationship to quality whenever delayed labels or human review arrive. Use minimum sample sizes, uncertainty bands, multiple consecutive-window rules, and severity levels. Construct synthetic shifts in length, vocabulary, language, and repetition to prove detectors fire, and simulate harmless volume changes to measure false alarms. Every alert needs an owner and action: investigate, route to shadow evaluation, limit traffic, or rollback.

Part 2 - Mathematical form and reasoning

For discrete reference distribution P and current distribution Q, Jensen– Shannon divergence is

$$\mathrm{JS}(P,Q) = \frac{1}{2}\,\mathrm{KL}(P\|M) + \frac{1}{2}\,\mathrm{KL}(Q\|M), \qquad M = \frac{P+Q}{2}.$$

For confidence c_i and correctness a_i available later, a calibration bin gap is $|\,\mathrm{mean}(c_i) - \mathrm{mean}(a_i)|$. Monitoring thresholds should be estimated from baseline variation and validated against known shifts, rather than chosen only for producing a visually convenient alert.

Part 3 - Hints, controls, and evidence

Separate data drift, prediction drift, quality drift, and system drift. Aggregate or hash features where possible and enforce retention limits. Partition by model version and major traffic segment so a mixture change is not mistaken for model change. Establish a stable reference and update it only through a reviewed process; automatically adapting the reference can normalize a persistent failure. Track missing telemetry as its own incident. Backtest thresholds on historical normal windows and injected shifts. Evidence includes detector power, false-alert rate, detection delay, sample-size requirement, dashboards, and an alert-to-action runbook.

Part 4 - Python code skeleton

```
import math
import torch

def normalized_histogram(values, bin_edges):
    counts = torch.histc(
        values.float(), bins=bin_edges.numel() - 1,
        min=float(bin_edges[0]), max=float(bin_edges[-1])
    )
    counts = counts + 1e-8
    return counts / counts.sum()

def jensen_shannon(reference, current):
    midpoint = 0.5 * (reference + current)
    first = (reference * (reference / midpoint).log()).sum()
    second = (current * (current / midpoint).log()).sum()
    return float((0.5 * first + 0.5 * second).item())

class DriftMonitor:
    def __init__(self, reference_features, minimum_samples, threshold):
        self.reference_features = reference_features
        self.minimum_samples = minimum_samples
        self.threshold = threshold
        self.consecutive_alerts = 0

    def evaluate_length_shift(self, current_lengths, bin_edges):
        if current_lengths.numel() < self.minimum_samples:
            return {"status": "insufficient_data"}
```

```
        reference = normalized_histogram(
            self.reference_features["lengths"], bin_edges
        )
        current = normalized_histogram(current_lengths, bin_edges)
        divergence = jensen_shannon(reference, current)
        if divergence > self.threshold:
            self.consecutive_alerts += 1
        else:
            self.consecutive_alerts = 0
        alert = self.consecutive_alerts >= 3
        return {
            "status": "evaluated",
            "js_divergence": divergence,
            "alert": alert,
            "consecutive_windows": self.consecutive_alerts,
        }

def E09(monitor, current_lengths, bin_edges):
    return monitor.evaluate_length_shift(current_lengths, bin_edges)
```

Use explicit bucket boundaries derived from the reference rather than relying on equal-width histograms when the distribution is highly skewed.

Part 5 - The Philosophy Behind the Exercise

Deployment changes knowledge from a static claim into a living hypothesis. The model was validated under one distribution; monitoring asks whether the world still resembles that evidence. Drift is not automatically failure, but it is a signal that old confidence may no longer be justified. Responsible operation keeps certainty proportional to current observation.

17.10.11 Exercise 10

Exercise Title: Run Long-Context Benchmarks on CUDA and Document Maximum Sequence Length Before Out-of-Memory Happens

Part 1 - Why this matters

The maximum usable context is not a property of the model alone. It depends on GPU capacity and fragmentation, batch, dtype, attention backend, training versus inference, gradient state, optimizer, layer count, model width, checkpointing, cache policy, and other processes on the device. Discovering it by immediately allocating an enormous tensor can terminate the experiment and leave allocator state unclear. A controlled benchmark maps a safe operating envelope.

Measure three modes separately: forward-only prompt processing, training with backward and optimizer state, and autoregressive inference with growing KV cache. Start from a known safe length, increase geometrically until failure, then refine between the last success and first failure. Run each trial in isolation, reset peak statistics, capture free memory before the trial, synchronize after work, and release local tensors. Catch only expected CUDA OOM errors; other errors may reveal shape, kernel, or numerical defects and must not be mislabeled as

memory limits.

Record sequence length, batch, dtype, attention backend, mode, latency, useful tokens per second, peak allocated and reserved bytes, free memory, success, exception, and output checksum. Repeat boundary trials because allocator history and background use may vary. Define a deployment limit below the experimental maximum, preserving headroom for concurrent requests and temporary workspace. Compare observed memory scaling with the estimator from E00 and explain changes when flash attention, activation checkpointing, or quantization is enabled.

Part 2 - Mathematical form and reasoning

Let L_s be the last successful length and L_f the first failing length. Refinement tests their interval until $L_f - L_s$ is within a chosen resolution. A production limit may be

$$L_{\text{prod}} = \max\{L : \widehat{M}(L) \leq (1-\rho)M_{\text{available}}\},$$

where ρ is a declared safety fraction. This limit may be lower than the isolated maximum because concurrent service memory includes

$$M_{\text{service}} = M_{\text{weights}} + \sum_r (M_{\text{request,r}} + M_{\text{KV,r}}) + M_{\text{workspace}} + M_{\text{reserve}}.$$

Part 3 - Hints, controls, and evidence

Record GPU name, memory, driver, CUDA, PyTorch, backend flags, and other active processes. Use fixed seeds but do not assume deterministic kernels. Warm a small case before boundary measurements. For training, include optimizer state and the actual loss/backward path. For decode, separate prompt length and generated length. Avoid repeated `empty_cache` calls inside a real request; they belong only between isolated benchmark trials. After an OOM, delete references, collect garbage, clear cache, and validate recovery with a small known-good trial. Evidence includes the complete configuration table, scaling curves, last success, first failure, recovery result, and chosen production margin.

Part 4 - Python code skeleton

```
import gc
import torch

def clean_after_trial(device):
    gc.collect()
    torch.cuda.empty_cache()
    torch.cuda.synchronize(device)

def run_isolated_forward(model, length, batch_size, vocabulary_size, device):
    torch.cuda.reset_peak_memory_stats(device)
    input_ids = torch.randint(
        0, vocabulary_size, (batch_size, length), device=device
    )
    attention_mask = torch.ones_like(input_ids)
    try:
```

```
        with torch.inference_mode():
            output = model(input_ids=input_ids, attention_mask=attention_mask)
        checksum = float(output.logits[:, -1, :].float().sum().item())
        torch.cuda.synchronize(device)
        result = {
            "length": length,
            "succeeded": True,
            "peak_allocated": torch.cuda.max_memory_allocated(device),
            "peak_reserved": torch.cuda.max_memory_reserved(device),
            "checksum": checksum,
        }
    except torch.OutOfMemoryError as error:
        result = {
            "length": length,
            "succeeded": False,
            "error": str(error),
        }
    del input_ids
    del attention_mask
    clean_after_trial(device)
    return result

def E10(model, vocabulary_size):
    device = torch.device("cuda:0")
    results = []
    for length in (1024, 2048, 4096, 8192, 16384, 32768):
        result = run_isolated_forward(
            model, length, 1, vocabulary_size, device
        )
        results.append(result)
        if not result["succeeded"]:
            break
    return results
```

Run a known-good small trial after failure and assert its checksum remains finite before proceeding to the refinement phase.

Part 5 - The Philosophy Behind the Exercise

A maximum discovered in isolation is a cliff, not a target. Production systems need distance from the cliff because workloads overlap and memory is not a perfectly predictable container. Capacity planning turns failure into measured territory and chooses a safe region where service remains recoverable.

17.10.12 Exercise 11

Exercise Title: Compare Deterministic vs Non-Deterministic Settings and Measure Their Performance Costs

Part 1 - Why this matters

Reproducibility helps debug regressions, compare experiments, and verify recovery. GPU libraries may choose algorithms whose parallel reduction order or atomic updates vary across runs. Forcing deterministic algorithms can disable faster kernels, change backend selection, increase memory, or reject unsupported operations. Conversely, fixed seeds without deterministic execution do not guarantee identical results. This exercise measures both behavior and cost.

Define two documented configurations. The deterministic configuration seeds Python and PyTorch, seeds all CUDA devices, enables deterministic algorithms, controls relevant backend benchmarking settings, and fixes data order. The performance configuration permits optimized backend choices while retaining seeds for approximate comparison. Recreate model and inputs from the same initial checkpoint for every trial. Run repeated forward, generation, and short training traces.

Compare logits, selected tokens, losses, gradients, parameters, runtime, throughput, peak memory, and kernel/backend choices. Measure divergence by step: a tiny floating difference may not initially change greedy tokens but can grow during training or sampling. Separate randomness intentionally introduced by dropout or sampling from nondeterministic execution. If an operation raises under deterministic mode, record it as an unsupported path and decide whether to replace it, accept documented nondeterminism, or restrict the configuration.

Part 2 - Mathematical form and reasoning

For repeated outputs $z^{(r)}$, numeric variation can be summarized by

$$D_{\max} = \max_{r,i} |z_i^{(r)} - z_i^{(1)}|,$$

and discrete agreement by

$$A = \frac{1}{R-1} \sum_{r=2}^{R} \mathbf{1}[\arg\max z^{(r)} = \arg\max z^{(1)}].$$

Performance cost of determinism is

$$C_t = \frac{t_{\text{det}} - t_{\text{fast}}}{t_{\text{fast}}} \times 100\%.$$

Report distributions, because mean cost may hide a large tail-latency change.

Part 3 - Hints, controls, and evidence

Log all determinism-related flags and environment requirements with versions. Reinitialize from identical weights before each repeated training trace. Disable dropout for pure kernel tests, then add it with controlled RNG. Use greedy decoding before stochastic sampling. Synchronize timing and warm configurations independently. Test multiple lengths because deterministic and optimized backend availability can depend on shape. Evidence includes repeated checksums, first divergence step, output agreement, performance percentiles, memory, unsupported operations, and a policy stating where exact repeatability is required.

Part 4 - Python code skeleton

```
import random
import torch
```

```
def configure_execution(seed, deterministic):
    random.seed(seed)
    torch.manual_seed(seed)
    if torch.cuda.is_available():
        torch.cuda.manual_seed_all(seed)
    torch.use_deterministic_algorithms(deterministic)
    if torch.backends.cudnn.is_available():
        torch.backends.cudnn.benchmark = not deterministic
        torch.backends.cudnn.deterministic = deterministic

@torch.inference_mode()
def repeated_forward(model_factory, input_ids, attention_mask,
                     deterministic, repetitions):
    outputs = []
    for repetition in range(repetitions):
        configure_execution(seed=1234, deterministic=deterministic)
        model = model_factory().eval().to(input_ids.device)
        logits = model(
            input_ids=input_ids, attention_mask=attention_mask
        ).logits
        outputs.append(logits.detach().cpu())
    reference = outputs[0]
    maximum_difference = 0.0
    all_tokens_equal = True
    for output in outputs[1:]:
        difference = float((reference - output).abs().max().item())
        maximum_difference = max(maximum_difference, difference)
        if not torch.equal(reference.argmax(-1), output.argmax(-1)):
            all_tokens_equal = False
    return maximum_difference, all_tokens_equal

def E11(model_factory, input_ids, attention_mask):
    deterministic_result = repeated_forward(
        model_factory, input_ids, attention_mask, True, 5
    )
    fast_result = repeated_forward(
        model_factory, input_ids, attention_mask, False, 5
    )
    return deterministic_result, fast_result
```

Benchmark time in a separate synchronized loop so repeated model construction does not contaminate inference latency.

Part 5 - The Philosophy Behind the Exercise

Determinism is a form of accountability: the ability to retrace a computational path. It has a cost because parallel hardware gains speed by allowing many valid execution orders. The right choice is contextual. Research debugging may demand strict replay; high-throughput service may accept bounded variation. What must never be accepted is undocumented uncertainty.

17.10.13 Exercise 12

Exercise Title: Implement Activation Checkpointing and Quantify Memory Savings for Long Context Training

Part 1 - Why this matters

Backpropagation normally stores intermediate activations from the forward pass so gradients can be computed later. Long-context Transformers create large attention and FFN activations across many layers. Activation checkpointing saves selected boundary tensors and recomputes the missing interior during backward. It reduces peak activation memory in exchange for additional computation, making otherwise impossible sequences trainable. It does not reduce parameter, gradient, optimizer, or input memory.

Checkpoint complete Transformer blocks or carefully chosen groups rather than individual trivial operations. Build identical checkpointed and ordinary models from one state dictionary. Use dropout and other random operations only after verifying RNG-state preservation; otherwise recomputation can use different masks and produce incorrect gradients. Compare forward loss, every parameter gradient, one optimizer update, peak memory, step latency, and tokens per second. Test several sequence lengths and checkpoint granularities.

Measure the maximum trainable context before and after checkpointing with the same precision and optimizer. Savings often grow with activation size, while the relative benefit is smaller when parameters or optimizer state dominate. Compilation, mixed precision, and distributed training can interact with checkpoint boundaries, so treat combined configurations as new experiments. Report both bytes saved and additional time; claiming success from a memory number alone ignores the compute budget paid during every backward pass.

Part 2 - Mathematical form and reasoning

For a composition $y = f_n \circ \cdots \circ f_1(x)$, ordinary backpropagation may store each intermediate $a_i = f_i(a_{i-1})$. Checkpointing stores selected a_k and recomputes missing activations when their gradients are needed. A simple partition into K segments trades activation storage against roughly one additional forward evaluation of checkpointed regions. The measured memory reduction is

$$R_M = 1 - \frac{M_{\text{checkpoint}}}{M_{\text{ordinary}}},$$

and time overhead is

$$C_t = \frac{t_{\text{checkpoint}} - t_{\text{ordinary}}}{t_{\text{ordinary}}}.$$

Part 3 - Hints, controls, and evidence

Use the current recommended checkpoint API and pass its reentrant behavior explicitly. Begin with dropout disabled, then test training randomness. Ensure at least one relevant input or parameter participates in gradients under the chosen API. Reset peak CUDA memory immediately before the step and synchronize timing. Compare gradients in float64 on a tiny model, then float32 under realistic tolerances. Test checkpoint counts of none, every block, and grouped blocks. Evidence includes gradient parity, parameter-update parity, memory and time

curves by length, maximum safe context, and documented interactions with compile and mixed precision.

Part 4 - Python code skeleton

```
import time
import torch
from torch import nn
from torch.utils.checkpoint import checkpoint

class CheckpointedStack(nn.Module):
    def __init__(self, blocks, use_checkpointing):
        super().__init__()
        self.blocks = nn.ModuleList(blocks)
        self.use_checkpointing = use_checkpointing

    def forward(self, hidden, attention_mask):
        for block in self.blocks:
            if self.use_checkpointing and self.training:
                hidden = checkpoint(
                    block, hidden, attention_mask, use_reentrant=False
                )
            else:
                hidden = block(hidden, attention_mask)
        return hidden

def measured_step(model, loss_function, optimizer, batch, device):
    torch.cuda.reset_peak_memory_stats(device)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    optimizer.zero_grad(set_to_none=True)
    logits = model(batch["input_ids"], batch["attention_mask"])
    loss = loss_function(logits, batch["labels"])
    loss.backward()
    optimizer.step()
    torch.cuda.synchronize(device)
    return {
        "loss": float(loss.item()),
        "seconds": time.perf_counter() - started,
        "peak_allocated": torch.cuda.max_memory_allocated(device),
    }

def E12(model, loss_function, optimizer, batch):
    device = next(model.parameters()).device
    return measured_step(model, loss_function, optimizer, batch, device)
```

Part 5 - The Philosophy Behind the Exercise

Checkpointing trades memory of the past for the labor of reconstructing it. This is a general systems principle: state can be stored or recomputed, and the right balance depends on which resource is scarce. The technique is valuable because it makes that exchange explicit and testable rather than allowing memory limits to dictate the experiment silently.

17.10.14 Exercise 13

Exercise Title: Implement Gradient Accumulation and Compare It Against True Large Batch Training Under Memory Constraints

Part 1 - Why this matters

Gradient accumulation processes several microbatches before one optimizer step, approximating the gradient of a larger batch without storing all activations simultaneously. Correct equivalence is subtle. Loss reduction, unequal valid- token counts, padding, dropout randomness, normalization behavior, gradient clipping, mixed-precision scaling, and scheduler timing can all make accumulated training differ from a true large batch.

Construct one logical batch and split it into explicit microbatches. Compare a single full-batch update with an accumulated update from identical parameters and optimizer state. For token-level losses with different padding, sum loss over valid tokens in each microbatch and divide accumulated gradients by the total valid-token count. Dividing every microbatch mean by the number of microbatches is correct only when their effective denominators match. Call zero-gradient and optimizer step once per logical batch.

Unscale gradients before clipping, clip once after accumulation, and advance the learning-rate scheduler according to optimizer updates rather than microbatches unless a different schedule is explicitly intended. Compare loss numerator, valid-token denominator, parameter gradients, parameter update, optimizer state, throughput, peak memory, and convergence. Begin with dropout disabled and a model without batch-dependent normalization, then explain residual differences under ordinary stochastic training.

Part 2 - Mathematical form and reasoning

For microbatch m with valid token set I_m, the desired logical-batch mean loss is

$$\mathcal{L} = \frac{\sum_{m=1}^{M} \sum_{i \in I_m} \ell_i}{\sum_{m=1}^{M} |I_m|}.$$

Therefore

$$\nabla \mathcal{L} = \frac{1}{N_{\text{valid}}} \sum_{m=1}^{M} \nabla \left(\sum_{i \in I_m} \ell_i \right).$$

Accumulating summed-loss gradients and normalizing by the total valid count matches the full logical batch up to floating-point operation order when model behavior is otherwise equivalent.

Part 3 - Hints, controls, and evidence

Use the exact same examples and ordering in both paths. Clone model and optimizer states. Set dropout to zero for the first parity test. Assert no optimizer or scheduler step occurs inside

the microbatch loop. Track the actual valid-token denominator. In distributed training, suppress unnecessary synchronization for nonfinal microbatches using the framework's supported mechanism. Compare maximum absolute and relative gradient error for each parameter. Then measure peak memory and step time. Evidence includes parity on uniform and variable-length batches, a deliberate wrong-reduction failure, memory savings, throughput cost, and longer-run convergence comparison.

Part 4 - Python code skeleton

```
import torch

def accumulated_step(model, optimizer, microbatches, padding_id):
    optimizer.zero_grad(set_to_none=True)
    total_valid_tokens = 0
    loss_numerators = []

    for microbatch in microbatches:
        logits = model(
            microbatch["input_ids"], microbatch["attention_mask"]
        )
        labels = microbatch["labels"]
        flat_logits = logits.reshape(-1, logits.size(-1))
        flat_labels = labels.reshape(-1)
        loss_sum = torch.nn.functional.cross_entropy(
            flat_logits, flat_labels,
            ignore_index=padding_id, reduction="sum"
        )
        valid_tokens = int(flat_labels.ne(padding_id).sum().item())
        loss_sum.backward()
        loss_numerators.append(float(loss_sum.detach().item()))
        total_valid_tokens += valid_tokens

    if total_valid_tokens == 0:
        raise ValueError("logical batch has no valid target tokens")
    for parameter in model.parameters():
        if parameter.grad is not None:
            parameter.grad.div_(total_valid_tokens)
    gradient_norm = torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)
    optimizer.step()
    mean_loss = sum(loss_numerators) / total_valid_tokens
    return mean_loss, float(gradient_norm)

def E13(model, optimizer, microbatches, padding_id):
    return accumulated_step(model, optimizer, microbatches, padding_id)
```

When using a gradient scaler, scale each summed microbatch loss, then unscale once, normalize, clip, and step through the scaler at the logical-batch boundary.

Part 5 - The Philosophy Behind the Exercise

Accumulation shows that a batch is a mathematical aggregation, not necessarily a single physical allocation. By separating the logical unit of learning from the hardware unit of execution, we gain flexibility. But equivalence exists only when denominators, randomness, and update timing preserve the same question the large batch would have asked.

17.10.15 Exercise 14

Exercise Title: Export Transformer Model Using TorchScript or ONNX and Validate Output Parity and Deployment Constraints

Part 1 - Why this matters

Export changes the execution environment and therefore introduces a new model boundary. Dynamic sequence lengths, masks, positional logic, caches, unsupported operators, precision, and backend-specific lowering can change behavior. A file that serializes successfully is not yet a valid deployment artifact. Export must begin with an explicit tensor contract and end with parity across the shapes and states the service will use.

Create a narrow wrapper around the stable forward path. Separate prefill and cached decode when deploying autoregressive generation. Inputs should include token IDs, attention mask, positions when needed, and flattened cache tensors in a fixed layer/key/value order. Outputs should include logits and updated cache. Keep tokenization, sampling, stop logic, request validation, and monitoring in a host layer unless their exported semantics are independently tested.

Export with TorchScript or ONNX, declaring dynamic batch, sequence, and cache axes where the target runtime supports them. Execute the artifact in the actual runtime and compare float tensors, greedy tokens, cache shapes, and full short generations against native PyTorch. Test batch one and many, multiple lengths, padding patterns, maximum context, and selected precision. Benchmark startup, prefill, decode, throughput, tail latency, size, and memory. Document fixed-shape requirements, unsupported operations, fallback paths, and runtime versions.

Part 2 - Mathematical form and reasoning

The deployment contract is

$$f_\theta(I, M, P, K_{<t}) \to (Z_t, K_{\le t}).$$

Parity requires shape and semantic agreement plus bounded numerical error:

$$\max_i |Z_i - \widehat{Z}_i| \le \epsilon_{\text{abs}} + \epsilon_{\text{rel}} \max_i |Z_i|.$$

Also measure token and sequence agreement because near-tied logits can satisfy a numeric tolerance while changing an autoregressive path.

Part 3 - Hints, controls, and evidence

Set evaluation and inference modes, freeze checkpoint and tokenizer, and make masks explicit. Avoid tracing data-dependent Python branches unless the traced shape and path are intentionally fixed. Give dynamic axes descriptive names and test them; metadata does not guarantee runtime support. Compare every cache layer and the first divergent generation step. Warm runtimes before steady timing and report compilation or session creation separately.

Verify model integrity with a checksum and version the preprocessing contract. Evidence includes interface schema, parity matrix, failing edge cases, performance table, supported shape envelope, and rollback artifact.

Part 4 - Python code skeleton

```
import torch
from torch import nn

class ExportableForward(nn.Module):
    def __init__(self, model):
        super().__init__()
        self.model = model

    def forward(self, input_ids, attention_mask):
        output = self.model(
            input_ids=input_ids, attention_mask=attention_mask
        )
        return output.logits

def compare_outputs(reference, candidate, absolute, relative):
    difference = (reference - candidate).abs()
    close = torch.allclose(
        reference, candidate, atol=absolute, rtol=relative
    )
    same_tokens = torch.equal(
        reference.argmax(dim=-1), candidate.argmax(dim=-1)
    )
    return {
        "close": close,
        "same_tokens": same_tokens,
        "maximum_error": float(difference.max().item()),
    }

@torch.inference_mode()
def E14(model, input_ids, attention_mask):
    model.eval()
    wrapper = ExportableForward(model)
    example = (input_ids, attention_mask)
    exported = torch.jit.trace(wrapper, example, strict=False)
    reference = wrapper(input_ids, attention_mask)
    candidate = exported(input_ids, attention_mask)
    result = compare_outputs(reference, candidate, 1e-5, 1e-4)
    if not result["close"]:
        raise AssertionError(str(result))
    return exported, result
```

Add dynamic-length tests and a dedicated cached-decode wrapper before using the artifact for generation.

Part 5 - The Philosophy Behind the Exercise

Export is a transfer of authority from one execution system to another. Trust cannot travel merely because weights did. It must be rebuilt through contracts, edge cases, numerical comparisons, and complete decisions. Portability means preserving behavior under a new mechanism, not merely producing a new format.

17.10.16 Exercise 15

Exercise Title: Build A/B Testing Plan for Two Transformer Models and Define Metrics and Rollback Strategy Clearly

Part 1 - Why this matters

Offline metrics cannot reproduce every production input, latency condition, or user interaction. A controlled A/B test estimates the effect of replacing model A with model B under real traffic. Without stable assignment, guardrails, sample-size planning, and a predeclared decision rule, ordinary traffic variation can be mistaken for improvement. A test must protect users while producing evidence, not expose everyone and hope averages look acceptable.

Write a hypothesis and primary metric before deployment. Add quality, safety, latency, error, cost, and resource guardrails. Define the unit of randomization: usually user or conversation rather than request, so one experience does not switch models unpredictably. Stratify or monitor major segments such as language, prompt length, device, region, and task. Pin tokenizer, wrapper policy, decoding settings, and infrastructure where the purpose is to isolate the model; if the whole system changes, state that the experiment measures the bundle.

Begin with offline gates and shadow traffic, then a canary fraction, then staged ramp-up. Specify automatic rollback thresholds for NaN rate, safety events, error rate, p95/p99 latency, memory, and primary-quality degradation. Include minimum samples and consecutive-window rules so one noisy minute does not cause oscillation, but severe events can trigger immediately. Preserve sticky routing, versioned telemetry, exposure logs, and an independent kill switch. Analyze intent-to-treat results and confidence intervals; do not repeatedly peek and stop when a favorable result appears without a sequential-testing design.

Part 2 - Mathematical form and reasoning

For outcome Y, estimated treatment effect is

$$\widehat{\Delta} = \overline{Y}_B - \overline{Y}_A.$$

For a binary failure rate with baseline p_A, minimum detectable effect and sample size should be chosen before the test using desired significance and power. Guardrail rollback can be represented as

$$\text{rollback} = mathbf{1}[\widehat{p}_B - p_A > \delta_p] \vee \mathbf{1}[q_{0.99,B} > L_{\max}] \vee \mathbf{1}[n_{\text{severe}} > 0],$$

subject to declared sample and window rules. Multiple metrics require correction or a hierarchy to prevent uncontrolled false discoveries.

Part 3 - Hints, controls, and evidence

Document eligibility, exclusions, assignment key, traffic fraction, duration, power assumptions, primary metric, guardrails, and decision owners. Run sample- ratio mismatch checks

to detect broken routing. Verify users remain in one arm and that telemetry carries assigned and actually served versions. Test rollback in staging before exposure. Plan for delayed outcomes and missing events. Analyze segment effects carefully without data-mining tiny groups. Evidence includes the signed test plan, prelaunch gate results, assignment audit, dashboards, rollback drill, effect estimates with uncertainty, and a decision record.

Part 4 - Python code skeleton

```
import hashlib

def stable_assignment(subject_id, experiment_name, treatment_fraction):
    material = (experiment_name + ":" + subject_id).encode("utf-8")
    digest = hashlib.sha256(material).digest()
    integer_value = int.from_bytes(digest[:8], byteorder="big")
    fraction = integer_value / float(2 ** 64)
    if fraction < treatment_fraction:
        return "model_b"
    return "model_a"

def should_rollback(window, limits):
    reasons = []
    if window["severe_safety_events"] > 0:
        reasons.append("severe safety event")
    if window["nan_rate"] > limits["maximum_nan_rate"]:
        reasons.append("NaN rate")
    if window["error_rate"] > limits["maximum_error_rate"]:
        reasons.append("error rate")
    if window["p99_latency_ms"] > limits["maximum_p99_latency_ms"]:
        reasons.append("p99 latency")
    enough_samples = window["requests"] >= limits["minimum_requests"]
    immediate = window["severe_safety_events"] > 0
    rollback = immediate or (enough_samples and len(reasons) > 0)
    return rollback, reasons

def E15(subject_ids, experiment_name, fraction, window, limits):
    assignments = {}
    for subject_id in subject_ids:
        assignments[subject_id] = stable_assignment(
            subject_id, experiment_name, fraction
        )
    rollback, reasons = should_rollback(window, limits)
    return assignments, rollback, reasons
```

In a real service, combine this stateless assignment with eligibility checks, experiment version, exposure logging, and a centrally controlled override.

Part 5 - The Philosophy Behind the Exercise

An A/B test is an experiment conducted inside another person's experience. Its scientific goal does not erase its duty of care. Good design limits exposure, predefines failure, and makes

retreat faster than debate. Evidence is valuable only when the process that obtains it respects both uncertainty and users.

17.10.17 Exercise 16

Exercise Title: Simulate Production Incident Where Model Produces NaNs or Garbage and Implement Auto-Rollback Mechanism

Part 1 - Why this matters

Production failures are not limited to exceptions. A model can return finite but meaningless repetition, invalid token IDs, empty outputs, confidence collapse, or outputs from mismatched preprocessing. NaNs may originate in corrupted weights, precision overflow, malformed masks, extreme inputs, or an incompatible runtime. If detection occurs only after users complain, monitoring and release controls have failed. This exercise rehearses detection, containment, rollback, and evidence preservation.

Deploy a stable version and a candidate behind an atomic routing pointer. Inject several faults in staging: nonfinite logits after a chosen request count, a wrong tokenizer version, repeated-token garbage, corrupted checkpoint checksum, and latency beyond timeout. At request boundaries validate input, model artifact, finite logits and probabilities, token range, stop behavior, repetition bounds, and output decoding. Aggregate fast service-level signals with consecutive- window rules, while severe integrity or safety faults trigger immediately.

Rollback must be idempotent and independent of the failing model process. Stop routing new traffic to the candidate, preserve in-flight policy, switch to a prevalidated artifact, verify it with a health corpus, and emit one incident record. Prevent automatic re-promotion. Retain request IDs, model and tokenizer versions, hashes, configuration, first bad step, numerical summaries, and system metrics while respecting privacy. Measure time to detect, time to contain, time to restore, failed-request count, and rollback success. Then repair the cause and add a regression test before any new canary.

Part 2 - Mathematical form and reasoning

Let h_t summarize a health window and G be safe-state constraints. The candidate remains eligible only if

$$h_t \in G \quad \text{for all required signals.}$$

A simple state machine is

$$\text{stable} \to \text{canary} \to \text{active},$$

with any guardrail violation transitioning to `rollback` and then `locked`. Recovery objectives include

$$\text{MTTD} = t_{\text{detect}} - t_{\text{fault}}, \qquad \text{MTTR} = t_{\text{healthy}} - t_{\text{detect}}.$$

Part 3 - Hints, controls, and evidence

Use a staging environment and synthetic data; never inject harmful faults into real user traffic. Keep the stable artifact resident or quickly loadable. Health checks must execute the

whole preprocessing-to-decoding path, not only test that the process responds. Differentiate bad request, transient infrastructure error, and model-version failure. Rate-limit rollback actions and use a compare-and- swap version guard so competing controllers cannot flap routing. Test rollback when the candidate process is frozen. Evidence includes incident timeline, triggering signals, version transitions, health-corpus results, MTTD, MTTR, affected requests, artifacts, root cause, and regression test.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import threading
import torch

@dataclass
class ModelVersion:
    name: str
    model: object
    tokenizer_hash: str
    checkpoint_hash: str

class AtomicRouter:
    def __init__(self, stable_version):
        self._lock = threading.Lock()
        self._active = stable_version
        self._stable = stable_version
        self._locked = False

    def current(self):
        with self._lock:
            return self._active

    def promote_candidate(self, candidate):
        with self._lock:
            if self._locked:
                raise RuntimeError("router is locked after incident")
            self._active = candidate

    def rollback(self, reason):
        with self._lock:
            self._active = self._stable
            self._locked = True
            return {"active": self._active.name, "reason": reason}

def validate_logits(logits, vocabulary_size, repetition_rate):
    if not bool(torch.isfinite(logits).all()):
        return False, "nonfinite logits"
    if logits.size(-1) != vocabulary_size:
        return False, "vocabulary mismatch"
    if repetition_rate > 0.95:
```

```
        return False, "garbage repetition threshold"
    return True, "healthy"

def E16(router, logits, vocabulary_size, repetition_rate):
    healthy, reason = validate_logits(
        logits, vocabulary_size, repetition_rate
    )
    if not healthy:
        return router.rollback(reason)
    return {"active": router.current().name, "reason": "none"}
```

Persist router state outside one process and require a verified health-corpus pass before unlocking in a real deployment.

Part 5 - The Philosophy Behind the Exercise

Resilience is not confidence that failure will never occur. It is the ability to recognize violated assumptions, reduce harm, restore a known state, and learn without erasing evidence. A rollback is not defeat; it is a designed expression of epistemic humility when the current system no longer deserves authority.

17.10.18 Exercise 17

Exercise Title: Stress Test Inference Service Under High Throughput and Detect Memory Leaks, Latency Spikes, and Cache Bugs

Part 1 - Why this matters

Model benchmarks execute orderly batches; real services receive bursts, variable prompts, different generation lengths, cancellations, timeouts, and malformed requests. Dynamic batching improves throughput but introduces queue delay and shared-state risk. Memory pools may remain reserved, while true leaks retain request tensors indefinitely. KV caches can be attached to the wrong row after batch compaction. A service can therefore pass single-request tests and fail under concurrency.

Build a load matrix over arrival rate, concurrency, prompt-length distribution, output-length distribution, batch-token limit, timeout, and precision. Include steady load, ramp, burst, soak, and overload tests. Use synthetic non-sensitive prompts with known outputs or checksums. Record offered and completed requests per second, queue time, first-token latency, inter-token latency, total latency, p50/p95/p99, errors, timeouts, cancellations, OOM, active requests, batch composition, GPU utilization, allocated/reserved memory, cache bytes, and output parity.

Track each request's immutable ID, prompt hash, logical position, cache handle, and generated prefix through batching and compaction. Compare selected requests with independent execution. After a request completes or cancels, assert its cache becomes unreachable and allocated memory at equal idle checkpoints does not drift across repeated cycles. Reserved memory may remain high because of the allocator; do not call that a leak without live allocation evidence. Increase load beyond capacity deliberately and verify bounded queues, backpressure, admission control, and graceful errors instead of uncontrolled latency and crash.

Part 2 - Mathematical form and reasoning

By Little's law, for stable average arrival rate λ, average response time W, and average requests in the system N,

$$N = \lambda W.$$

As offered load approaches service capacity, queue delay can rise sharply even if model compute per batch is unchanged. Define idle-checkpoint memory drift

$$D_r = M^{(r)}_{\text{allocated,idle}} - M^{(1)}_{\text{allocated,idle}}.$$

Persistent positive D_r across equal cycles indicates retained allocations. Cache correctness requires request-to-cache identity remain invariant under every batch reorder.

Part 3 - Hints, controls, and evidence

Separate load generator resources from inference resources. Synchronize clocks and preserve request IDs. Warm the service before measured load. Use a closed- loop test for controlled concurrency and an open-loop test for realistic arrivals; state which one produced each result. Generate cancellations during prefill and decode. Inject one slow and one very long request to detect head-of-line blocking. Capture allocation snapshots at defined idle barriers, not random moments. Test that overload invokes admission limits. Evidence includes load-versus-throughput and tail-latency curves, saturation point, memory-over-time plot, parity samples, cache ownership audit, leak reproducer, and chosen service limits.

Part 4 - Python code skeleton

```
import time
import torch

class ServiceMetrics:
    def __init__(self):
        self.requests = []
        self.idle_memory = []

    def record_request(self, request_id, queued_at, started_at,
                       first_token_at, completed_at, status):
        self.requests.append({
            "request_id": request_id,
            "queue_seconds": started_at - queued_at,
            "first_token_seconds": first_token_at - queued_at,
            "total_seconds": completed_at - queued_at,
            "status": status,
        })

    def record_idle_memory(self, device, cycle):
        torch.cuda.synchronize(device)
        self.idle_memory.append({
            "cycle": cycle,
            "allocated": torch.cuda.memory_allocated(device),
            "reserved": torch.cuda.memory_reserved(device),
```

```
        })

def verify_cache_ownership(active_requests, cache_registry):
    active_ids = set()
    for request in active_requests:
        active_ids.add(request["request_id"])
    cache_ids = set(cache_registry.keys())
    if active_ids != cache_ids:
        missing = active_ids - cache_ids
        stale = cache_ids - active_ids
        raise AssertionError({"missing_cache": missing, "stale_cache": stale})

def detect_allocated_drift(idle_memory, allowed_bytes):
    if len(idle_memory) < 2:
        return False, 0
    baseline = idle_memory[0]["allocated"]
    latest = idle_memory[-1]["allocated"]
    drift = latest - baseline
    return drift > allowed_bytes, drift

def E17(metrics, active_requests, cache_registry, allowed_bytes):
    verify_cache_ownership(active_requests, cache_registry)
    return detect_allocated_drift(metrics.idle_memory, allowed_bytes)
```

The actual load generator should schedule requests independently of the service process and emit timestamps for every lifecycle transition.

Part 5 - The Philosophy Behind the Exercise

Concurrency turns private state into shared risk. A cache, queue, and GPU are useful because many requests coordinate around them, but coordination must never erase identity or fairness. Stress testing asks whether the system preserves its promises when resources become contested, which is when those promises matter most.

17.10.19 Exercise 18

Exercise Title: Create a Production Readiness Checklist Covering Performance, Monitoring, Safety, and Data Quality

Part 1 - Why this matters

Production readiness is not a final accuracy threshold. It is evidence that the model, data pipeline, inference controller, infrastructure, monitoring, safety controls, and recovery process behave together under normal and abnormal conditions. Checklists prevent familiar risks from disappearing during deadline pressure, but only if each item is an enforceable gate with an owner and artifact. A box labeled “performance tested” is too vague to protect a release.

Organize gates into artifact identity, data and tokenizer, model correctness, numerical stability, performance and capacity, service behavior, monitoring, safety and privacy, security, deployment, rollback, and operations. For every gate record requirement, test, threshold, evidence location, owner, date, environment, status, and expiry or review trigger. Examples

include tokenizer- checkpoint compatibility, mask and cache parity, finite-output tests, quality by segment, p99 latency under target load, maximum safe context with headroom, drift detector validation, typed errors, adversarial input handling, privacy retention, artifact checksum, canary plan, and successful rollback drill.

Automate gates that can be computed and require explicit sign-off for judgments. Block release on missing evidence rather than treating unknown as pass. Define waiver authority, reason, expiration, compensating control, and rollback trigger. Run the checklist on the exact artifact and configuration to be deployed; a result from an earlier checkpoint or different precision is not transferable. After launch, convert relevant gates into continuous monitors and schedule revalidation when model, tokenizer, runtime, hardware, traffic, or policy changes.

Part 2 - Mathematical form and reasoning

Let gates $g_i \in \{\text{pass}, \text{fail}, \text{unknown}, \text{waived}\}$. Release eligibility is

$$E = \bigwedge_{i \in \mathcal{B}} \mathbf{1}[g_i = \text{pass}] \wedge \bigwedge_{j \in \mathcal{W}} \mathbf{1}[g_j \in \{\text{pass}, \text{waived}\}],$$

where $\mathcal{B}$ are non-waivable blockers and $\mathcal{W}$ controlled gates. Unknown is not pass. Each waiver must satisfy $t < t_{\text{expiry}}$ and retain an authorized owner and compensating control.

Part 3 - Hints, controls, and evidence

Use stable gate identifiers so failures can be tracked across releases. Include artifact hashes and environment in every evidence record. Separate launch blockers from warnings but keep both visible. Test the checklist validator with missing, stale, failed, and expired-waiver cases. Require rollback artifact and health corpus before promotion. Verify dashboards and alerts receive real canary telemetry. Conduct incident and overload drills. Evidence is the machine-readable checklist, linked test outputs, sign-offs, waiver registry, deployment decision, and post-launch verification. Review the list after incidents so operational learning becomes a stronger future gate.

Part 4 - Python code skeleton

```
from datetime import datetime, timezone

BLOCKING_GATES = (
    "artifact_integrity",
    "tokenizer_compatibility",
    "mask_and_cache_parity",
    "finite_outputs",
    "quality_thresholds",
    "capacity_with_headroom",
    "safety_tests",
    "rollback_drill",
)

def waiver_is_valid(gate, current_time):
    waiver = gate.get("waiver")
    if waiver is None:
```

```
        return False
    required = ("owner", "reason", "compensating_control", "expires_at")
    for field in required:
        if field not in waiver:
            return False
    expiry = datetime.fromisoformat(waiver["expires_at"])
    return current_time < expiry

def validate_readiness(checklist):
    current_time = datetime.now(timezone.utc)
    errors = []
    for gate_id in BLOCKING_GATES:
        if gate_id not in checklist:
            errors.append("missing gate: " + gate_id)
            continue
        gate = checklist[gate_id]
        if "evidence" not in gate or not gate["evidence"]:
            errors.append("missing evidence: " + gate_id)
        status = gate.get("status", "unknown")
        if status == "pass":
            continue
        if status == "waived" and waiver_is_valid(gate, current_time):
            errors.append("blocking gate cannot be waived: " + gate_id)
        else:
            errors.append("blocking gate not passed: " + gate_id)
    return len(errors) == 0, errors

def E18(checklist):
    eligible, errors = validate_readiness(checklist)
    if not eligible:
        raise RuntimeError("\n".join(errors))
    return {"release_eligible": True, "validated_gates": len(checklist)}
```

Add nonblocking gates with governed waivers separately; the sample treats every listed gate as non-waivable.

Part 5 - The Philosophy Behind the Exercise

Readiness is not confidence produced by familiarity with the system. It is a publicly inspectable chain of evidence and responsibility. A checklist is valuable when it gives uncertainty a status, failure an owner, and exceptions an expiration. It transforms “we think it is ready” into a claim that can be challenged before users bear the cost.

17.10.20 Exercise 19

Exercise Title: Produce a Final Transformer Engineering Report Summarizing Architecture, Training, Efficiency, and Deployment

Part 1 - Why this matters

This report closes the Transformer track by connecting the model's mathematical design to its physical and operational behavior. It must explain not only what was built, but what evidence supports its correctness, how efficiency changes its behavior, where long context becomes unsafe, which deployment constraints remain, and how the system detects and recovers from failure. A polished sample and one benchmark cannot carry that responsibility.

Begin with experiment identity: code, checkpoint, tokenizer, dataset, runtime, driver, hardware, seeds, precision, attention backend, compilation mode, and configuration hashes. Summarize architecture and training: attention, positions, masks, objectives, optimizer, schedule, gradient behavior, validation quality, and known data limitations. Link to correctness tests for causal masking, cache parity, tiny-task overfitting, checkpoint resume, and export.

Present efficiency as a set of controlled tradeoffs. Include quadratic memory prediction versus measurement, standard versus flash-style attention, sliding- window quality by dependency distance, KV-cache latency and bytes per token, float32/float16/int8 quality and performance, compile break-even and graph behavior, profiler phase shares, activation-checkpoint savings, accumulation parity, deterministic cost, and maximum safe context. Then document production: request contract, capacity, tail latency, overload behavior, monitoring and drift, A/B design, safety/privacy controls, incident drill, rollback time, stress test, and readiness decision. Preserve negative results and unresolved risks. End with recommended defaults, exceptions, owners, and measurable revision triggers.

Part 2 - Mathematical form and reasoning

Represent a deployment configuration c by

$$R(c) = (Q_c, L_c, T_c, M_c, C_c, S_c, F_c),$$

where Q is quality, L tail latency, T throughput, M memory, C cost, S safety performance, and F failure rate. No scalar "best" exists without declared weights and constraints. A feasible configuration satisfies

$$Q_c \geq Q_{\min}, \quad L_c \leq L_{\max}, \quad M_c \leq M_{\text{budget}}, \quad S_c \geq S_{\min},$$

under the stated workload distribution. Report uncertainty, length buckets, and sample counts so averages do not conceal unsafe regions.

Part 3 - Hints, controls, and evidence

Use a fixed report schema and generate tables from structured records. Separate measurement, interpretation, recommendation, and unresolved question. State timing boundaries, warm-up, repetitions, padding efficiency, backend selection, and excluded failures. Link each default to evidence and each limitation to an owner or acceptance decision. Include first failing and last safe configurations, not only successful maxima. Validate report completeness automatically and have a reviewer reproduce selected checks from hashes and commands. The final report should remain useful after the author leaves the project.

Part 4 - Python code skeleton

```
import json
from pathlib import Path
```

```
REQUIRED_SECTIONS = (
    "identity_and_artifacts",
    "architecture",
    "training_and_quality",
    "attention_and_long_context",
    "cache_quantization_compile",
    "cuda_profile_and_capacity",
    "export_and_runtime",
    "service_contract",
    "monitoring_and_drift",
    "ab_test_and_rollback",
    "stress_and_incidents",
    "readiness_decision",
    "recommended_defaults",
    "limitations_and_owners",
)

def validate_final_report(report):
    errors = []
    for section in REQUIRED_SECTIONS:
        if section not in report:
            errors.append("missing section: " + section)
    identity = report.get("identity_and_artifacts", {})
    identity_fields = (
        "code_hash", "checkpoint_hash", "tokenizer_hash",
        "runtime_version", "device", "precision"
    )
    for field in identity_fields:
        if field not in identity:
            errors.append("missing identity: " + field)
    readiness = report.get("readiness_decision", {})
    if "status" not in readiness or "evidence_ids" not in readiness:
        errors.append("readiness decision is incomplete")
    defaults = report.get("recommended_defaults", {})
    required_defaults = (
        "maximum_context", "maximum_batch_tokens",
        "precision", "attention_backend", "rollback_version"
    )
    for field in required_defaults:
        if field not in defaults:
            errors.append("missing default: " + field)
    if errors:
        raise ValueError("\n".join(errors))

def save_final_report(report, path_text):
    validate_final_report(report)
    path = Path(path_text)
    path.parent.mkdir(parents=True, exist_ok=True)
```

```
    with path.open("w", encoding="utf-8") as handle:
        json.dump(report, handle, indent=2, sort_keys=True)

def E19(report):
    path = "reports/trf08_final_transformer_engineering_report.json"
    save_final_report(report, path)
    return path
```

Create the human-readable narrative from this same record so the conclusions and the machine-validated evidence cannot silently disagree.

Part 5 - The Philosophy Behind the Exercise

Engineering ends neither at accuracy nor deployment. It reaches maturity when capability, cost, uncertainty, and responsibility are described in one coherent account. The report is a transfer of stewardship: it tells future researchers what the system can do, what it consumes, when it fails, and why its present authority should—or should not—continue.

Book 18

Large Language Models

18.1 Introduction

18.1.1 What will the book teach you

This book studies the Large Language Model as a complete learning and engineering system. An LLM is not defined merely by containing Transformer blocks, nor by crossing an arbitrary parameter count. It is a language model whose architecture, training objective, data scale, optimization process, inference machinery, and post-training procedures combine to produce broad capabilities across many language tasks. The word "large" therefore refers to more than weights stored in memory. It also refers to the scale of training tokens, compute, context, behavioral coverage, evaluation, and operational infrastructure required to make the model useful and reliable.

The architectural core of the book is the decoder-only Transformer studied in the previous volume. Tokens are embedded, supplied with positional information, processed through repeated causal self-attention and feed-forward blocks, and projected into logits over the vocabulary. The model is trained to predict the next token under a causal factorization:

$$p_\theta(x_1, \ldots, x_T) = \prod_{t=1}^{T} p_\theta(x_t \mid x_{<t}).$$

This objective appears narrow, but the prediction problem becomes extremely rich when the training distribution contains natural language, code, mathematics, dialogue, structured data, and explanations. To predict well, the model must learn regularities involving syntax, semantics, style, discourse, entities, facts, procedures, and recurring patterns of reasoning. The book will examine this relationship without turning it into mythology. A model can produce a convincing reasoning trace without possessing human understanding, and it can reproduce a fact-shaped sequence without operating as a verified knowledge base. Behavioral competence, internal representation, memorization, generalization, and human-like understanding are different claims and require different evidence.

The first chapter establishes what makes a model an LLM. It separates the Transformer architecture from the larger system constructed through scale, data, and training. Encoder-only models such as BERT learn powerful contextual representations but are not organized for unrestricted left-to-right generation in the same way as decoder-only models. Encoder-decoder models condition a target sequence on a distinct source, while GPT-style models express prompts, instructions, context, and responses within one causal token stream. The reader will implement a minimal GPT-style skeleton, inspect causal logits, estimate forward-pass computation, and

compare small and larger language models on controlled tasks. The goal is to replace the vague definition "a very large Transformer" with a precise account of architecture, objective, scale, and behavior.

Scaling will be treated as an empirical relationship rather than a promise that more parameters automatically create intelligence. Increasing parameters can expand representational capacity, but useful improvement also depends on the amount, diversity, quality, and coverage of data; optimization stability; and the compute used to connect them. Parameter count and context length are independent axes: a model may contain many weights yet accept a short context, or use a long context while remaining comparatively small. Apparent emergent abilities will be examined with attention to metric thresholds, prompting, evaluation resolution, and genuine changes in model behavior. The reader will learn to ask which capability improved, under what distribution, and whether the measurement could have made a gradual change look sudden.

The tokenization and context chapter makes the model's input representation explicit. An LLM does not read words directly. A tokenizer maps text into a sequence of discrete identifiers, and the choice of vocabulary changes sequence length, efficiency, rare-string behavior, multilingual coverage, code handling, and the boundaries at which the model observes structure. Character, word, and subword tokenization will be compared, and Byte Pair Encoding will be implemented conceptually so vocabulary construction is understood as an algorithm rather than a hidden preprocessing service. Special tokens, padding, attention masks, shifted labels, and decoding must use one versioned vocabulary contract. A tokenizer mismatch can make a correct checkpoint produce garbage while every tensor shape remains valid.

Context will be studied as both information and cost. The context window is the finite token region available to a prediction; material outside it cannot directly influence the model. Truncation can remove the instruction, evidence, or earlier state that the current answer requires. Sliding windows preserve local continuity but can separate distant dependencies. Packed sequences reduce padding waste but require careful boundaries so one document cannot attend to another. Rotary and absolute positional methods behave differently when evaluated beyond training lengths. The exercises will measure context memory, attention cost, prompt sensitivity, OOM boundaries, and failures caused by masking or off-by-one label shifts. Long context will not be treated as useful merely because a model accepts many tokens; retrieval quality across position and the ability to use distant evidence must be measured.

The pretraining chapter examines how a corpus becomes a learning signal. Text must be collected, licensed or authorized, cleaned, deduplicated, filtered, tokenized, split, sampled, and arranged into training sequences. Dataset scale cannot compensate automatically for systematic contamination, duplication, incorrect language balance, unsafe material, or train-test leakage. The reader will compare clean and noisy corpora, measure loss against token frequency, study rare-token failures, and distinguish memorization from generalization through controlled overlap experiments. Data quality becomes increasingly important at scale because the model receives an enormous number of repeated lessons about what patterns deserve probability. Architecture determines what can be learned; data determines much of what is learned.

The next-token loss for valid target positions is

$$\mathcal{L}_{\mathrm{NLL}} = -\frac{1}{N_{\mathrm{valid}}} \sum_{b,t} m_{b,t} \log p_\theta(x_{b,t} \mid x_{b,<t}),$$

where $m_{b,t}$ excludes padding or other unsupervised positions. This equation will be connected directly to tensor shapes, reduction rules, and gradient scaling. A misplaced target shift can let the model see the answer or predict the wrong position. An incorrect mean across

padded batches can change gradient magnitude as sequence composition changes. The book will use tiny-corpus overfitting, token-level loss inspection, gradient accumulation, CUDA profiling, and controlled batch experiments to prove that pretraining optimizes the stated objective before larger runs are trusted.

Pretraining teaches a model to continue text distributions; it does not by itself define the behavior of a helpful assistant. The instruction-tuning chapter studies supervised fine-tuning, in which prompts, instructions, and responses are organized into a training format and loss is commonly applied to the intended response region. Prompt templates, boundary tokens, masking, and conversation roles are part of the learned task. If prompt tokens are masked or supervised incorrectly, the model may learn formatting while missing the requested content. The reader will build instruction datasets, implement the SFT loss, compare behavior before and after tuning, and evaluate instruction following under changes in wording rather than relying on familiar templates.

Full fine-tuning changes every eligible parameter and can require substantial memory for gradients and optimizer states. Parameter-efficient methods such as LoRA introduce trainable low-rank updates while leaving base weights frozen. For a weight matrix W, a low-rank adaptation can be represented as

$$W' = W + \frac{\alpha}{r} BA,$$

where A and B have rank dimension r. The method reduces trainable state, but it does not guarantee equal quality, eliminate activation memory, or prevent catastrophic forgetting. The exercises will compare full and low-rank tuning, learning rates, schedulers, gradient accumulation, prompt dropout, domain continued pretraining, and multi-task versus single-task data. Evaluation will include retained base capabilities so specialization is not mistaken for unqualified improvement.

The alignment chapter addresses the gap between likely continuation and desired behavior. Human preference data differs from ordinary supervised labels because it compares responses under criteria such as helpfulness, relevance, honesty, style, and safety. The book will explain the conceptual RLHF pipeline, preference modeling, policy optimization, and Direct Preference Optimization. A typical DPO objective compares the policy's preference margin with that of a reference policy:

$$\mathcal{L}_{\mathrm{DPO}} = -\log \sigma\left(\beta \left[\log \frac{\pi_\theta(y_w \mid x)}{\pi_{\mathrm{ref}}(y_w \mid x)} - \log \frac{\pi_\theta(y_l \mid x)}{\pi_{\mathrm{ref}}(y_l \mid x)}\right]\right),$$

where y_w and y_l are preferred and rejected responses. The equation does not remove the human choices embedded in the dataset, the annotator guidelines, or the value of β. Alignment is not a single universal direction; it is a set of behavioral decisions whose benefits, trade-offs, and failure cases must be documented.

Safety will be studied as part of training and deployment rather than a final filter attached after capability work. Preference noise, reward hacking, over-alignment, mode collapse, excessive refusal, unsafe compliance, and distribution shift can all produce failures. The reader will build edge-case evaluation sets, red-team prompts, refusal and safety policies, helpfulness-harmlessness comparisons, and production checklists. The objective is neither a model that refuses everything nor one that answers every request. It is a system whose behavior is governed by explicit policies, measured across realistic and adversarial inputs, and supported by escalation or human review when automatic judgment is insufficient.

The inference chapter turns a trained checkpoint into a service. Autoregressive generation remains sequential across produced tokens, even though each model step contains highly par-

allel tensor operations. KV caching avoids recomputing past keys and values, but creates state whose positions, batch rows, beams, devices, and lifecycle must remain correct. The reader will implement and test cache parity, batched variable-length prompts, streaming generation, stop-token logic, rate limits, timeouts, cold and warm starts, long-prompt policies, and canary deployment. Performance will be separated into queue time, tokenization, host-to-device transfer, prefill, time to first token, inter-token latency, and complete request time. Throughput and user-perceived latency will be treated as related but different objectives.

Long-running services introduce failure modes that do not appear in notebooks. Request-local caches can leak, a cancelled request can leave state behind, dynamic batching can attach cache rows to the wrong user, and one oversized prompt can create head-of-line blocking or OOM. Monitoring must distinguish allocated from reserved CUDA memory, expected cache growth from leaks, model errors from malformed requests, and temporary latency variation from capacity failure. The exercises will stress high-QPS service paths, verify cache ownership, test backpressure and timeouts, and construct alerting and rollback procedures. Production inference is therefore studied as a stateful concurrent system, not as a loop around `model.forward`.

The quantization and deployment chapter examines how fewer bits change storage, bandwidth, kernels, and behavior. Post-training quantization modifies a trained model using scales and calibration, whereas quantization-aware training exposes the model to quantization effects during optimization. Int8 and int4 can reduce weight memory substantially, but the actual speedup depends on hardware support, batch, operator coverage, and conversion overhead. Outliers can dominate scales; some attention, normalization, embedding, or output components may be more sensitive than others. The reader will compare quality, logits, hallucination rate, latency, memory, power, compatibility, and concurrency before and after quantization. A smaller artifact is not automatically a better deployment.

Deployment tests will include output parity, saturation and NaN detection, precision fallback, ONNX or other export constraints, limited-memory devices, artifact integrity, and rollback. A quantized model may produce mostly similar tokens while failing systematically on rare inputs or long contexts. For this reason, evaluation must include targeted edge cases and complete generation, not only mean weight reconstruction error. Stakeholder documentation will state what became faster or smaller, what quality changed, which hardware is required, and which conditions trigger fallback to a higher-precision version.

The evaluation and reliability chapter addresses one of the defining weaknesses of LLMs: a probable continuation can be fluent without being true. Hallucination is not one homogeneous error. It can involve unsupported claims, contradiction with supplied context, fabricated entities or citations, stale knowledge, incorrect tool results, or confident continuation beyond available evidence. The reader will build targeted evaluation sets, separate factual and creative tasks, vary temperature, compare model sizes, test paraphrases and domain shift, and record failure patterns. The model's confidence will be compared with correctness because probability concentration is not a certificate of truth.

Reliability requires multiple forms of evidence. Exact-match and reference metrics can be useful on closed tasks, while factuality may require verified sources or expert review. Calibration measures whether confidence corresponds to observed correctness. Abstention gives the model a way to express insufficient support, but it must be evaluated for both missed answers and prevented errors. Self-consistency can improve some reasoning tasks by comparing multiple samples, yet agreement among samples from the same flawed distribution does not establish truth. Reliability dashboards will combine quality, hallucination categories, confidence mismatch, latency, drift, safety, and human-review outcomes rather than compressing trust into a

single score.

Retrieval-augmented generation will be introduced first as a reliability method and then developed as a complete system. Retrieval can provide current or domain-specific evidence without encoding every update into model parameters. However, RAG can fail because of document ingestion, chunking, embedding, indexing, retrieval recall, ranking, prompt construction, context competition, or unsupported generation. A retrieved passage is not automatically relevant, and a relevant passage is not automatically used correctly. The reader will compare retrieval augmentation with fine-tuning, evaluate recall and answer quality separately, and require answers to remain grounded in verified tool results.

The final chapter expands the LLM from a text generator into an agentic system. Tools allow the model to retrieve documents, query databases, call structured services, calculate, or act in an external environment. Tool use creates an authority boundary: generated text is a proposal, while a tool call can read or change real state. Structured arguments must be validated against schemas; permissions must be least-privilege; tool outputs must be treated as data rather than instructions; and side effects may require confirmation or idempotency. The reader will implement tool routing, SQL and vector-search integrations, result verification, multi-turn memory, planning, loop detection, partial-error recovery, monitoring, and concurrency tests.

Agents and RAG will be evaluated end to end. Retrieval recall can improve while answer accuracy declines; a planner can produce an elegant sequence whose first tool call is invalid; memory can preserve useful state or retain a corrupted assumption; repeated retries can turn a small tool failure into an infinite loop. The final engineering report will document architecture boundaries, allowed tools, data provenance, latency budgets, stop conditions, safety rules, failure handling, and human oversight. The intended outcome is not an agent that acts as often as possible, but one whose actions are justified, constrained, observable, and recoverable.

Across all chapters, PyTorch remains central. Tiny GPT-style models will be implemented deeply enough to expose embeddings, causal attention, logits, losses, gradients, precision, memory, and device placement. CUDA experiments will measure rather than assume acceleration. Large-model concepts will be tested on small controlled systems where mechanisms can be inspected, failures can be injected, and results can be reproduced. The purpose is not to pretend that one workstation reproduces frontier-scale pretraining. It is to understand the laws, interfaces, and engineering decisions that remain valid when scale increases.

By the end of the book, the reader should be able to explain an LLM as a chain of accountable transformations: authorized data becomes token sequences; causal prediction creates a base model; post-training changes interaction behavior; inference converts logits into decisions under resource limits; evaluation challenges claims of quality and reliability; retrieval and tools connect the model to external evidence and action; monitoring and rollback keep the deployed system inside its supported operating region. The final objective is not merely to run an LLM. It is to understand what gives the model its capabilities, what limits those capabilities, and what evidence is required before its outputs or actions deserve trust.

18.1.2 Why this book comes after the Transformer

The Transformer book established the computational substrate required for this volume. The reader implemented scaled dot-product and multi-head attention, positional representations, residual blocks, Layer Normalization, feed-forward networks, token embeddings, causal masks, optimization, decoder-only generation, cross-attention, long-context techniques, caching, quantization, export, and production controls. Those mechanisms explain how a Transformer computes. They do not yet explain how a broadly capable language system is created, adapted,

evaluated, served, and governed.

An LLM is built from Transformer mechanisms, but the system-level questions change with scale. Data composition becomes a primary design decision. Small alignment errors can be repeated across billions of token predictions. Fine-tuning can improve instruction following while erasing capabilities. Preference optimization can reduce one failure while increasing refusal or mode collapse. Inference state can consume more memory than expected under concurrent long requests. Quantization can make deployment possible while changing rare behaviors. Evaluation must confront open-ended correctness, hallucination, and uncertainty. Tools transform generated tokens into proposed actions with real permissions and consequences.

This book therefore does not repeat the Transformer as if LLM were merely a new name for the same architecture. It uses the Transformer as known machinery and studies the additional layers that create an LLM system: scale, corpus design, instruction data, preferences, safety policy, serving infrastructure, reliability measurement, retrieval, tool use, and operational control. Coming after the Transformer allows each new capability to be traced back to known tensor operations while keeping the larger social and engineering system visible.

The transition also prevents a common conceptual mistake. A Transformer forward pass produces logits. An LLM product produces an experience through tokenizer, prompt format, context selection, decoding, policy, tools, monitoring, and user interaction. Two products can use the same base checkpoint and behave very differently because these surrounding systems differ. Understanding the architecture is necessary; understanding the LLM requires following the full path from training evidence to deployed consequence.

18.1.3 How to study this book

Begin every exercise by defining the claim being tested. “The model improved” is not a sufficient claim. Specify whether the expected change concerns token loss, instruction following, factuality, calibration, refusal behavior, retrieval grounding, latency, memory, throughput, or recovery. Write the baseline, intervention, controlled variables, metrics, failure threshold, and evidence to save before running code. Open-ended outputs make selective interpretation easy; predeclared evaluation protects the experiment from choosing only favorable examples.

Preserve the complete artifact identity. Record code version, checkpoint hash, tokenizer hash, dataset and split fingerprints, prompt template, special-token IDs, model configuration, random seed, PyTorch and CUDA versions, GPU, precision, attention backend, quantization, decoding policy, and stopping rules. A metric without these conditions cannot be reproduced or compared honestly. When a checkpoint is fine-tuned, retain the base identity and adaptation configuration so changes can be attributed.

Use small models and synthetic tasks to test mechanisms before expensive runs. Overfit a tiny corpus to validate the next-token pipeline. Create unique token sequences to expose target-shift and mask errors. Construct preference pairs whose intended ordering can be calculated. Inject a false retrieved document, invalid tool argument, corrupt cache position, NaN logit, or delayed tool response and verify that the system detects the fault. A successful output is weak evidence; a regression test that fails under a known bug is much stronger.

Keep the code explicit. Write tensor shapes and semantic axes before reshaping. Avoid compressed expressions that conceal data flow. Separate tokenization, model execution, logits processing, sampling, cache update, stopping, tool validation, and evaluation into observable steps. Compare manual PyTorch implementations with trusted optimized operations under matched parameters and inputs. Forward parity, gradient parity, sequence parity, and performance are different tests and should not be substituted for one another.

Treat data as part of the executable specification. Inspect raw examples, normalized text, token IDs, boundaries, masks, labels, preference order, source documents, metadata, and split assignment. Search for duplicates and leakage before training. Document authorization, provenance, and filtering. When the task changes from pretraining to instruction tuning or preference learning, state precisely which tokens receive loss and what behavioral signal each example expresses.

Evaluate base capability and changed behavior together. After fine-tuning, measure the target task and a retained-capability suite. After alignment, measure helpfulness, safety, false refusal, diversity, and calibration. After quantization, measure memory and latency alongside logits, sequences, rare cases, and hallucination. After retrieval, measure retrieval recall separately from answer correctness. After adding tools, measure argument validity, execution success, result grounding, side-effect safety, and loop termination. Every optimization creates a new hypothesis about what remains invariant.

Use CUDA measurements correctly. Warm kernels and runtimes, synchronize timing boundaries, separate cold start from steady state, and report prompt prefill, time to first token, inter-token latency, total latency, and throughput. Record allocated and reserved memory, peak usage, KV-cache bytes, and the workload that produced them. Compare batch sizes and context lengths rather than reporting one idealized configuration. A maximum that succeeds once is not a production limit; preserve safety headroom and test concurrent requests.

Treat hallucination and safety evaluation as adversarial science. Do not ask only questions the model is known to answer. Include rare entities, misleading premises, ambiguous instructions, paraphrases, domain shifts, unsupported requests, and conflicting retrieved evidence. Separate factual, creative, and agentic contexts because desired behavior differs. Record confident errors and appropriate abstentions. Human review should use written criteria and agreement checks rather than unaudited impressions.

For RAG and agents, trace provenance and authority. Every final claim should be connected to retrieved evidence or a declared model inference. Every tool call should include validated arguments, permission scope, result status, and request identity. Tool outputs can fail partially or contain untrusted text. Set maximum steps, retry budgets, timeouts, cancellation, and human-confirmation boundaries. An agent that reaches the correct answer through an unsafe action path has not passed the exercise.

Maintain an engineering notebook throughout the book. For every exercise store the question, mathematical objective, data contract, configuration, hypothesis, expected failure, raw measurements, examples, plots, interpretation, limitation, and regression test. At the end of each chapter, turn these records into the requested report or checklist. By the final chapter, the notebook should form a complete LLM systems manual connecting training, post-training, inference, reliability, retrieval, tools, and production response.

18.1.4 The Chapters (LLM00 - LLM08) included in this book

- LLM00 - What Makes a Model an LLM
- LLM01 - Tokenization and Context Mechanics
- LLM02 - Pretraining Objective and Data
- LLM03 - Instruction Tuning and Fine-Tuning
- LLM04 - Alignment, Preferences, and Safety

- LLM05 - Inference, KV Cache, and Serving
- LLM06 - Quantization and Deployment
- LLM07 - Evaluation, Hallucination, and Reliability
- LLM08 - Agents, Tools, and RAG Systems

18.2 LLM00

Chapter Title: What Makes a Model an LLM
Specialization: Large Language Model Foundations

18.2.1 Exercise 00

Exercise Title: Define LLM Precisely as Decoder-Only Transformer Trained on Next-Token Prediction Objective

Part 1 - Why this matters

The phrase "large language model" is often used as if it referred to one precise architecture. It does not. A Transformer is an architectural family; an LLM is a trained language system whose behavior emerges from an architecture, a tokenization rule, a probability objective, a large corpus, an optimization process, and an inference procedure. This exercise begins by separating those layers. Without this separation, it is easy to attribute a behavior to the network when it was actually caused by the tokenizer, the data, the decoding rule, or post-training.

For this book, the central reference model is a decoder-only Transformer trained autoregressively. The model receives token identifiers representing a prefix and returns one logit for every vocabulary item at every position. A causal mask prevents a position from receiving information from future positions. During training, all positions can be evaluated in parallel because the complete sequence is already available; during generation, one new token is selected, appended, and used to request the next distribution. The same conditional probability rule therefore connects training and inference even though their execution patterns differ.

The word "large" must be treated as a systems description rather than a magic parameter threshold. Model width, depth, vocabulary, context length, corpus size, training compute, and serving resources can all be large in different ways. A 100-million-parameter decoder and a 70-billion-parameter decoder may implement the same mathematical objective, yet their learned capabilities, costs, failure modes, and operating requirements differ radically. Your definition must preserve the common mechanism without pretending that scale is irrelevant.

You will construct a tiny probability example rather than beginning with a massive checkpoint. The tiny example lets you inspect every token, logit, probability, shifted target, and loss term. It also exposes an essential fact: next-token prediction does not require the network to store a table of verified facts or to possess human intentions. It requires the network to assign useful conditional probabilities. Any higher-level capability must ultimately be expressed through those distributions.

The exercise is complete only when you can state what evidence would falsify your definition. An encoder-only masked-language model, a decoder with random weights, a trained decoder without an inference tokenizer, and a retrieval database are not interchangeable objects. Classify each one and justify the classification using architecture, objective, training state, and operational behavior rather than brand names.

Part 2 - Mathematical form and reasoning

Let a tokenizer map text to a sequence $x_{1:T} = (x_1, \ldots, x_T)$ where each x_t belongs to a vocabulary of size V. An autoregressive language model factorizes the joint probability as

$$p_\theta(x_{1:T}) = \prod_{t=1}^{T} p_\theta(x_t \mid x_{<t}).$$

Given input identifiers $X \in \{0, \ldots, V-1\}^{B \times T}$, the decoder produces logits

$$Z = f_\theta(X) \in \mathbb{R}^{B \times T \times V}.$$

For next-token training, the prediction at source position t is compared with the token at position $t+1$:

$$\mathcal{L} = -\frac{1}{N_{\text{valid}}} \sum_{b=1}^{B} \sum_{t=1}^{T-1} m_{b,t} \log \operatorname{softmax}(Z_{b,t,:})_{X_{b,t+1}}.$$

The mask $m_{b,t}$ distinguishes real targets from padding or ignored regions. Write the shapes of the shifted logits and targets before calling cross entropy. Explain why a one-position error can produce a decreasing loss while training the wrong conditional relationship.

Part 3 - Hints, controls, and evidence

1. Create a vocabulary of at least seven tokens, including beginning, ending, and padding tokens. Write both token-to-identifier and identifier-to-token mappings explicitly.
2. Construct a batch of two short sequences. Print the input prefix and the target token at every trained position before computing any loss.
3. Create deterministic logits for which the correct next token is known. Compute one softmax row and one negative log-likelihood term manually.
4. Compare the manual mean with `torch.nn.functional.cross_entropy` after reshaping from $(B, T-1, V)$ to $(B(T-1), V)$.
5. Inject an off-by-one target error. Record why shapes and finite-value checks pass even though the semantic contract fails.
6. Finish with a four-column classification table: object, architecture, training objective, and whether it qualifies as the operational LLM studied in this book.

Required evidence includes the token alignment table, logit shape, probability normalization check, manual loss, library loss, and the deliberately failing alignment case.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def build_vocabulary():
    token_to_id = {}
    token_to_id["<pad>"] = 0
```

```
    token_to_id["<bos>"] = 1
    token_to_id["<eos>"] = 2
    token_to_id["large"] = 3
    token_to_id["models"] = 4
    token_to_id["predict"] = 5
    token_to_id["tokens"] = 6

    id_to_token = {}
    for token in token_to_id:
        token_id = token_to_id[token]
        id_to_token[token_id] = token
    return token_to_id, id_to_token

def shift_for_next_token(logits, input_ids):
    shifted_logits = ...
    shifted_targets = ...
    return shifted_logits, shifted_targets

def manual_nll(logit_row, target_id):
    probabilities = ...
    target_probability = ...
    loss = ...
    return loss, probabilities

def E00(device):
    torch.manual_seed(17)
    token_to_id, id_to_token = build_vocabulary()
    input_ids = torch.tensor(..., device=device, dtype=torch.long)
    logits = torch.tensor(..., device=device, dtype=torch.float32)
    shifted_logits, shifted_targets = shift_for_next_token(
        logits, input_ids
    )
    manual_loss, probabilities = manual_nll(
        shifted_logits[0, 0], shifted_targets[0, 0]
    )
    library_loss = F.cross_entropy(
        shifted_logits.reshape(-1, shifted_logits.shape[-1]),
        shifted_targets.reshape(-1),
        ignore_index=token_to_id["<pad>"]
    )
    assert shifted_logits.shape[:2] == shifted_targets.shape
    assert torch.isfinite(library_loss)
    assert torch.allclose(probabilities.sum(),
                          torch.tensor(1.0, device=device))
    return manual_loss, library_loss, id_to_token
```

Part 5 - The Philosophy Behind the Exercise

An LLM can appear to discuss law, poetry, software, or itself, yet every outward sentence

passes through the same narrow mechanism: a conditional distribution over the next token. This does not make the behavior trivial. Simple local objectives can produce rich global structures when they are optimized over enormous and varied data. It does mean that explanations of intelligence must remain connected to the actual computational contract.

The deeper lesson is to resist category errors. Architecture is not training; training is not knowledge verification; probability is not truth; fluency is not intention; and scale is not a proof of understanding. Precise definitions do not reduce the wonder of the system. They give us the language needed to investigate it honestly, improve it deliberately, and identify where confidence exceeds evidence.

18.2.2 Exercise 01

Exercise Title: Explain Difference Between Transformer Architecture and LLM as a Scaled System

Part 1 - Why this matters

A Transformer block specifies a computation: attention mixes information between positions, a feed-forward network transforms each position, residual paths preserve signal, and normalization controls scale. None of these components states which text becomes tokens, which examples are legal to train on, how long optimization continues, or how outputs are decoded and evaluated. Calling the architecture itself an LLM therefore hides most of the system that determines observable behavior.

In this exercise you will build two models with the same decoder architecture but place them in different system contexts. One will keep random weights and an inconsistent tokenizer. The other will use aligned tokenization, a small training corpus, next-token loss, deterministic evaluation, and a generation loop. Equal Python classes will not produce equal language systems. This is the cleanest way to demonstrate that architecture is a necessary component but not a complete description.

Scale enters at several coupled boundaries. Increasing parameters without enough data can produce memorization or poor utilization. Increasing data without compute can leave the model undertrained. Increasing context length changes activation memory and the distribution of training examples. Increasing serving batch size improves throughput but changes latency. A scaled system is therefore a budget allocation problem, not a single number attached to a model card.

Record artifacts explicitly: tokenizer version, vocabulary, model configuration, parameter initialization, dataset checksum, optimizer state, random seeds, precision, device, and decoding configuration. A checkpoint without these dependencies is not a reproducible language system. It is only a tensor artifact whose intended semantics may no longer be recoverable.

Part 2 - Mathematical form and reasoning

Represent the architecture by a function family f_θ, but represent the operational system by a composition

$$\mathcal{S}(s) = D_\psi(G_\gamma(f_{\theta^*}(T_\phi(s)))),$$

where T_ϕ is tokenization, θ^* is obtained from an optimization procedure and dataset, G_γ is a decoding policy, and D_ψ converts token identifiers into user-visible text. Training can be written as

$$\theta^* = \arg\min_{\theta} \mathbb{E}_{x\sim\mathcal{D}} \left[\mathcal{L}_{\text{NTP}}(f_\theta, T_\phi(x))\right].$$

This notation makes a crucial point: changing ϕ, $\mathcal{D}$, the optimizer, or γ can change the system while f remains unchanged.

Part 3 - Hints, controls, and evidence

1. Define one decoder configuration and instantiate two independent copies with identical initial weights.
2. Run both copies before training to prove architectural parity.
3. Train only one copy on a deterministic micro-corpus. Keep the other as a frozen architectural control.
4. Evaluate both with the same prompts and decoding policy. Separate loss, token accuracy, and generated examples.
5. Replace the trained model's tokenizer with a deliberately permuted vocabulary. Explain why the checkpoint is unchanged while behavior collapses.
6. Create an artifact manifest containing every dependency required to reproduce the trained system.

Do not claim that the micro-model is a production LLM. The experiment isolates the logical distinction; it does not reproduce industrial scale.

Part 4 - Python code skeleton

```
import copy
import hashlib
import torch

def count_parameters(model):
    total = 0
    for parameter in model.parameters():
        total = total + parameter.numel()
    return total

def dataset_checksum(encoded_examples):
    payload = encoded_examples.cpu().numpy().tobytes()
    return hashlib.sha256(payload).hexdigest()

def make_manifest(model, tokens, config, data, device):
    manifest = {}
    manifest["architecture"] = model.__class__.__name__
    manifest["parameter_count"] = count_parameters(model)
    manifest["vocabulary"] = dict(tokens)
    manifest["configuration"] = dict(config)
    manifest["dataset_sha256"] = dataset_checksum(data)
```

```
    manifest["device"] = str(device)
    manifest["torch_version"] = torch.__version__
    return manifest

def E01(model_factory, train_function, evaluate_function,
        token_to_id, encoded_data, config, device):
    architecture_only = model_factory(config).to(device)
    trained_system = model_factory(config).to(device)
    trained_system.load_state_dict(
        copy.deepcopy(architecture_only.state_dict())
    )
    before_a = evaluate_function(architecture_only, encoded_data)
    before_b = evaluate_function(trained_system, encoded_data)
    assert torch.allclose(before_a, before_b)
    train_function(trained_system, encoded_data, config)
    after_control = evaluate_function(architecture_only, encoded_data)
    after_trained = evaluate_function(trained_system, encoded_data)
    manifest = make_manifest(trained_system, token_to_id,
                             config, encoded_data, device)
    return after_control, after_trained, manifest
```

Part 5 - The Philosophy Behind the Exercise

Modern AI is often discussed as if intelligence resides in a single file of weights. In practice, capability is distributed across choices made before, during, and after optimization. Data selects the experiences available to the model; tokenization selects the representational atoms; objectives decide what counts as success; decoding turns probabilities into actions; infrastructure decides what can be delivered reliably.

Thinking in systems protects research from architectural mythology. A powerful component may fail inside a weak pipeline, while a modest component can become useful inside a carefully designed one. The responsible unit of analysis is not only the neural network but the complete chain that converts human data into a deployed behavior.

18.2.3 Exercise 02

Exercise Title: Identify Why Encoder-Only Models Like BERT Are Not Used as Generative LLMs

Part 1 - Why this matters

Encoder-only models and decoder-only models may both contain Transformer blocks, embeddings, attention, and feed-forward networks, yet they are trained to answer different probability questions. An encoder commonly receives bidirectional context and reconstructs selected masked tokens. A causal decoder must predict each token using only the permitted prefix. Confusing the two objectives leads to generation procedures that leak future information during training or require an expensive and unnatural re-masking process at every output step.

This exercise does not argue that encoder-only models are weak. Bidirectional context is extremely useful for classification, retrieval, reranking, token labeling, and representation learning. The point is narrower: their standard masked-language objective does not directly define a normalized left-to-right factorization for open-ended generation. A model can be adapted

or embedded in a larger generative system, but that does not make the original objective autoregressive.

You will construct one sequence and two visibility matrices. In the bidirectional matrix, ordinary tokens can exchange information in both directions. In the causal matrix, row t can use only columns up to t. You will then demonstrate leakage by changing a future token. A bidirectional representation at an earlier position may change; a correctly causal decoder representation at that position must remain invariant in evaluation mode.

Finally, you will compare one-pass training contracts. Masked-language modeling predicts a selected subset using surrounding observed tokens. Next-token prediction supplies supervision at almost every non-padding transition and matches the prefix available during autoregressive generation. The comparison must include both what each objective gains and what it gives up.

Part 2 - Mathematical form and reasoning

For a masked set M, an encoder objective is commonly expressed as

$$\mathcal{L}_{\text{MLM}} = -\sum_{t \in M} \log p_\theta(x_t \mid x_{\setminus M}).$$

The conditioning set can include tokens on both sides of t. A causal decoder uses

$$\mathcal{L}_{\text{CLM}} = -\sum_{t=1}^{T-1} \log p_\theta(x_{t+1} \mid x_{\le t}).$$

Define the causal visibility matrix by

$$C_{i,j} = \begin{cases} 0, & j \le i, \\ -\infty, & j > i. \end{cases}$$

When C is added before softmax, attention weights above the main diagonal must be zero. This is an executable no-future-information contract.

Part 3 - Hints, controls, and evidence

1. Print the bidirectional and causal visibility matrices for a sequence of length five.
2. Use identical embeddings and projection weights in two attention computations; change only the mask.
3. Change the final token while preserving the prefix. Compare outputs at positions zero through three in evaluation mode.
4. Assert exact or tolerance-based prefix invariance for the causal path. Treat a violation as leakage, not harmless numerical variation.
5. Count supervised positions for MLM with different mask ratios and for next-token prediction on the same non-padding sequence.
6. End with a task table showing where encoder-only, decoder-only, and encoder-decoder architectures are natural choices.

Part 4 - Python code skeleton

```
import torch

def build_causal_mask(sequence_length, device):
    allowed = torch.ones(sequence_length, sequence_length,
                         device=device, dtype=torch.bool)
    allowed = torch.tril(allowed)
    mask = torch.zeros(sequence_length, sequence_length,
                       device=device, dtype=torch.float32)
    mask = mask.masked_fill(~allowed, float("-inf"))
    return mask

def attention(x, w_q, w_k, w_v, mask=None):
    q = x @ w_q
    k = x @ w_k
    v = x @ w_v
    scores = q @ k.transpose(-2, -1)
    scores = scores / (q.shape[-1] ** 0.5)
    if mask is not None:
        scores = scores + mask
    weights = torch.softmax(scores, dim=-1)
    output = weights @ v
    return output, weights

def E02(device):
    torch.manual_seed(22)
    sequence_length = 5
    dimension = 8
    x_a = torch.randn(1, sequence_length, dimension, device=device)
    x_b = x_a.clone()
    x_b[:, -1, :] = torch.randn(1, dimension, device=device)
    w_q = torch.randn(dimension, dimension, device=device)
    w_k = torch.randn(dimension, dimension, device=device)
    w_v = torch.randn(dimension, dimension, device=device)
    causal_mask = build_causal_mask(sequence_length, device)
    causal_a, causal_weights = attention(
        x_a, w_q, w_k, w_v, causal_mask
    )
    causal_b, _ = attention(x_b, w_q, w_k, w_v, causal_mask)
    bidirectional_a, _ = attention(x_a, w_q, w_k, w_v)
    bidirectional_b, _ = attention(x_b, w_q, w_k, w_v)
    assert torch.allclose(causal_a[:, :-1], causal_b[:, :-1])
    assert not torch.allclose(bidirectional_a[:, :-1],
                              bidirectional_b[:, :-1])
    return causal_weights
```

Part 5 - The Philosophy Behind the Exercise

Every learning objective defines a particular kind of ignorance. The encoder pretends selected pieces are missing while allowing the rest of the scene to be seen. The causal decoder

pretends the future has not happened. Neither view is universally correct; each creates a different task and therefore a different kind of representation.

Generation is not merely classification repeated many times. It is a commitment to construct the future under an information boundary. Once that boundary is understood, the causal mask stops looking like a minor implementation detail and becomes the mathematical expression of what the model is allowed to know.

18.2.4 Exercise 03

Exercise Title: Explain Why Decoder-Only Architecture Is Ideal for Autoregressive Generation

Part 1 - Why this matters

Autoregressive generation repeatedly answers one question: given the tokens already available, what distribution should be assigned to the next token? A decoder-only Transformer aligns naturally with this process because every training position solves the same conditional problem under a causal mask. The network can be trained on complete sequences in parallel and then reused one step at a time without changing its probabilistic meaning.

The word "ideal" must not be interpreted as "always best." Encoder-decoder models are often natural when generation is tightly conditioned on a separate source, and non-autoregressive methods can reduce latency for particular tasks. The decoder-only design is ideal in the narrower engineering sense that one token stream, one causal objective, and one stack can represent prompts, demonstrations, tool outputs, and generated continuations without requiring a separate encoder interface.

You will compare teacher-forced evaluation with incremental generation. In the teacher-forced pass, all prefix positions are computed together but future visibility is masked. In incremental generation, the model processes an initial prompt, selects a token, appends it, and repeats. When dropout is disabled and the same full-prefix computation is used, the last-position logits from both methods must agree. This parity is the bridge between the training objective and the generation loop.

The experiment must also expose the cost of naive decoding. Recomputing every earlier key and value at every step repeats work. Later chapters will introduce the KV cache, but this exercise should already measure how the processed token count grows when the full prefix is evaluated repeatedly. Architectural suitability does not remove the need for inference engineering.

Part 2 - Mathematical form and reasoning

For prompt tokens $x_{1:P}$ and generated tokens $x_{P+1:P+G}$,

$$x_t \sim p_\theta(\cdot \mid x_{<t}), \qquad t = P+1, \ldots, P+G.$$

Teacher forcing evaluates conditionals for many t in one masked pass. Naive generation evaluates prefixes of lengths $P, P+1, \ldots, P+G-1$, processing

$$N_{\text{naive}} = GP + \frac{G(G-1)}{2}$$

token positions across the G decoding steps. Caching does not remove the sequential choice of tokens, but it avoids recomputing unchanged prefix states.

Part 3 - Hints, controls, and evidence

1. Put the model in evaluation mode and fix every random seed before testing parity.
2. For a known sequence, compare the last-position logits from the full causal pass with logits obtained after supplying the identical prefix.
3. Implement greedy selection first. Record the chosen identifier and its probability at each generation step.
4. Assert that the sequence grows by exactly one token per step and never exceeds the positional-embedding limit.
5. Compute N_{naive} manually and confirm it with a counter in the generation loop.
6. Add an end-of-sequence condition and distinguish a valid stop from a hard maximum-length cutoff.

Part 4 - Python code skeleton

```
import torch

@torch.no_grad()
def greedy_generate(model, prompt_ids, maximum_new_tokens, eos_id=None):
    model.eval()
    generated = prompt_ids.clone()
    processed_positions = 0
    trace = []
    for step in range(maximum_new_tokens):
        logits = model(generated)
        processed_positions = processed_positions + generated.shape[1]
        next_logits = logits[:, -1, :]
        probabilities = torch.softmax(next_logits, dim=-1)
        next_id = torch.argmax(probabilities, dim=-1, keepdim=True)
        trace_item = {}
        trace_item["step"] = step
        trace_item["prefix_length"] = generated.shape[1]
        trace_item["next_id"] = int(next_id.item())
        trace_item["probability"] = float(
            probabilities.gather(1, next_id).item()
        )
        trace.append(trace_item)
        generated = torch.cat((generated, next_id), dim=1)
        if eos_id is not None and int(next_id.item()) == eos_id:
            break
    return generated, trace, processed_positions

def E03(model, full_sequence, prompt_length, device):
    model = model.to(device)
    full_sequence = full_sequence.to(device)
    prompt = full_sequence[:, :prompt_length]
```

```
    model.eval()
    with torch.no_grad():
        full_logits = model(full_sequence)
        prefix_logits = model(prompt)
    assert torch.allclose(full_logits[:, prompt_length - 1, :],
                          prefix_logits[:, -1, :], atol=1e-5)
    generated, trace, processed = greedy_generate(model, prompt, 8)
    return generated, trace, processed
```

Part 5 - The Philosophy Behind the Exercise

Autoregression turns prediction into construction. At every step the model's own output becomes part of the next input, so a local decision changes the future context from which all later decisions are made. This feedback explains both the flexibility of open-ended generation and its sensitivity to early errors.

The decoder-only architecture succeeds because its training rule respects the same direction of time used during generation. Yet alignment of objectives does not guarantee reliable long-horizon behavior. The architecture gives a coherent mechanism for continuation; data, optimization, decoding, retrieval, and verification decide whether the continuation deserves trust.

18.2.5 Exercise 04

Exercise Title: Implement a Minimal GPT-Style Model Skeleton Using PyTorch Modules

Part 1 - Why this matters

Conceptual knowledge becomes engineering knowledge when every symbolic object has a concrete tensor contract. In this exercise you will assemble a small GPT-style decoder from PyTorch modules while keeping the implementation open enough to inspect. The goal is not to reproduce a production model or to hide complexity behind `nn.Transformer`. The goal is to see token embeddings, position embeddings, causal self-attention, residual paths, layer normalization, the feed-forward network, and the language-model head as one continuous computation.

The model will use pre-normalization: each sublayer receives a normalized version of the residual stream, and its output is added back to that stream. This is a deliberate architectural choice because it supports stable gradient flow in deeper decoders. A single exercise cannot establish superiority for all settings, but the code must make the placement visible rather than allowing it to disappear inside a library default.

Shape reasoning is central. Input identifiers have shape (B, T). Embeddings produce (B, T, d_{model}). Attention splits the final dimension into H heads, yielding (B, H, T, d_k) where $d_k = d_{\text{model}}/H$. The score tensor is (B, H, T, T), and the output head returns (B, T, V). Every reshape must be followed by an explicit semantic explanation because a tensor can have the expected number of elements while assigning them to the wrong axes.

The model should optionally tie the token embedding weights to the output projection. Weight tying does not make input and output roles identical; it shares the vocabulary geometry and reduces parameters. You will count parameters with and without tying, verify storage identity, and explain why the output still represents logits rather than embeddings.

This skeleton will become a reference artifact for later exercises. It must support CPU and CUDA, reject sequences longer than its context limit, preserve dtype and device, and expose

enough intermediate state to debug masks and activations. Clean contracts now prevent vague diagnoses later.

Part 2 - Mathematical form and reasoning

For token embeddings $E \in \mathbb{R}^{V \times d}$ and position embeddings $P \in \mathbb{R}^{T_{\max} \times d}$,

$$H_{b,t}^{(0)} = E_{X_{b,t}} + P_t.$$

A pre-normalized block computes

$$U^{(\ell)} = H^{(\ell)} + \mathrm{MHA}(\mathrm{LN}_1(H^{(\ell)})),$$

$$H^{(\ell+1)} = U^{(\ell)} + \mathrm{FFN}(\mathrm{LN}_2(U^{(\ell)})).$$

After the final normalization,

$$Z = \mathrm{LN}_f(H^{(L)})W_{\mathrm{vocab}}^{\mathsf{T}}, \qquad Z \in \mathbb{R}^{B \times T \times V}.$$

The exercise must verify that every row $Z_{b,t,:}$ is produced without access to $X_{b,t+1:T}$.

Part 3 - Hints, controls, and evidence

1. Use a configuration with $V = 101$, $d = 64$, four heads, two blocks, and a context of 32 before testing larger values.
2. Assert that d is divisible by the number of heads in the constructor.
3. Register the causal mask as a buffer so it follows device movement but is not optimized as a parameter.
4. Use `contiguous()` before reshaping a transposed head tensor. Explain why the memory layout may no longer be contiguous.
5. Test prefix invariance by altering suffix identifiers and comparing earlier logits in evaluation mode.
6. Run a loss and backward pass. Report parameter count, output shape, finite-loss status, and gradient norm for every major module.

Part 4 - Python code skeleton

```
import torch
import torch.nn as nn
import torch.nn.functional as F

class CausalSelfAttention(nn.Module):
    def __init__(self, d_model, number_of_heads,
                 maximum_sequence_length, dropout_probability):
        super().__init__()
        assert d_model % number_of_heads == 0
        self.number_of_heads = number_of_heads
```

```
        self.head_dimension = d_model // number_of_heads
        self.qkv = nn.Linear(d_model, 3 * d_model, bias=False)
        self.output_projection = nn.Linear(d_model, d_model, bias=False)
        self.attention_dropout = nn.Dropout(dropout_probability)
        self.residual_dropout = nn.Dropout(dropout_probability)
        mask = torch.ones(maximum_sequence_length,
                          maximum_sequence_length, dtype=torch.bool)
        mask = torch.tril(mask)
        self.register_buffer("causal_mask", mask, persistent=False)

    def forward(self, x, return_weights=False):
        batch_size, sequence_length, d_model = x.shape
        qkv = self.qkv(x)
        q, k, v = torch.chunk(qkv, chunks=3, dim=-1)
        q = q.view(batch_size, sequence_length,
                   self.number_of_heads, self.head_dimension)
        k = k.view(batch_size, sequence_length,
                   self.number_of_heads, self.head_dimension)
        v = v.view(batch_size, sequence_length,
                   self.number_of_heads, self.head_dimension)
        q = q.transpose(1, 2)

```

Part 5 - The Philosophy Behind the Exercise

A large model is built from operations small enough to inspect. The apparent mystery comes from composition, learned parameters, data volume, and scale, not from an unknowable primitive hidden inside the network. Reconstructing the skeleton restores a sense of causality: every logit has a path through visible operations and every failure must enter through some contract.

At the same time, understanding the skeleton is not equivalent to understanding the trained system. Source code explains what the model can compute; training history explains which computation it learned. Engineering maturity requires holding both truths at once.

18.2.6 Exercise 05

Exercise Title: Verify Causal Mask Is the Only Structural Difference From Encoder Transformer

Part 1 - Why this matters

This title contains a claim that must be tested, not repeated. If an encoder block and a decoder-only block are deliberately constructed with identical self-attention projections, feed-forward networks, normalization placement, residual paths, positional representation, and dimensions, then changing bidirectional visibility to causal visibility can be the only difference in the block computation. Real model families, however, may also differ in special tokens, objectives, pooling, normalization conventions, positional schemes, output heads, and post-training. The controlled statement is valid; the unqualified universal statement is not.

You will create a paired-block experiment. Both paths receive the same tensor and use the same parameters. One receives no future mask; the other receives a triangular mask. If the final token changes, the bidirectional output at earlier positions can change, while the causal output must remain fixed. If the mask is removed, both implementations must become numerically equal. This establishes what the mask alone changes under matched conditions.

The most dangerous masking bugs are silent. A mask can have the right two-dimensional shape but the wrong orientation. It can be applied after softmax, allowing forbidden positions to affect normalization. It can contain zeros and ones that are added to scores instead of booleans used for filling. It can broadcast over the wrong axes. Your test suite must be designed to make each error observable.

The final report must distinguish structural, objective, and system-level differences. Causal visibility belongs to structure. Next-token prediction belongs to the training objective. Corpus scale and decoding belong to the system. This taxonomy prevents one correct experiment from being stretched beyond what it actually proves.

Part 2 - Mathematical form and reasoning

With matched Q, K, and V, bidirectional attention is

$$A_{\text{bi}} = \text{softmax}\left(\frac{QK^{\mathsf{T}}}{\sqrt{d_k}}\right)V,$$

while causal attention is

$$A_{\text{causal}} = \text{softmax}\left(\frac{QK^{\mathsf{T}}}{\sqrt{d_k}} + C\right)V.$$

For every row i and column $j > i$, a correct mask implies

$$\operatorname{softmax}(S + C)_{i,j} = 0.$$

The mask must be applied before softmax because forbidden entries must be excluded from the normalization denominator.

Part 3 - Hints, controls, and evidence

1. Copy one state dictionary into both blocks; never compare independently initialized blocks.
2. Disable dropout and use `eval()` while checking equality.
3. Test four masks: correct lower triangular, reversed upper triangular, all-visible, and a mask applied after softmax.
4. Assert that forbidden weights are exactly zero or within a stated tolerance.
5. Modify one suffix token and measure maximum prefix-output difference.
6. Write a conclusion with two lists: what the experiment proves and what it does not prove.

Part 4 - Python code skeleton

```
import copy
import torch

def maximum_forbidden_weight(weights):
    sequence_length = weights.shape[-1]
    forbidden = torch.triu(
        torch.ones(sequence_length, sequence_length,
                   device=weights.device, dtype=torch.bool),
        diagonal=1
    )
    selected = weights.masked_select(forbidden)
    if selected.numel() == 0:
        return torch.tensor(0.0, device=weights.device)
    return selected.abs().max()

def compare_blocks(encoder_block, causal_block, x, x_changed):
    encoder_block.eval()
    causal_block.eval()
    encoder_block.load_state_dict(copy.deepcopy(causal_block.state_dict()))
    with torch.no_grad():
        encoder_a, encoder_weights = encoder_block(x, return_weights=True)
        encoder_b, _ = encoder_block(x_changed, return_weights=True)
        causal_a, causal_weights = causal_block(x, return_weights=True)
        causal_b, _ = causal_block(x_changed, return_weights=True)
    prefix_causal_error = (causal_a[:, :-1] -
                           causal_b[:, :-1]).abs().max()
```

```
    prefix_encoder_change = (encoder_a[:, :-1] -
                             encoder_b[:, :-1]).abs().max()
    forbidden_weight = maximum_forbidden_weight(causal_weights)
    return prefix_causal_error, prefix_encoder_change, forbidden_weight

def E05(encoder_block, causal_block, device):
    x = torch.randn(2, 6, 32, device=device)
    x_changed = x.clone()
    x_changed[:, -1, :] = torch.randn(2, 32, device=device)
    causal_error, encoder_change, forbidden = compare_blocks(
        encoder_block, causal_block, x, x_changed
    )
    assert causal_error < 1e-6
    assert encoder_change > 0.0
    assert forbidden < 1e-7
    return causal_error, encoder_change, forbidden
```

Part 5 - The Philosophy Behind the Exercise

Scientific precision often depends on adding the phrase "all else being equal." Without it, a useful local truth becomes a misleading universal claim. Controlled comparison is the discipline of creating that equality, observing one changed cause, and then refusing to claim more than the experiment supports.

The causal mask is small in code but profound in meaning. It changes the model's information boundary. Yet it does not explain data quality, scale, instruction following, or safety. Good research learns both to recognize the importance of one mechanism and to resist making it responsible for everything.

18.2.7 Exercise 06

Exercise Title: Explain Scaling Laws and Why LLM Quality Improves With Model Size and Data

Part 1 - Why this matters

Scaling laws describe regular empirical relationships between loss and resources such as parameters, training tokens, and compute. They are valuable because large training runs are too expensive to choose by intuition alone. Small experiments can be fitted to a trend and used to compare budget allocations. A scaling law is therefore a planning instrument and a scientific hypothesis, not a guarantee that every downstream capability improves smoothly.

Increasing model size expands representational capacity, while increasing data provides more statistical evidence and reduces repeated exposure to the same examples. Either resource can become a bottleneck. A large model trained on too few tokens may be underutilized or overfit its corpus; a small model exposed to an enormous corpus may lack capacity to absorb the structure. Compute-optimal training asks how parameters and tokens should grow together under a fixed budget.

You will not attempt to establish an industrial scaling law. Instead, train a grid of tiny decoder models across multiple widths and dataset sizes. Keep the tokenizer, validation set, optimizer family, and reporting procedure fixed. Record validation negative log-likelihood,

parameter count, tokens seen, estimated compute, and variance across seeds. The aim is to learn the mechanics of scaling analysis and its uncertainty.

Loss is the cleanest quantity for this experiment because it is directly tied to the training distribution, but users care about capabilities and reliability. You must therefore include a small downstream probe and check whether its trend matches the loss trend. A better average log-loss can coexist with unchanged or noisy task accuracy, especially when the probe contains few examples or a threshold effect.

Part 2 - Mathematical form and reasoning

A simplified separable scaling model can be written as

$$L(N, D) = L_\infty + AN^{-\alpha} + BD^{-\beta},$$

where N is parameter count, D is the number of training tokens, and L_∞ is an irreducible floor under the chosen data distribution and setup. Approximate dense Transformer training compute is often modeled as

$$C \approx kND,$$

where k depends on whether forward, backward, and optimizer costs are included. State the convention used in your estimate. In log space, a power law becomes approximately linear over the region in which the model is valid.

Part 3 - Hints, controls, and evidence

1. Use at least three parameter scales and three token budgets. Do not change multiple hidden hyperparameters without recording them.
2. Train every configuration for at least three seeds and preserve the same held-out validation examples.
3. Record both unique corpus tokens and total token presentations; repeated epochs do not create new information.
4. Plot validation loss against parameters, tokens, and estimated compute on logarithmic axes.
5. Fit only the observed region and show residuals. Do not extrapolate beyond the data without a visibly marked uncertainty warning.
6. Include one deliberately data-starved large model and one capacity-limited small model to expose different bottlenecks.

Part 4 - Python code skeleton

```
import math
import torch

def parameter_count(model):
    total = 0
    for parameter in model.parameters():
```

```
        if parameter.requires_grad:
            total = total + parameter.numel()
    return total

def estimate_training_flops(parameters, tokens, factor=6.0):
    return factor * parameters * tokens

def run_scaling_grid(model_factory, train_and_evaluate,
                     model_configs, token_budgets, seeds, device):
    records = []
    for config in model_configs:
        for token_budget in token_budgets:
            for seed in seeds:
                torch.manual_seed(seed)
                model = model_factory(config).to(device)
                parameters = parameter_count(model)
                metrics = train_and_evaluate(
                    model, token_budget, seed, device
                )
                record = {}
                record["parameters"] = parameters
                record["tokens"] = token_budget
                record["seed"] = seed
                record["validation_loss"] = metrics["loss"]
                record["probe_accuracy"] = metrics["accuracy"]
                record["estimated_flops"] = estimate_training_flops(
                    parameters, token_budget
                )
                records.append(record)
    return records

def E06(model_factory, train_and_evaluate, device):
    configurations = ...
    token_budgets = [10000, 30000, 90000]
    seeds = [17, 29, 43]
    records = run_scaling_grid(model_factory, train_and_evaluate,
                               configurations, token_budgets,
                               seeds, device)
    return records
```

Part 5 - The Philosophy Behind the Exercise

Scaling laws reveal that progress can emerge from disciplined accumulation: more capacity, more evidence, and more computation combined under a stable objective. This is a powerful counterweight to stories that attribute every advance to one architectural invention. Engineering scale can transform what a known mechanism is capable of expressing.

But regular curves can create false certainty. They summarize a region of observation, a data distribution, and a measurement definition. They do not promise truthfulness, safety, or

universal competence. The mature response to a scaling law is neither dismissal nor worship; it is to use the pattern while preserving the conditions under which it was measured.

18.2.8 Exercise 07

Exercise Title: Distinguish Between Parameter Count Scaling and Context Length Scaling

Part 1 - Why this matters

Parameter count and context length are frequently combined into one vague idea of a "larger" model. They change different resources. More parameters increase the persistent capacity and storage of the network. A longer context increases the amount of request-specific information that can be processed at once and, for dense attention, expands intermediate activation and score tensors. One is primarily a model-state axis; the other is primarily a per-sequence computation axis.

A model with many parameters and a short context may encode rich statistical patterns but be unable to read a long document in one request. A smaller model with a longer context may accept the document but fail to use distant evidence reliably. Context capacity is not context utilization. Positional extrapolation, attention dilution, training-length distribution, and retrieval placement can all cause effective performance to degrade before the formal token limit is reached.

You will produce two independent scaling sweeps. The parameter sweep keeps sequence length fixed and varies depth or width. The context sweep keeps model weights fixed and varies sequence length. For each case, record latency, peak memory, theoretical attention-score elements, and task quality. This separation prevents the conclusion "larger is slower" from hiding which resource caused the change.

On CUDA, benchmarking must account for asynchronous execution. Warm up kernels, synchronize around timings, reset peak-memory statistics, and distinguish allocated from reserved memory. An out-of-memory boundary is not a universal property of the architecture; it depends on batch size, precision, gradient storage, implementation, and other processes using the device.

Part 2 - Mathematical form and reasoning

For a simplified decoder with L layers and width d, parameter count is dominated by terms proportional to

$$N_\theta \approx L(4d^2 + 8d^2) + Vd,$$

where the first terms roughly represent attention projections and a four-times-expanded feed-forward network. Dense attention scores require

$$N_{\text{scores}} = BHT^2$$

elements per layer before memory-efficient kernels are considered. Increasing d changes parameter and matrix-multiplication costs; increasing T changes the quadratic pair count. These axes must be measured independently.

Part 3 - Hints, controls, and evidence

1. Build a table with rows for parameter scale and columns for context length, but change only one axis within each controlled comparison.

2. Use at least four context lengths that double successively. Verify that the input distribution remains meaningful at each length.

3. Record inference and training separately because saved activations and gradients substantially change memory.

4. Add a long-distance retrieval probe by placing one required token at different distances from the final query.

5. Report formal context limit, tested context limit, and effective quality limit as three different values.

6. Catch out-of-memory exceptions only to record the failed configuration; clear references and CUDA cache before continuing safely.

Part 4 - Python code skeleton

```
import time
import torch

def benchmark_forward(model, input_ids, repeats):
    device = input_ids.device
    model.eval()
    with torch.no_grad():
        for _ in range(5):
            model(input_ids)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        torch.cuda.reset_peak_memory_stats(device)
    start = time.perf_counter()
    with torch.no_grad():
        for _ in range(repeats):
            logits = model(input_ids)
    if device.type == "cuda":
        torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - start
    peak = 0
    if device.type == "cuda":
        peak = torch.cuda.max_memory_allocated(device)
    return elapsed / repeats, peak, logits.shape

def context_sweep(model, vocabulary_size, lengths, device):
    records = []
    for sequence_length in lengths:
        input_ids = torch.randint(
            0, vocabulary_size, (1, sequence_length), device=device
        )
        latency, peak, shape = benchmark_forward(model, input_ids, 20)
        record = {}
```

```
        record["context"] = sequence_length
        record["latency_seconds"] = latency
        record["peak_bytes"] = peak
        record["logit_shape"] = tuple(shape)
        records.append(record)
    return records

def E07(models, vocabulary_size, device):
    context_lengths = [32, 64, 128, 256]
    results = {}
    for model_name in models:
        model = models[model_name].to(device)
        results[model_name] = context_sweep(
            model, vocabulary_size, context_lengths, device
        )
    return results
```

Part 5 - The Philosophy Behind the Exercise

Capacity and access are different forms of power. Parameters determine what patterns a model can preserve in its learned structure. Context determines what evidence can be made available for a particular decision. More memory of the world does not guarantee attention to the present document, and access to a long document does not guarantee the ability to reason over it.

This distinction generalizes beyond LLMs. Whenever a system is called "larger," ask what grew, which bottleneck moved, which cost changed, and which capability was actually measured. Precision in resource language is a form of precision in thought.

18.2.9 Exercise 08

Exercise Title: Explain Emergent Abilities and Why They Appear Only After Certain Scale

Part 1 - Why this matters

An ability is often called emergent when measured performance appears near chance for smaller models and then rises sharply beyond a scale region. This description is tempting because it suggests a qualitative transition: the model suddenly acquired a new skill. Some transitions may reflect real interactions between capacity, data diversity, and optimization. Others can be created or exaggerated by discontinuous metrics, sparse evaluation, prompt sensitivity, or plotting only a few model sizes. This exercise teaches you to distinguish an observed threshold from an explanation of that threshold.

Consider exact-match accuracy. A model that gradually increases the probability of a correct multi-token answer may receive a score of zero until every token is correct, then jump to one. Negative log-likelihood can reveal smooth improvement underneath the apparently sudden accuracy change. Likewise, multiple-choice accuracy changes discretely when the highest-scoring option crosses another option, even if their probability margin moved smoothly for many scales.

You will simulate and measure both possibilities. First, create synthetic model outputs whose correct-answer probability improves smoothly with a scale variable. Evaluate them with continuous log-loss, token accuracy, exact match, and a thresholded pass/fail score. Second, use a family of small trained models on a compositional task and repeat the analysis across

seeds. If a transition survives metric changes and dense scale sampling, it becomes stronger evidence for behavioral emergence, though not yet proof of a specific internal mechanism.

The phrase "only after certain scale" must therefore be used carefully. Scale can make a representation learnable, an optimization path accessible, or a weak signal usable. But the location of the apparent threshold can move when the dataset, prompt, decoding, number of examples, or metric changes. Your report should use confidence intervals and explicitly separate capability from measurement resolution.

Part 2 - Mathematical form and reasoning

Let s denote log-scale and let the correct-answer probability improve smoothly:

$$p_{\text{correct}}(s) = \sigma(a(s - s_0)).$$

Continuous negative log-likelihood is

$$L(s) = -\log p_{\text{correct}}(s),$$

whereas a thresholded metric may be

$$M(s) = \mathbb{I}\left[p_{\text{correct}}(s) > \tau\right].$$

Although p and L vary continuously, M changes discontinuously. For a dataset of n binary outcomes, report uncertainty such as $\sqrt{\hat{p}(1-\hat{p})/n}$ or use bootstrap intervals rather than presenting a single accuracy point as exact.

Part 3 - Hints, controls, and evidence

1. Sample at least twenty scale values for the synthetic demonstration; three widely separated points can manufacture a visual cliff.
2. Plot probability, log-loss, exact match, and thresholded success against the same horizontal axis.
3. For trained models, use multiple seeds at every scale and retain all individual runs.
4. Evaluate alternate prompt phrasings and answer formats to measure whether the threshold is behaviorally stable.
5. Bootstrap task examples and show a confidence band around every metric.
6. Classify your conclusion as metric-induced, behaviorally robust, or inconclusive. Do not infer an internal circuit without inspecting one.

Part 4 - Python code skeleton

```
import torch

def simulated_probabilities(scale_values, slope, midpoint):
    logits = slope * (scale_values - midpoint)
    return torch.sigmoid(logits)
```

```
def exact_threshold_metric(probabilities, threshold):
    return (probabilities > threshold).to(torch.float32)

def bootstrap_accuracy(correct_vector, repetitions, generator):
    estimates = torch.empty(repetitions, dtype=torch.float64)
    number_of_examples = correct_vector.numel()
    for repetition in range(repetitions):
        indices = torch.randint(
            0, number_of_examples, (number_of_examples,),
            generator=generator
        )
        sample = correct_vector[indices]
        estimates[repetition] = sample.to(torch.float64).mean()
    lower = torch.quantile(estimates, 0.025)
    upper = torch.quantile(estimates, 0.975)
    return lower, upper

def E08():
    scales = torch.linspace(0.0, 10.0, steps=41,
                            dtype=torch.float64)
    probabilities = simulated_probabilities(scales, 1.2, 5.0)
    negative_log_likelihood = -torch.log(probabilities)
    thresholded = exact_threshold_metric(probabilities, 0.5)
    return {
        "scale": scales,
        "probability": probabilities,
        "nll": negative_log_likelihood,
        "thresholded": thresholded,
    }
```

Part 5 - The Philosophy Behind the Exercise

Humans are drawn to moments of sudden transformation. A curve crossing a line looks like birth: before the line, the ability did not exist; after it, the ability exists. But measurement is an interpretation layered on behavior. A threshold may tell us as much about our scoring rule as about the system being scored.

The philosophical discipline here is neither to deny emergence nor to announce it too easily. New system-level behavior can arise from quantitative growth, just as many interacting components can produce properties absent from each component alone. The responsible researcher asks whether the transition is stable across measurements, what mechanism could support it, and what evidence would make the claim weaker.

18.2.10 Exercise 09

Exercise Title: Compare Small Language Model vs LLM on Same Task and Analyze Failure Modes

Part 1 - Why this matters

Comparing a small language model with an LLM is difficult because real models usually differ in more than parameter count. They may use different tokenizers, training corpora, instruction tuning, context limits, precision, chat templates, and decoding defaults. A result that favors the larger model cannot be attributed to scale unless those differences are controlled or explicitly reported. This exercise is therefore as much about experimental design as model quality.

Choose a task suite with several distinct demands: local pattern completion, long-distance retrieval, instruction following, factual recall from provided context, and an intentionally unanswerable question. The same prompts and scoring rules must be applied to both models. Exact match alone is insufficient; record token-level likelihood when available, answer validity, latency, memory, and calibrated abstention behavior.

Failure analysis should be organized by mechanism. Capacity failure occurs when the model cannot represent or execute the pattern. Context failure occurs when the needed evidence is truncated or ignored. Tokenization failure appears when an input is fragmented or encoded inconsistently. Decoding failure occurs when the probability distribution is usable but the selection rule creates loops or premature endings. Hallucination occurs when a fluent unsupported continuation is preferred over acknowledging missing evidence.

Scale may reduce some failures while creating new operational risks. The larger model can be slower, more expensive, harder to reproduce, and more persuasive when wrong. Your recommendation must depend on task requirements and error cost, not on a single average quality score.

Part 2 - Mathematical form and reasoning

For task categories $c = 1, \ldots, C$, define per-category accuracy

$$A_c = \frac{1}{n_c} \sum_{i:y_i=c} \mathbb{I}(\hat{y}_i = y_i).$$

If an application assigns cost w_c to each failure category, a simple risk estimate is

$$R = \sum_{c=1}^{C} w_c(1 - A_c).$$

For paired prompts, compare models using the difference per example rather than only two independent means. Report confidence intervals and the number of ties. Quality-per-cost can be summarized, but it must not erase high-severity failure types.

Part 3 - Hints, controls, and evidence

1. Freeze prompts, chat templates, stop conditions, temperature, and random seeds before running either model.

2. Confirm that every prompt fits both context windows; otherwise label the comparison as a context-limit test.

3. Store raw outputs before manual annotation so the evaluation can be audited.

4. Create explicit labels for unsupported claim, ignored instruction, formatting failure, repetition, truncation, and correct abstention.

5. Measure first-token latency, total latency, generated tokens per second, and peak memory separately.

6. Select at least five examples where the smaller model wins and analyze why; do not treat them as noise to be discarded.

Part 4 - Python code skeleton

```
import time
import torch

def evaluate_one_model(model_name, generate_function, examples, device):
    records = []
    for example_index in range(len(examples)):
        example = examples[example_index]
        if device.type == "cuda":
            torch.cuda.synchronize(device)
            torch.cuda.reset_peak_memory_stats(device)
        start = time.perf_counter()
        output = generate_function(example["prompt"])
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        elapsed = time.perf_counter() - start
        peak_memory = 0
        if device.type == "cuda":
            peak_memory = torch.cuda.max_memory_allocated(device)
        record = {}
        record["model"] = model_name
        record["example_id"] = example["id"]
        record["category"] = example["category"]
        record["reference"] = example["reference"]
        record["output"] = output["text"]
        record["generated_tokens"] = output["token_count"]
        record["latency_seconds"] = elapsed
        record["peak_memory_bytes"] = peak_memory
        records.append(record)
    return records

def E09(small_generate, large_generate, examples, device):
    small_records = evaluate_one_model(
        "small", small_generate, examples, device
    )
    large_records = evaluate_one_model(
        "large", large_generate, examples, device
    )
    return small_records, large_records
```

Part 5 - The Philosophy Behind the Exercise

Comparison is not a race with one universal finish line. A model is better only with respect to a purpose, a resource budget, an error distribution, and a set of consequences. The largest

system may be the strongest general tool while a smaller system remains the wiser choice for a narrow, private, low-latency, or high-volume application.

Failure analysis also changes the moral character of evaluation. An average score hides who is harmed by which error and how confidently the system presents it. A responsible comparison does not merely ask which model wins. It asks what each model fails to do, when the failure becomes dangerous, and whether the system surrounding it can detect and recover.

18.2.11 Exercise 10

Exercise Title: Run Minimal LLM Forward Pass on CUDA and Confirm Correct Logit Shapes

Part 1 - Why this matters

Moving a model to CUDA is not equivalent to moving one tensor. Parameters, registered buffers, input identifiers, masks, and any newly created temporary tensors must share compatible devices. A CPU positional index added to a CUDA embedding will fail immediately, while an unregistered mask can remain on the CPU even after `model.to(device)`. Device discipline should therefore be verified as a set of invariants, not inferred from one successful parameter.

The forward contract for a decoder-only language model is precise. Integer input identifiers of shape (B, T) produce floating-point logits of shape (B, T, V). Batch size and sequence length are preserved, while the final axis enumerates the vocabulary. The logits are not probabilities and should not be forced into the interval $[0, 1]$. Applying softmax is needed only when a probability distribution is explicitly required.

This exercise will compare CPU and CUDA copies under evaluation mode. Copy the same state dictionary, use the same identifiers, disable dropout, and compare logits with a tolerance appropriate to the dtype. A small numerical difference does not imply semantic disagreement, but a shape mismatch, device mismatch, non-finite value, or changed argmax pattern requires investigation.

The benchmark must respect CUDA asynchrony. CPU wall-clock time measured before the queued kernels finish is not GPU latency. Use warm-up iterations and explicit CUDA synchronization before and after the timed region. Report small and larger batches because kernel launch overhead can make CUDA counterproductive for tiny workloads.

Part 2 - Mathematical form and reasoning

For $X \in \mathbb{N}^{B \times T}$ and vocabulary size V,

$$f_\theta(X) = Z \in \mathbb{R}^{B \times T \times V}.$$

Probabilities for a selected position are

$$p_{b,t,v} = \frac{\exp(Z_{b,t,v} - m_{b,t})}{\sum_{u=1}^{V} \exp(Z_{b,t,u} - m_{b,t})}, \qquad m_{b,t} = \max_u Z_{b,t,u}.$$

Subtracting the maximum leaves the distribution mathematically unchanged while improving numerical stability. Define maximum absolute and relative CPU–GPU errors and state the tolerance before observing them.

Part 3 - Hints, controls, and evidence

1. If CUDA is unavailable, fail with a clear message; do not silently label a CPU run as a CUDA experiment.

2. Inspect every named parameter and buffer after moving the model.
3. Test at least three (B, T) pairs, including $B = 1$ and the maximum configured context.
4. Verify identifier dtype is `torch.long` and logit dtype matches the model parameters.
5. Compare CPU and CUDA in float32 first. Mixed precision belongs to a separate controlled comparison.
6. Report warm-up count, repetitions, synchronization points, and peak allocated memory.

Part 4 - Python code skeleton

```
import copy
import time
import torch

def assert_model_device(model, expected_device):
    for name, parameter in model.named_parameters():
        assert parameter.device == expected_device, name
    for name, buffer in model.named_buffers():
        assert buffer.device == expected_device, name

def timed_cuda_forward(model, input_ids, repeats):
    model.eval()
    with torch.no_grad():
        for _ in range(10):
            model(input_ids)
    torch.cuda.synchronize(input_ids.device)
    torch.cuda.reset_peak_memory_stats(input_ids.device)
    start = time.perf_counter()
    with torch.no_grad():
        for _ in range(repeats):
            logits = model(input_ids)
    torch.cuda.synchronize(input_ids.device)
    elapsed = time.perf_counter() - start
    peak = torch.cuda.max_memory_allocated(input_ids.device)
    return logits, elapsed / repeats, peak

def E10(model, vocabulary_size):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for E10")
    cpu_model = copy.deepcopy(model).cpu().eval()
    cuda_device = torch.device("cuda:0")
    cuda_model = copy.deepcopy(model).to(cuda_device).eval()
    assert_model_device(cuda_model, cuda_device)
    cpu_ids = torch.randint(0, vocabulary_size, (4, 32),
                            dtype=torch.long)
    cuda_ids = cpu_ids.to(cuda_device)
```

```
    with torch.no_grad():
        cpu_logits = cpu_model(cpu_ids)
    cuda_logits, latency, peak = timed_cuda_forward(
        cuda_model, cuda_ids, repeats=50
    )
    assert cuda_logits.shape == (4, 32, vocabulary_size)
    assert torch.isfinite(cuda_logits).all()
    maximum_error = (cpu_logits - cuda_logits.cpu()).abs().max()
    assert torch.allclose(cpu_logits, cuda_logits.cpu(),
                          atol=1e-5, rtol=1e-4)
    return maximum_error, latency, peak
```

Part 5 - The Philosophy Behind the Exercise

Accelerators do not change the mathematical purpose of the model, but they change which scales of experimentation are physically possible. CUDA is therefore not a decorative deployment option in modern language modeling. It is part of the material foundation that determines training time, batch size, context length, and the questions researchers can afford to ask.

Hardware power also demands epistemic discipline. A computation running on a GPU is not automatically correct, fast, or reproducible. The lesson is to make the boundary between mathematical invariants and hardware-specific behavior visible, then verify both.

18.2.12 Exercise 11

Exercise Title: Estimate FLOPs for One Forward Pass and Explain Why LLM Training Is Expensive

Part 1 - Why this matters

Parameter count is an incomplete measure of computational cost. The same model can require very different work at different batch sizes and sequence lengths. Attention introduces a term that grows quadratically with sequence length, while projection and feed-forward terms scale approximately linearly in tokens and quadratically in width. FLOP estimation makes these relationships explicit before a training run consumes hours or days.

A FLOP convention must be declared. This exercise counts one multiplication and one addition as two floating-point operations. Some reports count a fused multiply-add as one, so unexplained numbers can differ by a factor of two even when both calculations are internally consistent. Bias operations, normalization, activation functions, and softmax are smaller than the dominant dense matrix products in many regimes, but omitting them should be documented.

You will derive an analytical estimate for one decoder forward pass and compare it with PyTorch profiler output or a module-hook estimate. The aim is not exact agreement at the last operation. The aim is to identify the dominant terms, check scaling ratios, and understand why theoretical FLOPs do not map directly to time. Memory traffic, kernel fusion, hardware utilization, precision, and communication can change achieved throughput.

Training is substantially more expensive than inference because backward propagation computes gradients through the forward graph and optimizers update large parameter states. A frequently used rough estimate relates training compute to parameters and tokens, but your report must show which costs are included. Long experiments also multiply per-step cost by dataset tokens, epochs, hyperparameter trials, failed runs, and evaluation passes.

Part 2 - Mathematical form and reasoning

For batch B, sequence length T, width d, FFN width d_f, heads whose dimensions sum to d, and L layers, dominant forward FLOPs per layer are approximately

$$F_{\text{QKV}} = 6BTd^2, \qquad F_{\text{out}} = 2BTd^2,$$

$$F_{\text{scores+values}} = 4BT^2d, \qquad F_{\text{FFN}} = 4BTdd_f.$$

The vocabulary projection adds

$$F_{\text{vocab}} = 2BTdV.$$

Thus

$$F_{\text{forward}} \approx L\left(8BTd^2 + 4BT^2d + 4BTdd_f\right) + 2BTdV.$$

Compare this architectural estimate with the coarse model-training heuristic $C_{\text{train}} \approx 6ND$ and explain why they answer different questions.

Part 3 - Hints, controls, and evidence

1. Calculate every term separately; a total alone cannot reveal the bottleneck.
2. Verify doubling rules: double B, double T, double d, and record the predicted ratio for each dominant term.
3. Include tied and untied vocabulary projections in the parameter count, while noting that tying does not remove output-projection compute.
4. Benchmark several shapes on CUDA and calculate achieved TFLOP/s from the declared estimate.
5. Explain why a small model may achieve poor hardware utilization despite a low FLOP count.
6. Extend the estimate to training tokens for one epoch and convert it to idealized time at a chosen sustained throughput, clearly labeling the result as an estimate.

Part 4 - Python code skeleton

```
def decoder_forward_flops(batch_size, sequence_length, d_model,
                          ffn_dimension, layers, vocabulary_size):
    qkv = 6 * batch_size * sequence_length * d_model * d_model
    attention_output = (
        2 * batch_size * sequence_length * d_model * d_model
    )
    attention_pairs = (
        4 * batch_size * sequence_length * sequence_length * d_model
    )
    feed_forward = (
        4 * batch_size * sequence_length * d_model * ffn_dimension
```

```
    )
    one_layer = qkv + attention_output + attention_pairs + feed_forward
    vocabulary = (
        2 * batch_size * sequence_length * d_model * vocabulary_size
    )
    total = layers * one_layer + vocabulary
    breakdown = {}
    breakdown["qkv_per_layer"] = qkv
    breakdown["attention_output_per_layer"] = attention_output
    breakdown["attention_pairs_per_layer"] = attention_pairs
    breakdown["ffn_per_layer"] = feed_forward
    breakdown["vocabulary"] = vocabulary
    breakdown["total"] = total
    return breakdown

def E11():
    base = decoder_forward_flops(
        batch_size=4, sequence_length=256, d_model=512,
        ffn_dimension=2048, layers=8, vocabulary_size=32000
    )
    doubled_context = decoder_forward_flops(
        batch_size=4, sequence_length=512, d_model=512,
        ffn_dimension=2048, layers=8, vocabulary_size=32000
    )
    ratio = doubled_context["total"] / base["total"]
    return base, doubled_context, ratio
```

Part 5 - The Philosophy Behind the Exercise

Compute estimation turns the word "large" into a chain of physical consequences. Every additional layer, token, and hidden dimension eventually becomes arithmetic, memory movement, electrical energy, elapsed time, and financial cost. Model design is therefore also resource ethics: experiments consume finite machines and opportunity.

Yet FLOPs are an abstraction, not the machine itself. Two systems can perform the same nominal arithmetic with very different efficiency. The deeper lesson is to use abstractions as maps: detailed enough to guide decisions, never confused with the territory they summarize.

18.2.13 Exercise 12

Exercise Title: Explain Why Data Quality Becomes More Important Than Architecture at Scale

Part 1 - Why this matters

Architecture defines the model's computational possibilities, but data decides which parts of those possibilities receive learning signal. When architecture and optimization are already strong, another small architectural modification may matter less than removing duplicated, corrupted, contradictory, leaked, or low-value examples. At scale, tiny contamination rates can correspond to millions of documents, and systematic bias can be reinforced across enormous training budgets.

"Data quality" is not one score. It includes provenance, legal authorization, language and domain coverage, factual reliability, formatting integrity, deduplication, toxicity policy, temporal relevance, privacy risk, and the ratio between useful signal and boilerplate. A filter that improves one dimension can damage another: aggressive deduplication may erase legitimate repeated forms, language identification can exclude mixed-language communities, and heuristic quality scoring can prefer polished dominant-domain text over valuable specialized material.

You will create matched training corpora for the same small decoder. The clean corpus contains controlled relationships. Variants introduce exact duplicates, near duplicates, shuffled targets, contradictory statements, and held-out test leakage. Train the same initialized model for the same token budget and compare validation loss, unique-example generalization, memorization, calibration, and per-domain performance. The point is to show that a lower training loss can coexist with a worse model.

Data leakage deserves special treatment. If evaluation examples or their close paraphrases enter training, the measured score no longer estimates generalization to unseen material. At large corpus scale, manual inspection is insufficient. Hashing, similarity search, temporal splits, source metadata, and document-level lineage are part of model methodology, not administrative extras.

Part 2 - Mathematical form and reasoning

Let the observed training distribution be a mixture

$$P_{\text{train}} = (1-\epsilon)P_{\text{useful}} + \epsilon P_{\text{corrupt}}.$$

The optimized objective becomes

$$\mathbb{E}_{x\sim P_{\text{train}}}[\ell_\theta(x)] = (1-\epsilon)\mathbb{E}_{P_{\text{useful}}}[\ell_\theta] + \epsilon\mathbb{E}_{P_{\text{corrupt}}}[\ell_\theta].$$

Even small ϵ can produce substantial gradient mass when corruption is repeated or has large loss. Define an effective unique-token ratio $D_{\text{unique}}/D_{\text{seen}}$ and report it beside total token count. For contamination, estimate exact and near-duplicate overlap separately.

Part 3 - Hints, controls, and evidence

1. Preserve one model initialization and reload it before training each data variant.
2. Keep total token presentations fixed so duplicated data does not gain an unreported compute advantage.
3. Split by source document before windowing; splitting windows first can place adjacent text in both train and validation sets.
4. Implement exact hashing, then add a normalized or token-shingle similarity check for near duplicates.
5. Report aggregate and per-domain metrics. A filter can improve the mean while destroying a minority domain.
6. Maintain a data card containing source, license or authorization, collection time, transformations, exclusions, and known blind spots.

Part 4 - Python code skeleton

```
import hashlib
import torch

def normalize_document(document):
    lowered = document.lower()
    pieces = lowered.split()
    normalized = " ".join(pieces)
    return normalized

def document_hash(document):
    normalized = normalize_document(document)
    return hashlib.sha256(normalized.encode("utf-8")).hexdigest()

def exact_deduplicate(documents):
    seen = set()
    kept = []
    removed = []
    for document in documents:
        fingerprint = document_hash(document)
        if fingerprint in seen:
            removed.append(document)
        else:
            seen.add(fingerprint)
            kept.append(document)
    return kept, removed

def contamination_report(training_documents, evaluation_documents):
    training_hashes = set()
    for document in training_documents:
        training_hashes.add(document_hash(document))
    contaminated = []
    for document in evaluation_documents:
        if document_hash(document) in training_hashes:
            contaminated.append(document)
    rate = len(contaminated) / max(1, len(evaluation_documents))
    return contaminated, rate

def E12(clean_documents, corrupted_documents, evaluation_documents):
    clean_unique, clean_removed = exact_deduplicate(clean_documents)
    corrupt_unique, corrupt_removed = exact_deduplicate(
        corrupted_documents
    )
    clean_overlap = contamination_report(
        clean_unique, evaluation_documents
    )
    corrupt_overlap = contamination_report(
        corrupt_unique, evaluation_documents
    )
```

```
    return clean_removed, corrupt_removed, clean_overlap, corrupt_overlap
```

Part 5 - The Philosophy Behind the Exercise

Training data is not passive fuel poured into a neutral machine. It is a selection of whose language, facts, errors, values, and absences become statistically influential. Curation is therefore both an engineering act and a choice about representation.

At scale, quality cannot mean cleanliness alone. A perfectly uniform corpus can be clean and impoverished. The deeper goal is traceable, lawful, diverse, purposeful evidence whose limitations remain visible. Architecture determines how a model learns; data determines much of what the model has the opportunity to become.

18.2.14 Exercise 13

Exercise Title: Identify Common Misconceptions About LLM Intelligence and Reasoning

Part 1 - Why this matters

LLM outputs invite human interpretation because they use the language of belief, certainty, memory, intention, and explanation. Some of these words are useful interface shorthand, but they can become misleading causal theories. A model saying "I know" does not provide direct evidence of a human-like mental state. A fluent chain of reasoning does not guarantee that the stated steps caused the answer. A correct answer does not prove the model can repeat the behavior under paraphrase or distribution shift.

The opposite misconception is equally damaging: "it only predicts tokens, so it cannot perform meaningful reasoning." Many algorithms can be implemented through sequences of conditional predictions, and next-token training can produce internal representations that support multi-step computation. The scientific question is not whether a preferred philosophical label applies. It is which behaviors are reproducible, which interventions change them, and which mechanisms are supported by evidence.

You will build a misconception audit around controlled prompt families. For each task, vary irrelevant wording, answer order, requested explanation, and presence of a misleading suggestion. Compare final accuracy, consistency, confidence, and reasoning-trace agreement. The goal is to expose where a strong impression comes from surface stability and where behavior survives genuine intervention.

The report must separate at least five claims: memorization, generalization, reasoning behavior, self-knowledge, and consciousness. Behavioral experiments can provide evidence about the first three. Self-reports alone are weak evidence about internal architecture and training history, and these exercises do not resolve consciousness. Clear boundaries strengthen the empirical claims that can be made.

Part 2 - Mathematical form and reasoning

For semantically equivalent prompt transformations $g \in \mathcal{G}$, define consistency

$$C(x) = \frac{1}{|\mathcal{G}|} \sum_{g \in \mathcal{G}} \mathbb{I}\left[a(g(x)) = a(x)\right].$$

To measure sensitivity to a misleading suggestion s, define

$$\Delta_s = P(\text{correct} \mid x) - P(\text{correct} \mid x + s).$$

A reasoning trace can be scored for internal validity separately from final answer accuracy. The resulting four cases—both correct, answer-only correct, trace-only valid, and both wrong—should not be collapsed into one number.

Part 3 - Hints, controls, and evidence

1. Write each misconception as a falsifiable claim before collecting model outputs.
2. Use prompt paraphrases that preserve semantics and distractors that change only irrelevant surface form.
3. Randomize option order in multiple-choice tasks and map outputs back to semantic answers before scoring.
4. Ask for an answer with and without an explanation. Test whether the final answer changes.
5. Include counterfactual problems not present verbatim in training-style templates.
6. Report what the experiment supports, what it contradicts, and what it cannot decide.

Part 4 - Python code skeleton

```
def evaluate_prompt_family(generate, family):
    records = []
    for variant_index in range(len(family["variants"])):
        prompt = family["variants"][variant_index]
        output = generate(prompt)
        record = {}
        record["variant_index"] = variant_index
        record["prompt"] = prompt
        record["answer"] = output["answer"]
        record["confidence"] = output["confidence"]
        record["reasoning"] = output["reasoning"]
        record["correct"] = (
            output["answer"] == family["reference_answer"]
        )
        records.append(record)
    return records

def consistency(records):
    if len(records) == 0:
        return 0.0
    reference_answer = records[0]["answer"]
    matches = 0
    for record in records:
        if record["answer"] == reference_answer:
            matches = matches + 1
    return matches / len(records)
```

```
def E13(generate, prompt_families):
    report = []
    for family in prompt_families:
        records = evaluate_prompt_family(generate, family)
        item = {}
        item["name"] = family["name"]
        item["records"] = records
        item["consistency"] = consistency(records)
        report.append(item)
    return report
```

Part 5 - The Philosophy Behind the Exercise

Language is both a window and a disguise. It reveals complex behavior, but it also encourages us to project familiar human causes onto unfamiliar machinery. Anthropomorphism can make interaction intuitive while making scientific explanation careless.

Intellectual maturity requires avoiding two comforting extremes: declaring the model a person because its words feel human, or declaring every capability meaningless because its mechanism differs from ours. The productive middle is empirical: define the behavior, intervene on the conditions, measure stability, and keep metaphysical certainty separate from engineering evidence.

18.2.15 Exercise 14

Exercise Title: Explain Why LLMs Are Probabilistic Next-Token Predictors Not Knowledge Bases

Part 1 - Why this matters

A knowledge base stores explicit records that can be queried, updated, traced to sources, and often constrained by a schema. An LLM stores distributed parameters optimized to predict tokens. It may reproduce many facts, combine patterns, and answer questions fluently, but there is no guaranteed one-to-one record corresponding to each claim. The distinction matters whenever users require freshness, provenance, exact updates, or transactional consistency.

Knowledge base retrieval normally returns an existing record or a declared absence. Language model decoding always has a distribution over possible next tokens, even when the requested fact was never supported by training data. This creates graceful language generation but also allows plausible fabrication. Temperature and sampling alter which continuation is selected; they do not transform the model into a verified source.

You will build a tiny key–value knowledge base beside a small language model interface. Query known keys, unknown keys, and keys whose values are updated after model training. The database path should return source identifiers and reflect updates immediately. The model path should return token probabilities and may continue even when evidence is absent. This side-by-side behavior makes the abstraction boundary concrete.

The exercise should not conclude that parameters contain no knowledge. Learned weights encode statistical information about language and the world, and that information can support impressive generalization. The conclusion is that the storage and access guarantees differ from an explicit database. A production system can combine both: retrieve authoritative records, expose their provenance, and use the model to interpret or communicate them.

Part 2 - Mathematical form and reasoning

A knowledge-base query can be represented as a partial function

$$K(q) = \begin{cases} (v, s), & q \text{ matches a stored record with source } s, \\ \bot, & \text{otherwise.} \end{cases}$$

An LLM instead produces

$$p_\theta(x_{t+1} = v \mid x_{\le t}), \qquad \sum_{v=1}^{V} p_\theta(v \mid x_{\le t}) = 1.$$

There is no built-in $\bot$ state unless training or system design makes an abstention token or response sufficiently probable. Entropy $H(p) = -\sum_v p_v \log p_v$ measures distributional uncertainty but is not a certificate that the generated factual claim is correct.

Part 3 - Hints, controls, and evidence

1. Store value, source, timestamp, and version for every database record.
2. Query exact keys, paraphrased keys, unknown keys, and conflicting keys.
3. Update one database value after the model checkpoint is frozen. Compare freshness behavior.
4. Generate multiple times with different temperatures and record factual variation.
5. Compare model confidence with evidence availability. A confident unknown answer is a central failure case.
6. Design a hybrid response that quotes the retrieved value, cites its source identifier, and abstains when retrieval returns $\bot$.

Part 4 - Python code skeleton

```
import math
import torch

class TinyKnowledgeBase:
    def __init__(self):
        self.records = {}

    def update(self, key, value, source, timestamp, version):
        record = {}
        record["value"] = value
        record["source"] = source
        record["timestamp"] = timestamp
        record["version"] = version
        self.records[key] = record

    def query(self, key):
```

```
        if key not in self.records:
            return None
        return dict(self.records[key])

def entropy_from_logits(logits):
    log_probabilities = torch.log_softmax(logits, dim=-1)
    probabilities = torch.exp(log_probabilities)
    entropy = -(probabilities * log_probabilities).sum(dim=-1)
    return entropy

def E14(model_query, device):
    knowledge_base = TinyKnowledgeBase()
    knowledge_base.update("capital_x", "alpha", "source-1",
                          "2028-01-01", 1)
    stored_before = knowledge_base.query("capital_x")
    model_before = model_query("What is capital_x?", device)
    knowledge_base.update("capital_x", "beta", "source-2",
                          "2028-08-22", 2)
    stored_after = knowledge_base.query("capital_x")
    model_after = model_query("What is capital_x?", device)
    unknown_record = knowledge_base.query("unknown_key")
    results = {}
    results["stored_before"] = stored_before
    results["stored_after"] = stored_after
    results["model_before"] = model_before
    results["model_after"] = model_after
    results["unknown_record"] = unknown_record
    return results
```

Part 5 - The Philosophy Behind the Exercise

Human conversation often treats remembered knowledge as if it were a searchable archive, but even human memory is reconstructive. LLMs intensify this difference: their fluency can make statistical reconstruction look like direct retrieval. The interface encourages users to ask database-shaped questions of a probability-shaped system.

The right response is not to demand that one abstraction become another. It is to compose systems according to their strengths. Databases provide explicit state and provenance; language models provide flexible interpretation and generation. Reliability grows when boundaries remain visible.

18.2.16 Exercise 15

Exercise Title: Analyze Failure Cases Where LLM Hallucinates Despite Large Scale

Part 1 - Why this matters

Hallucination is not eliminated by adding parameters because the next-token objective rewards probable continuation, not automatic verification against an authoritative world state. Larger models can improve factual recall, instruction following, and contextual reasoning, yet

still produce unsupported claims when evidence is absent, ambiguous, outdated, conflicting, or buried in long context. Their language quality can make those errors more persuasive.

Use a precise operational definition. In this exercise, a hallucinated claim is a factual assertion not supported by the allowed evidence set. This separates grounding from truth in the abstract: a response may accidentally be true but unsupported by the supplied documents, or faithfully grounded in a source that is itself wrong. Both situations matter, but they are different failure classes.

Construct an adversarial evaluation set containing nonexistent entities, unanswerable questions, false premises, conflicting documents, outdated facts, and prompts requesting invented citations. Require the model to provide claims, evidence identifiers, and an abstention when support is missing. Evaluate each claim rather than scoring only the complete response, because one fluent answer can mix supported and unsupported statements.

Interventions should be tested independently: lower temperature, explicit abstention instruction, retrieval, source-constrained generation, and a post-generation verifier. None should be assumed to solve the problem. Lower temperature can make the same unsupported answer more deterministic; retrieval can add irrelevant or malicious evidence; a verifier can share the generator's biases.

Part 2 - Mathematical form and reasoning

Let response r contain claims $c_1, \ldots, c_m$ and let E be the permitted evidence. Define support

$$s(c_i, E) \in \{0, 1\}.$$

The claim-level unsupported rate is

$$H(r, E) = \frac{1}{m} \sum_{i=1}^{m} \left(1 - s(c_i, E)\right).$$

For unanswerable prompts, define abstention recall

$$R_{\text{abstain}} = \frac{\text{correct abstentions on unanswerable prompts}}{\text{number of unanswerable prompts}}.$$

Also measure answer rate on answerable prompts so a system cannot achieve perfect hallucination avoidance by refusing everything.

Part 3 - Hints, controls, and evidence

1. Write the allowed evidence and answerability label before generating any response.
2. Split model output into atomic claims. Define an annotation rule for compound sentences.
3. Store prompt, model version, sampling configuration, retrieved passages, response, claim labels, and reviewer notes.
4. Use at least two reviewers for a subset and report disagreement.
5. Test whether confidence language correlates with support. Strong wording is not calibrated probability.
6. Compare interventions using both unsupported-claim rate and useful-answer rate, then inspect regressions by failure category.

Part 4 - Python code skeleton

```
def unsupported_claim_rate(claim_records):
    if len(claim_records) == 0:
        return 0.0
    unsupported = 0
    for record in claim_records:
        if not record["supported"]:
            unsupported = unsupported + 1
    return unsupported / len(claim_records)

def abstention_metrics(response_records):
    unanswerable = 0
    correct_abstentions = 0
    answerable = 0
    useful_answers = 0
    for record in response_records:
        if record["answerable"]:
            answerable = answerable + 1
            if record["useful_and_supported"]:
                useful_answers = useful_answers + 1
        else:
            unanswerable = unanswerable + 1
            if record["abstained"]:
                correct_abstentions = correct_abstentions + 1
    abstention_recall = correct_abstentions / max(1, unanswerable)
    useful_answer_rate = useful_answers / max(1, answerable)
    return abstention_recall, useful_answer_rate

def E15(generate, evaluation_cases, configurations):
    all_runs = []
    for configuration in configurations:
        for case in evaluation_cases:
            response = generate(case["prompt"], configuration)
            run = {}
            run["case_id"] = case["id"]
            run["configuration"] = dict(configuration)
            run["evidence"] = case["evidence"]
            run["answerable"] = case["answerable"]
            run["response"] = response
            run["claims"] = ...
            all_runs.append(run)
    return all_runs
```

Part 5 - The Philosophy Behind the Exercise

Fluency and truth answer different questions. Fluency asks whether a sequence fits learned patterns of language. Truth asks whether claims correspond to reality or to trusted evidence.

The two often correlate because human text contains knowledge, but their separation is where hallucination lives.

Large scale can make a model more knowledgeable and more convincing at the same time. This increases usefulness and raises the cost of misplaced trust. The philosophical goal is not a system that never speaks under uncertainty; such a system may be useless. It is a system that recognizes the limits of its evidence, communicates them honestly, and yields to verification when consequences demand it.

18.2.17 Exercise 16

Exercise Title: Compare GPT-Style vs Encoder-Decoder Models for Language Generation

Part 1 - Why this matters

GPT-style and encoder-decoder Transformers can both generate language, but they organize conditioning differently. A decoder-only model concatenates source, instructions, demonstrations, and response into one causally processed token stream. An encoder-decoder model builds bidirectional source representations, then generates target tokens causally while accessing the source through cross-attention. The difference affects masks, parameter allocation, caching, training examples, and deployment.

For open-ended continuation, one-stream modeling is simple and flexible. For translation, summarization, and structured transformation, a separate encoder can represent the entire source bidirectionally before the first target token is produced. Cross-attention also keeps source and target roles explicit. Neither design is universally superior; model scale, data, pretraining, prompt format, and implementation efficiency can dominate the architectural difference.

You will compare tiny matched models on two synthetic tasks: continuation and source-conditioned reversal or mapping. Match parameter counts approximately, use the same token vocabulary and optimizer budget, and report any remaining difference. For the decoder-only model, define exactly which loss positions are ignored so source tokens are not accidentally scored as target output. For the encoder-decoder model, define source padding, target padding, and target causal masks separately.

At inference time, measure source processing and per-token decoding. The encoder-decoder path can encode the source once and cache it; the decoder-only path represents the source in its self-attention cache. Both still generate target tokens sequentially. The useful comparison is not a slogan about parallelism but a measured decomposition of work and quality.

Part 2 - Mathematical form and reasoning

Decoder-only conditional generation can be written as

$$p_\theta(y_{1:M} \mid x_{1:S}) = \prod_{t=1}^{M} p_\theta(y_t \mid x_{1:S}, y_{<t}).$$

The encoder-decoder has the same output factorization but constructs encoder memory

$$H_x = \mathrm{Encoder}_\theta(x_{1:S}),$$

and predicts

$$p_\theta(y_t \mid H_x, y_{<t}).$$

For decoder-only supervised training, a loss mask m_t can restrict gradients to response positions:

$$\mathcal{L} = -\frac{\sum_t m_t \log p_\theta(z_{t+1} \mid z_{\le t})}{\sum_t m_t}.$$

Part 3 - Hints, controls, and evidence

1. Use the same special-token identifiers and document the different input layouts for both models.
2. Match trainable parameter count within a declared tolerance; exact matching is not required but unreported differences are unacceptable.
3. Verify every mask visually on one short padded batch.
4. Train on identical source–target pairs and equal numbers of target-token updates.
5. Report continuation and transformation tasks separately; averaging them can hide architectural specialization.
6. Measure encoder or prompt prefill latency, per-token decode latency, peak memory, accuracy, and failure examples.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def decoder_only_loss(logits, combined_ids, response_mask):
    shifted_logits = logits[:, :-1, :]
    shifted_targets = combined_ids[:, 1:]
    shifted_mask = response_mask[:, 1:]
    token_losses = F.cross_entropy(
        shifted_logits.reshape(-1, shifted_logits.shape[-1]),
        shifted_targets.reshape(-1), reduction="none"
    )
    token_losses = token_losses.view_as(shifted_targets)
    weighted = token_losses * shifted_mask.to(token_losses.dtype)
    return weighted.sum() / shifted_mask.sum().clamp_min(1)

def encoder_decoder_loss(logits, target_ids, padding_id):
    shifted_logits = logits[:, :-1, :]
    shifted_targets = target_ids[:, 1:]
    return F.cross_entropy(
        shifted_logits.reshape(-1, shifted_logits.shape[-1]),
        shifted_targets.reshape(-1), ignore_index=padding_id
    )

def E16(decoder_only_model, encoder_decoder_model,
        decoder_batch, encoder_decoder_batch):
```

```
    decoder_logits = decoder_only_model(decoder_batch["combined_ids"])
    decoder_loss = decoder_only_loss(
        decoder_logits,
        decoder_batch["combined_ids"],
        decoder_batch["response_mask"]
    )
    encoder_decoder_logits = encoder_decoder_model(
        encoder_decoder_batch["source_ids"],
        encoder_decoder_batch["target_ids"][:, :-1]
    )
    sequence_loss = encoder_decoder_loss(
        encoder_decoder_logits,
        encoder_decoder_batch["target_ids"],
        encoder_decoder_batch["padding_id"]
    )
    return decoder_loss, sequence_loss
```

Part 5 - The Philosophy Behind the Exercise

Architecture encodes a theory about relationships. The decoder-only model says that source and response can inhabit one temporal stream. The encoder-decoder model says that understanding the source and producing the target deserve distinct computational roles connected through attention.

Neither theory is complete in isolation. Real success depends on what the task requires, what data teaches, and what hardware can serve. The exercise teaches architectural pluralism: understand the commitments of each design deeply enough to choose, rather than converting historical popularity into a universal law.

18.2.18 Exercise 17

Exercise Title: Explain Why Instruction Tuning Changes Behavior Without Changing Architecture

Part 1 - Why this matters

A pretrained language model learns broad continuation patterns. When given a question, it may continue with another question, imitate a forum thread, produce metadata, or answer directly. Instruction tuning changes the distribution of desired continuations by training on prompt–response examples. The decoder blocks, attention equations, dimensions, and vocabulary head can remain exactly the same while the parameters move toward behavior that treats instructions as requests for useful responses.

This distinction demonstrates why architecture alone cannot explain a chat model. Two checkpoints instantiated from the same class can differ sharply in format following, refusal behavior, verbosity, tool syntax, and response style. Those differences may arise from supervised fine-tuning, preference optimization, safety data, system prompts, or decoding policies. The class definition reveals none of that history.

You will fine-tune a tiny pretrained decoder on a small instruction dataset. Before and after training, evaluate held-out paraphrases, formatting requirements, conflicting instructions, and a control set of ordinary language modeling examples. Use a response-only loss mask so the

objective focuses on the desired answer region. Also run a deliberately incorrect all-token-loss variant to reveal how masking changes the learning signal.

Behavioral improvement must be paired with retention analysis. Fine-tuning can overfit templates, cause catastrophic forgetting, or teach superficial cue matching. Measure base-task loss and instruction-task success throughout training. A checkpoint that follows the training templates perfectly but fails paraphrases has learned a narrow mapping, not general instruction following.

Part 2 - Mathematical form and reasoning

Starting from pretrained parameters θ_0, supervised instruction tuning optimizes

$$\theta_{\text{SFT}} = operatorname * arg\,min_\theta - \sum_{(u,r)\in\mathcal{D}_{\text{SFT}}} \sum_{t\in\text{response}} \log p_\theta(r_t \mid u, r_{<t}).$$

The architecture f_θ is unchanged, but generally $f_{\theta_{\text{SFT}}}(x) \neq f_{\theta_0}(x)$ because optimization changes the parameter values. Define retention as a change in base validation loss ΔL_{base} and instruction gain as $\Delta A_{\text{instruction}}$.

Part 3 - Hints, controls, and evidence

1. Save the pretrained state dictionary and configuration before fine-tuning. Afterward, prove the key names and tensor shapes are unchanged.
2. Construct response masks from token boundaries, not character lengths. Print one full alignment table.
3. Keep a frozen copy of the pretrained checkpoint for paired evaluation.
4. Test unseen instructions that vary wording and output format.
5. Evaluate at several fine-tuning steps to observe instruction gain and base-capability forgetting as trajectories.
6. Compare response-only loss, all-token loss, and one intentionally shifted mask. Treat the shifted mask as a semantic failure even if loss decreases.

Part 4 - Python code skeleton

```
import copy
import torch
import torch.nn.functional as F

def response_only_loss(logits, input_ids, response_mask):
    prediction_logits = logits[:, :-1, :]
    target_ids = input_ids[:, 1:]
    target_mask = response_mask[:, 1:]
    losses = F.cross_entropy(
        prediction_logits.reshape(-1, prediction_logits.shape[-1]),
        target_ids.reshape(-1), reduction="none"
    )
```

```
    losses = losses.view_as(target_ids)
    weighted = losses * target_mask.to(losses.dtype)
    return weighted.sum() / target_mask.sum().clamp_min(1)

def architecture_signature(model):
    signature = {}
    for name, tensor in model.state_dict().items():
        signature[name] = tuple(tensor.shape)
    return signature

def E17(pretrained_model, instruction_batches, optimizer_factory,
        evaluation_function, device):
    frozen_base = copy.deepcopy(pretrained_model).to(device).eval()
    tuned_model = copy.deepcopy(pretrained_model).to(device)
    signature_before = architecture_signature(tuned_model)
    optimizer = optimizer_factory(tuned_model.parameters())
    trajectory = []
    for batch in instruction_batches:
        tuned_model.train()
        optimizer.zero_grad(set_to_none=True)
        logits = tuned_model(batch["input_ids"].to(device))
        loss = response_only_loss(
            logits,
            batch["input_ids"].to(device),
            batch["response_mask"].to(device)
        )
        loss.backward()
        optimizer.step()
        trajectory.append(float(loss.detach().cpu()))
    signature_after = architecture_signature(tuned_model)
    assert signature_before == signature_after
    base_metrics = evaluation_function(frozen_base)
    tuned_metrics = evaluation_function(tuned_model)
    return trajectory, base_metrics, tuned_metrics
```

Part 5 - The Philosophy Behind the Exercise

The same structure can support different habits. Architecture defines the space of possible transformations; training shapes which transformations become likely. This is why behavior cannot be read directly from a network diagram. History is embedded in parameter values.

Instruction tuning also shows that helpfulness is not a natural consequence of language modeling alone. It is a learned relationship between requests and responses, created from human examples and preferences. That relationship can be improved, biased, forgotten, or manipulated. Understanding its origin makes the interface less magical and its governance more accountable.

18.2.19 Exercise 18

Exercise Title: Write a Conceptual Summary Explaining LLM as System Not Just Model

Part 1 - Why this matters

This exercise consolidates the chapter into an engineering system map. A model checkpoint is only one stateful component in a chain that begins with authorized data and ends with monitored behavior. Tokenizers, data pipelines, distributed training, post-training, evaluation suites, inference engines, caches, retrievers, safety policies, and user interfaces all introduce assumptions and failure modes. A summary that discusses only attention blocks misses the object that users actually encounter.

Construct the summary as a causal trace. Begin with source documents and their provenance. Follow normalization, deduplication, tokenization, sequence packing, next-token labels, optimization, checkpoint selection, instruction tuning, preference or safety stages, model packaging, and inference. Then include prompt construction, retrieval, decoding, tool execution, response validation, monitoring, feedback, and rollback. For each boundary, state what enters, what leaves, and what can silently go wrong.

Ownership matters. Data engineers, model researchers, infrastructure teams, safety specialists, product engineers, domain reviewers, and operators may control different parts of the system. A failure can cross these boundaries: a tokenizer mismatch may look like model corruption; stale retrieval may look like hallucination; a serving cache leak may look like privacy failure in the model. The report should assign observable checks and response responsibility.

Your system description must include lifecycle time. Data and model versions change, knowledge becomes stale, dependencies receive updates, evaluation sets leak, user distributions shift, and attackers adapt. "The model passed" is not a permanent system property. Reliability requires continuous evidence and a recoverable version history.

Part 2 - Mathematical form and reasoning

Represent the deployed response as

$$r = \mathcal{P}_\omega \left(\mathcal{D}_\gamma \left(f_\theta \left(\mathcal{C}_\rho(T_\phi(u), R_\eta(u)) \right) \right) \right),$$

where T tokenizes, R retrieves evidence, $\mathcal{C}$ builds context, f_θ produces logits, $\mathcal{D}$ decodes, and $\mathcal{P}$ applies post-processing or policy. System risk can be decomposed conceptually as

$$P(F) = 1 - \prod_{i=1}^{K} \left(1 - P(F_i \mid F^c_{<i}) \right),$$

while remembering that component failures are often dependent. The formula is a prompt to model interfaces, not a claim that real failures are independent.

Part 3 - Hints, controls, and evidence

1. Draw a system boundary diagram with training and inference paths shown separately.
2. For every component record version, owner, input contract, output contract, invariant, metric, and recovery action.
3. Trace one correct request and at least five injected failures end to end.
4. Include privacy, licensing, security, latency, cost, and factual quality; do not reduce the system to model accuracy.
5. Identify which tests run before release, continuously online, and after an incident.

6. Finish with a concise claim: which properties belong to the model, which belong to the surrounding system, and which emerge only from their interaction.

Part 4 - Python code skeleton

```
class LLMSystemAudit:
    def __init__(self):
        self.components = []
        self.events = []

    def register_component(self, name, version, owner,
                           input_contract, output_contract,
                           invariant, recovery_action):
        component = {}
        component["name"] = name
        component["version"] = version
        component["owner"] = owner
        component["input_contract"] = input_contract
        component["output_contract"] = output_contract
        component["invariant"] = invariant
        component["recovery_action"] = recovery_action
        self.components.append(component)

    def record_event(self, request_id, component_name,
                     status, evidence, latency_seconds):
        event = {}
        event["request_id"] = request_id
        event["component"] = component_name
        event["status"] = status
        event["evidence"] = evidence
        event["latency_seconds"] = latency_seconds
        self.events.append(event)

    def failures_for_request(self, request_id):
        failures = []
        for event in self.events:
            if event["request_id"] == request_id:
                if event["status"] != "ok":
                    failures.append(event)
        return failures

def E18():
    audit = LLMSystemAudit()
    audit.register_component(...)
    audit.record_event(...)
    return audit
```

Part 5 - The Philosophy Behind the Exercise

A system is more than the sum of its components because interfaces create new properties. A model cannot leak another user's cache if no shared serving cache exists; a retriever cannot make the model cite a source if its metadata is discarded; a safe checkpoint cannot prevent an external tool from executing an unauthorized action. Interaction creates both capability and risk.

This systems view changes responsibility. It prevents teams from blaming the model for every pipeline failure or treating the model as innocent of every behavior mediated through its outputs. Responsibility follows design choices, evidence, authority, and consequences across the whole chain.

18.2.20 Exercise 19

Exercise Title: Produce a One-Page Mental Model of How LLMs Actually Work

Part 1 - Why this matters

After studying many mechanisms, a researcher needs a compact mental model that remains accurate under pressure. The purpose of one page is not to remove depth. It is to preserve the causal backbone so that new details have a correct place to attach. A good mental model should help diagnose an unexpected output, design an experiment, explain the system to another engineer, and identify when a claim exceeds available evidence.

Your page must follow one request from text to response. Text is tokenized into identifiers. Embeddings place tokens and positions into vectors. Repeated decoder blocks use causal attention and feed-forward transformations to update the residual stream. The language head converts the final state at each position into vocabulary logits. A decoding rule selects a token, appends it, and repeats. Learned weights came from next-token optimization over data and may have been altered by instruction and preference tuning.

The same page must include what this mechanism does not guarantee. Logits are not facts, probability is not correctness, context capacity is not faithful context use, parameter count is not reasoning proof, and fluent explanation is not a transparent record of internal causality. Retrieval, tools, policies, and verification can extend the system, but each adds an interface that must be tested.

Although the final artifact is one page, it must be earned through compression. Every arrow should be supported by an exercise from this chapter. Every word such as "learns," "remembers," "reasons," or "knows" must be either defined operationally or replaced with a more precise statement. Simplicity is the last stage of understanding, not the first.

Part 2 - Mathematical form and reasoning

The minimum mathematical spine is

$$x_{1:T} = T_\phi(s), \qquad Z = f_\theta(x_{1:T}), \qquad p = \mathrm{softmax}(Z_{:,T,:}), \qquad x_{T+1} \sim \pi_\gamma(p),$$

with training objective

$$\min_\theta - \sum_t \log p_\theta(x_{t+1} \mid x_{\le t}).$$

The page should label shapes (B, T), (B, T, d), and (B, T, V) and show the causal information boundary. Add a separate systems ring for data, post-training, retrieval, tools, evaluation, serving, monitoring, and rollback.

Part 3 - Hints, controls, and evidence

1. Use exactly three layers of explanation: mechanism, learned behavior, and deployed system. Do not mix them in one unlabeled paragraph.
2. Include one forward arrow for computation and one feedback arrow for training or operational monitoring.
3. Attach at least six invariants: identifier range, context limit, causal mask, logit shape, probability normalization, and evidence boundary.
4. Add a "can" column and a "does not guarantee" column.
5. Test the page by using it to diagnose a tokenizer mismatch, a future-mask leak, a hallucinated citation, and an out-of-memory failure.
6. Ask another reader to explain the model using only the page. Record which arrows or terms remain ambiguous and revise them.

Part 4 - Python code skeleton

```
def inspect_one_generation_step(system, text):
    trace = {}
    token_ids = system.tokenizer.encode(text)
    trace["text"] = text
    trace["token_ids"] = token_ids
    trace["token_count"] = len(token_ids)

    input_ids = system.to_tensor(token_ids)
    trace["input_shape"] = tuple(input_ids.shape)
    logits = system.model(input_ids)
    trace["logit_shape"] = tuple(logits.shape)

    last_logits = logits[:, -1, :]
    probabilities = system.softmax(last_logits)
    trace["probability_sum"] = float(probabilities.sum().item())
    next_id = system.decode_policy(probabilities)
    trace["next_id"] = int(next_id.item())
    trace["next_token"] = system.tokenizer.decode([trace["next_id"]])

    assert trace["token_count"] <= system.maximum_context
    assert trace["logit_shape"][-1] == system.vocabulary_size
    assert abs(trace["probability_sum"] - 1.0) < 1e-5
    return trace

def E19(system, diagnostic_prompts):
    traces = []
    for prompt in diagnostic_prompts:
        traces.append(inspect_one_generation_step(system, prompt))
    return traces
```

Part 5 - The Philosophy Behind the Exercise

A mental model is a tool for deciding what to notice. If it contains only the neural network, data failures become invisible. If it contains only system components, the probability mechanism becomes mystical. If it uses human mental language without operational definitions, impressions replace causes. The best mental model is compact enough to remember and precise enough to resist these distortions.

The chapter ends where serious LLM engineering begins: not with the claim that the model is merely autocomplete, and not with the claim that scale created an oracle. It is a learned probabilistic machine embedded in a human-designed system. Its capabilities are real, its limitations are consequential, and both must be studied through mechanisms, controlled experiments, and evidence.

18.3 LLM01

Chapter Title: Tokenization and Context Mechanics
Specialization: Language Representation and Context Engineering

18.3.1 Exercise 00

Exercise Title: Implement BPE Tokenization Conceptually and Explain Why Tokens Are Not Words

Part 1 - Why this matters

An LLM never receives words directly. It receives integer identifiers produced by a tokenizer whose vocabulary and segmentation rules were learned or designed before model training. The sentence visible to a user and the token sequence visible to the model are therefore different objects. Spaces, punctuation, capitalization, digits, Unicode normalization, and repeated byte patterns can all change the sequence length and boundaries.

Byte Pair Encoding begins with small symbols and repeatedly merges the most frequent adjacent pair. Frequent fragments become single vocabulary entries, while rare words remain compositions of smaller pieces. This produces an open vocabulary without allocating a separate identifier to every possible word. A token may be a complete word, part of a word, punctuation joined to whitespace, a byte fragment, or another learned unit. Calling every token a word hides the actual computational sequence.

You will implement the training phase and encoding phase of a small BPE system without using a tokenizer library. The implementation must preserve word-end or boundary information so that merging does not accidentally erase how text can be reconstructed. You will print pair frequencies at every iteration, choose a deterministic tie-breaking rule, store merges in rank order, and then replay those rules when encoding unseen text.

The experiment must also expose failure cases. A tokenizer trained on one domain may fragment another domain heavily. Different Unicode representations of visually similar text may produce different tokens. A merge that is legal inside one pre-tokenized word should not silently cross a boundary unless the tokenizer design explicitly permits it. These are not cosmetic details: they change context usage, embedding lookup, training frequency, and inference cost.

Part 2 - Mathematical form and reasoning

Let the current symbol sequence for corpus item n be $s^{(n)} = (s_1^{(n)}, \ldots, s_{L_n}^{(n)})$. The frequency of adjacent pair (a, b) is

$$f(a,b) = \sum_{n} \sum_{i=1}^{L_n - 1} \mathbb{I}\left[s_i^{(n)} = a \wedge s_{i+1}^{(n)} = b\right].$$

At merge step k, select

$$(a_k, b_k) = \arg\max_{(a,b)} f(a,b)$$

and replace every non-overlapping occurrence with the new symbol $a_k \| b_k$. Encoding applies the learned merges in rank order, not by recalculating corpus frequencies for each new sentence.

Part 3 - Hints, controls, and evidence

1. Normalize text using one declared Unicode policy and retain the original text for round-trip comparison.
2. Begin from visible characters for transparency, while explaining why production byte-level BPE starts from bytes.
3. Count adjacent pairs using explicit loops and show how overlapping pairs are handled.
4. Break equal-frequency ties lexicographically so repeated runs learn the same vocabulary.
5. Encode one training word, one unseen morphological variant, one number, and one non-English example.
6. Assert that decoding the encoded symbols reconstructs the normalized input exactly. Report token count and fragmentation ratio for every case.

Part 4 - Python code skeleton

```
from collections import defaultdict
import unicodedata

def initial_symbols(text):
    normalized = unicodedata.normalize("NFC", text)
    words = normalized.split(" ")
    sequences = []
    for word in words:
        symbols = []
        for character in word:
            symbols.append(character)
        symbols.append("</w>")
        sequences.append(symbols)
    return sequences

def count_pairs(sequences):
    frequencies = defaultdict(int)
    for symbols in sequences:
        for index in range(len(symbols) - 1):
```

```
            pair = (symbols[index], symbols[index + 1])
            frequencies[pair] = frequencies[pair] + 1
    return frequencies

def merge_pair(symbols, selected_pair):
    merged = []
    index = 0
    while index < len(symbols):
        can_merge = index + 1 < len(symbols)
        if can_merge:
            current_pair = (symbols[index], symbols[index + 1])
            if current_pair == selected_pair:
                merged.append(symbols[index] + symbols[index + 1])
                index = index + 2
                continue
        merged.append(symbols[index])
        index = index + 1
    return merged

def pair_sort_key(item):
    pair = item[0]
    frequency = item[1]
    return (-frequency, pair)

def train_bpe(texts, number_of_merges):
    sequences = []
    for text in texts:
        sequences.extend(initial_symbols(text))
    learned_merges = []
    for _ in range(number_of_merges):
        frequencies = count_pairs(sequences)
        if len(frequencies) == 0:
            break
        ordered = sorted(frequencies.items(), key=pair_sort_key)
        selected_pair = ordered[0][0]
        learned_merges.append(selected_pair)
        updated = []
        for symbols in sequences:
            updated.append(merge_pair(symbols, selected_pair))
        sequences = updated
    return learned_merges, sequences

def E00():
    corpus = ["low lower lowest", "newer wider"]
    merges, final_sequences = train_bpe(corpus, 12)
    return merges, final_sequences
```

Part 5 - The Philosophy Behind the Exercise

Tokenization shows that representation is never neutral. Before the neural network learns anything, a prior system has decided what counts as a reusable unit. Frequent patterns receive compact symbols; rare patterns consume more positions. The model's apparent language is built on this hidden segmentation.

The deeper lesson is that meaning does not live inside token boundaries. Human concepts can span many tokens, and one token can participate in many meanings. BPE is a compression-informed interface between text and computation, not a theory of words or understanding. Knowing this prevents us from mistaking the model's storage units for the structure of language itself.

18.3.2 Exercise 01

Exercise Title: Compare Character Word and Subword Tokenization and Measure Vocabulary Explosion

Part 1 - Why this matters

Character, word, and subword tokenization allocate complexity differently. Character tokenization uses a small vocabulary but produces long sequences. Word tokenization produces short sequences for familiar text but requires an enormous vocabulary and an unknown-token policy. Subword tokenization occupies the middle: a moderate learned vocabulary represents common strings compactly while decomposing rare strings into reusable pieces.

Vocabulary size affects more than a lookup table. Token embeddings and the language-model output projection commonly contain terms proportional to Vd_{model}. A large word vocabulary increases parameters and output logit compute. A small character vocabulary reduces those costs but increases sequence length, causing more Transformer activations and potentially much more attention work. Subword design is therefore a trade between vocabulary-axis and sequence-axis cost.

You will build all three tokenizers over identical train and test corpora. The test corpus must include unseen words, spelling variants, identifiers, numbers, punctuation, and at least two languages. Measure vocabulary size, average tokens per sentence, characters per token, unknown rate, round-trip fidelity, and estimated attention-score elements. A tokenizer cannot be judged solely on the training corpus it memorized.

Word splitting also requires a definition. Splitting only on spaces mishandles punctuation and languages without spaces; lowercasing destroys case information; Unicode normalization can join or separate code points. State each rule rather than calling the output "words" as if the boundary were universally obvious.

Part 2 - Mathematical form and reasoning

For tokenizer τ and documents d_i, define vocabulary size $V_\tau = |\mathcal{V}_\tau|$ and average sequence length

$$\bar{T}_\tau = \frac{1}{N}\sum_{i=1}^{N} |\tau(d_i)|.$$

Embedding parameters scale as $V_\tau d$, while dense attention pair count for batch B and heads H scales as

$$P_\tau = BH\bar{T}_\tau^2.$$

Unknown rate for a word vocabulary is

$$r_{\text{UNK}} = \frac{N_{\text{unknown tokens}}}{N_{\text{test tokens}}}.$$

Report distributions as well as means because rare long examples can dominate memory failures.

Part 3 - Hints, controls, and evidence

1. Learn all vocabularies using training text only; test text must not alter the vocabulary.
2. Reserve special symbols explicitly and include them in parameter counts.
3. Measure percentiles of tokenized length, not only the average.
4. Report unknown-token rate and round-trip reconstruction separately. An unknown placeholder can preserve length while destroying content.
5. Estimate embedding bytes for float32, float16, and tied output weights.
6. Create a decision table showing which tokenizer wins on vocabulary, sequence length, openness, and multilingual robustness.

Part 4 - Python code skeleton

```
import torch

def character_tokens(text):
    tokens = []
    for character in text:
        tokens.append(character)
    return tokens

def whitespace_word_tokens(text):
    pieces = text.split()
    tokens = []
    for piece in pieces:
        tokens.append(piece)
    return tokens

def build_vocabulary(tokenized_documents, special_tokens):
    token_to_id = {}
    for token in special_tokens:
        token_to_id[token] = len(token_to_id)
    for document_tokens in tokenized_documents:
        for token in document_tokens:
            if token not in token_to_id:
                token_to_id[token] = len(token_to_id)
    return token_to_id

def tokenizer_metrics(tokenized_documents, vocabulary_size,
```

```
                    d_model, batch_size, heads):
    lengths = []
    for tokens in tokenized_documents:
        lengths.append(len(tokens))
    length_tensor = torch.tensor(lengths, dtype=torch.float64)
    metrics = {}
    metrics["vocabulary_size"] = vocabulary_size
    metrics["mean_length"] = float(length_tensor.mean())
    metrics["maximum_length"] = int(length_tensor.max())
    metrics["embedding_parameters"] = vocabulary_size * d_model
    mean_length = metrics["mean_length"]
    metrics["mean_attention_pairs"] = (
        batch_size * heads * mean_length * mean_length
    )
    return metrics

def E01(training_documents, test_documents, subword_encode):
    character_train = []
    word_train = []
    for document in training_documents:
        character_train.append(character_tokens(document))
        word_train.append(whitespace_word_tokens(document))
    character_vocabulary = build_vocabulary(character_train, ["<pad>"])
    word_vocabulary = build_vocabulary(word_train, ["<pad>", "<unk>"])
    subword_test = []
    for document in test_documents:
        subword_test.append(subword_encode(document))
    return character_vocabulary, word_vocabulary, subword_test
```

Part 5 - The Philosophy Behind the Exercise

Every tokenizer chooses where to pay for linguistic diversity. Word models pay in vocabulary, character models pay in time, and subword models negotiate between them. There is no representation without cost; there are only different places where cost and information loss appear.

Vocabulary explosion is also a reminder that language is productive. Humans continually invent names, compounds, numbers, and spellings. A closed list of words cannot anticipate them all. Subwords succeed not because they discover the final atoms of meaning, but because composition is a practical answer to an open world.

18.3.3 Exercise 02

Exercise Title: Explain Context Window and Why LLMs Forget Beyond Max Length

Part 1 - Why this matters

The context window is the maximum token sequence that a model invocation can represent under its configured positional mechanism and serving limits. It is not the model's learned knowledge, a permanent conversation memory, or a promise that every token inside the window

will influence the answer equally. Context is temporary request state; parameters are persistent learned state.

When a conversation exceeds the allowed length, some policy must change the input. A system may reject the request, remove earliest tokens, summarize prior turns, retrieve selected memories, or use a model designed for a longer window. If the relevant evidence is removed, the model cannot attend to it in that invocation. Saying the model "forgot" is convenient, but the immediate cause may be that the serving pipeline never supplied the evidence.

Even evidence inside the formal limit can be used poorly. Long-context quality depends on positional training, attention patterns, placement, distractors, and the model's ability to retrieve and combine distant information. Formal context length, accepted input length, and effective usable context must be measured as different properties.

You will implement a context manager that records every truncation decision. Then build a key-retrieval task where a unique fact appears at the beginning, middle, or end of a long sequence. Compare hard left truncation, right truncation, head–tail preservation, and evidence-aware selection. The experiment should make information loss visible before asking the model to answer.

Part 2 - Mathematical form and reasoning

Let a tokenized request have length T and maximum context C. A left truncation operator is

$$\tau_{\text{left}}(x_{1:T}) = \begin{cases} x_{1:T}, & T \le C, \\ x_{T-C+1:T}, & T > C. \end{cases}$$

If required evidence occupies index set R, evidence retention is

$$\rho = \frac{|R \cap I_{\text{kept}}|}{|R|}.$$

Model accuracy should be reported conditioned on $\rho = 1$ and $\rho < 1$. Otherwise pipeline loss and model failure are mixed together.

Part 3 - Hints, controls, and evidence

1. Count tokens after applying the exact production tokenizer, not by words or characters.
2. Preserve mandatory system and safety instructions before allocating the remaining context budget.
3. Return kept and removed token ranges from every truncation function.
4. Place the required fact at several normalized positions and add irrelevant distractors.
5. Distinguish failure caused by removed evidence from failure with retained evidence.
6. Test lengths below, exactly equal to, and one token above the maximum.

Part 4 - Python code skeleton

```
def left_truncate(token_ids, maximum_context):
    original_length = len(token_ids)
    if original_length <= maximum_context:
        return token_ids[:], [], (0, original_length)
    first_kept = original_length - maximum_context
    kept = token_ids[first_kept:]
    removed = token_ids[:first_kept]
    return kept, removed, (first_kept, original_length)

def head_tail_truncate(token_ids, maximum_context, head_tokens):
    if len(token_ids) <= maximum_context:
        return token_ids[:]
    if head_tokens > maximum_context:
        raise ValueError("head allocation exceeds context")
    tail_tokens = maximum_context - head_tokens
    kept = []
    kept.extend(token_ids[:head_tokens])
    if tail_tokens > 0:
        kept.extend(token_ids[-tail_tokens:])
    return kept

def evidence_retention(evidence_indices, kept_start, kept_end):
    retained = 0
    for index in evidence_indices:
        if kept_start <= index and index < kept_end:
            retained = retained + 1
    return retained / max(1, len(evidence_indices))

def E02(token_ids, evidence_indices, context_sizes):
    records = []
    for context_size in context_sizes:
        kept, removed, interval = left_truncate(
            token_ids, context_size
        )
        record = {}
        record["context"] = context_size
        record["kept_length"] = len(kept)
        record["removed_length"] = len(removed)
        record["retention"] = evidence_retention(
            evidence_indices, interval[0], interval[1]
        )
        records.append(record)
    return records
```

Part 5 - The Philosophy Behind the Exercise

Context is often described as memory, but it is closer to a temporary field of attention prepared by the surrounding system. What is absent cannot be used; what is present is not guaranteed to be understood. This distinction separates storage, access, and effective reasoning.

Forgetting is therefore not always a defect inside the model. It can be a policy decision made by a tokenizer, prompt builder, cache, or truncation rule. The ethical and engineering lesson is to make those invisible editorial decisions auditable, because they decide which parts of a conversation continue to exist for the machine.

18.3.4 Exercise 03

Exercise Title: Build Dataset That Produces Sliding Context Windows Correctly

Part 1 - Why this matters

Long token streams must be converted into finite training examples. A sliding window dataset selects a context of length C and a target shifted by one token. The operation appears simple, yet errors in the final valid index, stride, document boundaries, padding, or target shift can make examples incomplete or teach relationships across unrelated documents.

Stride controls overlap. A stride of one produces many highly redundant windows; a stride equal to context length produces non-overlapping blocks; an intermediate stride trades sample count against coverage and repeated compute. Overlap can expose each transition under multiple prefixes, but it also changes the effective weighting of central tokens relative to boundary tokens.

Document boundaries require an explicit policy. Concatenating documents with no separator teaches the model that the end of one document is followed directly by the beginning of another. Inserting an end-of-document token makes the transition visible. Preventing windows from crossing documents avoids synthetic cross-document contexts but can waste short tails. The correct choice depends on the training design and must be recorded.

You will implement both a single-stream dataset and a document-aware dataset. For a tiny numbered sequence, enumerate every expected input and target by hand. Then test different strides, drop-last behavior, and sequences shorter than the requested window. Dataset correctness must be proven before DataLoader performance is measured.

Part 2 - Mathematical form and reasoning

For token sequence length N, context length C, and stride S, a full input–target example requires $C + 1$ tokens. Valid start positions satisfy

$$i_k = kS, \qquad i_k + C < N.$$

The number of full windows is

$$K = \begin{cases} 0, & N < C + 1, \\ \left\lfloor \dfrac{N - C - 1}{S} \right\rfloor + 1, & N \geq C + 1. \end{cases}$$

Each example is $X^{(k)} = x_{i_k:i_k+C}$ and $Y^{(k)} = x_{i_k+1:i_k+C+1}$. Verify the first and final examples against this formula.

Part 3 - Hints, controls, and evidence

1. Use the sequence $[0, 1, \ldots, 9]$ with several context and stride values and write the expected windows before coding.

2. Reject non-positive context and stride values in the constructor.

3. Return cloned or freshly indexed tensors so accidental mutation of one sample does not corrupt the dataset.

4. Test length $C-1$, C, $C+1$, and $C+2$ explicitly.

5. For multiple documents, verify no input crosses a boundary unless an end-of-document token is intentionally inserted.

6. Count how many times each source transition appears under overlapping windows and discuss weighting bias.

Part 4 - Python code skeleton

```
import torch
from torch.utils.data import Dataset

class SlidingContextDataset(Dataset):
    def __init__(self, token_ids, context_length, stride):
        if token_ids.ndim != 1:
            raise ValueError("token_ids must be one-dimensional")
        if context_length <= 0 or stride <= 0:
            raise ValueError("context and stride must be positive")
        self.token_ids = token_ids
        self.context_length = context_length
        self.stride = stride
        available = token_ids.numel() - context_length - 1
        if available < 0:
            self.number_of_windows = 0
        else:
            self.number_of_windows = available // stride + 1

    def __len__(self):
        return self.number_of_windows

    def __getitem__(self, index):
        if index < 0 or index >= self.number_of_windows:
            raise IndexError("window index is out of range")
        start = index * self.stride
        input_end = start + self.context_length
        target_end = input_end + 1
        input_ids = self.token_ids[start:input_end].clone()
        target_ids = self.token_ids[start + 1:target_end].clone()
        return input_ids, target_ids

def E03():
    token_ids = torch.arange(10, dtype=torch.long)
    dataset = SlidingContextDataset(token_ids, context_length=4,
                                    stride=2)
    observed = []
```

```
    for index in range(len(dataset)):
        input_ids, target_ids = dataset[index]
        observed.append((input_ids, target_ids))
        assert torch.equal(input_ids[1:], target_ids[:-1])
    assert len(dataset) == 3
    return observed
```

Part 5 - The Philosophy Behind the Exercise

A dataset is not merely stored information; it is a procedure that decides what the model repeatedly experiences. Sliding windows create a local view of a long world. Stride, boundaries, and repetition determine which transitions become common and which context relationships are never shown.

This is why data loaders deserve the same scrutiny as model layers. A perfectly implemented network cannot recover an example that was misaligned before it arrived. Learning begins with the geometry of exposure, and the dataset is where that geometry is constructed.

18.3.5 Exercise 04

Exercise Title: Debug Off-By-One Errors in Next-Token Label Shifting

Part 1 - Why this matters

Next-token training depends on a one-position semantic relationship: logits at position t predict the identifier at $t+1$. An off-by-one bug can preserve tensor ranks, produce finite loss, and even decrease during training while teaching the model to copy the current token or predict two steps ahead. Shape validation alone cannot detect this class of error.

The safest approach is to inspect one readable sequence before batching. If the tokens are `<bos> the model learns <eos>`, the row generated from `<bos>` must be compared with `the`; the row generated from `the` must be compared with `model`. Special tokens and padding must participate according to an explicit policy. Whether the final content token predicts `<eos>` changes stopping behavior later.

You will implement a correct shifter and three faulty variants: no shift, two-step shift, and a shift that moves logits and labels in the same direction but loses the intended pairing. Train a tiny model on a deterministic repeating sequence and compare learned transition tables. The correct model should assign high probability to the known successor; the copy-label model should learn an identity mapping.

The exercise also covers padding masks. The ignore mask must be shifted with the target tokens. If it remains aligned to the input, a real target can be dropped or a padding target can contribute loss. Print the flattened valid pairs used by cross entropy so reduction never hides the error.

Part 2 - Mathematical form and reasoning

For logits $Z \in \mathbb{R}^{B\times T\times V}$ and identifiers $X \in \mathbb{N}^{B\times T}$, correct alignment is

$$Z' = Z_{:,:T-1,:}, \qquad Y = X_{:,1:T}.$$

The loss is

$$\mathcal{L} = -\frac{1}{N_{\text{valid}}} \sum_{b,t} m_{b,t+1} \log \operatorname{softmax}(Z_{b,t,:})_{X_{b,t+1}}.$$

For a two-step target, $Y = X_{:,2:T}$ requires $Z = Z_{:,:T-2,:}$; mixing these lengths should fail an assertion instead of being silently reshaped.

Part 3 - Hints, controls, and evidence

1. Decode every input–target pair for one batch and inspect it manually.
2. Assert Z'.shape[: 2] = Y.shape before flattening.
3. Use `reshape`, not an arbitrary slice chosen only to make element counts match.
4. Track the number of valid targets and verify it equals the expected non-padding transitions.
5. Overfit a tiny sequence until the correct transition probability is near one; then inspect what each faulty variant learned.
6. Add a regression test that intentionally swaps in each faulty shifter and must fail semantic assertions.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def correct_shift(logits, input_ids, padding_id):
    prediction_logits = logits[:, :-1, :]
    target_ids = input_ids[:, 1:]
    valid_mask = target_ids != padding_id
    assert prediction_logits.shape[:2] == target_ids.shape
    return prediction_logits, target_ids, valid_mask

def no_shift_bug(logits, input_ids, padding_id):
    prediction_logits = logits
    target_ids = input_ids
    valid_mask = target_ids != padding_id
    return prediction_logits, target_ids, valid_mask

def masked_next_token_loss(logits, input_ids, padding_id):
    prediction_logits, target_ids, valid_mask = correct_shift(
        logits, input_ids, padding_id
    )
    token_losses = F.cross_entropy(
        prediction_logits.reshape(-1, prediction_logits.shape[-1]),
        target_ids.reshape(-1), reduction="none"
    )
    token_losses = token_losses.view_as(target_ids)
    selected = token_losses.masked_select(valid_mask)
    if selected.numel() == 0:
```

```
        raise ValueError("batch contains no valid next-token targets")
    return selected.mean()

def E04(model, input_ids, padding_id):
    logits = model(input_ids)
    loss = masked_next_token_loss(logits, input_ids, padding_id)
    assert torch.isfinite(loss)
    return loss
```

Part 5 - The Philosophy Behind the Exercise

An off-by-one error is a lesson in the difference between numerical validity and semantic truth. Computers can optimize exactly the wrong question with complete discipline. A decreasing number does not certify that the number represents the objective we intended.

Alignment is therefore a form of meaning. The model learns the relationship encoded by index positions, not the relationship described in comments. Deep learning engineering begins when we treat those indices as scientific claims that require direct evidence.

18.3.6 Exercise 05

Exercise Title: Implement Attention Mask for Variable-Length Contexts

Part 1 - Why this matters

A batch often contains sequences of different lengths. Padding creates a common rectangular tensor, but padding positions are not evidence and must not influence attention or loss. In a causal decoder, two restrictions must be combined: a query cannot see future keys, and no query should use a padding key. These masks represent different semantics and usually have different source shapes.

The key-padding mask prevents real queries from attending to padded keys. Padded query rows also require a policy. They may produce arbitrary finite outputs if their loss is ignored, or their outputs may be explicitly zeroed. Confusing key masking with query masking can create rows in which every score is negative infinity, causing softmax to return NaN. Your implementation must prevent all-masked rows or define a safe output for them.

Mask convention is a common source of bugs. Some APIs use `True` to mean allowed, others use `True` to mean blocked, and additive masks use zero and negative infinity. Broadcasting from (B, T) to $(B, 1, 1, T)$ is correct for key visibility, while causal visibility commonly starts as $(1, 1, T, T)$. Print the combined shape and an example matrix before trusting it.

You will construct a batch with lengths $[5, 3, 1]$, compare masked batched output with separate unpadded computations, and verify equality at real positions. This equivalence test is stronger than merely checking that padding attention weights look small.

Part 2 - Mathematical form and reasoning

Let $c_{i,j} = 1$ when $j \le i$ and let $k_{b,j} = 1$ for a real key. Combined visibility is

$$v_{b,i,j} = c_{i,j} \wedge k_{b,j}.$$

The masked score is

$$\widetilde{S}_{b,h,i,j} = \begin{cases} S_{b,h,i,j}, & v_{b,i,j} = 1, \\ -\infty, & v_{b,i,j} = 0. \end{cases}$$

For every real query i, attention weights must sum to one over permitted keys and equal zero elsewhere.

Part 3 - Hints, controls, and evidence

1. Build the length-derived key mask explicitly using position comparison.
2. Keep a boolean allowed mask until the final `masked_fill`; avoid adding integer zeros and ones to logits.
3. Assert that every real query has at least one allowed key, normally itself.
4. Compare each real prefix with a separately evaluated unpadded sequence.
5. Verify padding token embeddings can change without affecting earlier real outputs.
6. Test left padding and right padding separately; positional indices and causal alignment differ.

Part 4 - Python code skeleton

```
import torch

def lengths_to_key_mask(lengths, maximum_length):
    positions = torch.arange(maximum_length, device=lengths.device)
    key_mask = positions.unsqueeze(0) < lengths.unsqueeze(1)
    return key_mask

def combined_allowed_mask(lengths, maximum_length):
    key_mask = lengths_to_key_mask(lengths, maximum_length)
    causal = torch.ones(maximum_length, maximum_length,
                        device=lengths.device, dtype=torch.bool)
    causal = torch.tril(causal)
    causal = causal.view(1, 1, maximum_length, maximum_length)
    key_mask = key_mask.view(lengths.shape[0], 1, 1, maximum_length)
    return causal & key_mask

def masked_attention(q, k, v, lengths):
    sequence_length = q.shape[-2]
    scores = q @ k.transpose(-2, -1)
    scores = scores / (q.shape[-1] ** 0.5)
    allowed = combined_allowed_mask(lengths, sequence_length)
    scores = scores.masked_fill(~allowed, float("-inf"))
    weights = torch.softmax(scores, dim=-1)
    output = weights @ v
    return output, weights, allowed

def E05(device):
    lengths = torch.tensor([5, 3, 1], device=device)
```

```
    q = torch.randn(3, 2, 5, 8, device=device)
    k = torch.randn(3, 2, 5, 8, device=device)
    v = torch.randn(3, 2, 5, 8, device=device)
    output, weights, allowed = masked_attention(q, k, v, lengths)
    forbidden_weights = weights.masked_select(~allowed)
    assert torch.isfinite(output).all()
    assert torch.all(forbidden_weights == 0)
    return output, weights
```

Part 5 - The Philosophy Behind the Exercise

A mask is a rule about relevance and permission. Padding says that some symbols exist only to satisfy storage geometry; causality says that some real symbols exist but are not yet available. Both appear as blocked matrix entries, yet they express different truths.

Reliable modeling depends on preserving such distinctions. When semantics are compressed into one tensor, the code must carry the explanation that the tensor alone cannot. Otherwise identical zeros can hide entirely different reasons for exclusion.

18.3.7 Exercise 06

Exercise Title: Demonstrate Context Truncation Failure on Long Documents

Part 1 - Why this matters

Long-document systems often fail before the model begins computation. A prompt builder may retain the latest conversation turns and remove an early definition, contract clause, measurement, or safety constraint. The model then answers from the surviving context, and the output can look like a reasoning failure even though the necessary evidence was never provided.

You will create long synthetic documents containing a unique key–value fact at controlled positions. The final question asks for that value. Tokenize the document, apply several truncation policies, and record whether the evidence span survives. Then query the model and separate pipeline failures from model retrieval failures. The distinction must appear in every result row.

Truncation can also damage structure without removing the central fact. Cutting inside a table row, code block, quotation, or multi-token entity can make the remaining text ambiguous. A token-safe cut is not automatically a semantically safe cut. Chunking should prefer document boundaries while still respecting the hard token budget.

The exercise should compare naive left truncation, head–tail preservation, query-aware chunk selection, and summarization. Query-aware selection can retain the relevant evidence but introduces a retriever whose errors must be measured. Summarization compresses more context but may omit details or alter negation. Every policy changes which failure is possible.

Part 2 - Mathematical form and reasoning

For evidence span $e = [a, b)$ and kept token indices K, define full-span retention

$$r_e = \mathbb{I}\left[\{a, a+1, \ldots, b-1\} \subseteq K\right].$$

Let A be answer correctness. Report

$$P(A = 1 \mid r_e = 1) \quad \text{and} \quad P(A = 1 \mid r_e = 0)$$

separately. A low first value indicates model or prompt-use failure; a low second value is normally expected and should not be labeled failure to read available evidence.

Part 3 - Hints, controls, and evidence

1. Generate documents from labeled sections so the exact token span of the fact is known after tokenization.
2. Test facts at 5, 25, 50, 75, and 95 percent of document length.
3. Add a distractor with a similar key but a different value.
4. Record original tokens, kept tokens, removed span, evidence retention, prompt sent, and answer.
5. Test a cut through the middle of the evidence span, not only total removal.
6. Require the model to return the evidence quotation and token range with the answer.

Part 4 - Python code skeleton

```
def span_fully_retained(span_start, span_end, kept_indices):
    kept_set = set(kept_indices)
    for index in range(span_start, span_end):
        if index not in kept_set:
            return False
    return True

def apply_left_truncation(token_ids, maximum_tokens):
    if len(token_ids) <= maximum_tokens:
        indices = list(range(len(token_ids)))
        return token_ids[:], indices
    first = len(token_ids) - maximum_tokens
    indices = list(range(first, len(token_ids)))
    return token_ids[first:], indices

def evaluate_policy(generate, cases, truncation_policy, maximum_tokens):
    records = []
    for case in cases:
        kept_tokens, kept_indices = truncation_policy(
            case["token_ids"], maximum_tokens
        )
        retained = span_fully_retained(
            case["span_start"], case["span_end"], kept_indices
        )
        response = generate(kept_tokens, case["question"])
        record = {}
        record["case_id"] = case["id"]
        record["evidence_retained"] = retained
```

```
        record["answer_correct"] = response == case["answer"]
        record["kept_length"] = len(kept_tokens)
        records.append(record)
    return records

def E06(generate, cases, maximum_tokens):
    return evaluate_policy(generate, cases, apply_left_truncation,
                           maximum_tokens)
```

Part 5 - The Philosophy Behind the Exercise

Truncation is an act of forgetting performed by the system on behalf of the model. It decides which past remains available and which past becomes computationally nonexistent. Because the removed text is invisible in the final prompt, this decision can also become invisible to the user.

Context engineering is therefore partly the ethics of omission. A system that must compress should reveal what it removed, preserve critical constraints, and avoid presenting answers as fully informed when its evidence was incomplete.

18.3.8 Exercise 07

Exercise Title: Compare Fixed Context vs Sliding Window Training Strategies

Part 1 - Why this matters

Fixed non-overlapping blocks divide a token stream into segments of length C. They are simple, efficient, and prevent repeated processing of most tokens, but relationships crossing a block boundary are never observed inside one example. Sliding windows overlap examples and can expose the same transition under more prefixes, but repeated tokens increase compute and change statistical weighting.

The comparison must control total token updates. If both datasets are trained for the same number of epochs, the overlapping dataset can present far more tokens and consume more compute. Any quality gain may come from additional training rather than the window strategy itself. Compare both equal-epoch and equal-token-budget regimes, and label them separately.

Boundary placement matters. A fixed scheme can randomly shift its starting offset each epoch to vary boundaries without full sliding overlap. Document-aware packing can avoid splitting short examples while filling most of the context. These intermediate strategies should be discussed rather than presenting two extremes as the only choices.

You will train matched small decoders on a synthetic task containing patterns that sometimes cross fixed boundaries. Evaluate ordinary next-token loss, boundary-transition loss, unique tokens seen, total token presentations, training time, and validation quality. The expected result should be stated before the experiment, then revised if measurements disagree.

Part 2 - Mathematical form and reasoning

For stream length N, context C, and stride S, approximate window count is

$$K(S) = \left\lfloor \frac{N - C - 1}{S} \right\rfloor + 1.$$

Total input token presentations are KC. The redundancy factor relative to unique stream tokens is approximately

$$R = \frac{KC}{N}.$$

For $S = C$, R is near one; for $S \ll C$, it can be much larger. Define a separate boundary set $\mathcal{B}$ and measure $L_{\mathcal{B}}$ so global loss cannot hide boundary failure.

Part 3 - Hints, controls, and evidence

1. Construct datasets from the identical token stream and verify every window start index.
2. Count total predicted tokens after masking, not only number of batches.
3. Compare equal epochs, equal optimizer steps, and equal valid-token budgets as different experiments.
4. Mark transitions that cross fixed-block boundaries and evaluate them separately.
5. Add randomized fixed offsets as a third strategy.
6. Report wall-clock time, tokens per second, redundancy, overall loss, and boundary loss across several seeds.

Part 4 - Python code skeleton

```
def window_starts(sequence_length, context_length, stride):
    starts = []
    start = 0
    while start + context_length < sequence_length:
        starts.append(start)
        start = start + stride
    return starts

def presentation_statistics(sequence_length, context_length, stride):
    starts = window_starts(sequence_length, context_length, stride)
    counts = [0] * sequence_length
    for start in starts:
        end = start + context_length
        for index in range(start, end):
            counts[index] = counts[index] + 1
    total_presentations = 0
    unique_presented = 0
    for count in counts:
        total_presentations = total_presentations + count
        if count > 0:
            unique_presented = unique_presented + 1
    redundancy = total_presentations / max(1, unique_presented)
    return starts, counts, redundancy
```

```
def E07(sequence_length, context_length):
    fixed = presentation_statistics(
        sequence_length, context_length, context_length
    )
    sliding = presentation_statistics(
        sequence_length, context_length, context_length // 4
    )
    return fixed, sliding
```

Part 5 - The Philosophy Behind the Exercise

Windows define the horizons from which the model learns. A boundary is not a natural break in the original text; it is an artifact of finite computation. Training strategy decides whether the artifact remains fixed, moves, or is softened through overlap.

The wider lesson is that efficiency and experience are coupled. Saving compute changes what the model sees, while increasing coverage changes what compute is spent repeatedly. Good engineering makes this exchange explicit and measures which repeated experiences actually create value.

18.3.9 Exercise 08

Exercise Title: Measure Memory Usage Growth as Context Length Increases

Part 1 - Why this matters

Increasing context length changes far more than the input tensor. Every layer creates token activations, attention projections, feed-forward intermediates, and, in a standard implementation, attention scores whose two sequence axes grow together. During training, many tensors must remain available for backpropagation. Parameter memory stays approximately fixed while activation memory can become the dominant cost.

PyTorch and CUDA expose several memory quantities. Allocated memory belongs to live tensors; reserved memory includes allocator-managed blocks kept for reuse; peak allocated memory records the highest live allocation since reset. External monitoring may include CUDA context, kernels, and other processes. Mixing these measurements can produce apparently contradictory reports, so the experiment must name the quantity and measurement boundary.

You will sweep context lengths that double successively while holding model, batch, precision, and implementation fixed. Measure inference, forward-plus-loss, and full training step separately. After each run, delete references to large tensors before continuing. The graph should show empirical memory and the theoretical number of attention-score elements; differences between them reveal other activations and memory-efficient kernel behavior.

An OOM result is censored data, not a zero or missing row to ignore. Record the attempted configuration, memory immediately before the operation, exception, and recovery. Do not continue with corrupted optimizer state after a failed step. Run stress tests in a disposable model instance and preserve a safety margin rather than filling the device used by other work.

Part 2 - Mathematical form and reasoning

For L layers, batch B, heads H, sequence T, and bytes per element s, the explicitly materialized attention score storage alone is

$$M_{\text{scores}} = LBHT^2 s.$$

Residual and feed-forward activations contain terms proportional to $LBTd$ and $LBTd_f$. If context doubles, the score term grows by four while linear activation terms grow by two. Actual peak memory is

$$M_{\text{peak}} = M_\theta + M_{\text{grad}} + M_{\text{optimizer}} + M_{\text{activations}} + M_{\text{workspace}},$$

with components depending on inference or training mode.

Part 3 - Hints, controls, and evidence

1. Start from a safely small context and stop before repeated OOM attempts threaten the session.
2. Reset peak memory immediately before each measured region and synchronize before reading the result.
3. Use fresh random inputs but identical dtype, batch, and vocabulary range.
4. Record allocated and reserved memory before and after the operation.
5. Compare `no_grad`, forward with graph retention, and backward passes.
6. Repeat each successful shape and report variation rather than a single measurement.

Part 4 - Python code skeleton

```
import gc
import torch

def measured_training_step(model, input_ids, targets, optimizer):
    device = input_ids.device
    torch.cuda.synchronize(device)
    torch.cuda.reset_peak_memory_stats(device)
    baseline = torch.cuda.memory_allocated(device)
    optimizer.zero_grad(set_to_none=True)
    logits = model(input_ids)
    loss = torch.nn.functional.cross_entropy(
        logits.reshape(-1, logits.shape[-1]), targets.reshape(-1)
    )
    loss.backward()
    optimizer.step()
    torch.cuda.synchronize(device)
    peak = torch.cuda.max_memory_allocated(device)
    return float(loss.detach().cpu()), peak - baseline

def E08(model, optimizer, vocabulary_size, context_lengths, device):
    if device.type != "cuda":
        raise RuntimeError("E08 requires CUDA memory measurements")
    records = []
    for context_length in context_lengths:
```

```
        input_ids = torch.randint(
            0, vocabulary_size, (1, context_length), device=device
        )
        targets = torch.randint(
            0, vocabulary_size, (1, context_length), device=device
        )
        try:
            loss, memory = measured_training_step(
                model, input_ids, targets, optimizer
            )
            records.append({"context": context_length,
                            "loss": loss, "peak_delta": memory,
                            "status": "ok"})
        except torch.OutOfMemoryError:
            records.append({"context": context_length,
                            "status": "oom"})
            del input_ids
            del targets
            gc.collect()
            torch.cuda.empty_cache()
            break
    return records
```

Part 5 - The Philosophy Behind the Exercise

Context has a physical body. Each additional token is not only another piece of meaning; it becomes vectors, matrix interactions, stored activations, memory traffic, and energy. The abstract promise of remembering more is limited by the material cost of making more information simultaneously available.

Measurement turns that limitation from frustration into knowledge. An OOM is not merely a crash but evidence about the boundary between an algorithm and a machine. Responsible engineering approaches that boundary deliberately, records it accurately, and leaves enough space for recovery.

18.3.10 Exercise 09

Exercise Title: Explain Why Long Context Is Quadratic in Attention Cost

Part 1 - Why this matters

Dense self-attention compares every query position with every permitted key position. A sequence of length T therefore creates T^2 potential pairs per head before causal masking removes future influence. The triangular mask changes which pairs contribute but a naive dense matrix implementation still allocates and computes a square score tensor.

Quadratic pair growth does not mean the entire Transformer is always quadratic. Projection and feed-forward layers contain large terms linear in T, and at short contexts or wide hidden dimensions they can dominate runtime. The point at which attention becomes the bottleneck depends on width, heads, batch, kernel efficiency, precision, and hardware. A complexity statement should guide measurement, not replace it.

You will count visible and materialized pairs, benchmark matrix multiplication across doubling lengths, and compare measured ratios with theoretical ratios. Then implement a local sliding-window visibility pattern to show how restricting each query to at most W keys changes pair count toward $\mathcal{O}(TW)$. This conceptual alternative sacrifices direct global access and therefore changes the model, not merely its speed.

Memory-efficient attention kernels can compute exact dense attention without materializing the complete score matrix in global memory. They reduce memory traffic and peak storage but do not change the logical all-pairs interaction or its arithmetic scaling. Distinguish algorithmic complexity, implementation memory, and measured latency in the final explanation.

Part 2 - Mathematical form and reasoning

For B batches and H heads,

$$N_{\text{dense}} = BHT^2, \qquad N_{\text{causal visible}} = BH\frac{T(T+1)}{2}.$$

Score and value aggregation require approximately

$$F_{\text{attention}} \approx 4BHT^2d_k = 4BT^2d$$

multiply-add FLOPs under the two-operation convention. With local window W, visible pairs are bounded by approximately $BHTW$ for $W \ll T$.

Part 3 - Hints, controls, and evidence

1. Generate a table for $T = 128$ through at least $T = 2048$ without allocating every theoretical tensor.
2. Show the ratio when T doubles for dense, causal-visible, and local attention.
3. Benchmark only after warm-up and CUDA synchronization.
4. Record head dimension and total model width; head count alone does not determine total projection width.
5. Compare explicit score materialization with a memory-efficient PyTorch attention primitive when available.
6. Explain which results demonstrate asymptotic growth and which reflect a particular kernel or GPU.

Part 4 - Python code skeleton

```
import time
import torch

def pair_counts(batch_size, heads, sequence_length, window=None):
    dense = batch_size * heads * sequence_length * sequence_length
    causal = (batch_size * heads * sequence_length *
              (sequence_length + 1) // 2)
    local = None
```

```
    if window is not None:
        local = batch_size * heads * sequence_length * min(
            sequence_length, window
        )
    return dense, causal, local

def benchmark_scores(q, k, repeats):
    for _ in range(10):
        q @ k.transpose(-2, -1)
    torch.cuda.synchronize(q.device)
    start = time.perf_counter()
    for _ in range(repeats):
        scores = q @ k.transpose(-2, -1)
    torch.cuda.synchronize(q.device)
    elapsed = time.perf_counter() - start
    return elapsed / repeats, scores.shape

def E09(device):
    records = []
    for sequence_length in [128, 256, 512, 1024, 2048]:
        dense, causal, local = pair_counts(
            2, 8, sequence_length, window=128
        )
        record = {}
        record["context"] = sequence_length
        record["dense_pairs"] = dense
        record["causal_visible_pairs"] = causal
        record["local_pairs_upper_bound"] = local
        records.append(record)
    return records
```

Part 5 - The Philosophy Behind the Exercise

Attention grants direct relationships by paying for possible relationships. The quadratic matrix is a map of who may consult whom. Global access is powerful because no chain of intermediaries is required, but universal access becomes expensive as the community of tokens grows.

Efficiency methods are therefore theories of relevance. Local windows, sparse patterns, retrieval, and compression each claim that not every pair deserves equal computational opportunity. Reducing cost means deciding which relationships can be omitted without losing the behavior we value.

18.3.11 Exercise 10

Exercise Title: Train Small LLM with Short Context on CUDA and Benchmark Speed

Part 1 - Why this matters

A short-context training run is the safest environment for validating the whole language-model pipeline: token batches, target alignment, causal attention, loss, backward propagation,

optimizer updates, CUDA placement, and throughput. Before scaling context or parameters, the model should deliberately overfit a small corpus. Failure to overfit indicates a correctness problem that more compute will only make expensive.

Benchmarking must separate data preparation, host-to-device transfer, forward, backward, and optimizer time. A low GPU utilization graph does not identify the bottleneck by itself. Small models may launch kernels too briefly to saturate the GPU, while a slow DataLoader can leave the device waiting. Report both end-to-end and device-only throughput.

You will train the MiniGPT reference from LLM00 using a context such as 32 or 64. Use pinned host memory and non-blocking transfer only when CUDA and DataLoader conditions support them. Synchronize at measurement boundaries, not after every operation during ordinary training, because excessive synchronization destroys pipeline overlap.

Correctness metrics come before speed. Log valid tokens, loss per valid token, gradient norm, learning rate, parameter finiteness, peak memory, and tokens per second. A fast loop that forgot `zero_grad`, shifted labels incorrectly, or timed only asynchronous kernel submission is not a benchmark.

Part 2 - Mathematical form and reasoning

If a measured interval processes N_{valid} targets in Δt, throughput is

$$Q = \frac{N_{\text{valid}}}{\Delta t} \quad \text{tokens per second.}$$

For batch B, context T, and K optimizer steps, the nominal count is KBT, but padding or ignored labels require counting the mask instead. Speedup from CPU to GPU is

$$S = \frac{t_{\text{CPU}}}{t_{\text{GPU}}},$$

reported for matched numerical work and batch configuration.

Part 3 - Hints, controls, and evidence

1. Set Python and PyTorch seeds, save configuration, and record GPU name and software versions.
2. Overfit one or a few batches before using the full training loader.
3. Warm up CUDA before starting benchmark timing.
4. Count valid target tokens from the loss mask each step.
5. Compare several batch sizes at fixed context and several contexts at fixed batch.
6. Report median step time after excluding warm-up, end-to-end throughput, device-only throughput, and peak memory.

Part 4 - Python code skeleton

```
import time
import torch
import torch.nn.functional as F
```

```
def train_step(model, batch, optimizer, device):
    input_ids = batch["input_ids"].to(device, non_blocking=True)
    target_ids = batch["target_ids"].to(device, non_blocking=True)
    valid_mask = batch["valid_mask"].to(device, non_blocking=True)
    optimizer.zero_grad(set_to_none=True)
    logits = model(input_ids)
    losses = F.cross_entropy(
        logits.reshape(-1, logits.shape[-1]),
        target_ids.reshape(-1), reduction="none"
    ).view_as(target_ids)
    selected = losses.masked_select(valid_mask)
    loss = selected.mean()
    loss.backward()
    gradient_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), 1.0
    )
    optimizer.step()
    return loss.detach(), gradient_norm.detach(), selected.numel()

def E10(model, loader, optimizer, device, maximum_steps):
    model.to(device)
    model.train()
    records = []
    iterator = iter(loader)
    for step in range(maximum_steps):
        try:
            batch = next(iterator)
        except StopIteration:
            iterator = iter(loader)
            batch = next(iterator)
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        start = time.perf_counter()
        loss, gradient_norm, valid_tokens = train_step(
            model, batch, optimizer, device
        )
        if device.type == "cuda":
            torch.cuda.synchronize(device)
        elapsed = time.perf_counter() - start
        records.append({"step": step, "loss": float(loss.cpu()),
                        "gradient_norm": float(gradient_norm.cpu()),
                        "tokens_per_second": valid_tokens / elapsed})
    return records
```

Part 5 - The Philosophy Behind the Exercise

Training a tiny model well is a more serious achievement than launching a large model carelessly. Small scale removes excuses: every tensor can be inspected, the data can be memo-

rized, and failures can be traced. It creates a laboratory where understanding is cheaper than guessing.

Speed acquires meaning only after correctness. Hardware can accelerate whatever objective we give it, including a broken one. The discipline of benchmarking is to prove the work, expose the measurement boundary, and only then celebrate how quickly the machine performed it.

18.3.12 Exercise 11

Exercise Title: Compare Generation Quality With Short vs Long Context

Part 1 - Why this matters

A longer context can improve generation only when it contains useful information and the model can exploit it. Adding irrelevant history can distract attention, shift style, increase latency, or expose conflicting instructions. Therefore the comparison is not "more tokens versus fewer tokens" in isolation; it is which evidence is available, where it is placed, and whether additional context changes the answer for the right reason.

Use the same model and decoding configuration for both conditions. A short prompt should contain the immediate query and minimum instructions. A long prompt should add controlled evidence, distractors, or conversation history. When testing the value of relevant context, the short version must omit the needed fact; when testing distraction, both versions must retain the fact and differ only in irrelevant content.

Generation quality needs task-specific metrics. For factual questions, measure evidence-supported accuracy and citation alignment. For continuation, measure held-out log-likelihood and human coherence ratings. For structured output, measure schema validity. Also record latency, prompt-token count, generated tokens, and failure categories. One subjective sample cannot establish a context-length effect.

You will create matched prompt pairs and randomize whether useful evidence appears near the beginning, middle, or end. Run multiple seeds for stochastic decoding and use paired differences per case. The analysis must identify positive context value, no effect, distraction, contradiction sensitivity, and truncation.

Part 2 - Mathematical form and reasoning

For quality metric q on case i, define paired context gain

$$\Delta_i = q(y_i^{\text{long}}, r_i) - q(y_i^{\text{short}}, r_i).$$

Mean gain is $\bar{\Delta} = N^{-1} \sum_i \Delta_i$, but report its distribution and confidence interval. A context-efficiency measure can be written as

$$E_{\text{context}} = \frac{\bar{\Delta}}{\overline{T_{\text{long}} - T_{\text{short}}}},$$

while recognizing that quality is rarely linear in tokens.

Part 3 - Hints, controls, and evidence

1. Use the exact same query, system instruction, decoding seed, and output budget across each pair.

2. Verify the long prompt does not exceed the actual context limit after tokenization.

3. Create relevant-only, distractor-only, relevant-plus-distractor, and conflicting-evidence conditions.

4. Log the token positions of required evidence.

5. Score claim support separately from fluency and formatting.

6. Inspect cases with negative Δ_i and explain whether failure came from distraction, position, contradiction, or changed truncation.

Part 4 - Python code skeleton

```
def paired_context_evaluation(generate, cases, decoding_config):
    records = []
    for case in cases:
        short_output = generate(
            case["short_prompt"], decoding_config
        )
        long_output = generate(
            case["long_prompt"], decoding_config
        )
        short_score = case["score_function"](
            short_output, case["reference"]
        )
        long_score = case["score_function"](
            long_output, case["reference"]
        )
        record = {}
        record["case_id"] = case["id"]
        record["condition"] = case["condition"]
        record["short_output"] = short_output
        record["long_output"] = long_output
        record["short_score"] = short_score
        record["long_score"] = long_score
        record["gain"] = long_score - short_score
        record["evidence_positions"] = case["evidence_positions"]
        records.append(record)
    return records

def E11(generate, cases, decoding_config):
    records = paired_context_evaluation(
        generate, cases, decoding_config
    )
    total_gain = 0.0
    for record in records:
        total_gain = total_gain + record["gain"]
    mean_gain = total_gain / max(1, len(records))
    return records, mean_gain
```

Part 5 - The Philosophy Behind the Exercise

More context is more opportunity, not more understanding. It expands the field from which the model may draw, but it also expands the field of distraction and conflict. Information has value only when a system can identify, preserve, and use what matters.

The experiment replaces a quantity myth with a relevance question. The best prompt is not necessarily the longest prompt. It is the smallest auditable context that preserves the evidence and constraints required for the decision.

18.3.13 Exercise 12

Exercise Title: Analyze Prompt Sensitivity Due to Tokenization Differences

Part 1 - Why this matters

Prompts that appear semantically equivalent to a human can become different token sequences. Leading spaces, newline style, capitalization, Unicode normalization, punctuation, and spelling variants can change token boundaries and counts. Because embeddings and later computations begin from those identifiers, small surface changes can alter the next-token distribution and the amount of context consumed.

Prompt sensitivity has multiple causes. Tokenization is one; learned association with formatting is another; stochastic decoding is a third. To attribute a change to tokenization, you must hold model, decoding, seed, and semantic intent fixed, then inspect the encoded sequences. A changed output alone does not prove that token boundaries caused the difference.

You will build families of prompts that differ by one controlled transformation: space insertion, newline replacement, case, Unicode normalization, punctuation, or a typographic character. Record identifiers, decoded token pieces, token count, shared-prefix length, logit divergence at the answer position, selected token, and final task outcome. Use greedy decoding for the primary experiment to remove sampling variance.

Some differences should be preserved rather than normalized away. Case can distinguish names; whitespace matters in Python; Unicode marks can change words. The goal is not to force all prompts into one form. It is to understand which normalizations are semantically safe for a particular application and to test them before deployment.

Part 2 - Mathematical form and reasoning

Let two surface forms s and s' map to token sequences $x = \tau(s)$ and $x' = \tau(s')$. Token edit distance can be normalized as

$$d_\tau(s, s') = \frac{\text{EditDistance}(x, x')}{\max(|x|, |x'|)}.$$

For next-token distributions p and q, use a symmetric divergence such as

$$\text{JSD}(p, q) = \frac{1}{2} D_{\text{KL}}(p \| m) + \frac{1}{2} D_{\text{KL}}(q \| m), \qquad m = \frac{p + q}{2}.$$

Compare divergence with token edit distance and task-output changes without assuming a linear relationship.

Part 3 - Hints, controls, and evidence

1. Preserve raw UTF-8 text and print Unicode code points for suspicious characters.

2. Decode each individual token piece, including visible markers for spaces or bytes.
3. Use greedy decoding and evaluation mode for deterministic comparisons.
4. Measure common token prefix length and the first changed token position.
5. Add transformations that should preserve meaning and transformations that intentionally change meaning as controls.
6. Create regression tests for the application's accepted prompt formats.

Part 4 - Python code skeleton

```
import unicodedata
import torch

def unicode_report(text):
    records = []
    for character in text:
        record = {}
        record["character"] = character
        record["code_point"] = "U+%04X" % ord(character)
        record["name"] = unicodedata.name(character, "UNKNOWN")
        records.append(record)
    return records

def jensen_shannon_divergence(logits_a, logits_b):
    log_p = torch.log_softmax(logits_a, dim=-1)
    log_q = torch.log_softmax(logits_b, dim=-1)
    p = torch.exp(log_p)
    q = torch.exp(log_q)
    mixture = 0.5 * (p + q)
    log_mixture = torch.log(mixture.clamp_min(1e-30))
    kl_p = (p * (log_p - log_mixture)).sum(dim=-1)
    kl_q = (q * (log_q - log_mixture)).sum(dim=-1)
    return 0.5 * (kl_p + kl_q)

def E12(model, tokenizer, prompt_variants, device):
    model.eval()
    records = []
    with torch.no_grad():
        base_ids = tokenizer.encode(prompt_variants[0])
        base_tensor = torch.tensor([base_ids], device=device)
        base_logits = model(base_tensor)[:, -1, :]
        for prompt in prompt_variants:
            token_ids = tokenizer.encode(prompt)
            input_ids = torch.tensor([token_ids], device=device)
            logits = model(input_ids)[:, -1, :]
            record = {}
```

```
            record["prompt"] = prompt
            record["token_ids"] = token_ids
            record["token_count"] = len(token_ids)
            record["jsd"] = float(
                jensen_shannon_divergence(base_logits, logits).cpu()
            )
            records.append(record)
    return records
```

Part 5 - The Philosophy Behind the Exercise

To a human reader, typography often appears to carry the same meaning through many surface forms. To a model, the surface is the entrance to meaning. The tokenizer converts tiny visual choices into different computational histories.

This does not imply that models merely react to typography. It shows that every abstract capability is reached through a concrete representation. Robustness means preserving behavior across variations that should be irrelevant while remaining sensitive to variations that genuinely change intent.

18.3.14 Exercise 13

Exercise Title: Implement Padding-Free Training Using Packed Sequences Conceptually

Part 1 - Why this matters

Padding wastes computation when many short sequences are expanded to the longest sequence in a batch. Packing concatenates multiple examples into fixed token blocks so more positions contain real training targets. However, naive concatenation allows tokens in one document to attend to a previous document, creating artificial cross-example context. Padding-free training is therefore a masking and position problem, not only a storage optimization.

A correct packed batch needs segment identifiers or cumulative boundaries. Attention is causal inside each segment but blocked across segments. Position indices can reset at each new example, depending on the positional scheme and training design. Loss should include valid within-segment next-token transitions and normally exclude a target that crosses from one example's final token to the next example's first token unless an explicit end-of-document transition is intended.

You will write a greedy packer that fills blocks of fixed capacity with tokenized examples. It must record token identifiers, segment identifiers, positions within segments, and a loss mask. Then build a block-diagonal causal attention mask and compare packed loss with the sum of separately evaluated sequence losses. Numerical parity establishes semantic equivalence before any throughput claim.

Packing efficiency depends on example ordering. Sorting by length can improve utilization but change data order and reduce stochastic mixing. Greedy packing is not always optimal. Record utilization and preserve a reproducible ordering policy rather than hiding the packing heuristic inside preprocessing.

Part 2 - Mathematical form and reasoning

Let segment label g_i identify the original example for packed position i. Allowed attention is

$$A_{i,j} = \mathbb{I}[j \le i]\mathbb{I}[g_i = g_j].$$

The next-token loss mask is

$$m_i = \mathbb{I}[g_i = g_{i+1}],$$

possibly extended to include a deliberate end-of-document target. Packing utilization is

$$U = \frac{N_{\text{real tokens}}}{N_{\text{blocks}} C}.$$

Part 3 - Hints, controls, and evidence

1. Start with three sequences whose lengths and boundaries can be inspected manually.
2. Never infer segment boundaries from token values; store segment IDs explicitly.
3. Reset position indices at segment boundaries and compare with continuous positions as a separate experiment.
4. Assert no allowed attention entry connects different segment IDs.
5. Compare packed and separate logits or losses in evaluation mode with dropout disabled.
6. Report real-token utilization, valid-target utilization, packing time, throughput, and any ordering change.

Part 4 - Python code skeleton

```
import torch

def pack_examples(examples, block_size, padding_id):
    blocks = []
    current_tokens = []
    current_segments = []
    current_positions = []
    segment_id = 0
    for example in examples:
        if len(example) > block_size:
            raise ValueError("example exceeds block size")
        if len(current_tokens) + len(example) > block_size:
            blocks.append((current_tokens, current_segments,
                           current_positions))
            current_tokens = []
            current_segments = []
            current_positions = []
        for position in range(len(example)):
            current_tokens.append(example[position])
            current_segments.append(segment_id)
            current_positions.append(position)
```

```
        segment_id = segment_id + 1
    if len(current_tokens) > 0:
        while len(current_tokens) < block_size:
            current_tokens.append(padding_id)
            current_segments.append(-1)
            current_positions.append(0)
        blocks.append((current_tokens, current_segments, current_positions))
    return blocks

def packed_attention_mask(segment_ids):
    same_segment = segment_ids[:, None] == segment_ids[None, :]
    real_segment = segment_ids[:, None] >= 0
    causal = torch.tril(torch.ones(
        segment_ids.numel(), segment_ids.numel(),
        device=segment_ids.device, dtype=torch.bool
    ))
    return same_segment & real_segment & causal

def E13(examples, block_size, padding_id, device):
    blocks = pack_examples(examples, block_size, padding_id)
    first_segments = torch.tensor(blocks[0][1], device=device)
    mask = packed_attention_mask(first_segments)
    row_segments = first_segments[:, None]
    column_segments = first_segments[None, :]
    cross_segment = (row_segments != column_segments) & mask
    assert not cross_segment.any()
    return blocks, mask
```

Part 5 - The Philosophy Behind the Exercise

Packing asks whether empty space can be removed without erasing boundaries. Efficiency wants examples close together; semantics requires them to remain distinct. The solution is not physical separation but an explicit rule about which positions may communicate.

This is a recurring idea in computation: structure can be virtual. Tokens share a tensor and a GPU kernel while inhabiting different informational worlds. The mask preserves those worlds, showing that optimization is safe only when it maintains the meaning of the original computation.

18.3.15 Exercise 14

Exercise Title: Debug Attention Mask Bugs That Leak Future Tokens

Part 1 - Why this matters

Future-token leakage allows a training position to use the answer it is supposed to predict. Loss can collapse rapidly and validation can look excellent if the same faulty mask is used everywhere. During real autoregressive generation, future tokens do not exist, so performance fails. This is one of the most dangerous bugs because optimization rewards it.

Leakage can arise from a missing mask, reversed triangle, wrong diagonal, broadcasting over query rather than key axes, mask application after softmax, or an optimized kernel receiving

the wrong causal flag. A plot of one mask is useful but insufficient; the strongest test changes the future and proves that earlier logits remain invariant.

You will implement a fault-injection suite. Each faulty mask must be expected to fail at least one property: forbidden weights equal zero, row sums remain one, prefix outputs are invariant to suffix changes, and incremental last-token logits match the corresponding full-sequence logits. A test that never fails under a known bug provides weak evidence.

Run tests in evaluation mode with dropout disabled and fixed weights. Numerical tolerances should be chosen before results are seen. When using mixed precision, distinguish small parity differences from structural leakage; forbidden weights should still be zero under correct masking.

Part 2 - Mathematical form and reasoning

Causality requires

$$\frac{\partial Z_{t,:}}{\partial X_j} = 0 \qquad \text{for all } j > t,$$

interpreted through discrete suffix intervention rather than literal gradients with respect to integer IDs. If sequences X and X' satisfy $X_{:\le t} = X'_{:\le t}$, then a deterministic causal model must satisfy

$$f_\theta(X)_{:,t,:} = f_\theta(X')_{:,t,:}.$$

This functional property tests the whole stack, not only one displayed mask.

Part 3 - Hints, controls, and evidence

1. Create two sequences with identical prefixes and entirely different suffixes.
2. Compare every prefix position, not only position zero.
3. Inject missing, reversed, and one-token-too-permissive masks.
4. Inspect attention weights in every layer and head while also testing final logits.
5. Compare full-sequence and prefix-only logits at the same position.
6. Make the regression suite run on CPU and CUDA; label tolerance differences without weakening the causal invariant.

Part 4 - Python code skeleton

```
import torch

def prefix_invariance_error(model, sequence_a, sequence_b,
                            prefix_length):
    model.eval()
    assert torch.equal(sequence_a[:, :prefix_length],
                       sequence_b[:, :prefix_length])
    with torch.no_grad():
        logits_a = model(sequence_a)
        logits_b = model(sequence_b)
```

```
    difference = logits_a[:, :prefix_length, :] - \
                 logits_b[:, :prefix_length, :]
    return difference.abs().max()

def full_prefix_parity_error(model, full_sequence, prefix_length):
    prefix = full_sequence[:, :prefix_length]
    model.eval()
    with torch.no_grad():
        full_logits = model(full_sequence)[:, prefix_length - 1, :]
        prefix_logits = model(prefix)[:, -1, :]
    return (full_logits - prefix_logits).abs().max()

def E14(model, vocabulary_size, device):
    torch.manual_seed(1401)
    sequence_a = torch.randint(
        0, vocabulary_size, (2, 12), device=device
    )
    sequence_b = sequence_a.clone()
    sequence_b[:, 6:] = torch.randint(
        0, vocabulary_size, (2, 6), device=device
    )
    invariance_error = prefix_invariance_error(
        model, sequence_a, sequence_b, 6
    )
    parity_error = full_prefix_parity_error(model, sequence_a, 6)
    assert invariance_error < 1e-5
    assert parity_error < 1e-5
    return invariance_error, parity_error
```

Part 5 - The Philosophy Behind the Exercise

Leakage is a false form of intelligence created by access to forbidden evidence. The model appears to predict because the experiment quietly allows it to read the answer. Better optimization makes the deception more convincing, not less.

Causality is therefore not inferred from high performance. It is proven through intervention: change what lies beyond the information boundary and show that the past remains unchanged. This principle extends far beyond attention masks to data leakage, temporal forecasting, and every evaluation where future evidence must remain genuinely unavailable.

18.3.16 Exercise 15

Exercise Title: Stress Test Context Handling on GPU Until OOM Happens

Part 1 - Why this matters

The maximum usable context on a GPU is not a number printed in the architecture configuration. It depends on model size, batch, precision, attention implementation, gradient requirements, optimizer state, fragmentation, and other allocations. A controlled stress test maps this operational boundary and reveals whether the system fails cleanly.

The phrase "until OOM" does not authorize reckless allocation. Begin from a safe baseline, grow context geometrically, stop at the first failure, and then use bounded search between the last success and first failure. Preserve a safety margin for CUDA context and recovery. Never stress a shared production GPU or run concurrent tests that can affect other users.

Measure inference and training separately. Inference under `torch.no_grad()` avoids gradients and saved activations; training adds the backward graph and optimizer storage. Also distinguish prefill from incremental decoding: prompt processing scales with full context, while KV cache grows linearly per generated token even though each decode step attends to all cached keys.

OOM recovery must be tested. The exception may leave Python references and gradients alive. Release the failed batch and outputs, set gradients to none, run garbage collection, clear unused cached blocks, and validate a small forward pass before continuing. If recovery fails, terminate the disposable process rather than pretending the session is healthy.

Part 2 - Mathematical form and reasoning

Let $M(T)$ be measured peak memory for context T and M_{safe} the allowed device budget. The operational maximum is

$$T^* = \max\{T : M(T) \leq M_{\text{safe}}\}.$$

Use a safety factor $0 < \eta < 1$ so $M_{\text{safe}} = \eta M_{\text{device}}$. After geometric bracketing, binary search reduces the interval, but memory step behavior need not be smooth because kernels and allocator bins can change discretely.

Part 3 - Hints, controls, and evidence

1. Record GPU total and free memory before the test and stop if the device is already under unrelated load.
2. Use a fresh model or subprocess for stress testing whenever possible.
3. Increase context by a modest factor such as 1.5 or 2, not an enormous jump.
4. Record success, latency, allocated peak, reserved peak, and exception text.
5. Verify recovery with a known small input after every OOM.
6. Report the largest tested success with batch, dtype, mode, kernel, and safety margin; never publish context length alone.

Part 4 - Python code skeleton

```
import gc
import torch

def try_context(model, context_length, vocabulary_size, device,
                training_mode):
    input_ids = None
    logits = None
    loss = None
```

```
    try:
        torch.cuda.reset_peak_memory_stats(device)
        input_ids = torch.randint(
            0, vocabulary_size, (1, context_length), device=device
        )
        if training_mode:
            model.zero_grad(set_to_none=True)
            logits = model(input_ids)
            loss = logits.float().square().mean()
            loss.backward()
        else:
            with torch.no_grad():
                logits = model(input_ids)
        torch.cuda.synchronize(device)
        peak = torch.cuda.max_memory_allocated(device)
        return True, peak, None
    except torch.OutOfMemoryError as error:
        return False, None, str(error)
    finally:
        del input_ids
        del logits
        del loss
        model.zero_grad(set_to_none=True)
        gc.collect()
        torch.cuda.empty_cache()

def E15(model, vocabulary_size, device):
    if device.type != "cuda":
        raise RuntimeError("E15 requires a CUDA device")
    results = []
    context_length = 128
    while True:
        success, peak, error = try_context(
            model, context_length, vocabulary_size, device, True
        )
        results.append({"context": context_length,
                        "success": success,
                        "peak": peak, "error": error})
        if not success:
            break
        context_length = context_length * 2
    return results
```

Part 5 - The Philosophy Behind the Exercise

A resource boundary becomes useful knowledge only when approached with respect. Stress testing is not destruction for its own sake; it is a controlled encounter with failure so that production does not discover the boundary first.

The maximum is also not the recommended operating point. Systems need room for variation, concurrency, and recovery. Maturity means knowing both how far the machine can be pushed and why ordinary operation should remain safely inside that limit.

18.3.17 Exercise 16

Exercise Title: Explain Why Context Extension Is Harder Than Parameter Scaling

Part 1 - Why this matters

Adding parameters changes model capacity while preserving the input domain when the architecture is scaled consistently. Extending context changes the domain of positions and relationships the model must process. Positions beyond the training range may be unseen, dense attention cost expands quadratically, and long-distance behavior must be taught with data that actually contains useful dependencies at those distances.

Absolute learned position tables have a direct shape limit: new rows must be initialized or interpolated. Sinusoidal and rotary methods can produce values at new positions, but mathematical availability is not proof that the network will use them reliably. Attention logits can change scale, phase relationships can move outside the trained distribution, and short-context behavior may regress after adaptation.

Context extension also changes systems infrastructure. Training batches may need gradient accumulation, sequence parallelism, memory-efficient attention, or smaller batch size. Evaluation must include evidence at many distances, positions, and distractor densities. Serving requires larger KV caches and new admission-control rules. A configuration field can be changed in seconds while the supporting training and validation remain substantial engineering work.

You will attempt a controlled extension of a small model beyond its original training length. Compare naive configuration change, position interpolation or scaling, and continued training on mixed short and long examples. Measure original-length loss, extended-length loss, retrieval by distance, memory, latency, and stability. Success requires retaining short-context quality as well as improving long-context performance.

Part 2 - Mathematical form and reasoning

If training positions are $p \in [0, C_{\text{train}} - 1]$ and the target context is C_{new}, a simple interpolation maps

$$p' = p \frac{C_{\text{train}} - 1}{C_{\text{new}} - 1}.$$

This keeps new positions inside the numerical training range but compresses relative distances. Extension quality should be expressed as a pair

$$(\Delta Q_{\text{long}}, \Delta Q_{\text{short}}),$$

not one long-context score. Compute and memory changes must be reported beside quality because T affects attention quadratically.

Part 3 - Hints, controls, and evidence

1. Save the original checkpoint and evaluate it on the full short-context suite before modification.

2. Test naive extension first as a failure baseline.

3. Continue training with a mixture of short and long examples rather than replacing the original distribution completely.

4. Evaluate key retrieval at multiple absolute positions and relative distances.

5. Inspect attention and activation magnitudes for numerical drift.

6. Report memory and latency at the old and new limits and define a rollback criterion for short-context regression.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def interpolate_position_table(old_table, new_length):
    old_length, dimension = old_table.shape
    source = old_table.transpose(0, 1).unsqueeze(0)
    resized = F.interpolate(
        source, size=new_length, mode="linear", align_corners=True
    )
    return resized.squeeze(0).transpose(0, 1)

def replace_position_embedding(model, new_length):
    old_weight = model.position_embedding.weight.detach()
    new_weight = interpolate_position_table(old_weight, new_length)
    new_embedding = torch.nn.Embedding(
        new_length, old_weight.shape[1],
        device=old_weight.device, dtype=old_weight.dtype
    )
    with torch.no_grad():
        new_embedding.weight.copy_(new_weight)
    model.position_embedding = new_embedding
    model.context = new_length
    return model

def E16(model, old_context, new_context, evaluation_function):
    original_metrics = evaluation_function(model, old_context)
    extended_model = replace_position_embedding(model, new_context)
    old_range_after = evaluation_function(extended_model, old_context)
    new_range = evaluation_function(extended_model, new_context)
    return original_metrics, old_range_after, new_range
```

Part 5 - The Philosophy Behind the Exercise

Capacity growth and horizon growth answer different ambitions. More parameters ask the model to hold richer transformations. More context asks it to remain coherent across a larger field of relationships. The second changes not only how much the model can know, but how far information must remain usable.

Extending a horizon is harder than opening a larger window. The system must learn what to preserve across the distance, how to locate it, and how not to lose its short-range competence. A numerical limit is easy to edit; an effective memory is earned through training and evidence.

18.3.18 Exercise 17

Exercise Title: Compare RoPE vs Absolute Positional Encoding for Long Context

Part 1 - Why this matters

Self-attention without positional information cannot distinguish permutations of the same token representations. Absolute positional embeddings add a vector associated with each index. Rotary Position Embedding instead rotates query and key coordinate pairs by position-dependent angles, making their dot products depend on relative displacement. These mechanisms introduce order through different geometry and extrapolate differently.

Learned absolute embeddings are flexible inside the trained table but have no native row beyond its length. Sinusoidal absolute embeddings can be evaluated beyond training positions but still inject position by addition. RoPE has no fixed lookup-table limit in its basic formula, yet high positions create angles outside the trained regime and finite precision can damage phase resolution. Long-context extensions often modify RoPE frequencies or position scaling, which changes the geometry and must be evaluated.

You will implement learned absolute positions and RoPE for a tiny attention module. Verify shapes, norm preservation under rotation, relative-shift behavior, and CPU–CUDA parity. Train matched models on an order-sensitive task within a short range, then test both inside and beyond that range. Do not claim general long-context superiority from one toy task; use it to expose mechanisms.

The comparison must preserve parameter fairness. Learned absolute embeddings add $C_{\max}d$ parameters, while basic RoPE does not. Record that difference, but also report runtime, memory, training convergence, short-range accuracy, and extrapolation. Position method is one component of long-context capability, not a substitute for long-context data.

Part 2 - Mathematical form and reasoning

Absolute embedding computes

$$h_t = e(x_t) + p_t.$$

For each two-dimensional pair of a query, RoPE applies

$$R(t\omega) = \begin{bmatrix} \cos(t\omega) & -\sin(t\omega) \\ \sin(t\omega) & \cos(t\omega) \end{bmatrix}.$$

Then

$$(R(i\omega)q)^{\mathsf{T}}(R(j\omega)k) = q^{\mathsf{T}}R((j-i)\omega)k,$$

so the dot product contains relative-position structure. Rotation should preserve vector norm up to numerical tolerance.

Part 3 - Hints, controls, and evidence

1. Require an even rotary dimension and state whether all or part of each head is rotated.

2. Compute sine and cosine in a stable dtype, then cast deliberately.
3. Assert norm preservation before integrating RoPE into attention.
4. Shift both query and key positions by the same offset and test dot-product behavior.
5. Train and evaluate across multiple lengths, including positions beyond the learned absolute table where that model must fail explicitly.
6. Compare base RoPE, scaled positions, and absolute embeddings without changing the remaining model configuration.

Part 4 - Python code skeleton

```
import torch

def rope_frequencies(rotary_dimension, device):
    indices = torch.arange(0, rotary_dimension, 2,
                           device=device, dtype=torch.float32)
    inverse_frequency = 1.0 / (
        10000.0 ** (indices / rotary_dimension)
    )
    return inverse_frequency

def apply_rope(x, positions):
    rotary_dimension = x.shape[-1]
    if rotary_dimension % 2 != 0:
        raise ValueError("rotary dimension must be even")
    inverse_frequency = rope_frequencies(
        rotary_dimension, x.device
    )
    angles = positions.to(torch.float32)[:, None] * \
             inverse_frequency[None, :]
    cosine = torch.cos(angles).to(x.dtype)
    sine = torch.sin(angles).to(x.dtype)
    even = x[..., 0::2]
    odd = x[..., 1::2]
    rotated_even = even * cosine - odd * sine
    rotated_odd = even * sine + odd * cosine
    output = torch.empty_like(x)
    output[..., 0::2] = rotated_even
    output[..., 1::2] = rotated_odd
    return output

def E17(device):
    positions = torch.arange(64, device=device)
    x = torch.randn(64, 32, device=device)
    rotated = apply_rope(x, positions)
    original_norm = torch.linalg.vector_norm(x, dim=-1)
```

```
    rotated_norm = torch.linalg.vector_norm(rotated, dim=-1)
    assert torch.allclose(original_norm, rotated_norm,
                          atol=1e-5, rtol=1e-5)
    return x, rotated
```

Part 5 - The Philosophy Behind the Exercise

Position is not contained in a token; it is a relationship introduced by the model. Absolute embeddings give every location an identity. RoPE gives relationships a changing phase. Both are mathematical ways of making order available to attention.

The comparison reveals a broader principle: representation determines which generalizations are natural. A table remembers locations it has rows for; a rotation expresses relative geometry that can be evaluated farther away. Yet a formula's ability to produce a number is not the same as a trained model's ability to use that number wisely.

18.3.19 Exercise 18

Exercise Title: Build Context Handling Debug Checklist

Part 1 - Why this matters

Context bugs cross subsystem boundaries. The raw prompt can be correct while Unicode normalization changes it; token IDs can be correct while truncation removes evidence; batch shapes can be correct while padding or causal masks are reversed; model outputs can be finite while label alignment is wrong. A useful checklist follows the request through every boundary instead of offering generic advice such as "check the shapes."

This exercise converts the chapter into an executable diagnostic framework. Each check needs an identifier, invariant, severity, observed evidence, and recommended action. Checks should fail loudly on a deliberately broken fixture. A checklist that consists only of prose depends on memory; an executable check can become a regression test.

Organize the framework into stages: raw text and normalization, tokenization, special tokens, window construction, truncation, packing, padding, positions, attention visibility, target shift, model context limit, CUDA memory, generation, and provenance. Include both preflight checks and post-output checks. Some failures should block execution, while others should emit metrics or warnings.

Fault injection is mandatory. Create fixtures with a tokenizer mismatch, off-by-one labels, removed evidence, reversed causal mask, cross-segment packed attention, incorrect position reset, and near-OOM context. Run the checklist and verify that each fault is detected by the intended check rather than an unrelated crash.

Part 2 - Mathematical form and reasoning

Represent invariant I_k as a boolean predicate over system state s:

$$I_k(s) \in \{0, 1\}.$$

Checklist coverage over injected faults F can be measured by

$$\text{Coverage} = \frac{|\{f \in F : \exists k,\ I_k(s_f) = 0\}|}{|F|}.$$

Also construct a detection matrix $D_{f,k}$ to identify checks that never fire, faults detected only incidentally, and overly broad checks that produce many false alarms.

Part 3 - Hints, controls, and evidence

1. Assign stable names such as `CTX-MASK-003` to every invariant.
2. Store expected, observed, severity, and remediation in structured results.
3. Separate hard failures from warnings and informational measurements.
4. Include one known-good fixture and require every blocking check to pass.
5. Inject one fault at a time before testing combinations.
6. Add the checklist to checkpoint evaluation and deployment regression tests, not only an interactive notebook.

Part 4 - Python code skeleton

```
class ContextCheckResult:
    def __init__(self, check_id, passed, severity,
                 expected, observed, remediation):
        self.check_id = check_id
        self.passed = passed
        self.severity = severity
        self.expected = expected
        self.observed = observed
        self.remediation = remediation

def check_length(token_ids, maximum_context):
    passed = len(token_ids) <= maximum_context
    return ContextCheckResult(
        "CTX-LENGTH-001", passed, "blocking",
        "token count <= maximum context", len(token_ids),
        "truncate with an audited policy or use a supported context"
    )

def check_next_token_alignment(input_ids, target_ids):
    passed = False
    if input_ids.shape == target_ids.shape:
        if input_ids.shape[1] > 1:
            passed = bool((input_ids[:, 1:] ==
                           target_ids[:, :-1]).all())
    return ContextCheckResult(
        "CTX-SHIFT-001", passed, "blocking",
        "input[:,1:] equals target[:,:-1]",
        "alignment inspected", "rebuild shifted targets"
    )

def E18(state):
    results = []
```

```
    results.append(check_length(
        state["token_ids"], state["maximum_context"]
    ))
    results.append(check_next_token_alignment(
        state["input_ids"], state["target_ids"]
    ))
    blocking_failure = False
    for result in results:
        if not result.passed and result.severity == "blocking":
            blocking_failure = True
    return results, blocking_failure
```

Part 5 - The Philosophy Behind the Exercise

A checklist is institutional memory. It preserves lessons after the person who discovered a failure has forgotten its details or left the project. Turning the lesson into an executable invariant converts painful experience into future protection.

But checklists are not substitutes for thought. They detect known classes of failure and can create false confidence when treated as complete. Their deepest value is cultural: they make assumptions visible, assign responsibility, and create a place where new knowledge can be added after every incident.

18.3.20 Exercise 19

Exercise Title: Write Practical Notes on Prompt Length Engineering

Part 1 - Why this matters

Prompt length engineering allocates a finite token budget among instructions, user content, retrieved evidence, examples, tool results, conversation history, and expected output. The maximum context is a hard upper bound, but a production system should operate below it to preserve output capacity, concurrency, memory, and recovery margin. Token budgeting must happen before the request reaches the model.

Every prompt region has a different priority. System and safety constraints may be mandatory. The latest user request may be essential. Retrieved passages can be ranked and shortened. Old conversation turns can be summarized, but summaries must preserve decisions, numbers, unresolved questions, and provenance. Few-shot examples can improve behavior while consuming tokens that might otherwise hold evidence.

The notes you produce must define an allocation policy rather than a collection of tips. Given maximum context C, reserve output budget G and safety margin M, leaving input budget $I = C - G - M$. Allocate mandatory regions first, then rank optional regions by expected value per token. Record every dropped or compressed region so failures can be reconstructed.

Test the policy under ordinary and adversarial conditions: an extremely long user document, many retrieved chunks, conflicting instructions, oversized tool output, multilingual text with high token expansion, and a request that needs a long answer. Measure token counts with the production tokenizer, not estimated words. The final notes should become a reusable prompt-budgeting standard.

Part 2 - Mathematical form and reasoning

The basic budget constraint is

$$C_{\text{system}} + C_{\text{history}} + C_{\text{user}} + C_{\text{retrieval}} + C_{\text{tools}} + G + M \leq C.$$

For optional region i with estimated utility u_i and cost c_i, selection resembles a constrained allocation problem

$$\max_{z_i \in \{0,1\}} \sum_i z_i u_i \quad \text{subject to} \quad \sum_i z_i c_i \leq I - C_{\text{mandatory}}.$$

Real utility is context-dependent, so heuristics require evaluation and fallback rather than being treated as an exact optimizer.

Part 3 - Hints, controls, and evidence

1. Define context, output, and safety budgets in configuration rather than scattered constants.
2. Tokenize each region separately and retain its start and end offsets in the assembled prompt.
3. Mark regions mandatory, compressible, droppable, or externalizable to retrieval.
4. Preserve a truncation manifest listing removed content and reason.
5. Reserve output tokens before filling input context; otherwise generation can terminate prematurely.
6. Evaluate answer quality, evidence retention, instruction retention, latency, cost, and truncation rate across realistic traffic distributions.

Part 4 - Python code skeleton

```
class PromptBudget:
    def __init__(self, maximum_context, output_reserve, safety_margin):
        self.maximum_context = maximum_context
        self.output_reserve = output_reserve
        self.safety_margin = safety_margin
        self.input_budget = maximum_context - output_reserve - safety_margin
        if self.input_budget <= 0:
            raise ValueError("no usable input budget remains")

def optional_region_priority(region):
    return region["priority"]

def assemble_prompt(tokenizer, mandatory_regions,
                    optional_regions, budget):
    selected = []
    dropped = []
    used_tokens = 0
    for region in mandatory_regions:
        token_ids = tokenizer.encode(region["text"])
```

```
        if used_tokens + len(token_ids) > budget.input_budget:
            raise ValueError("mandatory regions exceed input budget")
        selected.append((region, token_ids))
        used_tokens = used_tokens + len(token_ids)

    ordered_optional = sorted(optional_regions,
                              key=optional_region_priority,
                              reverse=True)
    for region in ordered_optional:
        token_ids = tokenizer.encode(region["text"])
        if used_tokens + len(token_ids) <= budget.input_budget:
            selected.append((region, token_ids))
            used_tokens = used_tokens + len(token_ids)
        else:
            dropped.append(region)
    return selected, dropped, used_tokens

def E19(tokenizer, mandatory_regions, optional_regions):
    budget = PromptBudget(4096, output_reserve=768,
                          safety_margin=128)
    return assemble_prompt(tokenizer, mandatory_regions,
                           optional_regions, budget)
```

Part 5 - The Philosophy Behind the Exercise

A prompt is an edited world presented to the model. Token budgeting determines which instructions, memories, and evidence exist inside that world. Length engineering is therefore not merely compression; it is the governance of attention under scarcity.

Good prompts do not maximize text. They preserve the smallest sufficient set of truths, constraints, and examples while leaving room for the model to respond. The final discipline is transparency: when the system must omit, summarize, or rank information, those decisions should remain visible enough to question and improve.

18.4 LLM02

Chapter Title: Pretraining Objective and Data
Specialization: Language Model Pretraining Engineering

18.4.1 Exercise 00

Exercise Title: Explain Next-Token Prediction Objective Mathematically

Part 1 - Why this matters

Next-token prediction is the central pretraining objective for a decoder-only LLM. Given a prefix, the model assigns a probability to every vocabulary token that could follow. The objective looks local because each term concerns one next token, but optimizing it across long and diverse sequences requires the model to capture grammar, discourse, facts, style, code structure, and dependencies that help reduce uncertainty.

The objective is teacher-forced during training. The complete correct sequence is available, and a causal mask allows every position to produce a prediction in one parallel forward pass without seeing future positions. At generation time, the correct future is unavailable and the model consumes its own selected tokens. The conditional rule is the same, while the distribution of prefixes can change because generation errors feed back into later steps.

You will derive the loss from joint-probability factorization and compute it by hand for a tiny vocabulary. Every symbol must be connected to a tensor axis. Then compare sequence sum, token mean, batch mean, and perplexity. Reduction choice matters when batches contain different numbers of padding or ignored tokens; averaging batch means can weight short sequences incorrectly.

The exercise must also clarify what the objective does not say. It does not label statements true or false, distinguish authorized from unauthorized data, or directly reward helpfulness and abstention. Those behaviors can correlate with text patterns or be added through later training, but the mathematical target remains the observed next token.

Part 2 - Mathematical form and reasoning

For token sequence $x_{1:T}$, the chain rule gives

$$p_\theta(x_{1:T}) = \prod_{t=1}^{T} p_\theta(x_t \mid x_{<t}).$$

Maximizing likelihood is equivalent to minimizing negative log-likelihood:

$$\mathcal{L}_{\text{NLL}} = -\frac{1}{N_{\text{valid}}} \sum_{b=1}^{B} \sum_{t=1}^{T-1} m_{b,t} \log p_\theta(x_{b,t+1} \mid x_{b,\le t}).$$

For logits $z_{b,t,v}$,

$$\log p_{b,t,y} = z_{b,t,y} - \log \sum_{v=1}^{V} e^{z_{b,t,v}}.$$

Perplexity is $\exp(\mathcal{L}_{\text{NLL}})$ when the loss uses natural logarithms and a consistent tokenization.

Part 3 - Hints, controls, and evidence

1. Use a vocabulary of four tokens and write logits for two prediction positions whose probabilities can be calculated manually.
2. Apply log-sum-exp stabilization by subtracting the maximum logit.
3. Show that the probabilities at each position sum to one.
4. Compare total NLL, mean token NLL, and perplexity without mixing their units.
5. Add padding and prove that masked token averaging matches the manual valid terms.
6. Explain why perplexities from different tokenizers are not directly comparable without accounting for token granularity.

Part 4 - Python code skeleton

```
import torch

def stable_log_softmax_row(logits):
    maximum = logits.max()
    shifted = logits - maximum
    log_denominator = torch.log(torch.exp(shifted).sum())
    return shifted - log_denominator

def manual_token_nll(logits, target_id):
    log_probabilities = stable_log_softmax_row(logits)
    return -log_probabilities[target_id]

def masked_sequence_nll(logits, target_ids, valid_mask):
    losses = torch.empty_like(target_ids, dtype=logits.dtype)
    for batch_index in range(logits.shape[0]):
        for time_index in range(logits.shape[1]):
            target_id = target_ids[batch_index, time_index]
            losses[batch_index, time_index] = manual_token_nll(
                logits[batch_index, time_index], target_id
            )
    selected = losses.masked_select(valid_mask)
    return selected.mean(), losses

def E00(device):
    logits = torch.tensor(
        [[[2.0, 0.0, -1.0, 1.0],
          [0.0, 3.0, 1.0, -2.0]]], device=device
    )
    targets = torch.tensor([[0, 1]], device=device)
    valid_mask = torch.tensor([[True, True]], device=device)
    mean_nll, token_losses = masked_sequence_nll(
        logits, targets, valid_mask
    )
    perplexity = torch.exp(mean_nll)
    assert torch.isfinite(mean_nll)
    return mean_nll, perplexity, token_losses
```

Part 5 - The Philosophy Behind the Exercise

A next-token objective turns language into a sequence of wagers. At every position the model distributes belief across possible continuations and is penalized by the surprise of what actually occurred. Across enough text, reducing surprise demands increasingly rich representations of regularity.

Yet likelihood follows the record it is given. It cannot independently decide whether the record is just, current, or true. The objective is powerful because prediction compresses structure; it is limited because statistical fit is not a complete theory of knowledge or responsibility.

18.4.2 Exercise 01

Exercise Title: Implement CrossEntropy Loss for LLM Training Correctly

Part 1 - Why this matters

PyTorch cross entropy combines log-softmax and negative log-likelihood in a numerically stable operation. Correct use still requires semantic preparation: logits must represent the current positions, targets must be the next tokens, the vocabulary axis must be last before flattening, targets must be integer identifiers, and padding or ignored positions must not influence the reduction.

The most common implementation produces logits of shape (B, T, V) and targets of shape (B, T). Some APIs expect class dimension second, but flattening to (BT, V) and (BT) avoids accidental interpretation of sequence length as the class axis. Flattening is safe only after alignment has been proved. Matching element counts cannot repair an incorrect shift.

You will implement loss with three reduction methods: valid-token mean, sequence mean followed by batch mean, and raw sum. On variable-length examples these are different objectives. Token mean weights each real token equally; sequence mean weights short and long examples equally. Choose deliberately and report valid token count so loss from different batches remains interpretable.

Test extreme logits, all-padding batches, non-contiguous tensors, and float16 inputs. The loss should fail clearly when no valid target exists. Mixed precision training may compute model operations in reduced precision while keeping stable loss and scaling behavior; do not manually softmax probabilities before passing them to cross entropy.

Part 2 - Mathematical form and reasoning

For valid target y_i and logits $z_i \in \mathbb{R}^V$,

$$\ell_i = -z_{i,y_i} + \log \sum_{v=1}^{V} e^{z_{i,v}}.$$

Token-mean reduction is

$$L_{\text{token}} = \frac{\sum_i m_i \ell_i}{\sum_i m_i}.$$

Sequence-balanced reduction is

$$L_{\text{sequence}} = \frac{1}{B} \sum_{b=1}^{B} \frac{\sum_t m_{b,t} \ell_{b,t}}{\sum_t m_{b,t}}.$$

The denominators define the statistical weighting and must be included in any gradient-accumulation equivalence test.

Part 3 - Hints, controls, and evidence

1. Print one decoded input–target alignment before flattening.
2. Assert target range is $[0, V-1]$ for all non-ignored positions.
3. Compare your masked implementation with PyTorch cross entropy using its ignored-target identifier argument.

4. Add a batch containing sequence lengths two and ten to expose reduction differences.
5. Test logits shifted by a large constant and verify loss is unchanged within tolerance.
6. Run backward and confirm every trainable path receives finite gradients.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def next_token_cross_entropy(logits, input_ids, padding_id):
    prediction_logits = logits[:, :-1, :]
    target_ids = input_ids[:, 1:]
    valid_mask = target_ids != padding_id
    if not valid_mask.any():
        raise ValueError("batch has no valid next-token targets")
    flat_logits = prediction_logits.reshape(
        -1, prediction_logits.shape[-1]
    )
    flat_targets = target_ids.reshape(-1)
    flat_losses = F.cross_entropy(
        flat_logits, flat_targets, reduction="none"
    )
    losses = flat_losses.view_as(target_ids)
    selected = losses.masked_select(valid_mask)
    return selected.mean(), selected.numel(), losses

def validate_target_range(target_ids, valid_mask, vocabulary_size):
    selected = target_ids.masked_select(valid_mask)
    assert selected.min() >= 0
    assert selected.max() < vocabulary_size

def E01(model, input_ids, padding_id):
    logits = model(input_ids)
    loss, valid_tokens, token_losses = next_token_cross_entropy(
        logits, input_ids, padding_id
    )
    loss.backward()
    assert torch.isfinite(loss)
    return loss.detach(), valid_tokens, token_losses.detach()
```

Part 5 - The Philosophy Behind the Exercise

Loss is the place where a model's world becomes judgment. Logits describe possibilities; targets identify what happened; reduction decides whose errors count how much. A tiny indexing or weighting choice silently changes the lesson the model receives.

The practical wisdom is to treat loss code as a specification, not plumbing. Every slice, mask, and denominator carries a claim about prediction and fairness between examples. Correct optimization begins with making those claims explicit.

18.4.3 Exercise 02

Exercise Title: Analyze Why LLMs Learn Syntax Before Semantics

Part 1 - Why this matters

During early language-model training, local structural regularities often become measurable before robust semantic behavior. Word order, punctuation, bracket closure, agreement, and common token transitions provide frequent and relatively consistent signals. Semantic relations can be rarer, distributed across longer contexts, ambiguous, and dependent on world knowledge. This is an empirical tendency, not a universal developmental law.

The conclusion depends on how syntax and semantics are measured. A syntax probe with easy frequent examples and a semantic probe with rare compositional examples creates an unfair race. You will build matched synthetic tasks in which surface grammar and latent meaning can be varied independently, then save model checkpoints throughout training. Probe both behaviors at equal example counts and report when each rises above a predefined threshold.

Examples should include grammatical nonsense, meaningful but grammatically corrupted sequences, unseen lexical substitutions, and compositional semantic relationships. Next-token loss alone cannot tell whether improvement came from memorizing frequent templates or representing an abstract rule. Generalization tests must change vocabulary while preserving the rule.

The analysis should examine gradient exposure. Count how often each syntactic pattern and semantic relation appears, how many tokens separate dependent elements, and how much label noise affects them. If syntax is learned first, connect the observation to frequency and dependency structure rather than claiming that the model experiences human cognitive stages.

Part 2 - Mathematical form and reasoning

Let $A_s(k)$ and $A_m(k)$ be syntax and semantic probe accuracy at optimization step k. Define threshold times

$$k_s^* = \min\{k : A_s(k) \geq \tau_s\}, \qquad k_m^* = \min\{k : A_m(k) \geq \tau_m\}.$$

Learning order is meaningful only with confidence intervals across seeds and matched baselines. Also track conditional loss by pattern category

$$L_c = \frac{1}{N_c} \sum_{i:y_i=c} \ell_i$$

so global token frequency does not hide rare semantic behavior.

Part 3 - Hints, controls, and evidence

1. Define syntax and semantic success operationally before training.
2. Match probe size, chance level, and lexical frequency as closely as possible.
3. Save checkpoints frequently during the first part of training.
4. Evaluate unseen word substitutions to separate templates from rules.
5. Repeat across seeds and bootstrap examples for uncertainty.

6. State whether the result supports earlier measurement, faster learning, or stronger final performance; these are different claims.

Part 4 - Python code skeleton

```
import torch

def category_accuracy(predictions, targets, categories):
    totals = {}
    correct = {}
    for index in range(targets.numel()):
        category = int(categories[index].item())
        if category not in totals:
            totals[category] = 0
            correct[category] = 0
        totals[category] = totals[category] + 1
        if predictions[index] == targets[index]:
            correct[category] = correct[category] + 1
    accuracies = {}
    for category in totals:
        accuracies[category] = correct[category] / totals[category]
    return accuracies

def probe_model(model, batches, device):
    model.eval()
    outputs = []
    with torch.no_grad():
        for batch in batches:
            logits = model(batch["input_ids"].to(device))
            selected = logits[batch["batch_index"],
                              batch["time_index"]]
            predictions = selected.argmax(dim=-1).cpu()
            outputs.append(category_accuracy(
                predictions, batch["targets"], batch["categories"]
            ))
    return outputs

def E02(checkpoints, syntax_batches, semantic_batches, device):
    trajectory = []
    for step, model in checkpoints:
        record = {}
        record["step"] = step
        record["syntax"] = probe_model(model, syntax_batches, device)
        record["semantics"] = probe_model(model, semantic_batches, device)
        trajectory.append(record)
    return trajectory
```

Part 5 - The Philosophy Behind the Exercise

Structure is often easier to observe than meaning because structure repeats in visible form. Semantics is relational: the same words can mean different things, and the same meaning can wear different words. Statistical learning encounters these signals with unequal clarity.

But "before" should not become "instead of." Syntax and semantics interact, and our probes divide them for analysis more sharply than language itself does. The exercise teaches humility about developmental stories: curves reveal when a test changed, not a complete inner history of understanding.

18.4.4 Exercise 03

Exercise Title: Build Tiny Text Corpus and Overfit LLM as Sanity Check

Part 1 - Why this matters

Before training on millions of tokens, a language-model pipeline should overfit a tiny corpus. A sufficiently capable model exposed repeatedly to a few short sequences should drive training loss very low and reproduce the learned continuations. If it cannot, the likely causes include target misalignment, broken causal masks, incorrect optimizer order, frozen parameters, excessive regularization, insufficient capacity, or tokenizer inconsistency.

Overfitting is usually undesirable for generalization, but here it is a diagnostic instrument. The target is not a useful language model. The target is evidence that data, model, loss, gradients, and generation form one coherent system. Keep the corpus human-readable so every expected transition can be inspected.

You will create a corpus with repeated deterministic patterns and one ambiguous prefix that has two valid continuations. The deterministic transitions should approach probability one; the ambiguous prefix should retain probability mass for both observed successors according to their empirical frequency. This shows that low loss does not require choosing one token when the data itself is uncertain.

After memorization, test exact training prompts, shorter prefixes, corrupted prefixes, and unseen recombinations. The model may memorize without generalizing. That is acceptable for the sanity check and becomes evidence for the later memorization analysis. Save the tiny corpus and configuration as a permanent regression fixture.

Part 2 - Mathematical form and reasoning

For empirical transition counts $n(x, y)$ after prefix state x, the maximum-likelihood categorical distribution is

$$\hat{p}(y \mid x) = \frac{n(x, y)}{\sum_{y'} n(x, y')}.$$

The irreducible empirical entropy at an ambiguous prefix is

$$H(\hat{p}) = -\sum_{y} \hat{p}(y \mid x) \log \hat{p}(y \mid x).$$

Therefore training loss need not reach zero when identical visible prefixes have different targets. Compare the observed final loss with this lower-bound intuition.

Part 3 - Hints, controls, and evidence

1. Use fewer than one hundred tokens and print every encoded sequence.

2. Disable dropout and weight decay for the strict memorization test.
3. Verify at least one parameter changes after the first optimizer step.
4. Log loss, gradient norm, deterministic transition probabilities, and generated output.
5. Stop only after a declared loss or accuracy criterion, not after an arbitrary number of epochs.
6. Add this overfit test to regression checks after model or data-pipeline refactors.

Part 4 - Python code skeleton

```
import copy
import torch
import torch.nn.functional as F

def one_training_step(model, input_ids, optimizer):
    optimizer.zero_grad(set_to_none=True)
    logits = model(input_ids)
    prediction_logits = logits[:, :-1, :]
    targets = input_ids[:, 1:]
    loss = F.cross_entropy(
        prediction_logits.reshape(-1, prediction_logits.shape[-1]),
        targets.reshape(-1)
    )
    loss.backward()
    gradient_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), 10.0
    )
    optimizer.step()
    return loss.detach(), gradient_norm.detach()

def E03(model, tiny_batch, optimizer, device, maximum_steps):
    model.to(device)
    tiny_batch = tiny_batch.to(device)
    initial_state = copy.deepcopy(model.state_dict())
    records = []
    for step in range(maximum_steps):
        model.train()
        loss, gradient_norm = one_training_step(
            model, tiny_batch, optimizer
        )
        records.append({"step": step, "loss": float(loss.cpu()),
                        "gradient_norm": float(gradient_norm.cpu())})
        if loss.item() < 0.02:
            break
    changed = False
    for name, tensor in model.state_dict().items():
```

```
        if not torch.equal(tensor.cpu(), initial_state[name].cpu()):
            changed = True
            break
    assert changed
    return records
```

Part 5 - The Philosophy Behind the Exercise

Overfitting a tiny corpus is a deliberate reduction of the world. By removing diversity and uncertainty, we ask a simpler question: can this pipeline learn at all? The test is powerful because failure cannot be excused by a difficult generalization problem.

Sanity checks are acts of humility. They refuse to let scale hide confusion. Before claiming emergent capability, the researcher proves that one small batch moves through the system exactly as intended.

18.4.5 Exercise 04

Exercise Title: Explain Curriculum Learning Effect in Large-Scale Pretraining

Part 1 - Why this matters

Curriculum learning changes the order or mixture in which training examples are presented. A simple-to-complex curriculum may stabilize early optimization, while a quality-first curriculum can establish clean language patterns before introducing noisier web data. Anti-curricula and fully shuffled mixtures provide controls. The same examples and compute can produce different trajectories because optimization is path-dependent.

"Difficulty" must be operationally defined. Document length, rarity, perplexity under a reference model, syntactic depth, noise score, and domain specialization measure different properties. Sorting by one can accidentally sort by language, source, or demographic group. A curriculum can improve the mean while delaying or excluding important coverage.

You will assign each example a transparent difficulty or quality field and compare shuffled, easy-to-hard, hard-to-easy, and staged mixtures. Match total valid tokens, optimizer steps, and final data exposure. Track early convergence, final validation loss, domain metrics, gradient norms, and forgetting when the mixture changes.

Large-scale pretraining rarely uses a single permanent ordering. Data mixtures can change over phases, and sampling weights can depend on domain size or quality. The experiment should therefore log the probability of drawing each category at every stage. A dataset list alone is insufficient to reproduce the training distribution.

Part 2 - Mathematical form and reasoning

Standard empirical risk uses a fixed data distribution P. A curriculum uses a time-dependent distribution P_k:

$$\theta_{k+1} = \theta_k - \eta_k \mathbb{E}_{x \sim P_k} \left[\nabla_\theta \ell(x; \theta_k) \right].$$

Although the final union of examples may be identical, different P_k changes the optimization path. Report exposure for category c as

$$E_c = \sum_k N_k P_k(c)$$

and verify matched totals when claiming an ordering-only comparison.

Part 3 - Hints, controls, and evidence

1. Define difficulty before viewing experimental outcomes.
2. Match initial weights, valid-token budget, learning-rate schedule, and final category exposure.
3. Log validation metrics by category throughout training, not only at the end.
4. Test multiple seeds because order effects can be noisy.
5. Inspect whether curriculum scoring correlates with language or source.
6. Separate faster early learning from better final quality and reduced training instability.

Part 4 - Python code skeleton

```
import random

def order_examples(examples, strategy, seed):
    ordered = list(examples)
    if strategy == "shuffled":
        generator = random.Random(seed)
        generator.shuffle(ordered)
    elif strategy == "easy_to_hard":
        ordered.sort(key=difficulty_value)
    elif strategy == "hard_to_easy":
        ordered.sort(key=difficulty_value, reverse=True)
    else:
        raise ValueError("unknown curriculum strategy")
    return ordered

def difficulty_value(example):
    return example["difficulty"]

def E04(train_function, evaluate_function, model_factory,
        examples, strategies, seeds):
    records = []
    for strategy in strategies:
        for seed in seeds:
            ordered = order_examples(examples, strategy, seed)
            model = model_factory(seed)
            trajectory = train_function(model, ordered)
            metrics = evaluate_function(model)
            record = {}
            record["strategy"] = strategy
            record["seed"] = seed
```

```
            record["trajectory"] = trajectory
            record["metrics"] = metrics
            records.append(record)
    return records
```

Part 5 - The Philosophy Behind the Exercise

Learning is shaped not only by what is experienced but by when it is experienced. Early examples alter the model that later examples encounter. Curriculum makes this temporal structure visible instead of pretending that a dataset is an unordered substance.

But deciding what is "easy" or "high quality" embeds judgment into the training path. A curriculum is therefore both an optimization strategy and an editorial theory of which language deserves to teach first. Its gains must be balanced against the voices and difficulties it may postpone.

18.4.6 Exercise 05

Exercise Title: Compare Clean Data vs Noisy Data and Observe Hallucination Effects

Part 1 - Why this matters

Noisy pretraining data can contain corrupted text, contradictory facts, fabricated citations, duplicated errors, broken markup, and mismatched question–answer pairs. A language model optimizes the observed tokens and does not receive an automatic marker distinguishing reliable statements from noise. Repeated or contextually predictable false claims can therefore become learned continuations.

To isolate the effect, create clean and noisy corpora with matched size and token frequency where possible. Initialize two models identically and expose them to equal valid-token budgets. The noisy corpus should include labeled noise types rather than a single random corruption rate. Random character damage, plausible false facts, contradictions, and invented references create different learning signals and should be evaluated separately.

Hallucination must be operationalized as generation of claims unsupported by the evidence. Use a separate prompt set with answerable and unanswerable cases, then measure factual accuracy, unsupported claim rate, abstention, calibration, and training loss. Noisy training can sometimes act as regularization, so a result should not be assumed in advance; inspect which noise types harm which behavior.

Cleaning also has risks. Filters may remove minority languages, informal but valid writing, or difficult domains. Report retention by source and category. The target is not text that looks polished to one heuristic, but a traceable corpus whose reliability and coverage serve the intended model.

Part 2 - Mathematical form and reasoning

Let the training distribution be

$$P_\epsilon = (1-\epsilon)P_{\text{clean}} + epsilonP_{\text{noise}}.$$

The expected gradient is the same mixture of component gradients. For response claims c_i and evidence E, unsupported rate is

$$H = \frac{1}{M}\sum_{i=1}^{M} \mathbb{I}[c_i \text{ is not supported by } E].$$

Compare H across noise levels while also reporting useful answer rate, because refusing all questions trivially reduces unsupported claims.

Part 3 - Hints, controls, and evidence

1. Preserve identical initialization and total valid-token exposure.
2. Create separate corruption functions for characters, labels, facts, citations, and contradictions.
3. Keep an untouched validation set with explicit evidence.
4. Annotate generated claims rather than scoring only complete responses.
5. Evaluate filter retention by language, domain, and source.
6. Publish raw examples where clean and noisy models differ, including cases where the noisy model unexpectedly wins.

Part 4 - Python code skeleton

```
import copy
import random

def corrupt_labels(records, corruption_probability, seed):
    generator = random.Random(seed)
    corrupted = copy.deepcopy(records)
    for record in corrupted:
        draw = generator.random()
        if draw < corruption_probability:
            original = record["answer"]
            record["answer"] = record["wrong_answer"]
            record["noise_type"] = "plausible_false_answer"
            record["original_answer"] = original
        else:
            record["noise_type"] = "clean"
    return corrupted

def unsupported_rate(claim_records):
    unsupported = 0
    total = 0
    for record in claim_records:
        total = total + 1
        if not record["supported"]:
            unsupported = unsupported + 1
    return unsupported / max(1, total)

def E05(model_factory, train_function, evaluate_function,
        clean_records, noise_levels):
```

```
    results = []
    for noise_level in noise_levels:
        training_records = corrupt_labels(
            clean_records, noise_level, seed=17
        )
        model = model_factory(seed=29)
        train_function(model, training_records)
        evaluation = evaluate_function(model)
        results.append({"noise_level": noise_level,
                        "evaluation": evaluation})
    return results
```

Part 5 - The Philosophy Behind the Exercise

A model cannot rise above its evidence by intention. It can infer, combine, and generalize, but the patterns presented as ordinary language become the material from which its expectations are formed. Noise is not simply dirt around the signal; sometimes it is a competing signal.

Data cleaning is therefore an epistemic responsibility. It decides which claims receive repetition and which sources receive trust. The goal is not artificial purity, but honest lineage, measured reliability, and enough diversity that cleaning does not become erasure.

18.4.7 Exercise 06

Exercise Title: Explain Why Data Diversity Beats Domain Specialization Early

Part 1 - Why this matters

Early pretraining constructs general representations of language, structure, and common reasoning patterns. A diverse mixture exposes the model to multiple genres, domains, languages, formats, and problem types. Narrow specialization can produce rapid gains on one domain but leave the model without transferable features and vulnerable to overfitting repeated templates.

The title is a hypothesis with conditions, not a universal rule. A model built only for a closed domain may benefit from specialized data, and low-quality diversity can be worse than excellent focused text. The experiment asks whether diversity during the early phase creates a stronger base for later adaptation under matched compute and data quality.

Train one model first on a balanced multi-domain mixture and another on a single domain. Then fine-tune both on the target domain using the same budget. Evaluate target quality, out-of-domain retention, sample efficiency, calibration, and robustness to reformulated inputs. Also compare a mixture that oversamples tiny domains so diversity does not merely mean proportional sampling from the largest source.

Data diversity must be measured. Counting sources is insufficient if most tokens come from one domain or if documents are duplicates. Report token share, effective sample size, unique documents, language coverage, and per-domain loss. The final recommendation should describe when specialization begins and what general capabilities must be protected.

Part 2 - Mathematical form and reasoning

For domains $d = 1, \ldots, D$ with sampling weights w_d,

$$P_{\text{mix}}(x) = \sum_{d=1}^{D} w_d P_d(x), \qquad \sum_d w_d = 1.$$

A simple diversity index is

$$H(w) = -\sum_d w_d \log w_d,$$

but it measures balance rather than semantic diversity. Evaluate transfer gain

$$G = A_{\text{target}}^{\text{diverse}\to\text{target}} - A_{\text{target}}^{\text{specialized}\to\text{target}}$$

across equal pretraining and adaptation tokens.

Part 3 - Hints, controls, and evidence

1. Match data quality thresholds and total token budgets across mixtures.
2. Use identical initial states and optimization schedules.
3. Evaluate every domain before and after target adaptation.
4. Include unseen formats within the target domain to test transfer rather than template memorization.
5. Report sampling weights and actual observed token counts.
6. Inspect negative transfer: diversity can introduce interference as well as useful shared structure.

Part 4 - Python code skeleton

```
import random

def sample_domain(domain_names, weights, generator):
    draw = generator.random()
    cumulative = 0.0
    for index in range(len(domain_names)):
        cumulative = cumulative + weights[index]
        if draw <= cumulative:
            return domain_names[index]
    return domain_names[-1]

def build_mixed_stream(domain_data, weights, number_of_examples, seed):
    generator = random.Random(seed)
    domain_names = list(domain_data.keys())
    positions = {}
    for name in domain_names:
        positions[name] = 0
    stream = []
    for _ in range(number_of_examples):
```

```
        name = sample_domain(domain_names, weights, generator)
        examples = domain_data[name]
        position = positions[name] % len(examples)
        stream.append({"domain": name, "example": examples[position]})
        positions[name] = positions[name] + 1
    return stream

def E06(train_and_evaluate, domain_data, diverse_weights,
        specialized_weights):
    diverse_stream = build_mixed_stream(
        domain_data, diverse_weights, 10000, seed=11
    )
    specialized_stream = build_mixed_stream(
        domain_data, specialized_weights, 10000, seed=11
    )
    diverse_result = train_and_evaluate(diverse_stream, seed=23)
    specialized_result = train_and_evaluate(
        specialized_stream, seed=23
    )
    return diverse_result, specialized_result
```

Part 5 - The Philosophy Behind the Exercise

Diversity gives learning more ways to discover what is shared. A structure first encountered in prose may support code; a relation learned in one domain may become a tool in another. Generality grows when representations must serve more than one narrow habit.

Specialization remains valuable, but timing matters. A broad foundation can be focused later; a narrow foundation may never encounter the concepts needed to expand. The principle is not that every source is equally useful, but that early learning should preserve the possibility of transfer.

18.4.8 Exercise 07

Exercise Title: Measure Loss vs Token Frequency Distribution

Part 1 - Why this matters

Language token frequencies are highly uneven. A small set of tokens appears constantly while many tokens are rare. Average cross entropy is dominated by frequent positions, so a model can improve global loss while rare names, symbols, scripts, or technical fragments remain poorly predicted. Frequency- conditioned analysis exposes this hidden distribution.

Token frequency alone does not determine difficulty. A rare token may be easy in a fixed phrase; a frequent token may be ambiguous across many contexts. Tokens also depend on tokenizer design: a rare word can become several common subwords, while an unusual Unicode sequence may fragment into rare bytes. Measure token frequency and contextual loss without treating either as a complete causal explanation.

You will count training occurrences, assign validation targets to logarithmic frequency bins, and compute mean NLL, accuracy, entropy, and example count for each bin. Add bootstrap intervals and display individual high-loss tokens. Use training counts only; computing frequency from validation leaks evaluation distribution into the analysis.

The experiment should compare early and late checkpoints. Frequent tokens may improve rapidly while rare-token loss changes slowly or irregularly. Also separate unseen tokens or fragments from merely rare ones. The vocabulary guarantees an identifier exists, not that pretraining provided enough examples to learn its use.

Part 2 - Mathematical form and reasoning

For token v, training frequency is

$$f_v = \sum_{i \in \text{train}} \mathbb{I}[y_i = v].$$

For frequency bin B_k, conditional loss is

$$L_k = \frac{1}{|I_k|} \sum_{i \in I_k} -\log p_\theta(y_i \mid x_i), \qquad I_k = \{i : f_{y_i} \in B_k\}.$$

Report $|I_k|$ because rare bins have higher variance. Correlation between $\log(f_v + 1)$ and token loss can summarize trend but cannot replace binned inspection.

Part 3 - Hints, controls, and evidence

1. Count only valid non-padding targets from the training set.
2. Use bins such as zero, one to nine, ten to ninety-nine, and larger ranges.
3. Accumulate loss sums and counts on tensors without storing every logit.
4. Decode representative high- and low-loss identifiers in every bin.
5. Separate punctuation, numbers, languages, and domain-specific tokens.
6. Repeat for multiple checkpoints and seeds to distinguish learning trend from sampling noise.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def frequency_bin(frequency):
    if frequency == 0:
        return 0
    if frequency < 10:
        return 1
    if frequency < 100:
        return 2
    if frequency < 1000:
        return 3
    return 4

def losses_by_frequency(logits, targets, training_counts):
```

```
    losses = F.cross_entropy(
        logits.reshape(-1, logits.shape[-1]),
        targets.reshape(-1), reduction="none"
    )
    flat_targets = targets.reshape(-1)
    sums = torch.zeros(5, device=logits.device, dtype=torch.float64)
    counts = torch.zeros(5, device=logits.device, dtype=torch.long)
    for index in range(flat_targets.numel()):
        token_id = int(flat_targets[index].item())
        frequency = int(training_counts[token_id].item())
        bin_id = frequency_bin(frequency)
        sums[bin_id] = sums[bin_id] + losses[index].to(torch.float64)
        counts[bin_id] = counts[bin_id] + 1
    means = sums / counts.clamp_min(1)
    return means, counts

def E07(model, validation_ids, training_counts):
    logits = model(validation_ids[:, :-1])
    targets = validation_ids[:, 1:]
    return losses_by_frequency(logits, targets, training_counts)
```

Part 5 - The Philosophy Behind the Exercise

An average gives every event a contribution but does not give every kind of event visibility. Frequent language defines the dominant gradient and the headline metric; rare language can remain a quiet frontier of failure.

Frequency analysis asks whose errors disappear inside the mean. It teaches that statistical success and equitable competence are not identical. A model of language should be judged not only where language is abundant, but where its evidence is scarce and its users may already be underrepresented.

18.4.9 Exercise 08

Exercise Title: Explain Memorization vs Generalization in LLMs

Part 1 - Why this matters

Memorization means reproducing information strongly tied to particular training examples; generalization means applying learned regularities to unseen examples. The two are not mutually exclusive. A model can memorize rare strings while generalizing grammar, and some factual recall may reasonably depend on repeated exposure. The scientific task is to measure behavior rather than assign one global label to the model.

Exact reproduction is strong evidence of memorization when the sequence is long, rare, and unlikely under ordinary language. Short common phrases are weak evidence because many sources share them. Generalization tests must prevent near-duplicate contamination and change surface form while preserving an underlying rule.

You will train a tiny model on synthetic templates containing unique canary strings plus compositional rules. Test exact canary extraction, paraphrased facts, held-out combinations, and completely unseen identifiers. Vary canary repetition and measure exposure: how much

more likely the canary becomes after training compared with a reference model or neighboring strings.

Privacy implications must be explicit. Do not insert real secrets, personal data, credentials, or copyrighted passages as canaries. Use generated strings with known provenance. The goal is to understand extraction risk and design audits, not to reproduce sensitive material.

Part 2 - Mathematical form and reasoning

For canary sequence c and reference set R, exposure can be approximated from rank:

$$\text{Exposure}(c) = \log_2 |R| - \log_2 \text{rank}(c),$$

where sequences are ranked by model loss. Generalization gap is

$$G = L_{\text{heldout}} - L_{\text{train}}.$$

Neither value alone is sufficient: low held-out loss can coexist with memorized rare examples, and high gap can result from distribution shift rather than only memorization.

Part 3 - Hints, controls, and evidence

1. Generate canaries randomly and record only synthetic provenance.
2. Compare repetition counts while holding total token budget fixed.
3. Evaluate exact prefixes, paraphrases, and rule-preserving novel combinations.
4. Search training and test corpora for exact and near-duplicate overlap.
5. Report extraction probability across sampling settings, not one lucky generation.
6. Separate privacy-risk memorization from useful learning of common structure in the conclusion.

Part 4 - Python code skeleton

```
import math
import torch
import torch.nn.functional as F

def sequence_nll(model, input_ids):
    logits = model(input_ids[:, :-1])
    targets = input_ids[:, 1:]
    loss = F.cross_entropy(
        logits.reshape(-1, logits.shape[-1]),
        targets.reshape(-1), reduction="sum"
    )
    return float(loss.detach().cpu())

def rank_canary(model, canary_ids, reference_sequences):
    canary_loss = sequence_nll(model, canary_ids)
    better_or_equal = 1
```

```
    for sequence in reference_sequences:
        reference_loss = sequence_nll(model, sequence)
        if reference_loss <= canary_loss:
            better_or_equal = better_or_equal + 1
    return better_or_equal, canary_loss

def E08(model, canary_ids, reference_sequences):
    rank, canary_loss = rank_canary(
        model, canary_ids, reference_sequences
    )
    population = len(reference_sequences) + 1
    exposure = math.log2(population) - math.log2(rank)
    return {"rank": rank, "loss": canary_loss,
            "exposure": exposure}
```

Part 5 - The Philosophy Behind the Exercise

Learning always preserves something from experience. The difficult question is whether the preserved structure travels beyond the example or remains attached to its surface. Memorization and generalization are not moral opposites; they are different relationships between past evidence and future behavior.

The responsibility arises when memorized detail was never meant to become extractable. Scale transforms data stewardship into model behavior. Protecting privacy begins before training and continues through auditing what the model can be induced to reveal.

18.4.10 Exercise 09

Exercise Title: Detect Data Leakage Using Train-Test Overlap Experiments

Part 1 - Why this matters

Evaluation is intended to estimate behavior on unseen data. If test documents, answers, or close paraphrases appear in training, scores can reflect retrieval or memorization instead of generalization. Large corpora make accidental overlap likely, especially when benchmarks are publicly posted, quoted, translated, or embedded in tutorials.

Exact hashing detects identical normalized documents but misses formatting changes and partial overlap. Token shingles, MinHash-style signatures, locality- sensitive search, and embedding similarity can detect near duplicates at different costs and false-positive rates. Detection should operate at document, window, and answer-string levels because leakage can be partial.

You will build clean, exactly contaminated, and paraphrase-contaminated training variants. Train matched tiny models and compare test loss, exact accuracy, and performance on a hidden clean control set. If the contaminated score rises only on leaked items, the apparent gain is invalid. Remove overlap and confirm the score returns toward the clean baseline.

Temporal provenance is another defense. Evaluation events created after the training cutoff are less likely to be included, but publication time and crawl time must be recorded. A leakage report should preserve matched examples and similarity evidence without exposing protected benchmark content unnecessarily.

Part 2 - Mathematical form and reasoning

For token-shingle sets $S(a)$ and $S(b)$, Jaccard similarity is

$$J(a,b) = \frac{|S(a) \cap S(b)|}{|S(a) \cup S(b)|}.$$

At threshold τ, estimated contamination rate is

$$r_{\text{contam}} = \frac{1}{|D_{\text{test}}|} \sum_{t \in D_{\text{test}}} \mathbb{I}\left[\max_{x \in D_{\text{train}}} J(x,t) \geq \tau\right].$$

Threshold choice trades missed paraphrases against false matches and must be validated on labeled pairs.

Part 3 - Hints, controls, and evidence

1. Normalize Unicode, whitespace, and boilerplate while retaining raw text.
2. Compute exact hashes before more expensive near-duplicate comparisons.
3. Use token shingles of several widths to detect local and broad overlap.
4. Label a sample of matches manually and report precision and recall.
5. Evaluate leaked, non-leaked, and hidden-control items separately.
6. Version the detector, threshold, corpus snapshot, and remediation action.

Part 4 - Python code skeleton

```
def token_shingles(token_ids, width):
    shingles = set()
    if len(token_ids) < width:
        shingles.add(tuple(token_ids))
        return shingles
    for start in range(len(token_ids) - width + 1):
        shingles.add(tuple(token_ids[start:start + width]))
    return shingles

def jaccard_similarity(set_a, set_b):
    union = set_a | set_b
    if len(union) == 0:
        return 1.0
    intersection = set_a & set_b
    return len(intersection) / len(union)

def find_overlaps(training_sequences, test_sequences, width, threshold):
    training_shingles = []
    for sequence in training_sequences:
        training_shingles.append(token_shingles(sequence, width))
    matches = []
    for test_index in range(len(test_sequences)):
        test_set = token_shingles(test_sequences[test_index], width)
```

```
        best_score = 0.0
        best_train_index = -1
        for train_index in range(len(training_shingles)):
            score = jaccard_similarity(
                training_shingles[train_index], test_set
            )
            if score > best_score:
                best_score = score
                best_train_index = train_index
        if best_score >= threshold:
            matches.append((test_index, best_train_index, best_score))
    return matches

def E09(training_sequences, test_sequences):
    return find_overlaps(training_sequences, test_sequences,
                         width=5, threshold=0.8)
```

Part 5 - The Philosophy Behind the Exercise

An examination ceases to measure learning when the answers were already inside the lesson. Data leakage creates the appearance of progress by dissolving the boundary between experience and evaluation.

At scale, innocence is not enough; overlap can occur without anyone intending to cheat. Scientific credibility requires provenance, detection, and willingness to discard flattering numbers. A lower clean score is more valuable than a high score whose meaning cannot be defended.

18.4.11 Exercise 10

Exercise Title: Train Tiny LLM on CUDA and Track Loss Scaling

Part 1 - Why this matters

This exercise joins the pretraining objective, corpus, model, optimizer, and CUDA execution into one measured run. The goal is not only to make loss decrease, but to understand how loss changes with tokens seen, parameter scale, and compute. Every run must record configuration and validation at matched token checkpoints.

Loss scaling can mean several things. Here it means empirical reduction of validation NLL as training tokens or model size increase, not mixed-precision gradient scaling. Use the term carefully. Train multiple tiny model sizes under controlled data and compare learning curves against tokens, wall time, and estimated FLOPs.

CUDA timing is asynchronous, and first iterations include initialization and kernel warm-up. Separate warm-up from measured training, synchronize only at measurement boundaries, and count valid target tokens rather than padded input positions. Track peak memory and tokens per second so a lower loss is accompanied by its resource cost.

Validation data must remain fixed and leak-free. Training loss can continue to fall through memorization while validation plateaus. Save checkpoints and raw metric records so later exercises can analyze frequency, memorization, and gradient behavior without rerunning every experiment.

Part 2 - Mathematical form and reasoning

For parameter count N, cumulative valid tokens D_k, and validation loss L_k, fit a descriptive relation such as

$$L(D) = L_\infty + AD^{-\beta}$$

over the observed region. Estimated training compute can be recorded as

$$C_k \approx 6ND_k.$$

The coefficient is a coarse dense-Transformer convention. State that it omits implementation details and use measured wall time beside it.

Part 3 - Hints, controls, and evidence

1. Verify the model overfits one batch before launching the sweep.
2. Evaluate at fixed cumulative-token milestones, not only epoch boundaries.
3. Record model parameters, valid tokens, train loss, validation loss, gradient norm, learning rate, throughput, and peak memory.
4. Use identical validation tokens and tokenizer across all scales.
5. Repeat seeds and plot individual trajectories plus a summary.
6. Stop and diagnose NaN or non-finite gradients immediately; never smooth them out of the log.

Part 4 - Python code skeleton

```
import time
import torch

def train_cuda(model, loader, optimizer, loss_function,

```

Part 5 - The Philosophy Behind the Exercise

Scaling curves transform training from an event into a trajectory. A final checkpoint hides how quickly learning began, where it slowed, and what resources were exchanged for each improvement. Tracking makes progress accountable.

CUDA supplies speed, but measurement supplies meaning. The research object is not merely a trained tensor file; it is the documented path from tokens and compute to changed predictive uncertainty.

18.4.12 Exercise 11

Exercise Title: Compare Training Stability Under Different Batch Sizes

Part 1 - Why this matters

Batch size changes the number of token losses averaged before one parameter update. Small batches produce noisier gradient estimates that can aid exploration but increase loss variance and instability. Large batches reduce sampling noise and improve hardware throughput up to a point, but consume more memory and may require learning-rate adjustment to preserve useful update magnitude.

For language models, sequences contain different numbers of valid targets. Batch size in sequences is therefore not the complete statistical batch size. Record valid tokens per update. Packing, padding, context length, and gradient accumulation can make two nominally equal batches contain very different amounts of supervision.

You will compare several microbatch sizes under two controls: equal optimizer steps and equal total valid tokens. Use identical data order where practical and repeat seeds. Measure loss variance, gradient norm, update norm, throughput, peak memory, NaN events, and final validation quality. Do not tune one batch size more extensively than the others without reporting it.

Learning-rate scaling should be a separate experiment. Linear or square-root rules are heuristics, not guarantees. Begin with a fixed learning rate to expose the direct batch effect, then run a declared scaling rule and compare stability.

Part 2 - Mathematical form and reasoning

For token gradients g_i, batch estimator is

$$\hat{g}_B = \frac{1}{B}\sum_{i=1}^{B} g_i, \qquad \operatorname{Var}(\hat{g}_B) \approx \frac{\Sigma}{B}$$

under an independence approximation that is imperfect for correlated tokens. Define update-to-parameter ratio

$$r_k = \frac{\|\theta_{k+1} - \theta_k\|_2}{\|\theta_k\|_2 + \epsilon}$$

and compare its distribution across batch configurations.

Part 3 - Hints, controls, and evidence

1. Report sequences, raw tokens, and valid target tokens per update.
2. Preserve data order or record every sampled example identifier.
3. Compare fixed and scaled learning rates as different tables.
4. Log step-level loss and gradient norms before aggregation into epochs.
5. Match total valid tokens when comparing final validation quality.
6. Explain throughput saturation and memory limits separately from statistical stability.

Part 4 - Python code skeleton

```
import torch

def parameter_norm(model):
    squared_sum = torch.zeros((), device=next(model.parameters()).device)
    for parameter in model.parameters():
        squared_sum = squared_sum + parameter.detach().float().square().sum()
    return torch.sqrt(squared_sum)

def snapshot_parameters(model):
    snapshots = []
    for parameter in model.parameters():
        snapshots.append(parameter.detach().clone())
    return snapshots

def update_norm(model, before):
    squared_sum = torch.zeros((), device=before[0].device)
    index = 0
```

```
    for parameter in model.parameters():
        difference = parameter.detach() - before[index]
        squared_sum = squared_sum + difference.float().square().sum()
        index = index + 1
    return torch.sqrt(squared_sum)

def E11(run_training, model_factory, batch_sizes, seeds):
    records = []
    for batch_size in batch_sizes:
        for seed in seeds:
            model = model_factory(seed)
            metrics = run_training(model, batch_size, seed)
            records.append({"batch_size": batch_size,
                            "seed": seed, "metrics": metrics})
    return records
```

Part 5 - The Philosophy Behind the Exercise

Batching decides how many experiences are allowed to speak before the model changes. A small batch lets each local sample influence the path strongly; a large batch seeks consensus across more evidence. Stability and responsiveness are two sides of this averaging choice.

There is no universally wise crowd size. The right batch emerges from data correlation, hardware, optimization, and the desired noise scale. Measurement replaces rules of thumb with an account of how collective evidence moves the model.

18.4.13 Exercise 12

Exercise Title: Analyze Gradient Noise in Token Prediction Objective

Part 1 - Why this matters

Each batch provides a sample estimate of the gradient over the full pretraining distribution. Different topics, token frequencies, sequence lengths, and ambiguous continuations produce different gradients. Their variation is gradient noise. Too much variation can destabilize updates; some noise can help optimization avoid narrow paths and improve generalization.

Token losses inside a sequence are correlated, so treating every token as an independent sample overstates effective batch size. Repeated documents and overlapping windows add more correlation. You will compare microbatch gradients using cosine similarity, norm variation, and an empirical noise scale while recording valid-token counts and domains.

Gradient measurement must occur before the optimizer modifies parameters. Create a fixed model state, compute gradients for multiple microbatches without stepping, flatten or summarize them consistently, and reset gradients between batches. Large flattened vectors can consume memory, so provide both exact tiny- model analysis and layer-wise statistics for larger models.

The final analysis should connect noise to learning rate and batch size without claiming a universal formula. Noise changes throughout training as predictions and data order change. Measure at several checkpoints and identify layers whose gradient directions disagree most across batches.

Part 2 - Mathematical form and reasoning

Let microbatch gradients be $g_1, \ldots, g_M$ and mean $\bar{g} = M^{-1} \sum_i g_i$. Empirical noise variance is

$$V = \frac{1}{M-1} \sum_i \|g_i - \bar{g}\|_2^2.$$

Signal magnitude is $S = \|\bar{g}\|_2^2$, giving descriptive ratio $V/(S + \epsilon)$. Pairwise directional agreement is

$$\cos(g_i, g_j) = \frac{g_i^\mathsf{T} g_j}{\|g_i\|_2 \|g_j\|_2}.$$

Report the estimator and sampling procedure rather than treating this ratio as a universal noise-scale definition.

Part 3 - Hints, controls, and evidence

1. Reload identical parameters before measuring each checkpoint condition.
2. Use `zero_grad(set_to_none=True)` between microbatches.
3. Normalize loss by valid tokens consistently.
4. Record domain, length, and token-frequency composition of each batch.
5. Compare exact flattened gradients with per-layer norms on a tiny model.
6. Repeat at early, middle, and late checkpoints.

Part 4 - Python code skeleton

```
import torch

def flattened_gradient(model):
    pieces = []
    for parameter in model.parameters():
        if parameter.grad is not None:
            pieces.append(parameter.grad.detach().reshape(-1).float())
    return torch.cat(pieces)

def collect_microbatch_gradients(model, batches, loss_function, device):
    gradients = []
    for batch in batches:
        model.zero_grad(set_to_none=True)
        input_ids = batch["input_ids"].to(device)
        logits = model(input_ids)
        loss = loss_function(logits, batch, device)
        loss.backward()
        gradients.append(flattened_gradient(model).cpu())
    return torch.stack(gradients)
```

```
def gradient_noise_statistics(gradient_matrix):
    mean_gradient = gradient_matrix.mean(dim=0)
    centered = gradient_matrix - mean_gradient
    variance = centered.square().sum(dim=1).sum()
    variance = variance / max(1, gradient_matrix.shape[0] - 1)
    signal = mean_gradient.square().sum()
    ratio = variance / signal.clamp_min(1e-30)
    return signal, variance, ratio

def E12(model, batches, loss_function, device):
    gradients = collect_microbatch_gradients(
        model, batches, loss_function, device
    )
    return gradient_noise_statistics(gradients)
```

Part 5 - The Philosophy Behind the Exercise

Optimization listens to a chorus of partial experiences. Gradient noise is the measure of their disagreement. Removing all disagreement would require hearing the whole distribution before every step, while listening to one voice at a time makes the path volatile.

Noise is not merely error around a true direction. It reveals heterogeneity in the data and can help determine which compromise the model learns. Understanding it means studying both optimization and the diversity of experiences that produce the gradients.

18.4.14 Exercise 13

Exercise Title: Implement Gradient Accumulation for Token-Level Training

Part 1 - Why this matters

Gradient accumulation simulates a larger effective batch by processing several microbatches before one optimizer step. It is essential when model activations or contexts do not fit at the desired batch size. Correct accumulation must match the gradient of the combined valid-token loss, including variable numbers of real targets per microbatch.

Dividing every microbatch loss by the number of accumulation steps is equivalent only when each microbatch contains the same statistical weight. With variable padding, the correct approach accumulates the sum of token losses and divides gradients by the total valid-token count. Otherwise short and long microbatches receive equal weight despite containing different supervision.

Optimizer stepping, gradient clipping, scheduler stepping, and gradient clearing occur once per effective batch, not once per microbatch. Mixed- precision scaling must preserve this order: scale each backward contribution, unscale once before clipping, then step and update the scaler. Remainder microbatches at the end of an epoch require a valid final step.

You will compare accumulated gradients and parameter updates with a true concatenated batch on a tiny deterministic model. Disable dropout or control its randomness for equivalence. Report maximum gradient and parameter differences before benchmarking memory savings.

Part 2 - Mathematical form and reasoning

For microbatch j with valid token set I_j, combined objective is

$$L = \frac{\sum_j \sum_{i \in I_j} \ell_i}{\sum_j |I_j|}.$$

Accumulate gradients of loss sums

$$g_{\text{sum}} = \sum_j \nabla_\theta \left(\sum_{i \in I_j} \ell_i \right)$$

then divide every gradient by $N = \sum_j |I_j|$ before clipping and stepping.

Part 3 - Hints, controls, and evidence

1. Compare against one concatenated batch from the same initial state.
2. Use loss reduction `sum` inside each microbatch and count valid targets.
3. Divide gradients once by total valid tokens.
4. Clip, step optimizer, and step scheduler once per effective batch.
5. Handle the final partial accumulation group explicitly.
6. Test equality in float64 on CPU before measuring reduced-precision CUDA.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def token_loss_sum(model, input_ids, valid_mask):
    logits = model(input_ids)
    prediction_logits = logits[:, :-1, :]
    targets = input_ids[:, 1:]
    target_mask = valid_mask[:, 1:]
    losses = F.cross_entropy(
        prediction_logits.reshape(-1, prediction_logits.shape[-1]),
        targets.reshape(-1), reduction="none"
    ).view_as(targets)
    return losses.masked_select(target_mask).sum(), int(target_mask.sum())

def accumulated_step(model, microbatches, optimizer, device):
    optimizer.zero_grad(set_to_none=True)
    total_valid_tokens = 0
    for batch in microbatches:
        input_ids = batch["input_ids"].to(device)
        valid_mask = batch["valid_mask"].to(device)
        loss_sum, valid_tokens = token_loss_sum(
            model, input_ids, valid_mask
        )
        loss_sum.backward()
```

```
        total_valid_tokens = total_valid_tokens + valid_tokens
    if total_valid_tokens == 0:
        raise ValueError("effective batch has no valid tokens")
    for parameter in model.parameters():
        if parameter.grad is not None:
            parameter.grad.div_(total_valid_tokens)
    gradient_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), 1.0
    )
    optimizer.step()
    return gradient_norm, total_valid_tokens

def E13(model, microbatches, optimizer, device):
    return accumulated_step(model, microbatches, optimizer, device)
```

Part 5 - The Philosophy Behind the Exercise

Accumulation separates when evidence is observed from when a decision is made. The model can listen to several microbatches without storing all their activations simultaneously, then combine their influence into one update.

Equivalence depends on weighting. Counting microbatches treats containers as equal; counting valid tokens treats observations as equal. The denominator is a small mathematical choice that determines whose evidence has authority in the effective batch.

18.4.15 Exercise 14

Exercise Title: Explain Why LLMs Can Imitate Reasoning Without Understanding

Part 1 - Why this matters

Pretraining corpora contain explanations, proofs, worked examples, debates, and step-by-step solutions. Next-token prediction can learn the surface and structural patterns of these traces. A model may produce a convincing chain that resembles reasoning even when the steps do not causally support the conclusion, the final answer was copied from a familiar template, or small perturbations destroy the behavior.

The title should not be converted into the opposite absolute claim that LLMs never perform useful computation. Behavioral reasoning can be tested through novel problems, interventions, consistency, intermediate-state validity, and out-of-distribution composition. The point is that a generated explanation by itself is insufficient evidence of the mechanism or depth of understanding.

You will construct task families with matched surface forms: familiar templates, novel variable substitutions, counterfactual rules, misleading intermediate steps, and answer choices whose order changes. Evaluate final answer and trace validity separately. Ask for answer-only and explanation-plus-answer outputs to test whether producing a trace improves, harms, or merely decorates performance.

Do not use private chain-of-thought as a required transparency mechanism. Instead, request concise verifiable calculations, externally checkable steps, tool results, or structured intermediate answers. The evaluation should focus on observable evidence rather than assuming a fluent narrative reveals hidden internal computation.

Part 2 - Mathematical form and reasoning

Let A indicate correct final answer and R indicate a valid supplied rationale. Report the joint table

$$P(A, R), \quad P(A, \neg R), \quad P(\neg A, R), \quad P(\neg A, \neg R).$$

For semantics-preserving transformations $g \in \mathcal{G}$, consistency is

$$C = \frac{1}{N|\mathcal{G}|} \sum_{i,g} \mathbb{I}[a(g(x_i)) = a(x_i)].$$

High trace fluency without validity or intervention stability supports imitation more than robust rule application.

Part 3 - Hints, controls, and evidence

1. Define a machine-checkable rule for intermediate-step validity.
2. Separate familiar templates from held-out compositional forms.
3. Randomize names, numbers, option order, and irrelevant wording.
4. Insert a plausible but wrong intermediate claim and test correction.
5. Compare answer-only with concise-verification formats.
6. State which behaviors were demonstrated without making claims about consciousness or inaccessible internal experience.

Part 4 - Python code skeleton

```
def joint_reasoning_counts(records):
    counts = {}
    counts["answer_and_rationale"] = 0
    counts["answer_only"] = 0
    counts["rationale_only"] = 0
    counts["neither"] = 0
    for record in records:
        answer = record["answer_correct"]
        rationale = record["rationale_valid"]
        if answer and rationale:
            counts["answer_and_rationale"] += 1
        elif answer and not rationale:
            counts["answer_only"] += 1
        elif not answer and rationale:
            counts["rationale_only"] += 1
        else:
            counts["neither"] += 1
    return counts

def E14(generate, task_families):
```

```
    records = []
    for family in task_families:
        for case in family["cases"]:
            output = generate(case["prompt"])
            record = {}
            record["family"] = family["name"]
            record["answer_correct"] = family["score_answer"](
                output, case
            )
            record["rationale_valid"] = family["score_rationale"](
                output, case
            )
            records.append(record)
    return records, joint_reasoning_counts(records)
```

Part 5 - The Philosophy Behind the Exercise

Explanation is behavior, not privileged access to cause. A model can produce the language of reasoning because such language has structure worth predicting. The narrative may be useful, mistaken, or post-hoc, just as human explanations can be.

The responsible position avoids both enchantment and dismissal. We test whether the system applies rules under change, exposes verifiable steps, and recognizes contradictions. Understanding becomes an empirical program of robustness and causal intervention rather than a judgment made from eloquence alone.

18.4.16 Exercise 15

Exercise Title: Compare Language Modeling vs Masked Modeling Objectives

Part 1 - Why this matters

Causal language modeling predicts each next token from the left prefix. Masked language modeling hides selected tokens and reconstructs them using context on both sides. The objectives use similar Transformer components but create different information boundaries and supervision patterns. Their natural uses therefore differ.

CLM supplies a target at nearly every transition and directly matches autoregressive generation. MLM can build bidirectional representations useful for classification, retrieval, and token labeling, but ordinary MLM does not define a left-to-right joint probability without an additional generation procedure. Comparing only final loss is meaningless because the conditioning sets and predicted positions differ.

You will construct the same token sequences for both objectives. For CLM, apply a causal mask and shift targets. For MLM, sample mask positions reproducibly, replace tokens according to a declared corruption policy, and compute loss only on selected positions. Measure supervised-token fraction, compute, representation probe quality, and generation suitability.

Masking policy affects difficulty. If every selected token is replaced by a visible mask symbol, pretraining creates a token absent from downstream inputs; some procedures retain or randomly replace a fraction. Record the policy and prevent unmasked target leakage through preprocessing.

Part 2 - Mathematical form and reasoning

Causal objective is

$$L_{\mathrm{CLM}} = -\sum_{t=1}^{T-1} \log p_\theta(x_{t+1} \mid x_{\le t}).$$

For sampled mask set M,

$$L_{\mathrm{MLM}} = -\sum_{t \in M} \log p_\theta(x_t \mid \widetilde{x}_{\setminus M}).$$

If masking rate is r, expected MLM supervised positions are approximately rT, compared with roughly $T-1$ for CLM, though the conditioning information is richer in MLM.

Part 3 - Hints, controls, and evidence

1. Use one tokenizer and identical raw sequences.
2. Print causal targets and MLM selected positions for a tiny example.
3. Seed mask sampling and verify targets are never taken from corrupted IDs.
4. Match valid target-token budgets rather than epochs when comparing optimization.
5. Evaluate a bidirectional classification probe and autoregressive generation separately.
6. Explain why objective-specific losses and perplexities are not directly comparable.

Part 4 - Python code skeleton

```
import torch

def build_mlm_example(input_ids, mask_token_id,
                      mask_probability, generator):
    random_values = torch.rand(
        input_ids.shape, generator=generator, device=input_ids.device
    )
    selected = random_values < mask_probability
    corrupted = input_ids.clone()
    targets = input_ids.clone()
    corrupted[selected] = mask_token_id
    targets[~selected] = -100
    return corrupted, targets, selected

def build_clm_example(input_ids):
    model_inputs = input_ids[:, :-1]
    targets = input_ids[:, 1:]
    return model_inputs, targets

def E15(input_ids, mask_token_id):
    generator = torch.Generator(device=input_ids.device)
    generator.manual_seed(1515)
```

```
    mlm_inputs, mlm_targets, selected = build_mlm_example(
        input_ids, mask_token_id, 0.15, generator
    )
    clm_inputs, clm_targets = build_clm_example(input_ids)
    results = {}
    results["mlm_inputs"] = mlm_inputs
    results["mlm_targets"] = mlm_targets
    results["mlm_supervised"] = int(selected.sum().item())
    results["clm_inputs"] = clm_inputs
    results["clm_targets"] = clm_targets
    results["clm_supervised"] = clm_targets.numel()
    return results
```

Part 5 - The Philosophy Behind the Exercise

Every objective creates an artificial absence. CLM hides the future; MLM hides selected pieces of the present. The model learns by reconstructing what the objective withholds, and the shape of that absence influences the representation that emerges.

Neither objective is language itself. Each is an educational game designed by engineers. Choosing between them means deciding which information boundary and downstream behavior best match the purpose of the system.

18.4.17 Exercise 16

Exercise Title: Analyze Failure Cases on Rare Tokens

Part 1 - Why this matters

Rare tokens often represent names, technical notation, minority scripts, unusual numbers, or tokenizer fragments created by uncommon byte patterns. Their embeddings and output rows receive fewer direct updates, and evaluation averages can hide their failures. Rare-token errors can be operationally important when the token identifies a medicine, legal clause, account code, or scientific symbol.

Rarity has several forms. A token may be globally rare but predictable in one fixed phrase, frequent as part of copied boilerplate but absent from diverse contexts, or composed from common subwords even though the complete word is rare. Analyze frequency, context diversity, fragmentation, and target loss together.

Build a held-out suite containing rare identifiers, long numbers, code symbols, multilingual names, and minimal pairs differing by one token. Measure target NLL, top-k rank, calibration, copy accuracy, and edit distance. Compare direct generation with a pointer or constrained-copy mechanism conceptually, because some applications should copy exact input strings instead of relying on parametric recall.

Do not expose real personal identifiers. Generate synthetic examples and retain their construction rules. Group results by frequency and semantic function, and inspect whether normalization or tokenization accidentally changes the expected target before blaming the model.

Part 2 - Mathematical form and reasoning

For target token y, rank is

$$r(y) = 1 + \sum_{v \neq y} \mathbb{I}[z_v > z_y].$$

Mean reciprocal rank for rare targets R is

$$\mathrm{MRR}_R = \frac{1}{|R|} \sum_{i \in R} \frac{1}{r(y_i)}.$$

Context diversity for token v can be approximated by the number or entropy of distinct neighboring token patterns, distinguishing repeated duplication from broad exposure.

Part 3 - Hints, controls, and evidence

1. Derive rarity from training targets only.
2. Verify tokenizer round-trip and expected token boundaries for every case.
3. Report loss, rank, top-k membership, and decoded alternatives.
4. Compare rare tokens with frequency-matched controls from different categories.
5. Test exact copying when the rare string is present in context.
6. Propose retrieval, constrained decoding, byte fallback, or human validation for high-consequence rare outputs.

Part 4 - Python code skeleton

```
import torch

def target_rank(logit_row, target_id):
    target_logit = logit_row[target_id]
    higher = (logit_row > target_logit).sum()
    return int(higher.item()) + 1

def analyze_rare_positions(logits, targets,
                           training_counts, rarity_threshold):
    records = []
    for batch_index in range(targets.shape[0]):
        for time_index in range(targets.shape[1]):
            target_id = int(targets[batch_index, time_index].item())
            frequency = int(training_counts[target_id].item())
            if frequency <= rarity_threshold:
                row = logits[batch_index, time_index]
                log_probability = torch.log_softmax(row, dim=-1)[target_id]
                record = {}
                record["target_id"] = target_id
                record["frequency"] = frequency
                record["nll"] = float((-log_probability).cpu())
                record["rank"] = target_rank(row, target_id)
                records.append(record)
    return records
```

```
def E16(model, input_ids, training_counts, rarity_threshold):
    logits = model(input_ids[:, :-1])
    targets = input_ids[:, 1:]
    return analyze_rare_positions(
        logits, targets, training_counts, rarity_threshold
    )
```

Part 5 - The Philosophy Behind the Exercise

Rarity is where a statistical system reveals whose experience it has scarcely seen. The model may be fluent in the center of the distribution while fragile at its edges. Those edges are not unimportant merely because they contribute little to an average.

Rare-token engineering asks when generation should yield to copying, retrieval, constraints, or human review. Competence includes knowing which details should not be reconstructed from uncertain memory.

18.4.18 Exercise 17

Exercise Title: Build Dataset Quality Checklist for LLM Pretraining

Part 1 - Why this matters

Pretraining data errors propagate into expensive model behavior. A dataset quality checklist converts broad intentions such as "clean and diverse" into auditable gates. It should cover authorization, provenance, integrity, deduplication, language and domain balance, privacy, benchmark contamination, harmful content policy, formatting, tokenization, and reproducibility.

Quality is multidimensional. A document can be syntactically clean but factually wrong, legally unusable, private, duplicated, or outside the model's intended domain. A single scalar filter score hides tradeoffs. Store individual signals, decision reasons, and retained source metadata so exclusion can be reviewed.

You will implement structured checks with stable identifiers, severity, pass or fail state, evidence, and remediation. Create good fixtures plus injected failures: invalid encoding, empty text, duplicate documents, leaked benchmark answers, secrets, mislabeled language, extreme token expansion, and corrupted markup. Every known fault must trigger the intended check.

Sampling audits complement automated checks. Human reviewers should inspect stratified samples across source, language, score band, and exclusion reason. Agreement and escalation rules must be documented. The checklist is a living artifact versioned with the exact corpus build.

Part 2 - Mathematical form and reasoning

For source group g, retention rate is

$$r_g = \frac{N_{g,\text{kept}}}{N_{g,\text{input}}}.$$

Disparity across groups can be summarized by $\max_g r_g - \min_g r_g$, while requiring interpretation of legitimate quality differences. Fault-detection coverage is

$$C = \frac{|\{f \in F : \text{at least one intended check detects } f\}|}{|F|}.$$

Neither metric proves quality; both make blind spots measurable.

Part 3 - Hints, controls, and evidence

1. Assign identifiers such as `DATA-PROV-001` and versions to checks.
2. Never discard raw provenance needed to audit a filtered document.
3. Separate blocking legal or privacy failures from quality warnings.
4. Measure retention by source, language, domain, and document-length band.
5. Maintain benchmark hashes and near-duplicate detection before training.
6. Require every corpus release to include checksums, configuration, counts, and known limitations.

Part 4 - Python code skeleton

```
class DataCheckResult:
    def __init__(self, check_id, passed, severity,
                 evidence, remediation):
        self.check_id = check_id
        self.passed = passed
        self.severity = severity
        self.evidence = evidence
        self.remediation = remediation

def check_nonempty(document):
    normalized = document["text"].strip()
    return DataCheckResult(
        "DATA-INTEGRITY-001", len(normalized) > 0, "blocking",
        {"normalized_length": len(normalized)},
        "remove empty documents or repair extraction"
    )

def check_provenance(document):
    required = ["source", "collected_at", "authorization"]
    missing = []
    for field in required:
        if field not in document or document[field] in [None, ""]:
            missing.append(field)
    return DataCheckResult(
        "DATA-PROV-001", len(missing) == 0, "blocking",
        {"missing_fields": missing},
        "restore provenance before admitting the document"
    )

def E17(documents):
    report = []
    for document in documents:
```

```
        results = []
        results.append(check_nonempty(document))
        results.append(check_provenance(document))
        report.append({"document_id": document["id"],
                       "results": results})
    return report
```

Part 5 - The Philosophy Behind the Exercise

A dataset checklist is a constitution for evidence. It defines which material may enter the learning process, which records must accompany it, and which harms require exclusion or review. Those decisions shape the eventual model even when they never appear in its architecture diagram.

No checklist can certify truth or justice completely. Its value is to make responsibility inspectable and revisable. Quality grows when decisions leave a trace and failures become new tests rather than forgotten incidents.

18.4.19 Exercise 18

Exercise Title: Explain Why More Data Beats Better Optimizers at Scale

Part 1 - Why this matters

Optimizer improvements can make training faster or more stable, but an optimizer cannot create missing linguistic evidence. Once a strong baseline optimizer is working well, expanding high-quality, diverse data can improve coverage, reduce repeated memorization, and expose new relationships. The title is a scaling hypothesis, not permission to ignore optimization or collect unlimited low-quality text.

Compare optimizer change and data expansion under matched compute. One axis trains the same data with two competent optimizers; the other trains the same model and optimizer with increasingly diverse token sets. Record training loss, validation loss, unique-token exposure, domain coverage, wall time, and stability. Better optimization may win early while more data improves the final generalization frontier.

Data quantity must distinguish unique information from repeated tokens. Duplicating a corpus increases token presentations without adding evidence. Optimizer tuning must receive a fair search budget; comparing a carefully tuned baseline with an untuned alternative proves little. Use several seeds and report the hyperparameter trials consumed.

At true scale, data availability, compute, and optimizer quality interact. Poor optimization can waste data; excessive data with insufficient compute leaves the model undertrained. The conclusion should identify the regime observed and the point at which data, model capacity, or optimization becomes limiting.

Part 2 - Mathematical form and reasoning

Let validation loss depend on model N, unique data D, and optimizer efficiency e_o:

$$L \approx L_\infty + AN^{-\alpha} + BD^{-\beta} + R(e_o, C),$$

where R represents optimization error under compute budget C. A better optimizer reduces R; more informative data reduces the data-limited term. This is a conceptual decomposition, not an identifiable law from one small experiment.

Part 3 - Hints, controls, and evidence

1. Use two established optimizer configurations and document tuning budget.
2. Compare unique data growth with pure duplication as a control.
3. Match compute, parameter count, tokenizer, and validation set.
4. Plot validation loss against unique tokens and total tokens separately.
5. Track domain coverage and rare-token performance.
6. State the observed regime and avoid extrapolating a tiny experiment to all industrial training.

Part 4 - Python code skeleton

```
def experimental_grid(model_factory, train_function,
                      optimizer_factories, data_variants, seeds):
    records = []
    for optimizer_name in optimizer_factories:
        optimizer_factory = optimizer_factories[optimizer_name]
        for data_name in data_variants:
            data = data_variants[data_name]
            for seed in seeds:
                model = model_factory(seed)
                optimizer = optimizer_factory(model.parameters())
                metrics = train_function(model, optimizer, data, seed)
                record = {}
                record["optimizer"] = optimizer_name
                record["data"] = data_name
                record["seed"] = seed
                record["unique_tokens"] = data["unique_token_count"]
                record["total_tokens"] = data["total_token_count"]
                record["metrics"] = metrics
                records.append(record)
    return records

def E18(model_factory, train_function,
        optimizer_factories, data_variants):
    seeds = [13, 31, 47]
    return experimental_grid(model_factory, train_function,
                             optimizer_factories, data_variants, seeds)
```

Part 5 - The Philosophy Behind the Exercise

Optimization determines how efficiently a learner extracts structure from experience. Data determines what experience exists to be extracted. A more skillful path through the same narrow world cannot substitute indefinitely for seeing a broader world.

The principle favors evidence over cleverness once the learning machinery is competent. Yet accumulation without curation is not wisdom. More data deserves its advantage only when it adds lawful, diverse, and meaningful information rather than multiplying noise.

18.4.20 Exercise 19

Exercise Title: Produce a Pretraining Design Report

Part 1 - Why this matters

The final exercise turns isolated experiments into a pretraining decision document. A design report should allow another team to understand the intended model, data rights, tokenizer, objective, scale, optimization, infrastructure, evaluation, risks, and stop criteria before expensive training begins. It is a commitment to measurable choices, not a retrospective story written after results are known.

Begin with purpose and exclusions. Define users, languages, domains, context, capabilities, and behaviors the base model is not expected to provide before post-training. Describe source provenance, authorization, privacy rules, deduplication, contamination controls, mixture weights, and quality audits. Include corpus versions and checksums.

Specify architecture and token economics: vocabulary, parameter count, context, expected tokens per document, target token budget, precision, FLOP estimate, GPU memory, parallelism, checkpoint frequency, and failure recovery. Define validation suites for loss, rare tokens, domains, memorization, leakage, hallucination, and safety-relevant content. Every release gate needs an owner and rollback action.

The report must include uncertainty and alternatives. State which claims are supported by pilot experiments, which are extrapolations, and what would cause the project to change data mixture, optimizer, model scale, or stop entirely. Include cost and environmental estimates without false precision.

Part 2 - Mathematical form and reasoning

Core budget constraints include

$$C_{\text{train}} \approx 6ND, \qquad M_{\text{train}} \leq M_{\text{available}}, \qquad \sum_d w_d = 1.$$

Define a vector of gates rather than one score:

$$G = (L_{\text{val}}, Q_{\text{domain}}, H_{\text{unsupported}}, R_{\text{rare}}, C_{\text{leak}}, P_{\text{privacy}}, S_{\text{stability}}).$$

Deployment or continuation is permitted only when every blocking component meets its declared threshold. Tradeoffs must be reviewed rather than hidden in an average.

Part 3 - Hints, controls, and evidence

1. Give every dataset, configuration, checkpoint, and evaluation suite a versioned identifier.
2. Include pilot scaling results and confidence ranges used for budget decisions.
3. List known exclusions and underrepresented groups explicitly.
4. Define automatic stop conditions for NaNs, loss spikes, privacy findings, or contamination.
5. Assign owners for data, model, infrastructure, evaluation, safety, and incident response.
6. End with a decision table comparing at least two feasible designs and the evidence for the selected one.

Part 4 - Python code skeleton

```
class PretrainingDesign:
    def __init__(self, design_id):
        self.design_id = design_id
        self.sections = {}
        self.gates = []

    def add_section(self, name, content):
        self.sections[name] = content

    def add_gate(self, gate_id, metric, threshold,
                 comparison, owner, rollback_action):
        gate = {}
        gate["gate_id"] = gate_id
        gate["metric"] = metric
        gate["threshold"] = threshold
        gate["comparison"] = comparison
        gate["owner"] = owner
        gate["rollback_action"] = rollback_action
        self.gates.append(gate)

    def missing_sections(self, required_sections):
        missing = []
        for section in required_sections:
            if section not in self.sections:
                missing.append(section)
        return missing

def E19():
    report = PretrainingDesign("LLM-PRETRAIN-V1")
    required = ["purpose", "data", "tokenizer", "architecture",
                "optimization", "compute", "evaluation",
                "risk", "recovery"]
    report.add_section("purpose", ...)
    report.add_section("data", ...)
    report.add_gate(...)
    missing = report.missing_sections(required)
    return report, missing
```

Part 5 - The Philosophy Behind the Exercise

A design report makes the future model answerable to decisions made before it exists. It records which evidence will shape it, which resources will be spent, which failures matter, and who has authority to stop the process.

Pretraining is often described as optimization at scale, but it is also the construction of a statistical inheritance. The report is where technical ambition meets stewardship. A well-designed model begins with a traceable reason for every major choice and a plan for what to do when reality disagrees.

18.5 LLM03

Chapter Title: Instruction Tuning & Fine-Tuning
Specialization: Post-Training and Behavioral Adaptation Engineering

18.5.1 Exercise 00

Exercise Title: Explain Instruction Tuning and Why It Changes Behavior Without Changing Architecture

Part 1 - Deep conceptual foundation

Pretraining teaches a decoder-only language model to estimate what text is likely to follow a prefix. Instruction tuning keeps that same causal language model, but changes the distribution of examples from arbitrary continuation to structured interactions: an instruction, optional context, and a desirable response. The architecture can remain completely unchanged. What changes is the conditional behavior that receives repeated probability mass during optimization.

This distinction is central. A pretrained model may know the information needed to answer a question yet continue the prompt as if it were a web page, imitate several speakers, or produce an unrelated completion. Supervised instruction fine-tuning presents many examples in which an instruction is followed by a direct, relevant response. Gradient descent then increases the likelihood of response patterns conditioned on instruction-like prefixes. The model is not given a new reasoning module or a new attention mechanism; existing parameters are reorganized toward a different behavioral mode.

Instruction tuning must therefore be separated from architecture, knowledge, and alignment. It can expose capabilities already latent in the base model, teach output conventions, and add some domain information. It does not prove that every response is truthful, safe, or grounded. A polished instruction format can make an incorrect answer more persuasive. The experiment must measure content correctness separately from format compliance.

In this exercise you will freeze a copy of a base model, fine-tune another copy on controlled instruction-response pairs, and compare both on familiar and paraphrased prompts. You will also inspect parameter names and tensor shapes before and after training to prove that the computational graph is unchanged while parameter values and output distributions move.

Part 2 - Mathematical model and reasoning

Let p_{θ_0} be the pretrained policy and let $D_{\mathrm{SFT}} = \{(x_i, y_i)\}_{i=1}^{N}$ contain instructions x_i and desired responses y_i. Instruction tuning solves

$$\theta^* = \arg\min_{\theta} - \sum_{i=1}^{N} \sum_{t=1}^{|y_i|} \log p_\theta(y_{i,t} \mid x_i, y_{i,<t}).$$

The architecture function f is unchanged:

$$z = f(x; \theta_0) \quad \longrightarrow \quad z' = f(x; \theta^*),$$

but the conditional distribution changes. A useful behavioral movement measure is the response-token log-probability gain

$$\Delta_i = \frac{1}{|y_i|} \sum_{t} \left[\log p_{\theta^*}(y_{i,t} \mid x_i, y_{i,<t}) - \log p_{\theta_0}(y_{i,t} \mid x_i, y_{i,<t}) \right].$$

Positive Δ_i shows that the desired response became more probable; it does not by itself establish correctness on unseen instructions.

Part 3 - Experiment, controls, and evidence

1. Record the model class, layer count, hidden size, parameter names, and parameter shapes before tuning.
2. Construct examples for direct answers and text transformations. Add classification and refusal cases so behavior is not tied to one template.
3. Save generations and target log-probabilities from the untouched base checkpoint.
4. Fine-tune a cloned checkpoint while keeping tokenizer and architecture fixed.
5. Compare exact prompts, paraphrases, unrelated base-language prompts, and deliberately ambiguous requests.
6. Report format compliance, semantic correctness, calibration, and retained base capability as separate metrics.
7. Prove architecture identity by comparing every parameter name and shape; then prove behavioral change by comparing logits and decoded responses.

Part 4 - Explicit PyTorch implementation

```
import copy
import torch

def describe_architecture(model):
    description = []
    for parameter_name, parameter in model.named_parameters():
        item = {}
        item["name"] = parameter_name
        item["shape"] = tuple(parameter.shape)
        description.append(item)
    return description

def mean_target_log_probability(model, input_ids, labels):
    logits = model(input_ids).logits
    log_probabilities = torch.log_softmax(logits[:, :-1, :], dim=-1)
    target_ids = labels[:, 1:]
    valid_mask = target_ids != -100
    safe_targets = target_ids.clone()
    safe_targets[~valid_mask] = 0
    selected = log_probabilities.gather(
        dim=-1, index=safe_targets.unsqueeze(-1)
    ).squeeze(-1)
    return selected.masked_select(valid_mask).mean()
```

```
def E00(base_model, training_batch, learning_rate):
    tuned_model = copy.deepcopy(base_model)
    before = describe_architecture(base_model)
    after = describe_architecture(tuned_model)
    assert before == after

    input_ids = training_batch["input_ids"]
    labels = training_batch["labels"]
    with torch.no_grad():
        base_score = mean_target_log_probability(
            base_model, input_ids, labels
        )

    optimizer = torch.optim.AdamW(
        tuned_model.parameters(), lr=learning_rate
    )
    optimizer.zero_grad(set_to_none=True)
    tuned_score = mean_target_log_probability(
        tuned_model, input_ids, labels
    )
    loss = -tuned_score
    loss.backward()
    optimizer.step()

    with torch.no_grad():
        new_score = mean_target_log_probability(
            tuned_model, input_ids, labels
        )
    return base_score, new_score, tuned_model
```

Part 5 - The Philosophy Behind the Exercise

Instruction tuning demonstrates that behavior is not identical to structure. The same network can act like an autocomplete engine, an assistant, a classifier, or a formatter depending on which conditional patterns its weights have been trained to prefer. This makes post-training powerful because a new behavioral interface need not require rebuilding the model from zero.

It also creates a moral and scientific obligation: fluent obedience must not be confused with truth or understanding. The exercise teaches us to ask not only whether the model follows a request, but what evidence shaped that obedience, which capabilities were displaced, and whether the new confidence is deserved.

18.5.2 Exercise 01

Exercise Title: Build Supervised Instruction Dataset and Validate Prompt-Response Alignment

Part 1 - Deep conceptual foundation

An instruction dataset is not merely a collection of text pairs. It is a behavioral specification encoded as token sequences. Roles, separators, end-of-response markers, system constraints,

context blocks, and assistant boundaries jointly determine what conditional task the model sees. If these elements are inconsistent, the model must spend capacity learning formatting accidents instead of the intended instruction-response relation.

The critical invariant is alignment. Every supervised response token must occupy the position predicted by the preceding token, while instruction and padding tokens must follow the chosen loss policy. A dataset can decode into plausible text and still be wrong by one position. It can also leak the response into the prompt, truncate away the end marker, or reuse the padding identifier as an ordinary token. These failures often lower training loss, making them dangerous rather than obvious.

Build a typed record with stable identifiers, source provenance, task family, instruction, optional context, response, template version, and quality status. Keep raw records separate from rendered examples so a future template change does not silently rewrite dataset identity. Validation must happen at the text level, token level, and batch level. Store rejected records with reasons rather than deleting evidence of preprocessing decisions.

The exercise will create a collator without compact programming shortcuts. It will render records, tokenize them, locate the response boundary, truncate under an explicit policy, pad the batch, and return both labels and metadata. Finally, it will decode several rows and print a token-by-token supervision map for human inspection.

Part 2 - Formal data contract

For record r_i, define a deterministic renderer g_v for template version v:

$$s_i = g_v(r_i) = p_i \| y_i \| e,$$

where p_i is the rendered prompt, y_i the response, and e the end token. If a_i is the first response-token index, labels satisfy

$$\ell_{i,t} = \begin{cases} -100, & t < a_i \text{ or position is padding}, \\ x_{i,t}, & t \geq a_i. \end{cases}$$

The sequence must preserve $a_i < T_i$, contain at least one supervised token, and terminate under the declared truncation rule.

Part 3 - Validation protocol

1. Reject empty instructions, empty responses, unknown roles, duplicate record identifiers, and invalid Unicode according to a documented policy.

2. Render with one versioned template and never search for a response string inside the full text; repeated text makes string matching ambiguous.

3. Tokenize prompt and response separately to obtain an authoritative boundary, then verify their concatenation under the tokenizer contract.

4. Prefer truncating optional context or prompt history before truncating the answer; log every truncated record.

5. Decode input identifiers, supervised labels, and the boundary token for a sample from every task family.

6. Test maximum length, one-token response, missing context, embedded role markers, and non-English text.

Part 4 - Explicit Python dataset builder

```
import torch

def validate_record(record):
    required = ["record_id", "instruction", "response", "task"]
    for field_name in required:
        if field_name not in record:
            raise ValueError("missing field: " + field_name)
    if len(record["instruction"].strip()) == 0:
        raise ValueError("instruction is empty")
    if len(record["response"].strip()) == 0:
        raise ValueError("response is empty")

def render_record(record):
    prompt = "<system>You are precise.</system>\n"
    prompt = prompt + "<user>" + record["instruction"]
    if "context" in record and len(record["context"]) > 0:
        prompt = prompt + "\n<context>" + record["context"] + "</context>"
    prompt = prompt + "</user>\n<assistant>"
    response = record["response"] + "</assistant>"
    return prompt, response

def encode_record(tokenizer, record, maximum_length):
    validate_record(record)
    prompt, response = render_record(record)
    prompt_ids = tokenizer.encode(prompt, add_special_tokens=False)
    response_ids = tokenizer.encode(response, add_special_tokens=False)
    if len(response_ids) == 0:
        raise ValueError("response produced no tokens")
    allowed_prompt = maximum_length - len(response_ids)
    if allowed_prompt < 1:
        raise ValueError("response does not fit maximum length")
    if len(prompt_ids) > allowed_prompt:
        prompt_ids = prompt_ids[-allowed_prompt:]
    input_ids = prompt_ids + response_ids
    labels = []
    position = 0
    while position < len(prompt_ids):
        labels.append(-100)
        position = position + 1
    position = 0
    while position < len(response_ids):
        labels.append(response_ids[position])
        position = position + 1
    return input_ids, labels, len(prompt_ids)

def E01(tokenizer, records, maximum_length, padding_id):
    encoded = []
```

```
    maximum_batch_length = 0
    seen_ids = set()
    for record in records:
        if record["record_id"] in seen_ids:
            raise ValueError("duplicate record identifier")
        seen_ids.add(record["record_id"])
        item = encode_record(tokenizer, record, maximum_length)
        encoded.append(item)
        if len(item[0]) > maximum_batch_length:
            maximum_batch_length = len(item[0])

    batch_inputs = []
    batch_labels = []
    for input_ids, labels, boundary in encoded:
        while len(input_ids) < maximum_batch_length:
            input_ids.append(padding_id)
            labels.append(-100)
        batch_inputs.append(input_ids)
        batch_labels.append(labels)
        assert labels[boundary] != -100
    return torch.tensor(batch_inputs), torch.tensor(batch_labels)
```

Part 5 - The Philosophy Behind the Exercise

A training example is a small constitution for model behavior. Formatting decides who is speaking, masking decides whose words are judged, and truncation decides which evidence survives. These are not neutral preprocessing details; they are assumptions translated into gradients.

The deeper lesson is traceability. If a model learns an undesirable response, we should be able to travel backward from output to checkpoint, batch, rendered sequence, raw record, and source decision. High-quality datasets preserve this chain of accountability instead of presenting text as anonymous fuel.

18.5.3 Exercise 02

Exercise Title: Implement SFT Loss with Causal Masking and Verify Correct Token-Level Supervision

Part 1 - Deep conceptual foundation

Supervised fine-tuning normally uses the same next-token cross entropy as pretraining, but only selected positions are allowed to contribute. The causal attention mask controls what each hidden state can read; the label mask controls which predictions are scored. Confusing these two masks is a fundamental error. A causal mask prevents future-token leakage, while a response-only label mask prevents prompt tokens from dominating the optimization target.

Assume the input sequence contains system text, user instruction, assistant response, and padding. At position t, the logit predicts token $t + 1$. Therefore the labels must be shifted consistently with logits. If labels are masked before the shift without checking the boundary, the first assistant token may be lost or the last prompt token may be trained as an answer. The

only safe method is to write the tensor shapes and inspect the boundary by token identifier and decoded text.

Response-only supervision is common but not universally optimal. Supervising the full conversation can help a model reproduce a serialization format, while response-only loss concentrates gradients on assistant behavior. The selected policy must be explicit. For multi-turn dialogue, assistant regions may appear more than once, so a single boundary index is insufficient; use a token-level role mask.

This exercise implements loss without relying on a model-provided loss field. You will compare it against a manual log-softmax calculation, test invariant behavior when padding is added, and verify that changing an ignored prompt label cannot alter the loss.

Part 2 - Mathematical form and invariants

For logits $z \in \mathbb{R}^{B\times(T-1)\times V}$, shifted targets y, and supervision mask m,

$$L_{\text{SFT}} = -\frac{1}{\sum_{b,t} m_{b,t}} \sum_{b,t} m_{b,t} \log \frac{\exp z_{b,t,y_{b,t}}}{\sum_{v=1}^{V} \exp z_{b,t,v}}.$$

Three required invariants are

$$\sum m > 0, \qquad y_{b,t} \in [0, V-1] \text{ when } m_{b,t} = 1, \qquad L(x\|\text{pad}) = L(x).$$

The last equality holds when added padding positions are properly masked and the model's valid logits are unchanged.

Part 3 - Verification protocol

1. Print the last two prompt tokens, first two response tokens, associated labels, and supervision flags.
2. Compare vectorized cross entropy with a manual loop on a tiny batch.
3. Change every ignored label to a different valid identifier and prove the masked loss is unchanged.
4. Append padding and confirm both numerator and valid-token denominator remain unchanged.
5. Create an all-ignored batch and require an immediate descriptive error.
6. Run backward and check every trainable gradient for finite values; also record the number of supervised tokens per batch.

Part 4 - Explicit PyTorch implementation

```
import torch
import torch.nn.functional as F

def prepare_shifted_tensors(logits, labels):
    prediction_logits = logits[:, :-1, :].contiguous()
    next_token_labels = labels[:, 1:].contiguous()
    if prediction_logits.shape[:2] != next_token_labels.shape:
```

```
        raise ValueError("logit and label positions are misaligned")
    return prediction_logits, next_token_labels

def response_only_sft_loss(logits, labels):
    prediction_logits, next_token_labels = prepare_shifted_tensors(
        logits, labels
    )
    valid_mask = next_token_labels != -100
    valid_count = int(valid_mask.sum().item())
    if valid_count == 0:
        raise ValueError("batch contains no supervised response token")
    vocabulary_size = prediction_logits.shape[-1]
    flat_logits = prediction_logits.reshape(-1, vocabulary_size)
    flat_labels = next_token_labels.reshape(-1)
    flat_losses = F.cross_entropy(
        flat_logits, flat_labels, ignore_index=-100, reduction="none"
    )
    token_losses = flat_losses.view_as(next_token_labels)
    loss_sum = token_losses.masked_select(valid_mask).sum()
    loss_mean = loss_sum / valid_count
    return loss_mean, loss_sum.detach(), valid_count, token_losses

def E02(model, input_ids, labels):
    output = model(input_ids=input_ids, use_cache=False)
    loss, loss_sum, valid_count, token_losses = response_only_sft_loss(
        output.logits, labels
    )
    loss.backward()
    for parameter_name, parameter in model.named_parameters():
        if parameter.requires_grad and parameter.grad is not None:
            if not torch.isfinite(parameter.grad).all():
                raise RuntimeError("non-finite gradient: " + parameter_name)
    return loss.detach(), loss_sum, valid_count, token_losses.detach()
```

Part 5 - The Philosophy Behind the Exercise

The loss mask is the boundary between context and judgment. The prompt may explain the task and influence every response state, yet a response-only mask says that the model is evaluated for what it answers, not for recreating the user's words. This is a precise statement about responsibility inside the training sequence.

Once this perspective is understood, masking stops being a technical nuisance. It becomes the mechanism by which designers decide which tokens deserve learning pressure. A silent off-by-one error is therefore not merely a bug; it changes the behavior the training process is authorized to produce.

18.5.4 Exercise 03

Exercise Title: Fine-Tune a Tiny LLM on Instructions and Compare Behavior Before vs After

Part 1 - Deep conceptual foundation

A successful fine-tuning demonstration needs more evidence than a falling training loss. The model must produce measurably better instruction-conditioned behavior on held-out examples, and the comparison must use the same tokenizer, decoding configuration, prompts, random seeds, and evaluation functions. Without these controls, a sampling difference can be mistaken for a learning effect.

The most informative small experiment begins with a tiny model and a synthetic task whose correct outputs are unambiguous. Include several operations such as copying, reversing, extracting a field, and returning a class label. Split by underlying content, not by rendered string, so template paraphrases cannot leak the answer. Record base-model outputs before any optimizer step, then train until the model can deliberately overfit the training subset. Overfitting here is a diagnostic: it proves the data, loss, gradients, and decoding path can work.

Evaluation should expose the difference between memorization and rule learning. Use four partitions: training examples, held-out inputs under the familiar template, paraphrased instructions, and unrelated language-modeling sequences. Improvement limited to the first partition indicates memorization. Improvement on held-out inputs but collapse on unrelated text indicates specialization with forgetting. Both observations are more useful than one average score.

You will save an immutable baseline artifact containing prompts, generations, token log-probabilities, and configuration. After training, rerun exactly the same evaluator. The report must show paired examples and aggregate metrics, including failures, rather than presenting only the best generations.

Part 2 - Experimental quantities

Let a_0 and a_1 be instruction accuracy before and after tuning, and b_0, b_1 be retained base-task scores. Define

$$\Delta_{\text{instruction}} = a_1 - a_0, \qquad \Delta_{\text{retention}} = b_1 - b_0.$$

The tuning result is not fully described by maximizing the first value. A simple constrained decision rule is

$$\max \Delta_{\text{instruction}} \quad \text{subject to} \quad \Delta_{\text{retention}} \geq -\epsilon.$$

Report confidence intervals across examples or seeds when the evaluation set is small.

Part 3 - Controlled experiment design

1. Clone the initial state dictionary and hash it before training.
2. Fix greedy decoding for deterministic before/after examples; evaluate sampling separately.
3. Log train and validation token loss, exact task accuracy, response format accuracy, and retained base loss at each evaluation interval.
4. Save the first checkpoint that passes the validation criterion rather than automatically choosing the final epoch.
5. Inspect at least ten paired failures and classify them as formatting, instruction misunderstanding, incorrect content, truncation, or decoding.

6. Repeat with multiple seeds to distinguish a reliable tuning effect from a lucky initialization or batch order.

Part 4 - Explicit PyTorch training experiment

```
import copy
import torch

def train_one_epoch(model, data_loader, optimizer, device):
    model.train()
    total_loss_sum = 0.0
    total_tokens = 0
    for batch in data_loader:
        input_ids = batch["input_ids"].to(device)
        labels = batch["labels"].to(device)
        optimizer.zero_grad(set_to_none=True)
        logits = model(input_ids=input_ids, use_cache=False).logits
        loss, loss_sum, valid_count, unused = response_only_sft_loss(
            logits, labels
        )
        loss.backward()
        torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)
        optimizer.step()
        total_loss_sum = total_loss_sum + float(loss_sum.item())
        total_tokens = total_tokens + valid_count
    return total_loss_sum / total_tokens

def evaluate_loss(model, data_loader, device):
    model.eval()
    total_loss_sum = 0.0
    total_tokens = 0
    with torch.no_grad():
        for batch in data_loader:
            input_ids = batch["input_ids"].to(device)
            labels = batch["labels"].to(device)
            logits = model(input_ids=input_ids, use_cache=False).logits
            loss, loss_sum, valid_count, unused = response_only_sft_loss(
                logits, labels
            )
            total_loss_sum = total_loss_sum + float(loss_sum.item())
            total_tokens = total_tokens + valid_count
    return total_loss_sum / total_tokens

def E03(base_model, train_loader, validation_loader,
        device, epochs, learning_rate):
    tuned_model = copy.deepcopy(base_model).to(device)
    optimizer = torch.optim.AdamW(
        tuned_model.parameters(), lr=learning_rate
```

```
    )
    history = []
    for epoch_index in range(epochs):
        train_loss = train_one_epoch(
            tuned_model, train_loader, optimizer, device
        )
        validation_loss = evaluate_loss(
            tuned_model, validation_loader, device
        )
        record = {}
        record["epoch"] = epoch_index
        record["train_loss"] = train_loss
        record["validation_loss"] = validation_loss
        history.append(record)
    return tuned_model, history
```

Part 5 - The Philosophy Behind the Exercise

Before-and-after evaluation turns fine-tuning from a story into a causal claim. The untouched checkpoint represents what would have happened without the intervention; the tuned checkpoint represents the new behavior. Fair controls allow the difference to be attributed to training rather than presentation.

The experiment also teaches humility. A model can become dramatically better at the measured task while becoming narrower elsewhere. Progress is a vector, not a single number, and responsible fine-tuning records both the ability gained and the flexibility spent to obtain it.

18.5.5 Exercise 04

Exercise Title: Analyze Overfitting Risk in Instruction Tuning with Small Datasets

Part 1 - Deep conceptual foundation

Small instruction datasets can change behavior quickly because every example is revisited many times. This makes them useful for controlled adaptation but also creates three forms of overfitting. Content overfitting memorizes particular answers. Template overfitting learns superficial role markers and wording. Behavioral overfitting applies the tuned style too broadly, even when the task requires a different response mode.

Training loss alone cannot separate these outcomes. A model may achieve almost zero loss by reproducing seen responses while failing on new values, paraphrased instructions, longer inputs, or a different order of fields. It may also lose general capabilities because repeated gradients from a narrow distribution move weights away from the pretrained solution. The experiment must therefore include a generalization grid, not one validation set drawn from the same template generator.

Construct training-size conditions such as 16, 64, 256, and 1024 examples. Hold optimizer steps or processed tokens constant when asking about dataset size; otherwise the smallest set receives more repetitions and the comparison mixes two causes. Evaluate checkpoints throughout training because the best generalization can occur before the minimum training loss.

The strongest evidence includes learning curves, train-validation gaps, exact duplicate checks, paraphrase performance, retained base loss, and output diversity. Measure variation across random seeds. A result that appears only under one seed is not a reliable property of the tuning recipe.

Part 2 - Mathematical diagnosis

For training risk $\widehat{R}_{\text{train}}$ and evaluation risk $\widehat{R}_{\text{eval}}$, define the observed gap

$$G = \widehat{R}_{\text{eval}} - \widehat{R}_{\text{train}}.$$

For an accuracy metric the sign is reversed, so always state the convention. To measure forgetting relative to the base model,

$$F = R_{\text{base-task}}(\theta^*) - R_{\text{base-task}}(\theta_0).$$

An early-stop score can combine distinct gates without hiding them:

$$S = A_{\text{heldout}} - \lambda F, \quad \text{subject to} \quad A_{\text{paraphrase}} \geq \tau.$$

Keep the component metrics visible even if a scalar is used for selection.

Part 3 - Experiment and failure analysis

1. Deduplicate before splitting and group variants of the same semantic task into one split.
2. Create evaluations for seen templates, unseen templates, unseen values, longer sequences, adversarial wording, and retained base behavior.
3. Match processed response tokens across dataset-size conditions.
4. Save checkpoints at frequent intervals and select using validation data, not the test set.
5. Plot training loss against every generalization metric to expose the point where further fitting begins to hurt.
6. Compare dropout, weight decay, fewer epochs, mixed-domain replay, and lower-capacity adapters as separate interventions.
7. Report means and dispersion across at least three seeds.

Part 4 - Explicit overfitting monitor

```
class FineTuningMonitor:
    def __init__(self):
        self.records = []

    def add(self, step, train_loss, validation_loss,
            paraphrase_accuracy, base_loss):
        record = {}
        record["step"] = step
        record["train_loss"] = train_loss
        record["validation_loss"] = validation_loss
```

```
        record["gap"] = validation_loss - train_loss
        record["paraphrase_accuracy"] = paraphrase_accuracy
        record["base_loss"] = base_loss
        self.records.append(record)

    def best_record(self, maximum_base_loss_increase, initial_base_loss):
        best = None
        for record in self.records:
            increase = record["base_loss"] - initial_base_loss
            if increase <= maximum_base_loss_increase:
                if best is None:
                    best = record
                else:
                    current_score = record["paraphrase_accuracy"]
                    best_score = best["paraphrase_accuracy"]
                    if current_score > best_score:
                        best = record
        return best

def E04(training_function, evaluation_function, conditions):
    results = []
    for condition in conditions:
        model, checkpoints = training_function(condition)
        condition_result = {}
        condition_result["condition"] = condition
        condition_result["checkpoints"] = []
        for checkpoint in checkpoints:
            metrics = evaluation_function(checkpoint)
            condition_result["checkpoints"].append(metrics)
        results.append(condition_result)
    return results
```

Part 5 - The Philosophy Behind the Exercise

Overfitting is not simply learning too much; it is learning the accidental surface of limited evidence more strongly than the transferable structure beneath it. Instruction data is especially vulnerable because repeated wording can make style look like capability.

The philosophical discipline is to reward transfer, not familiarity. A model should earn our confidence by succeeding when names, values, phrasing, and contexts change. The gap between recognition and generalization is where a fine-tuning experiment becomes scientific.

18.5.6 Exercise 05

Exercise Title: Implement Prompt Templates and Measure Sensitivity to Wording Changes

Part 1 - Deep conceptual foundation

Prompt templates serialize an abstract interaction into tokens. Phrases such as “Instruction”, XML-style role tags, chat special tokens, whitespace, and response prefixes are not invisible wrappers. They become part of the model’s conditioning context and can acquire

strong statistical associations during fine-tuning. A model trained on one rigid template may perform well only when the deployment request resembles that surface form.

Sensitivity must be measured by preserving semantic intent while changing presentation. Create paraphrases, reorder harmless fields, vary politeness, change separators, remove redundant instructions, and introduce irrelevant but benign context. Do not call arbitrary string corruption robustness: a malformed prompt can genuinely change meaning. Each variant needs a declared semantic equivalence judgment.

Templates must be versioned and shared between training and inference. A missing assistant prefix or different end marker can cause large behavioral changes even when the user text is identical. The tokenizer also matters: visually small whitespace changes may alter multiple subword boundaries. Store rendered token identifiers in diagnostic logs so the investigation can move beyond string appearance.

This exercise builds a renderer registry and an invariance evaluation. Each underlying example is rendered through multiple valid templates. The model is scored on content, format, refusal behavior, response length, and log probability. The unit of analysis is the semantic example, allowing variance across templates to be measured within the same task.

Part 2 - Sensitivity measures

For semantic item i and templates $k = 1, \ldots, K$, let $a_{i,k}$ be content accuracy. Define item sensitivity

$$S_i = \max_k a_{i,k} - \min_k a_{i,k},$$

and log-probability dispersion

$$V_i = \frac{1}{K} \sum_k \left(\ell_{i,k} - \bar{\ell}_i \right)^2 .$$

For binary accuracy, also report the fraction of items whose prediction changes under at least one semantics-preserving variant. Low average sensitivity is not enough if failures cluster in a critical task family.

Part 3 - Robustness protocol

1. Define a canonical structured record before rendering any string.
2. Implement at least four template families and give each an immutable version identifier.
3. Verify that every renderer preserves instruction, context, and expected response semantics.
4. Tokenize each variant and record token count, boundary index, and special tokens.
5. Evaluate paired variants with deterministic decoding and a content-aware grader.
6. Fine-tune once on one template and once on template mixtures under equal token budgets.
7. Identify whether robustness gains come from diverse wording or simply more examples.

Part 4 - Explicit template and evaluation code

```
def render_plain(record):
    text = "Instruction:\n" + record["instruction"]
    text = text + "\nResponse:\n"
    return text

def render_chat(record):
    text = "<user>" + record["instruction"] + "</user>\n"
    text = text + "<assistant>"
    return text

def render_question(record):
    text = "Please complete the following task.\n"
    text = text + record["instruction"] + "\nAnswer:"
    return text

def build_renderers():
    renderers = {}
    renderers["plain_v1"] = render_plain
    renderers["chat_v1"] = render_chat
    renderers["question_v1"] = render_question
    return renderers

def evaluate_prompt_sensitivity(records, generate, score):
    renderers = build_renderers()
    results = []
    for record in records:
        item = {}
        item["record_id"] = record["record_id"]
        item["variants"] = []
        for template_name in renderers:
            prompt = renderers[template_name](record)
            response = generate(prompt)
            metric = score(response, record["expected"])
            variant = {}
            variant["template"] = template_name
            variant["prompt"] = prompt
            variant["response"] = response
            variant["score"] = metric
            item["variants"].append(variant)
        results.append(item)
    return results

def E05(records, generate, score):
    return evaluate_prompt_sensitivity(records, generate, score)
```

Part 5 - The Philosophy Behind the Exercise

Language allows the same intention to wear many forms. A model that understands only the familiar costume has learned a password, not an instruction. Prompt robustness therefore

tests whether behavior is attached to meaning or to a particular ritual of words.

At the same time, complete invariance is neither possible nor desirable because wording can genuinely change meaning. The goal is disciplined sensitivity: stable under irrelevant variation, responsive to meaningful distinctions, and honest about uncertainty when the distinction is ambiguous.

18.5.7 Exercise 06

Exercise Title: Compare Multi-Task vs Single-Task Instruction Tuning

Part 1 - Deep conceptual foundation

Single-task tuning concentrates every update on one behavior. It can reach high accuracy rapidly, but its gradients may specialize the shared representation so strongly that other capabilities deteriorate. Multi-task instruction tuning mixes task families and can encourage reusable instruction-following patterns, yet poorly chosen mixtures allow large or easy tasks to dominate.

A fair comparison cannot use the same number of epochs because an epoch has a different token count for different mixtures. Match total supervised tokens, optimizer steps, model initialization, and evaluation schedule. Decide whether sampling weights operate at record level, sequence level, or response-token level. Long-response tasks receive greater influence under token-mean loss even if records are sampled equally.

Positive transfer occurs when adding other tasks improves a target task. Negative transfer occurs when competing gradients hurt it. Average accuracy can hide both: improvements on common easy tasks may outweigh severe degradation on a rare critical task. Measure each task, macro average, worst-task score, and retained base capability. Inspect per-task gradient similarity on selected batches to understand interaction rather than merely observing it.

The exercise compares a specialist, a uniform multi-task model, and a balanced mixture model. The balanced strategy may use temperature sampling or explicit task quotas. The conclusion must state which deployment goal is being optimized: peak specialist quality, broad competence, robustness to new task wording, or cost-efficient shared serving.

Part 2 - Mixture and gradient reasoning

For task distributions D_k and weights w_k,

$$L(\theta) = \sum_{k=1}^{K} w_k L_k(\theta), \qquad w_k \geq 0, \quad \sum_k w_k = 1.$$

If raw dataset sizes are n_k, temperature sampling can use

$$w_k = \frac{n_k^\alpha}{\sum_j n_j^\alpha},$$

where $\alpha = 1$ follows data frequency and $\alpha = 0$ samples tasks uniformly. For gradients g_i and g_j, cosine similarity

$$c_{ij} = \frac{g_i^\top g_j}{\|g_i\|\|g_j\|}$$

is diagnostic evidence of local agreement or conflict, not a permanent property of the tasks.

Part 3 - Matched comparison

1. Create at least four task families with independent train, validation, and test content.
2. Train single-task baselines and multi-task models from the same initial checkpoint.
3. Match supervised response-token count and optimization schedule.
4. Report per-task accuracy, macro average, worst-task score, template robustness, and retained base loss.
5. Record realized sampling proportions instead of trusting configured weights.
6. Inspect gradient cosine similarity on fixed probe batches at several training steps.
7. Vary α and explain which tasks gain or lose as the mixture changes.

Part 4 - Explicit task sampler

```
import math
import random

class TemperatureTaskSampler:
    def __init__(self, task_records, alpha, seed):
        self.task_records = task_records
        self.random = random.Random(seed)
        self.task_names = []
        raw_weights = []
        for task_name in task_records:
            self.task_names.append(task_name)
            count = len(task_records[task_name])
            raw_weights.append(math.pow(count, alpha))
        total = sum(raw_weights)
        self.weights = []
        for raw_weight in raw_weights:
            self.weights.append(raw_weight / total)

    def sample_task(self):
        value = self.random.random()
        cumulative = 0.0
        index = 0
        while index < len(self.task_names):
            cumulative = cumulative + self.weights[index]
            if value <= cumulative:
                return self.task_names[index]
            index = index + 1
        return self.task_names[-1]

    def sample_record(self):
        task_name = self.sample_task()
        records = self.task_records[task_name]
        record_index = self.random.randrange(len(records))
```

```
        return task_name, records[record_index]

def E06(task_records, alpha, seed, number_of_samples):
    sampler = TemperatureTaskSampler(task_records, alpha, seed)
    realized_counts = {}
    samples = []
    for sample_index in range(number_of_samples):
        task_name, record = sampler.sample_record()
        samples.append(record)
        if task_name not in realized_counts:
            realized_counts[task_name] = 0
        realized_counts[task_name] = realized_counts[task_name] + 1
    return samples, realized_counts
```

Part 5 - The Philosophy Behind the Exercise

Multi-task training asks whether competence can be shared. When tasks reinforce one another, the model learns abstractions broader than any single dataset. When they conflict, the final behavior reflects a negotiated balance imposed by sampling weights and gradients.

There is no neutral mixture. Giving a task more probability is giving its errors more authority over the model. The engineering responsibility is to make that allocation explicit and evaluate the weakest important capability, not merely celebrate a rising average.

18.5.8 Exercise 07

Exercise Title: Implement LoRA Conceptually and Explain Parameter-Efficiency Benefits

Part 1 - Deep conceptual foundation

Full fine-tuning stores gradients and optimizer state for every trainable base parameter. Low-Rank Adaptation, or LoRA, freezes a selected weight matrix W and learns an additive update represented by two much smaller matrices. Instead of assuming the task-specific update needs all $d_{\text{out}}d_{\text{in}}$ degrees of freedom, LoRA constrains it to a rank-r subspace.

This is a hypothesis about adaptation geometry, not a magical compression of the entire training process. It substantially reduces trainable parameters and optimizer state, but activations from the base network still consume memory and must participate in backward computation so gradients reach the adapters. Sequence length, batch size, and checkpointing therefore remain important.

The frozen layer computes $xW^\top$. The adapter adds a down projection from d_{in} to r, followed by an up projection to d_{out}. Initialize the up projection to zero so the wrapped layer begins exactly equal to the base layer; initialize the down projection with a small random distribution so both factors can eventually learn. If both factors start at zero, their gradients can remain trapped.

You will implement the wrapper explicitly, freeze base parameters, verify exact initial parity, count trainable parameters, run backward, and prove that only adapter matrices receive gradients. Then merge the update into a copied base weight and verify output parity for deployment.

Part 2 - Low-rank parameterization

For $W \in \mathbb{R}^{d_o \times d_i}$,

$$W' = W + \Delta W, \qquad \Delta W = \frac{\alpha}{r} BA,$$

where $A \in \mathbb{R}^{r \times d_i}$ and $B \in \mathbb{R}^{d_o \times r}$. The adapter parameter count is

$$P_{\text{LoRA}} = r(d_i + d_o),$$

compared with $P_{\text{full}} = d_i d_o$. The ratio predicts parameter-state savings, not total runtime-memory savings. Rank bounds the update: $\text{rank}(BA) \leq r$.

Part 3 - Required proofs and experiments

1. Wrap one linear layer and assert bitwise or tight numerical parity before training because $B = 0$.
2. Print every parameter with its shape, trainable status, and gradient presence after backward.
3. Compare theoretical and measured trainable parameter counts.
4. Test several ranks under matched optimization tokens. Report quality against adapter size for ranks 1, 4, 8, and 16.
5. Apply LoRA separately to attention projections and feed-forward layers to measure placement sensitivity.
6. Merge BA into a copied weight, disable the adapter path, and verify inference parity.
7. State whether biases and normalization parameters are frozen or trained.

Part 4 - LoRA implemented from first principles

```
import math
import torch
import torch.nn as nn
import torch.nn.functional as F

class LoRALinear(nn.Module):
    def __init__(self, base_layer, rank, alpha):
        super().__init__()
        if rank <= 0:
            raise ValueError("rank must be positive")
        self.base_layer = base_layer
        self.rank = rank
        self.alpha = alpha
        for parameter in self.base_layer.parameters():
            parameter.requires_grad = False
        input_size = base_layer.in_features
        output_size = base_layer.out_features
        self.adapter_down = nn.Parameter(
            torch.empty(rank, input_size)
```

```
        )
        self.adapter_up = nn.Parameter(
            torch.zeros(output_size, rank)
        )
        nn.init.kaiming_uniform_(self.adapter_down, a=math.sqrt(5.0))

    def forward(self, inputs):
        base_output = self.base_layer(inputs)
        hidden = F.linear(inputs, self.adapter_down)
        update = F.linear(hidden, self.adapter_up)
        scale = self.alpha / self.rank
        return base_output + scale * update

    def merged_weight(self):
        scale = self.alpha / self.rank
        update = torch.matmul(self.adapter_up, self.adapter_down)
        return self.base_layer.weight.detach() + scale * update.detach()

def count_parameters(module):
    total = 0
    trainable = 0
    for parameter in module.parameters():
        total = total + parameter.numel()
        if parameter.requires_grad:
            trainable = trainable + parameter.numel()
    return total, trainable

def E07(linear_layer, inputs, rank, alpha):
    with torch.no_grad():
        reference = linear_layer(inputs)
    wrapped = LoRALinear(linear_layer, rank, alpha)
    initial = wrapped(inputs)
    assert torch.allclose(reference, initial, atol=1e-6, rtol=1e-6)
    total, trainable = count_parameters(wrapped)
    return wrapped, total, trainable
```

Part 5 - The Philosophy Behind the Exercise

LoRA expresses a powerful engineering wager: adapting behavior may require a directional correction rather than rewriting the model's entire memory. The low-rank constraint turns that wager into a measurable hypothesis about how many independent directions the new task needs.

Efficiency should not be romanticized. Saving optimizer state does not erase data quality, evaluation, activation cost, or forgetting. LoRA is valuable because it makes experiments cheaper and adaptations modular, while still requiring the same intellectual discipline about what the model is being taught.

18.5.9 Exercise 08

Exercise Title: Fine-Tune Using LoRA and Compare Quality vs Full Fine-Tuning

Part 1 - Deep conceptual foundation

Comparing LoRA with full fine-tuning requires more than reporting trainable parameter counts. The methods have different capacity, memory behavior, optimal learning rates, and regularization effects. A fair study begins from the same base checkpoint, uses identical data order and token budget, tunes each method within a declared search budget, and evaluates both target quality and retained capabilities.

Full fine-tuning can express any update to eligible weights, but that flexibility may overfit small data or produce greater forgetting. LoRA restricts updates and often tolerates a larger learning rate, yet too-small rank or poor module placement can create an adaptation bottleneck. Equal learning rates are not necessarily fair; equal hyperparameter-search resources are more defensible.

Measure peak allocated GPU memory after resetting statistics and synchronizing CUDA. Separate model parameters, gradients, optimizer state, and activations in the explanation. Measure throughput after warm-up steps because first-iteration kernel setup distorts results. At inference, compare the unmerged adapter path with a merged checkpoint to determine whether adapter overhead matters.

Quality evaluation should include exact instruction accuracy, semantic scoring, prompt-variant robustness, rare task families, and base-model retention. Report the Pareto frontier: one method may win quality while the other wins memory and storage. Avoid forcing a single winner when deployment constraints differ.

Part 2 - Comparison quantities

For method m, define an efficiency vector

$$E_m = (Q_m, R_m, M_m, U_m, T_m, S_m),$$

where Q is target quality, R retention, M peak memory, U updates per second, T trainable parameters, and S checkpoint size. A useful relative memory saving is

$$\rho_M = 1 - \frac{M_{\text{LoRA}}}{M_{\text{full}}}.$$

It must be measured for the same batch, sequence length, precision, and checkpointing setting.

Part 3 - Matched benchmark design

1. Clone one base checkpoint into independent full and LoRA runs.
2. Search learning rate for both methods and rank plus alpha for LoRA under equal trial budgets.
3. Match processed supervised tokens and evaluation intervals.
4. Warm up CUDA, reset peak-memory statistics, synchronize around timing, and repeat measurements.

5. Evaluate training data, held-out content, paraphrased prompts, and base retention with the same decoding configuration.

6. Save LoRA adapters separately, merge a copy, and verify merged-logit parity.

7. Report means across seeds and a table of quality, memory, speed, and checkpoint storage.

Part 4 - Explicit benchmark instrumentation

```
import time
import torch

def trainable_parameter_count(model):
    count = 0
    for parameter in model.parameters():
        if parameter.requires_grad:
            count = count + parameter.numel()
    return count

def benchmark_training_steps(model, optimizer, batches, device):
    model.train()
    if device.type == "cuda":
        torch.cuda.empty_cache()
        torch.cuda.reset_peak_memory_stats(device)
        torch.cuda.synchronize(device)
    start_time = time.perf_counter()
    processed_tokens = 0
    for batch in batches:
        input_ids = batch["input_ids"].to(device)
        labels = batch["labels"].to(device)
        optimizer.zero_grad(set_to_none=True)
        logits = model(input_ids=input_ids, use_cache=False).logits
        loss, unused_sum, valid_count, unused_losses = (
            response_only_sft_loss(logits, labels)
        )
        loss.backward()
        optimizer.step()
        processed_tokens = processed_tokens + valid_count
    if device.type == "cuda":
        torch.cuda.synchronize(device)
        peak_memory = torch.cuda.max_memory_allocated(device)
    else:
        peak_memory = 0
    elapsed = time.perf_counter() - start_time
    result = {}
    result["tokens_per_second"] = processed_tokens / elapsed
    result["peak_memory_bytes"] = peak_memory
    result["trainable_parameters"] = trainable_parameter_count(model)
```

```
    return result

def E08(full_model, lora_model, full_optimizer,
        lora_optimizer, batches, device):
    full_result = benchmark_training_steps(
        full_model, full_optimizer, batches, device
    )
    lora_result = benchmark_training_steps(
        lora_model, lora_optimizer, batches, device
    )
    return full_result, lora_result
```

Part 5 - The Philosophy Behind the Exercise

Parameter efficiency changes who can experiment. A method that preserves most quality while reducing optimizer memory and checkpoint size can make adaptation available on hardware that cannot support full fine-tuning. That is a practical expansion of research access.

But efficiency is meaningful only relative to a purpose. A smaller adapter is not better if it fails the critical task, and a tiny quality gain may not justify an enormous operational cost. The comparison teaches decision-making across several dimensions rather than devotion to one fashionable technique.

18.5.10 Exercise 09

Exercise Title: Debug Catastrophic Forgetting After Fine-Tuning

Part 1 - Deep conceptual foundation

Catastrophic forgetting occurs when adaptation to a new distribution damages previously useful behavior. In LLM fine-tuning it can appear as increased base language-model loss, degraded general knowledge, loss of multilingual ability, excessive use of the new response style, or failure on instructions outside the tuned domain. The model has not literally erased a discrete database; parameter updates changed shared representations and conditional probabilities.

Diagnosis requires a frozen pre-tuning baseline and a retained evaluation suite that spans capabilities you care about. Run this suite before training and at regular checkpoints. A final comparison cannot reveal when forgetting began or whether early stopping could have prevented it. Track per-domain changes because an overall mean can conceal collapse in a small language or task family.

Common causes include excessive learning rate, too many repeated epochs, a narrow dataset, unbalanced response lengths, full-model updates, and optimizer state that produces large early movement. Remedies include lower learning rate, fewer steps, LoRA, mixed replay from the base distribution, stronger regularization toward the initial weights, and a more diverse instruction mixture. Each remedy must be tested against new-task quality; preventing all movement also prevents learning.

This exercise uses parameter drift and functional drift together. Parameter distance shows how far weights moved, while KL divergence and retained metrics show whether behavior changed. A large weight movement can be harmless under symmetries; a small movement in a sensitive subspace can matter greatly.

Part 2 - Drift and retention mathematics

For original parameters θ_0 and tuned parameters θ,

$$D_\theta = \frac{\|\theta - \theta_0\|_2}{\|\theta_0\|_2}.$$

On retained prompts x, functional drift can be measured as

$$D_{\mathrm{KL}} = \mathbb{E}_{x,t}\left[\mathrm{KL}\left(p_{\theta_0}(\cdot \mid x_{\le t}) \parallel p_\theta(\cdot \mid x_{\le t})\right)\right].$$

A replay objective is

$$L = L_{\mathrm{new}} + \lambda L_{\mathrm{replay}},$$

with λ selected using both adaptation and retention gates.

Part 3 - Root-cause investigation

1. Establish base scores for language modeling, instruction following, languages, and domain tasks before tuning.
2. Evaluate every checkpoint on new-task and retained suites.
3. Measure layer-wise relative parameter drift and identify where movement concentrates.
4. Compare output KL divergence on fixed retained prompts.
5. Reproduce the failure with fixed data order and seed before changing the recipe.
6. Test lower learning rate, early stopping, LoRA, replay, and weight anchoring one at a time.
7. Declare acceptable forgetting thresholds in advance and reject a model that violates any critical gate.

Part 4 - Explicit forgetting diagnostics

```
import torch
import torch.nn.functional as F

def relative_parameter_drift(base_model, tuned_model):
    base_parameters = dict(base_model.named_parameters())
    drifts = {}
    for name, tuned_parameter in tuned_model.named_parameters():
        base_parameter = base_parameters[name].to(tuned_parameter.device)
        numerator = torch.linalg.vector_norm(
            tuned_parameter.detach() - base_parameter.detach()
        )
        denominator = torch.linalg.vector_norm(base_parameter.detach())
        denominator = torch.clamp(denominator, min=1e-12)
        drifts[name] = float((numerator / denominator).item())
    return drifts
```

```
def output_kl_divergence(base_logits, tuned_logits, valid_mask):
    base_log_probabilities = F.log_softmax(base_logits, dim=-1)
    tuned_log_probabilities = F.log_softmax(tuned_logits, dim=-1)
    base_probabilities = torch.exp(base_log_probabilities)
    token_kl = torch.sum(
        base_probabilities *
        (base_log_probabilities - tuned_log_probabilities),
        dim=-1
    )
    return token_kl.masked_select(valid_mask).mean()

def E09(base_model, tuned_model, retained_input_ids, valid_mask):
    base_model.eval()
    tuned_model.eval()
    with torch.no_grad():
        base_logits = base_model(retained_input_ids).logits
        tuned_logits = tuned_model(retained_input_ids).logits
        functional_drift = output_kl_divergence(
            base_logits, tuned_logits, valid_mask
        )
    parameter_drifts = relative_parameter_drift(base_model, tuned_model)
    return functional_drift, parameter_drifts
```

Part 5 - The Philosophy Behind the Exercise

Learning and forgetting are two views of the same movement. To become more responsive to new evidence, a finite model must redistribute capacity and probability. The engineering question is not whether weights change, but whether the change sacrifices abilities the system still promises to provide.

Retention tests make those promises explicit. They remind us that improvement has a history: a new specialist behavior should be judged together with the knowledge, languages, and flexibility inherited from the base model.

18.5.11 Exercise 10

Exercise Title: Run Instruction Fine-Tuning on CUDA and Profile Memory vs Throughput

Part 1 - Deep conceptual foundation

CUDA fine-tuning performance is governed by more than model size. Sequence length controls attention and activation cost, response-only masking controls how many tokens contribute to useful gradients, padding controls wasted computation, and optimizer choice controls persistent state. A run can show high GPU utilization while training mostly on padding, so utilization must be interpreted beside supervised tokens per second.

Track each major memory category separately. The persistent categories include parameters, gradients, and optimizer states. Activations, temporary workspaces, and allocator reservations require separate measurements. Allocated memory is not the same as reserved memory, and neither value equals device-wide usage. Reset peak statistics before measurement. Warm up the model and synchronize around wall-clock timing, but not inside every measured step.

Benchmark a matrix of batch size, sequence length, precision, gradient checkpointing, and full versus LoRA fine-tuning. Keep actual token shapes fixed inside each condition. Record total tokens and supervised response tokens; the latter reflects useful SFT work when prompts are long. Include time spent in data transfer if the goal is end-to-end throughput, or exclude it explicitly if measuring kernels only.

The exercise will build a device-safe step, measure peaks, detect out-of-memory conditions, and write a result for every attempted configuration. Failed conditions are evidence about the hardware boundary and must not disappear from the table.

Part 2 - Performance quantities

For elapsed time Δt, total input tokens N_{all}, and supervised tokens N_{sup},

$$Q_{\text{all}} = \frac{N_{\text{all}}}{\Delta t}, \qquad Q_{\text{sup}} = \frac{N_{\text{sup}}}{\Delta t}.$$

Padding efficiency is

$$\eta_{\text{pad}} = \frac{N_{\text{nonpad}}}{BT},$$

and response supervision density is $\eta_{\text{sup}} = N_{\text{sup}}/N_{\text{nonpad}}$. These explain why two batches with equal shapes can deliver different learning value.

Part 3 - Benchmark protocol

1. Verify model, inputs, labels, masks, and adapter parameters reside on the same CUDA device.
2. Run warm-up steps that are excluded from timing and memory reporting.
3. Reset peak statistics, synchronize, measure many steps, and synchronize once at the end.
4. Record allocated and reserved peaks, step time, total-token throughput, supervised-token throughput, and padding efficiency.
5. Repeat each condition after a clean model reconstruction to avoid allocator history bias.
6. Catch out-of-memory errors, record the failing configuration, release references, and continue only after safe cleanup.
7. Use a profiler on representative steps after the broad benchmark identifies interesting conditions.

Part 4 - Explicit CUDA measurement code

```
import time
import torch

def cuda_training_benchmark(model, optimizer, batches, device):
    if device.type != "cuda":
        raise ValueError("this benchmark requires a CUDA device")
    model.train()
```

```
    for warmup_index in range(2):
        batch = batches[warmup_index]
        input_ids = batch["input_ids"].to(device, non_blocking=True)
        labels = batch["labels"].to(device, non_blocking=True)
        optimizer.zero_grad(set_to_none=True)
        logits = model(input_ids=input_ids, use_cache=False).logits
        loss, unused_sum, unused_count, unused_losses = (
            response_only_sft_loss(logits, labels)
        )
        loss.backward()
        optimizer.step()

    torch.cuda.synchronize(device)
    torch.cuda.reset_peak_memory_stats(device)
    start = time.perf_counter()
    total_tokens = 0
    supervised_tokens = 0
    for batch_index in range(2, len(batches)):
        batch = batches[batch_index]
        input_ids = batch["input_ids"].to(device, non_blocking=True)
        labels = batch["labels"].to(device, non_blocking=True)
        optimizer.zero_grad(set_to_none=True)
        logits = model(input_ids=input_ids, use_cache=False).logits
        loss, unused_sum, valid_count, unused_losses = (
            response_only_sft_loss(logits, labels)
        )
        loss.backward()
        optimizer.step()
        total_tokens = total_tokens + input_ids.numel()
        supervised_tokens = supervised_tokens + valid_count
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - start
    result = {}
    result["all_tokens_per_second"] = total_tokens / elapsed
    result["supervised_tokens_per_second"] = supervised_tokens / elapsed
    result["peak_allocated"] = torch.cuda.max_memory_allocated(device)
    result["peak_reserved"] = torch.cuda.max_memory_reserved(device)
    return result

def E10(model, optimizer, batches):
    device = torch.device("cuda:0")
    model.to(device)
    return cuda_training_benchmark(model, optimizer, batches, device)
```

Part 5 - The Philosophy Behind the Exercise

Performance engineering asks what the hardware is spending effort on. A GPU can be busy without being useful, and a fast step can carry little supervision if most tokens are padding or prompt context. Measurement must therefore connect silicon activity to learning value.

The hardware limit is not an embarrassment to hide; it is part of the model's experimental world. By documenting where memory fails and throughput changes, we transform resource constraints from surprises into design knowledge.

18.5.12 Exercise 11

Exercise Title: Compare Learning Rates and Schedulers for Stable Instruction Tuning

Part 1 - Deep conceptual foundation

Fine-tuning begins from a model that already contains useful structure, so the learning rate controls both adaptation speed and preservation. A rate that is too small can leave the model near its base behavior; a rate that is too large can destroy useful representations within a few updates. The best value depends on whether all parameters or only adapters are trained, the effective batch size, sequence distribution, optimizer, and number of steps.

Warmup protects the earliest updates, when optimizer moments are not yet representative and batches can produce unusually large movement. Decay controls how the remaining update budget is distributed. Linear and cosine schedules can reach similar final rates while allocating different learning rates to middle steps. A scheduler must advance on optimizer updates, not micro-batches, when gradient accumulation is used.

A proper sweep records the actual learning rate, gradient norm before clipping, update norm, loss, validation score, and retention score. Final loss alone misses early spikes and recovery. Compare schedules with the same total optimizer updates and warmup definition. If a run diverges, record the first non-finite step and the preceding metrics.

This exercise implements warmup plus cosine decay explicitly so step semantics are transparent. It then compares several peak learning rates and scheduler families across fixed seeds, selecting a configuration only when it passes both adaptation and retention gates.

Part 2 - Schedule equations

For optimizer step s, warmup length W, and total steps S, a warmup-cosine multiplier is

$$m(s) = \begin{cases} \dfrac{s+1}{W}, & s < W, \\ \dfrac{1}{2}\left[1 + \cos\left(\pi \dfrac{s-W}{S-W}\right)\right], & s \geq W. \end{cases}$$

The learning rate is $\eta_s = \eta_{\max} m(s)$. Relative update magnitude can be monitored as

$$U_s = \frac{\|\theta_{s+1} - \theta_s\|_2}{\|\theta_s\|_2}.$$

Large spikes in U_s may reveal instability even while loss remains finite.

Part 3 - Controlled sweep

1. Choose logarithmically spaced peak learning rates separately for full and LoRA tuning.
2. Match total optimizer updates, warmup fraction, data order, and evaluation intervals.
3. Log the learning rate after every scheduler update and verify the first, peak, and final values manually.
4. Record unclipped gradient norm and parameter-update norm.

5. Evaluate held-out instructions, prompt variants, and retained base tasks at intermediate checkpoints.

6. Repeat promising conditions across seeds and reject configurations whose variance is unacceptable.

7. Explain whether the winning schedule improves optimization, retention, or both.

Part 4 - Explicit scheduler implementation

```
import math

class WarmupCosineSchedule:
    def __init__(self, optimizer, maximum_lr,
                 warmup_steps, total_steps):
        if warmup_steps < 1:
            raise ValueError("warmup_steps must be positive")
        if total_steps <= warmup_steps:
            raise ValueError("total_steps must exceed warmup_steps")
        self.optimizer = optimizer
        self.maximum_lr = maximum_lr
        self.warmup_steps = warmup_steps
        self.total_steps = total_steps
        self.step_index = 0

    def multiplier(self, step_index):
        if step_index < self.warmup_steps:
            return (step_index + 1) / self.warmup_steps
        progress_numerator = step_index - self.warmup_steps
        progress_denominator = self.total_steps - self.warmup_steps
        progress = progress_numerator / progress_denominator
        progress = min(progress, 1.0)
        return 0.5 * (1.0 + math.cos(math.pi * progress))

    def step(self):
        multiplier = self.multiplier(self.step_index)
        learning_rate = self.maximum_lr * multiplier
        for parameter_group in self.optimizer.param_groups:
            parameter_group["lr"] = learning_rate
        self.step_index = self.step_index + 1
        return learning_rate

def E11(optimizer, maximum_lr, warmup_steps, total_steps):
    schedule = WarmupCosineSchedule(
        optimizer, maximum_lr, warmup_steps, total_steps
    )
    learning_rates = []
    for step_index in range(total_steps):
```

```
        learning_rate = schedule.step()
        learning_rates.append(learning_rate)
    assert learning_rates[0] < maximum_lr
    assert learning_rates[warmup_steps - 1] == maximum_lr
    return learning_rates
```

Part 5 - The Philosophy Behind the Exercise

The learning rate is the scale at which new evidence is allowed to rewrite an existing model. Warmup begins cautiously, the peak permits adaptation, and decay gradually limits later disruption. A schedule is therefore a temporal policy for trust in gradients.

Stable tuning is not the absence of movement. It is movement whose magnitude is proportional to evidence and whose consequences are observed. The experiment teaches that optimization settings are part of the meaning of fine-tuning, not mere knobs attached after the data is chosen.

18.5.13 Exercise 12

Exercise Title: Implement Gradient Accumulation for Long Prompts Under Memory Constraints

Part 1 - Deep conceptual foundation

Long prompts increase activation memory, often forcing a small micro-batch. Gradient accumulation processes several micro-batches before one optimizer update, approximating a larger batch without storing all activations simultaneously. Correctness depends on the loss denominator. In response-only SFT, micro-batches may contain very different numbers of supervised tokens, so dividing each micro-batch mean by the number of accumulation steps is generally not equivalent to a global token mean.

The exact solution is to accumulate the sum of token losses and divide by the total number of supervised tokens across the update window. Because the total is not known until all micro-batches are inspected, one approach is to know valid counts from the collator, scale each loss sum by the window total, and backpropagate. Another approach accumulates unnormalized gradients then divides gradients before the optimizer step. The second is explicit and handles variable token counts cleanly.

Incomplete final windows need their own denominator; never divide by the planned number of micro-batches when fewer were processed. Gradient clipping must occur after normalization and, in mixed precision, after unscaling. Scheduler steps and global-step counters advance once per optimizer update, not once per micro-batch.

The experiment will compare accumulated gradients with a physically concatenated batch under dropout disabled and deterministic ordering. It will test unequal response lengths and an incomplete final window, then measure the memory and throughput tradeoff on CUDA.

Part 2 - Exact token-weighted equivalence

For micro-batch j with token-loss sum S_j and valid count n_j, the desired window loss is

$$L_{\text{window}} = \frac{\sum_{j=1}^{K} S_j}{\sum_{j=1}^{K} n_j}.$$

If $g_j = \nabla_\theta S_j$, the normalized accumulated gradient is

$$g = \frac{\sum_j g_j}{\sum_j n_j}.$$

Averaging micro-batch means instead gives each micro-batch equal weight and is incorrect when n_j differs.

Part 3 - Equivalence and stress tests

1. Disable dropout and use one immutable initial state for accumulated and concatenated comparisons.
2. Create micro-batches with deliberately unequal supervised-token counts.
3. Compare every trainable gradient before optimizer update using explicit tolerances.
4. Compare parameters after one update and explain remaining floating-point differences.
5. Test an incomplete final accumulation window.
6. Clip only after gradients have been normalized by the window token count.
7. Report peak memory, supervised tokens per second, and optimizer updates per second for several accumulation factors.

Part 4 - Token-correct accumulation code

```
import torch

def divide_gradients(model, denominator):
    if denominator <= 0:
        raise ValueError("gradient denominator must be positive")
    for parameter in model.parameters():
        if parameter.grad is not None:
            parameter.grad.div_(denominator)

def accumulated_update(model, optimizer, micro_batches,
                       device, maximum_gradient_norm):
    model.train()
    optimizer.zero_grad(set_to_none=True)
    total_valid_tokens = 0
    total_loss_value = 0.0
    for batch in micro_batches:
        input_ids = batch["input_ids"].to(device)
        labels = batch["labels"].to(device)
        logits = model(input_ids=input_ids, use_cache=False).logits
        mean_loss, loss_sum, valid_count, unused_losses = (
            response_only_sft_loss(logits, labels)
        )
        differentiable_loss_sum = mean_loss * valid_count
        differentiable_loss_sum.backward()
```

```
        total_valid_tokens = total_valid_tokens + valid_count
        total_loss_value = total_loss_value + float(loss_sum.item())

    divide_gradients(model, total_valid_tokens)
    gradient_norm = torch.nn.utils.clip_grad_norm_(
        model.parameters(), maximum_gradient_norm
    )
    optimizer.step()
    mean_window_loss = total_loss_value / total_valid_tokens
    return mean_window_loss, float(gradient_norm), total_valid_tokens

def E12(model, optimizer, micro_batches, device):
    return accumulated_update(
        model, optimizer, micro_batches, device, 1.0
    )
```

Part 5 - The Philosophy Behind the Exercise

Gradient accumulation separates when evidence is observed from when parameters are changed. Several small views of the data can jointly authorize one update, allowing limited memory to approximate a larger statistical decision.

But equivalence depends on whose tokens receive weight. If every micro-batch is treated equally despite different response lengths, convenience silently changes the objective. Resource-saving methods remain scientifically valid only when their mathematical meaning is preserved.

18.5.14 Exercise 13

Exercise Title: Validate Determinism and Reproducibility in Fine-Tuning Runs

Part 1 - Deep conceptual foundation

Reproducibility means another run can reconstruct the experimental conditions and obtain behavior within declared tolerances. Exact determinism is a narrower goal: repeating the same run produces identical intermediate and final values. CUDA kernels, floating-point reduction order, data-loader workers, dropout, sampling, library versions, and distributed communication can all introduce variation.

Seeds are necessary but insufficient. Record the base checkpoint hash, dataset manifest and order, tokenizer files, template version, code revision, hyperparameters, precision, hardware, drivers, PyTorch version, deterministic flags, and environment. Save optimizer and scheduler states if resuming. Changing the number of workers can change random augmentation or batching unless worker seeds are controlled.

Perform two modes. In strict mode, enable deterministic algorithms and fail when PyTorch encounters an unsupported nondeterministic operation. In realistic mode, use production performance settings and quantify variability across seeds. Exact equality is not always worth a large performance cost, but unmeasured variability is not acceptable.

Compare more than the final metric. Hash the data order, record early losses, compare parameter tensors, and evaluate paired outputs. If runs diverge at step zero, suspect initialization or data. If they diverge after a specific kernel, profile that region. If parameters differ slightly but behavior remains stable, report both numerical and functional reproducibility.

Part 2 - Reproducibility statistics

For metric values $q_1, \ldots, q_R$ across runs,

$$\overline{q} = \frac{1}{R}\sum_{r=1}^{R} q_r, \qquad s_q = \sqrt{\frac{1}{R-1}\sum_{r}(q_r - \overline{q})^2}.$$

For parameter vectors θ_a and θ_b, report

$$D_{a,b} = \frac{\|\theta_a - \theta_b\|_2}{\max(\|\theta_a\|_2, \epsilon)}.$$

Zero $D_{a,b}$ is expected only in a strict deterministic configuration. A functional tolerance must be tied to the intended use.

Part 3 - Reproduction protocol

1. Capture configuration, code, data, tokenizer, base checkpoint, software, and hardware identifiers before training.
2. Seed Python and PyTorch CPU/CUDA generators before model creation.
3. Configure data-loader generators and worker initialization explicitly.
4. Run two strict repetitions and compare batch identifiers, step losses, gradients, and final parameters.
5. Run at least three production-mode seeds and report metric dispersion and paired prediction disagreement.
6. Resume from a checkpoint and compare against an uninterrupted run at the same global step.
7. Document every setting that was relaxed for performance and its measured effect.

Part 4 - Explicit deterministic setup and comparison

```
import os
import random
import torch

def configure_reproducibility(seed, strict):
    random.seed(seed)
    torch.manual_seed(seed)
    if torch.cuda.is_available():
        torch.cuda.manual_seed_all(seed)
    if strict:
        torch.use_deterministic_algorithms(True)
        torch.backends.cudnn.benchmark = False

```

Part 5 - The Philosophy Behind the Exercise

Reproducibility is the memory of an experiment. Without it, a result belongs to a vanished arrangement of code, data, hardware, and chance. Recording that arrangement allows knowledge to survive the original machine and researcher.

Determinism is not always the final goal, but accountability is. When results vary, the variation must become an observed quantity rather than an excuse. Science advances when another run can challenge the same claim under the same conditions.

18.5.15 Exercise 14

Exercise Title: Build Evaluation Set to Measure Instruction Following Accuracy

Part 1 - Deep conceptual foundation

Instruction following is multidimensional. A response can understand the task but violate a requested format, obey the format but contain incorrect content, answer correctly while ignoring a constraint, or refuse a valid request. One binary score cannot explain these cases. The evaluation set must convert the deployment contract into observable dimensions.

Start with a task taxonomy: extraction, transformation, classification, reasoning, constrained generation, tool-like structured output, context-grounded answering, clarification, and

refusal where appropriate. Within every family, vary difficulty, prompt wording, response length, languages, and distractors. Separate semantic templates and underlying content across splits so the test set does not reward memorized renderings.

Every item needs an identifier, provenance, instruction, optional context, reference information, scoring method, critical constraints, and failure severity. Exact match is suitable for strict labels and serialized outputs; numeric tolerance suits calculations; set or span scoring suits extraction; human or model-assisted rubrics may be needed for open responses. Automated graders must themselves be validated against human judgments on a sample.

Prevent evaluation contamination. Hash normalized examples and near-duplicate representations before training. Keep test prompts access-controlled and versioned. When an item changes, increment the suite version rather than silently altering history. Report confidence intervals and per-slice results, especially for safety-critical or underrepresented cases.

Part 2 - Metric decomposition

For each response define indicators C for content, F for format, K for constraint satisfaction, and R for appropriate refusal behavior. A strict success can be

$$I_{\text{success}} = C \cdot F \cdot K \cdot R.$$

Macro task accuracy is

$$A_{\text{macro}} = \frac{1}{K} \sum_{k=1}^{K} \frac{1}{n_k} \sum_{i \in k} I_{\text{success},i}.$$

Also report the individual component rates; the product alone cannot identify the reason for failure.

Part 3 - Evaluation construction protocol

1. Derive task families and severity levels from intended uses and known failure risks.
2. Write scoring rules before observing candidate model outputs.
3. Include canonical prompts, paraphrases, irrelevant context, conflicting constraints, and boundary conditions.
4. Group all variants of one semantic item into the same split.
5. Validate automated graders against blinded human labels and report their agreement.
6. Freeze a versioned test set and maintain a separate development set for prompt and hyperparameter decisions.
7. Publish macro, micro, per-task, per-difficulty, and worst-slice metrics together with representative failures.

Part 4 - Explicit evaluation framework

```
def exact_match(candidate, reference):
    return int(candidate.strip() == reference.strip())

def required_substrings(candidate, requirements):
    passed = True
    for requirement in requirements:
        if requirement not in candidate:
            passed = False
    return int(passed)

def grade_item(item, candidate):
    content = exact_match(candidate, item["reference"])
    constraints = required_substrings(
        candidate, item["required_substrings"]
    )
    format_score = item["format_grader"](candidate)
    success = content * constraints * format_score
    result = {}
    result["item_id"] = item["item_id"]
    result["task"] = item["task"]
    result["content"] = content
    result["constraints"] = constraints
    result["format"] = format_score
    result["success"] = success
    return result

def E14(items, generate):
    results = []
    task_totals = {}
    task_successes = {}
    for item in items:
        candidate = generate(item["prompt"])
        result = grade_item(item, candidate)
        results.append(result)
        task = result["task"]
        if task not in task_totals:
            task_totals[task] = 0
            task_successes[task] = 0
        task_totals[task] = task_totals[task] + 1
        task_successes[task] = task_successes[task] + result["success"]
    task_accuracy = {}
    for task in task_totals:
        task_accuracy[task] = task_successes[task] / task_totals[task]
    return results, task_accuracy
```

Part 5 - The Philosophy Behind the Exercise

Evaluation is where the phrase “follows instructions” receives a definition. Without a taxonomy and rubric, the phrase expands or contracts to fit whatever output the model produced.

A good evaluation makes success difficult to fake.

Metrics are promises translated into tests. Their limitations must remain visible, because what is omitted from the suite can become invisible to the project. Measurement does not merely observe progress; it directs which kind of progress the training team will notice.

18.5.16 Exercise 15

Exercise Title: Analyze Failure Modes Where Model Obeys Style but Misses Content

Part 1 - Deep conceptual foundation

Instruction-tuned models often learn visible conventions faster than semantic requirements. They produce headings, confident tone, JSON braces, disclaimers, or step-by-step prose while the underlying answer is wrong. Style tokens are frequent, locally predictable, and shared across many examples; difficult content may be rare and require longer dependencies. A falling token loss can therefore reward polished surfaces before factual or logical competence.

The failure must be decomposed. Format validity asks whether the response parses. Schema validity asks whether required fields and types exist. Constraint validity asks whether requested limits are respected. Semantic correctness asks whether values and claims answer the task. Groundedness asks whether claims are supported by provided context. These dimensions should never be collapsed into one formatting score.

Create adversarial pairs in which an incorrect answer is perfectly styled and a correct answer is poorly styled. A grader that consistently prefers the first has learned the wrong objective. For structured outputs, parse the response and validate values independently. For explanations, extract final claims and test them against references or executable checks where possible.

Root causes can include superficial training targets, imbalanced easy examples, reference responses with unnecessary verbosity, a grader biased toward style, or insufficient domain capability in the base model. Fixes differ: rebalance data, add hard negatives, improve content verification, continue domain pretraining, or simplify the requested schema. More SFT steps cannot create missing knowledge reliably.

Part 2 - Failure decomposition

Let $F_i, S_i, C_i, G_i \in \{0, 1\}$ denote format, schema, content, and grounding success. The dangerous style-content failure rate is

$$R_{\text{surface}} = \frac{1}{N} \sum_{i=1}^{N} F_i S_i (1 - C_i).$$

Conditional content accuracy among well-formatted outputs is

$$A_{C|FS} = \frac{\sum_i F_i S_i C_i}{\sum_i F_i S_i}.$$

Report both: a model can improve format rate while conditional content accuracy falls.

Part 3 - Failure investigation

1. Build paired examples that independently vary style quality and content correctness.
2. Use parsers for JSON or code syntax, but evaluate field values and program behavior separately.

3. Group failures into wrong fact, wrong calculation, ignored evidence, unsupported inference, contradiction, and incomplete answer.
4. Compare token-level loss for shared style prefixes and content-bearing tokens.
5. Inspect whether training data contains many reusable shells with weak or noisy answers.
6. Add verified hard examples and hard negatives, then measure content gains without sacrificing necessary format.
7. Require the report to include convincing-looking failures, not only obvious malformed outputs.

Part 4 - Separate format and content graders

```
import json

def parse_json_response(response):
    try:
        value = json.loads(response)
        return True, value
    except json.JSONDecodeError:
        return False, None

def grade_structured_answer(response, reference):
    format_valid, value = parse_json_response(response)
    schema_valid = False
    content_valid = False
    if format_valid and isinstance(value, dict):
        if "answer" in value and "reason" in value:
            schema_valid = True
            content_valid = value["answer"] == reference["answer"]
    result = {}
    result["format_valid"] = int(format_valid)
    result["schema_valid"] = int(schema_valid)
    result["content_valid"] = int(content_valid)
    surface_failure = format_valid and schema_valid and not content_valid
    result["surface_failure"] = int(surface_failure)
    return result

def E15(responses, references):
    if len(responses) != len(references):
        raise ValueError("response and reference counts differ")
    results = []
    surface_failures = 0
    for index in range(len(responses)):
        result = grade_structured_answer(
            responses[index], references[index]
        )
```

```
        results.append(result)
        surface_failures = surface_failures + result["surface_failure"]
    rate = surface_failures / len(results)
    return results, rate
```

Part 5 - The Philosophy Behind the Exercise

Human readers naturally trust organized language. Headings, precision, and confident explanations signal competence in ordinary communication, so models can exploit our expectations without intention simply by reproducing those patterns. This makes surface quality an especially dangerous substitute for truth.

The exercise teaches epistemic separation: presentation tells us how an answer is expressed; evidence tells us whether it should be believed. A responsible system must earn both scores independently.

18.5.17 Exercise 16

Exercise Title: Implement Prompt Dropout and Measure Robustness Gains

Part 1 - Deep conceptual foundation

Prompt dropout is a data transformation that randomly removes optional or redundant prompt components during training. Its purpose is to stop the model from relying on one superficial cue when the semantic task remains recoverable from other fields. Examples include dropping a polite preamble, optional task description, redundant label list, or nonessential demonstration.

This must never be implemented as uncontrolled token deletion. Removing negation, a safety condition, a unit, required context, or role boundary can change the correct response and create mislabeled data. Define prompt components structurally and label each as required, optional, or conditionally droppable. Apply dropout before rendering so tags and separators remain syntactically valid.

The experiment compares no dropout with several probabilities under the same token and update budget. Because dropout shortens prompts, equal steps do not imply equal processed tokens; report both. Evaluate canonical prompts, missing optional fields, reordered fields, paraphrases, and prompts missing required information. The last category should trigger clarification or uncertainty, not the same confident answer.

Robustness gain must not be confused with under-conditioning. If aggressive dropout causes the model to ignore useful context, performance may look stable only because it produces generic responses. Measure context utilization and content specificity in addition to task accuracy.

Part 2 - Stochastic transformation

Let prompt components be $c_1, \ldots, c_M$ with optional set O. For $j \in O$, sample

$$d_j \sim \text{Bernoulli}(1 - p_j), \qquad \widetilde{x} = g(c_j : d_j = 1 \text{ or } j \notin O).$$

The response label remains valid only if

$$y^*(\widetilde{x}) = y^*(x).$$

That invariance is a data-design claim requiring validation, not an automatic consequence of deletion.

Part 3 - Robustness experiment

1. Parse prompts into named components and classify each component's semantic necessity.
2. Define dropout probabilities per component rather than one probability for arbitrary tokens.
3. Seed the transformation and log the component-presence mask for every rendered example.
4. Verify that role markers, response boundary, and required evidence are never dropped.
5. Compare canonical, optional-component-missing, paraphrased, and required-information-missing evaluation slices.
6. Measure accuracy, specificity, clarification behavior, prompt token count, and retained base capability.
7. Inspect whether robustness persists when several optional cues disappear simultaneously.

Part 4 - Structured prompt dropout code

```
import random

def apply_prompt_dropout(record, probabilities, random_generator):
    transformed = {}
    transformed["instruction"] = record["instruction"]
    transformed["response"] = record["response"]
    presence = {}
    optional_fields = ["preamble", "hint", "format_reminder"]
    for field_name in optional_fields:
        if field_name in record:
            probability = probabilities[field_name]
            keep_value = random_generator.random() >= probability
            presence[field_name] = keep_value
            if keep_value:
                transformed[field_name] = record[field_name]
    if "context" in record:
        transformed["context"] = record["context"]
        presence["context"] = True
    return transformed, presence

def render_dropout_record(record):
    text = ""
    ordered_fields = ["preamble", "instruction", "context",
                      "hint", "format_reminder"]
    for field_name in ordered_fields:
```

```
        if field_name in record:
            text = text + "<" + field_name + ">"
            text = text + record[field_name]
            text = text + "</" + field_name + ">\n"
    text = text + "<assistant>"
    return text

def E16(records, probabilities, seed):
    random_generator = random.Random(seed)
    outputs = []
    for record in records:
        transformed, presence = apply_prompt_dropout(
            record, probabilities, random_generator
        )
        item = {}
        item["prompt"] = render_dropout_record(transformed)
        item["response"] = transformed["response"]
        item["presence"] = presence
        outputs.append(item)
    return outputs
```

Part 5 - The Philosophy Behind the Exercise

Prompt dropout asks the model to find what is essential beneath redundant expression. By varying optional cues, training can weaken dependence on ritual and strengthen dependence on the task's stable meaning.

Yet subtraction is only wise when meaning survives. Removing necessary context and retaining the old answer teaches certainty without evidence. Robustness is not indifference to information; it is the ability to distinguish essential information from accidental presentation.

18.5.18 Exercise 17

Exercise Title: Compare SFT vs Continued Pretraining on Domain Text

Part 1 - Deep conceptual foundation

Continued pretraining and supervised instruction fine-tuning solve different problems. Continued pretraining exposes a base model to unlabeled domain text under next-token prediction, adapting vocabulary, style, facts, and statistical regularities. SFT presents explicit instruction-response behavior and teaches how the model should act when asked. Domain knowledge and instruction behavior can overlap, but neither objective is a substitute for the other.

If the model lacks familiarity with specialized concepts, SFT examples may be too sparse to build the necessary representations. Continued pretraining can help, followed by SFT to make the knowledge accessible through instructions. Conversely, if the model already knows the domain but answers in the wrong format, continued pretraining may merely make it imitate domain documents; response-masked SFT is the more direct intervention.

The comparison needs four arms from one base checkpoint: no adaptation, continued pretraining only, SFT only, and continued pretraining followed by SFT. Match compute or processed tokens according to the question being asked and report both. Use separate domain-language-modeling validation, domain question answering, instruction following, and general

retention suites. Ensure that evaluation answers do not occur verbatim in either training corpus.

Data formatting must remain distinct. Continued pretraining typically supervises all valid next tokens in domain documents. SFT supervises assistant response regions. Accidentally applying response-only masks to raw domain text discards most signal; applying full-document loss to chat examples may overemphasize prompt reproduction.

Part 2 - Objective comparison

Continued pretraining minimizes

$$L_{\mathrm{CPT}} = -\frac{1}{N_D} \sum_{x \in D} \sum_{t} \log p_\theta(x_t \mid x_{<t}),$$

while SFT minimizes

$$L_{\mathrm{SFT}} = -\frac{1}{N_R} \sum_{(u,y)} \sum_{t \in R(y)} \log p_\theta(y_t \mid u, y_{<t}).$$

The sequential pipeline is

$$\theta_1 = \mathrm{CPT}(\theta_0, D), \qquad \theta_2 = \mathrm{SFT}(\theta_1, I).$$

Order matters because the second stage can modify gains and losses from the first.

Part 3 - Four-arm experiment

1. Build domain-document and instruction datasets with independent provenance, deduplication, and evaluation contamination checks.
2. Clone one base state into the four experimental arms.
3. Use objective-appropriate labels and verify supervision density.
4. Match a compute budget and additionally report processed tokens and optimizer updates.
5. Evaluate domain perplexity, closed-book domain accuracy, context-grounded accuracy, instruction compliance, and general retention.
6. Inspect whether CPT improves knowledge but worsens assistant formatting, and whether SFT restores the interface.
7. Select the simplest pipeline that meets all capability and retention gates rather than assuming two stages are always better.

Part 4 - Explicit label-policy separation

```
import torch

def build_cpt_labels(input_ids, attention_mask):
    labels = input_ids.clone()
    labels[attention_mask == 0] = -100
    return labels
```

```
def build_sft_labels(input_ids, assistant_mask, attention_mask):
    labels = input_ids.clone()
    labels[assistant_mask == 0] = -100
    labels[attention_mask == 0] = -100
    if not (labels != -100).any():
        raise ValueError("SFT example has no assistant supervision")
    return labels

def supervision_density(labels, attention_mask):
    valid_input_tokens = int(attention_mask.sum().item())
    supervised_tokens = int((labels != -100).sum().item())
    if valid_input_tokens == 0:
        raise ValueError("empty sequence")
    return supervised_tokens / valid_input_tokens

def E17(input_ids, attention_mask, assistant_mask):
    cpt_labels = build_cpt_labels(input_ids, attention_mask)
    sft_labels = build_sft_labels(
        input_ids, assistant_mask, attention_mask
    )
    result = {}
    result["cpt_labels"] = cpt_labels
    result["sft_labels"] = sft_labels
    result["cpt_density"] = supervision_density(
        cpt_labels, attention_mask
    )
    result["sft_density"] = supervision_density(
        sft_labels, attention_mask
    )
    return result
```

Part 5 - The Philosophy Behind the Exercise

Knowing a domain and knowing how to respond within it are different forms of adaptation. Continued pretraining changes what patterns feel familiar; SFT changes which behavior follows a request. Treating them as identical obscures the reason an intervention succeeds or fails.

The deeper principle is objective-task alignment. Training should apply pressure where the deficiency actually lives. New knowledge requires evidence; new conduct requires demonstrations of conduct. Strong systems often need both, but in an intentional order.

18.5.19 Exercise 18

Exercise Title: Build Fine-Tuning Debugging Checklist Covering Masks, LR, and Data

Part 1 - Deep conceptual foundation

A debugging checklist converts recurring failures into an ordered diagnostic process. Fine-tuning pipelines can lower loss while remaining semantically wrong, so the order should begin

with data and target alignment before optimizer tuning. Changing learning rate cannot repair shifted labels, and adding memory cannot repair response leakage.

The first layer is identity: base checkpoint, tokenizer, special tokens, template version, dataset manifest, and code configuration. The second is data: duplicates, empty responses, split leakage, truncation, role boundaries, and decoded samples. The third is tensors: shapes, dtypes, devices, attention masks, assistant masks, labels, valid-token counts, and causal behavior. Only after these pass should optimization, memory, quality, retention, and reproducibility be investigated.

Every checklist item needs a test, expected result, severity, evidence path, and remediation. "Check the mask" is too vague. A strong item says: append padding, recompute loss, and assert unchanged valid-token mean within tolerance. Automate deterministic invariants and reserve human review for semantic quality.

The exercise builds a gate-based diagnostic report. Blocking failures stop the run before expensive training. Warnings permit continuation but remain visible. The checklist also includes deliberate fault injection: wrong shift, missing assistant mask, duplicate data, excessive learning rate, and device mismatch. A diagnostic is trusted only after it detects a known failure.

Part 2 - Gate model

Let checks produce $c_i \in \{0, 1\}$ and let blocking set B contain conditions required for correctness. The run-ready state is

$$R = \prod_{i \in B} c_i.$$

For nonblocking warnings with weights w_i, define a visible risk score

$$Q = \sum_{i \notin B} w_i(1 - c_i).$$

Q may prioritize review, but it must not override $R = 0$. Correctness gates cannot be averaged away.

Part 3 - Ordered debugging checklist

1. Verify hashes and versions for checkpoint, tokenizer, template, dataset, and configuration.
2. Decode raw, rendered, tokenized, shifted, truncated, and padded examples from every task family.
3. Assert causal masking, response-only labels, target range, nonzero valid tokens, and padding-loss invariance.
4. Overfit one batch and a tiny dataset before a full run.
5. Confirm intended trainable parameters and finite nonzero gradients.
6. Sweep learning rate, inspect gradient/update norms, and verify scheduler steps correspond to optimizer steps.
7. Monitor validation, paraphrase robustness, and retained capability for overfitting and forgetting.

8. Reproduce the run, resume from checkpoint, and inject known faults to test diagnostic coverage.

Part 4 - Executable checklist structure

```
class DiagnosticCheck:
    def __init__(self, check_id, blocking, function, remediation):
        self.check_id = check_id
        self.blocking = blocking
        self.function = function
        self.remediation = remediation

    def run(self, context):
        passed, evidence = self.function(context)
        result = {}
        result["check_id"] = self.check_id
        result["blocking"] = self.blocking
        result["passed"] = bool(passed)
        result["evidence"] = evidence
        result["remediation"] = self.remediation
        return result

def run_diagnostics(checks, context):
    results = []
    ready = True
    for check in checks:
        result = check.run(context)
        results.append(result)
        if result["blocking"] and not result["passed"]:
            ready = False
    return ready, results

def check_supervised_tokens(context):
    labels = context["labels"]
    count = int((labels != -100).sum().item())
    return count > 0, {"supervised_tokens": count}

def E18(context):
    checks = []
    checks.append(DiagnosticCheck(
        "nonempty_supervision", True, check_supervised_tokens,
        "repair assistant boundaries and label construction"
    ))
    ready, results = run_diagnostics(checks, context)
    return {"ready": ready, "results": results}
```

Part 5 - The Philosophy Behind the Exercise

Debugging is the practice of refusing mystery. A failed run is not explained by calling fine-tuning unstable; it is explained by tracing evidence until a specific contract is shown to be broken or a hypothesis is falsified.

A checklist preserves hard-earned knowledge against memory and pressure. It makes quality less dependent on who happens to notice a subtle symptom. The best checklist is not paperwork after engineering; it is accumulated engineering made executable.

18.5.20 Exercise 19

Exercise Title: Produce an Instruction Tuning Engineering Report with Lessons Learned

Part 1 - Deep conceptual foundation

The final report must reconstruct the complete fine-tuning argument: which base model was adapted, what behavior was desired, how records were sourced and rendered, which tokens were supervised, which parameters were trainable, how optimization was controlled, and what evidence justifies the selected checkpoint. It is not a chronological diary and not a gallery of successful outputs. It is a decision document that includes failed hypotheses.

Begin with scope and non-goals. State the intended users, task families, languages, context limits, response policy, and behaviors the fine-tune does not promise. Document dataset provenance, authorization, template versions, deduplication, split logic, truncation, task mixture, response length, and quality review. Provide distributions, not only totals.

The training section must specify full or parameter-efficient tuning, exact trainable modules, loss mask, valid-token reduction, optimizer, scheduler, precision, accumulation, clipping, seeds, hardware, throughput, memory, and checkpoint recovery. The evaluation section must compare the base and tuned models on target tasks, paraphrases, content versus format, retained abilities, and meaningful failure slices. Include uncertainty across seeds.

Finish with a decision table and traceable gates. Identify which configuration was selected, which alternatives were rejected, and why. List known limitations, monitoring recommendations, rollback conditions, and the next experiment that would reduce the most important uncertainty. A report becomes valuable when a future engineer can challenge its conclusion without recreating hidden context.

Part 2 - Decision model

Let the evaluation vector be

$$G = (A_{\text{task}}, A_{\text{para}}, C_{\text{content}}, F_{\text{format}}, R_{\text{retention}}, M_{\text{peak}}, Q_{\text{throughput}}).$$

A release candidate is acceptable only if every blocking requirement holds:

$$\text{Accept}(G) = \bigwedge_{j \in B} [g_j \ \text{ meets } \ \tau_j] \, .$$

Cost or preference scores may rank candidates after they pass gates, but cannot compensate for a failed correctness or safety requirement.

Part 3 - Required report evidence

1. Include immutable identifiers for model, tokenizer, code, data, template, configuration, checkpoints, and evaluation suite.

2. Show decoded supervision examples and automated mask tests.

3. Compare full tuning and LoRA, or explain with evidence why one was excluded.
4. Present learning curves, gradient behavior, memory, throughput, and failure events rather than only the final epoch.
5. Report paired base-versus-tuned examples chosen by a fixed sampling rule.
6. Separate content, style, prompt robustness, and retention results.
7. Record rejected configurations and lessons learned from at least one injected or naturally occurring failure.
8. End with owners, rollback triggers, limitations, and a prioritized next experiment.

Part 4 - Structured report and gate builder

```
class InstructionTuningReport:
    def __init__(self, report_id):
        self.report_id = report_id
        self.sections = {}
        self.gates = []
        self.lessons = []

    def add_section(self, name, evidence):
        self.sections[name] = evidence

    def add_gate(self, name, value, threshold,
                 comparison, blocking, owner):
        gate = {}
        gate["name"] = name
        gate["value"] = value
        gate["threshold"] = threshold
        gate["comparison"] = comparison
        gate["blocking"] = blocking
        gate["owner"] = owner
        if comparison == "greater_or_equal":
            gate["passed"] = value >= threshold
        elif comparison == "less_or_equal":
            gate["passed"] = value <= threshold

```

Part 5 - The Philosophy Behind the Exercise

An engineering report is institutional memory with a standard of proof. It preserves not only what was built, but why one design was trusted over another, which evidence was missing, and where confidence should end.

Instruction tuning gives designers unusual influence over a model's visible conduct. The final report is where that influence becomes accountable. It turns behavioral change from an impressive demonstration into a traceable decision that can be reproduced, criticized, monitored, and reversed.

18.6 LLM04

Chapter Title: Alignment, Preferences, and Safety
Specialization: Preference Optimization and Safety Engineering

18.6.1 Exercise 00

Exercise Title: Explain Alignment Problem and Why Raw LLMs Can Be Unsafe

Part 1 - Deep conceptual foundation

A raw language model is optimized to predict continuations from its training distribution. That objective rewards statistical likelihood, not truth, helpfulness, privacy, fairness, or compliance with a deployment policy. Useful behavior can emerge because useful text exists in the corpus, but the objective does not reliably select it when harmful, deceptive, outdated, or unsupported continuations are also plausible.

Alignment is the problem of making model behavior reliably serve specified human purposes and constraints across ordinary, ambiguous, adversarial, and unfamiliar inputs. It is not one

universal target. Users, operators, affected people, and legal or cultural contexts can value outcomes differently. A real system therefore needs an explicit behavioral policy, a method for resolving conflicts, and an escalation path where automatic behavior is insufficient.

Raw models can expose several risks: following dangerous patterns found in data, revealing memorized private strings, confidently inventing claims, amplifying bias, obeying malicious instructions embedded in untrusted context, or failing to distinguish a legitimate request from an unsafe one. Scale does not remove the mismatch; it can increase both capability and the persuasiveness of errors.

This exercise builds a threat model rather than assuming that "unsafe" is one binary property. Define actors, assets, permitted uses, misuse cases, accidental failures, affected groups, severity, likelihood, and available controls. Compare the raw model with an instruction-tuned model on a defensively designed prompt suite and separate helpfulness, factuality, refusal appropriateness, privacy, and robustness.

Part 2 - Formalizing imperfect objectives

Let $U(y \mid x)$ represent desired utility and let L_{LM} be next-token loss. In general,

$$\arg\min_{\theta} L_{\text{LM}}(\theta) \neq \arg\max_{\theta} \mathbb{E}[U(y \mid x)].$$

Alignment introduces proxy signals $\widehat{U}$, but proxies can also be incomplete. Risk can be organized as

$$R = \sum_{c} P(c)\, I(c),$$

where c is a failure class, $P(c)$ its estimated occurrence probability, and $I(c)$ its impact. Do not hide catastrophic low-frequency cases inside one average.

Part 3 - Threat-model experiment

1. Specify intended users, permitted tasks, protected assets, and non-goals.
2. Build benign, ambiguous, boundary, adversarial, and distribution-shift prompt slices without including operational harmful content.
3. Write expected behaviors before viewing model responses.
4. Score helpfulness, correctness, refusal precision, privacy, and policy compliance separately.
5. Compare raw and aligned checkpoints under identical decoding settings.
6. Record both unsafe compliance and excessive refusal.
7. Assign each failure an owner, mitigation layer, and residual-risk decision.

Part 4 - Explicit risk registry

```
class AlignmentRisk:
    def __init__(self, risk_id, category, severity, likelihood):
        self.risk_id = risk_id
        self.category = category
```

```
        self.severity = severity
        self.likelihood = likelihood
        self.controls = []

    def add_control(self, control_name, owner, evidence):
        control = {}
        control["name"] = control_name
        control["owner"] = owner
        control["evidence"] = evidence
        self.controls.append(control)

    def score(self):
        return self.severity * self.likelihood

def E00(risk_definitions):
    registry = []
    for definition in risk_definitions:
        risk = AlignmentRisk(
            definition["risk_id"], definition["category"],
            definition["severity"], definition["likelihood"]
        )
        registry.append(risk)
    def risk_score(item):
        return item.score()
    registry.sort(key=risk_score, reverse=True)
    return registry
```

Part 5 - The Philosophy Behind the Exercise

Prediction learns what people have written; alignment asks what a system should do. The distance between those questions is where responsibility enters model engineering. No amount of likelihood optimization can choose values that were never made explicit.

Alignment is therefore not the removal of all uncertainty or disagreement. It is the disciplined construction of behavior, evidence, boundaries, and accountability while acknowledging whose interests shaped the target.

18.6.2 Exercise 01

Exercise Title: Define Human Preference Data and How It Differs from Supervised Labels

Part 1 - Deep conceptual foundation

Supervised fine-tuning usually provides a desired response and asks the model to increase its likelihood. Preference data instead compares candidate responses for the same prompt and records which one is better under a rubric. The signal is relational: "chosen is preferred to rejected." It need not assert that the chosen response is perfect or that the rejected response is always unacceptable.

Preference judgments capture qualities that are difficult to encode as one reference string, such as relevance, clarity, calibrated uncertainty, safe boundary handling, and adherence to constraints. They also contain human subjectivity. Annotators may disagree, misunderstand

the domain, be influenced by verbosity, or apply the rubric inconsistently. The dataset must preserve annotator identifiers or groups, confidence, rubric version, tie or abstention, and reason codes when allowed by privacy policy.

Pair construction matters. If chosen responses are systematically longer, contain a familiar phrase, or come from one generator, a model can learn that shortcut instead of the intended preference. Randomize presentation order, balance nuisance features, include hard pairs, and audit position and length bias. Never force a ranking where responses are equivalent or the annotator lacks expertise.

The exercise will represent pairwise judgments, validate prompt identity, detect contradictory cycles and duplicate reversals, and calculate inter-rater agreement. It will keep raw annotations separate from aggregated training pairs so uncertainty is not erased prematurely.

Part 2 - Pairwise probability model

For latent utility $r(x, y)$, the Bradley–Terry model defines

$$P(y_a \succ y_b \mid x) = \sigma\left(r(x, y_a) - r(x, y_b)\right).$$

Unlike a class label attached to one response, the target depends on a pair and context. If annotators j provide labels v_{ij}, report agreement and the empirical preference probability rather than discarding minority judgments:

$$\widehat{p}_i = \frac{1}{m_i} \sum_{j=1}^{m_i} v_{ij}.$$

Part 3 - Dataset quality protocol

1. Store prompt, both candidates, presentation order, rubric version, annotator group, choice, tie, abstention, confidence, and reason codes.
2. Verify both responses answer the identical semantic prompt.
3. Reject self-pairs, exact duplicate candidates, and reversed duplicate records with incompatible labels.
4. Audit choice rate by candidate position, length, generator, and style.
5. Preserve disagreements and adjudicate only under a documented rule.
6. Create gold and repeated items to estimate annotator consistency.
7. Split by prompt family so paraphrased versions do not leak across sets.

Part 4 - Explicit preference records

```
class PreferencePair:
    def __init__(self, pair_id, prompt_id, prompt,
                 chosen, rejected, rubric_version):
        if chosen.strip() == rejected.strip():
            raise ValueError("preference candidates are identical")
        self.pair_id = pair_id
```

```
        self.prompt_id = prompt_id
        self.prompt = prompt
        self.chosen = chosen
        self.rejected = rejected
        self.rubric_version = rubric_version
        self.annotations = []

    def add_annotation(self, annotator_group, choice, confidence):
        if choice not in ["chosen", "rejected", "tie", "abstain"]:
            raise ValueError("invalid preference choice")
        annotation = {}
        annotation["annotator_group"] = annotator_group
        annotation["choice"] = choice
        annotation["confidence"] = confidence
        self.annotations.append(annotation)

def E01(raw_pairs):
    pairs = []
    identifiers = set()
    for record in raw_pairs:
        if record["pair_id"] in identifiers:
            raise ValueError("duplicate pair identifier")
        identifiers.add(record["pair_id"])
        pair = PreferencePair(
            record["pair_id"], record["prompt_id"], record["prompt"],
            record["chosen"], record["rejected"], record["rubric_version"]
        )
        pairs.append(pair)
    return pairs
```

Part 5 - The Philosophy Behind the Exercise

A supervised label says what answer to imitate. A preference says which of two possibilities better reflects a judgment. That distinction makes preference data flexible, but it also reveals that the target is neither objective nor complete.

Human disagreement is not always noise to eliminate. It can be evidence that a prompt is ambiguous, a value is contested, or expertise is uneven. Responsible alignment preserves this information before converting judgment into gradient.

18.6.3 Exercise 02

Exercise Title: Explain RLHF Pipeline Conceptually and Identify Its Components

Part 1 - Deep conceptual foundation

Reinforcement Learning from Human Feedback is a family of pipelines that uses human judgments to shape a language-model policy. A common pipeline contains a pretrained model, supervised instruction tuning, response collection, preference annotation, reward-model training, policy optimization, a reference policy, and continuous evaluation. Each component can fail independently.

The reward model learns to assign higher scalar scores to preferred responses. It is a proxy for the annotation rubric, not a universal measure of goodness. Policy optimization then searches for responses that score well while a KL penalty limits movement away from a reference model. Without this constraint, the policy can exploit reward-model errors and move into regions where the proxy has little training support.

RLHF is iterative. As the policy changes, it produces new responses, changing the distribution on which judgments are needed. Offline preference quality does not guarantee online policy safety. Evaluations and red-team tests must surround the loop, and severe failures should stop policy updates rather than waiting for an average reward to improve.

This exercise maps every artifact and interface: tokenization, prompts, candidates, annotations, reward scores, policy log-probabilities, reference log-probabilities, advantages, checkpoints, and gates. You will simulate the data flow without implementing a harmful-capability optimizer.

Part 2 - Reward and policy objectives

Reward-model pairwise loss is

$$L_{\mathrm{RM}} = -\log \sigma(r_\phi(x, y_w) - r_\phi(x, y_l)).$$

A regularized policy objective has the conceptual form

$$\max_\theta \mathbb{E}_{y\sim\pi_\theta}[r_\phi(x, y)] - \beta\, \mathrm{KL}(\pi_\theta \| \pi_{\mathrm{ref}}).$$

Reward increase is not sufficient evidence; the evaluation vector must include helpfulness, safety, truthfulness, refusal precision, diversity, and drift.

Part 3 - Pipeline audit

1. Name the owner, version, input contract, output contract, and validation for every stage.
2. Prove tokenizer and chat-template identity across policy, reference, and reward model.
3. Evaluate reward accuracy on held-out annotators and hard preference pairs.
4. Monitor KL, response length, entropy, reward variance, and safety gates during policy optimization.
5. Keep reference and reward checkpoints immutable within one experiment.
6. Add stop conditions for reward spikes, KL divergence, mode collapse, and critical evaluation regressions.
7. Document where new human review enters the iteration loop.

Part 4 - Pipeline artifact registry

```
class RLHFStage:
    def __init__(self, name, version, inputs, outputs, owner):
        self.name = name
        self.version = version
        self.inputs = inputs
```

```
        self.outputs = outputs
        self.owner = owner
        self.validation = []

    def add_validation(self, check_name, threshold):
        self.validation.append({
            "check_name": check_name,
            "threshold": threshold
        })

def E02():
    stages = []
    stages.append(RLHFStage(
        "supervised_policy", "v1", ["instruction_data"],
        ["sft_checkpoint"], "model_team"
    ))
    stages.append(RLHFStage(
        "preference_collection", "v1", ["prompts", "candidates"],
        ["ranked_pairs"], "data_team"
    ))
    stages.append(RLHFStage(
        "reward_model", "v1", ["ranked_pairs"],
        ["reward_checkpoint"], "reward_team"
    ))
    stages.append(RLHFStage(
        "policy_optimization", "v1",
        ["sft_checkpoint", "reward_checkpoint", "reference_checkpoint"],
        ["aligned_checkpoint"], "optimization_team"
    ))
    return stages
```

Part 5 - The Philosophy Behind the Exercise

RLHF turns judgments into an optimization system. Every translation—rubric to annotation, annotation to reward, reward to policy—compresses meaning and can lose information. The pipeline must preserve enough evidence to inspect those losses.

Human feedback does not place a human conscience inside the model. It creates a measured pressure toward observed preferences. The difference matters because proxies require monitoring wherever the policy can discover their blind spots.

18.6.4 Exercise 03

Exercise Title: Implement Preference Pair Dataset and Validate Ranking Consistency

Part 1 - Deep conceptual foundation

A preference training item contains one prompt and at least two candidate responses. Both sequences must share the same prompt tokens and differ only in the response region. If templates, truncation, or system messages differ, the loss may learn those artifacts instead of the ranking.

Tokenization must preserve complete chosen and rejected responses whenever possible. Apply the identical prompt truncation policy to both branches. Record response boundaries and masks so log-probabilities are computed only over the candidate response. If one response is truncated more aggressively, its score is no longer comparable.

Ranking consistency includes more than chosen-not-equal-rejected. A dataset can contain reverse duplicates, cycles such as $A \succ B$, $B \succ C$, $C \succ A$, and the same pair judged under different rubrics. Cycles may reflect legitimate contextual tradeoffs or annotation noise; detect and investigate them instead of silently forcing transitivity.

This exercise constructs paired tensors with explicit loops, validates shared prompts and response masks, and builds a directed graph for contradiction analysis. It also reports length and presentation biases by split.

Part 2 - Pair contract

For prompt tokens p, chosen response c, and rejected response r:

$$x_w = p \| c, \qquad x_l = p \| r.$$

Response masks satisfy $m_{w,t} = 0$ over p and 1 over c, with the analogous rule for r. Pair validation requires equal prompt prefixes and at least one scored token on both branches.

Part 3 - Validation tests

1. Render the prompt once and reuse its token identifiers for both branches.
2. Reserve response capacity before truncating the shared prompt.
3. Verify response masks begin at the same semantic boundary.
4. Reject identical candidates and exact reverse duplicates.
5. Detect cycles per prompt and rubric; route them for review.
6. Audit chosen rate against response length, order, generator, and style.
7. Decode paired tensors and supervision masks from every edge case.

Part 4 - Explicit paired encoding

```
def encode_pair(tokenizer, record, maximum_length):
    prompt_ids = tokenizer.encode(record["prompt"], add_special_tokens=False)
    chosen_ids = tokenizer.encode(record["chosen"], add_special_tokens=False)
    rejected_ids = tokenizer.encode(
        record["rejected"], add_special_tokens=False
    )
    if chosen_ids == rejected_ids:
        raise ValueError("candidates tokenize identically")
    maximum_response = max(len(chosen_ids), len(rejected_ids))
    allowed_prompt = maximum_length - maximum_response
    if allowed_prompt < 1:
        raise ValueError("candidate response exceeds maximum length")
```

```
    if len(prompt_ids) > allowed_prompt:
        prompt_ids = prompt_ids[-allowed_prompt:]

    chosen_input = prompt_ids + chosen_ids
    rejected_input = prompt_ids + rejected_ids
    chosen_mask = []
    rejected_mask = []
    for position in range(len(chosen_input)):
        chosen_mask.append(int(position >= len(prompt_ids)))
    for position in range(len(rejected_input)):
        rejected_mask.append(int(position >= len(prompt_ids)))
    return chosen_input, rejected_input, chosen_mask, rejected_mask

def E03(tokenizer, records, maximum_length):
    encoded = []
    seen = set()
    for record in records:
        key = (record["prompt_id"], record["chosen"], record["rejected"])
        reverse = (record["prompt_id"], record["rejected"], record["chosen"])
        if key in seen or reverse in seen:
            raise ValueError("duplicate or reversed preference pair")
        seen.add(key)
        encoded.append(encode_pair(tokenizer, record, maximum_length))
    return encoded
```

Part 5 - The Philosophy Behind the Exercise

A preference pair is a controlled comparison. Its scientific value comes from holding the prompt constant so one behavioral difference can be judged. When the two branches contain hidden formatting differences, the comparison loses its meaning.

Consistency does not require pretending every value judgment is transitive. Detection should precede correction. Contradictions can reveal noise, ambiguity, or genuine conflicts that a scalar reward cannot faithfully represent.

18.6.5 Exercise 04

Exercise Title: Implement DPO Objective Conceptually and Compare to RLHF

Part 1 - Deep conceptual foundation

Direct Preference Optimization trains a policy directly from chosen and rejected responses while comparing it with a frozen reference policy. It avoids fitting a separate reward model and avoids online reinforcement-learning rollouts in the basic offline form. This simplifies the pipeline, but it does not remove dependence on preference quality, reference choice, coverage, or evaluation.

DPO increases the policy's chosen-versus-rejected log-probability margin relative to the same margin under the reference. The reference prevents the objective from rewarding differences already present before alignment and anchors the update. The temperature parameter β controls the strength of this comparison; its practical effect depends on data and optimization conventions.

Sequence log-probabilities must include response tokens only. Summing favors length-dependent magnitudes; averaging changes the objective. Use the formulation declared by the experiment and audit response-length effects. The policy and reference must use identical tokenization, templates, masks, and precision-aware log-softmax.

The exercise implements DPO loss from logits and contrasts system properties: RLHF can collect on-policy behavior and optimize arbitrary learned rewards, but is operationally complex and vulnerable to reward hacking. DPO is simpler and often stable offline, but remains bounded by fixed pair coverage.

Keep a frozen copy of raw pair-level scores. Aggregated accuracy can hide a small set of severe reversals, especially on policy-boundary prompts.

Part 2 - DPO equation

Let

$$\Delta_\theta = \log \pi_\theta(y_w \mid x) - \log \pi_\theta(y_l \mid x)$$

and define Δ_{ref} analogously. Then

$$L_{\text{DPO}} = -\log \sigma \left(\beta(\Delta_\theta - \Delta_{\text{ref}})\right).$$

Report chosen and rejected rewards, margin accuracy, KL-related drift proxies, and held-out behavior rather than loss alone.

Part 3 - Correctness protocol

1. Freeze the reference model and prove it receives no gradients.
2. Compute response-only sequence log-probabilities for all four branches.
3. Verify initial policy-reference identity gives zero relative margins.
4. Swap chosen and rejected responses and confirm the loss changes as expected.
5. Compare vectorized loss with a manual one-pair calculation.
6. Sweep β and monitor preference accuracy, diversity, and retention.
7. Evaluate on held-out prompt families and policy edge cases.

Part 4 - Explicit PyTorch DPO loss

```
import torch
import torch.nn.functional as F

def response_log_probability(logits, labels, response_mask):
    prediction_logits = logits[:, :-1, :]
    target_ids = labels[:, 1:]
    valid_mask = response_mask[:, 1:].bool()
    log_probabilities = F.log_softmax(prediction_logits, dim=-1)
    selected = log_probabilities.gather(
        dim=-1, index=target_ids.unsqueeze(-1)
```

```
    ).squeeze(-1)
    selected = selected * valid_mask
    return selected.sum(dim=-1)

def dpo_loss(policy_chosen, policy_rejected,
             reference_chosen, reference_rejected, beta):
    policy_margin = policy_chosen - policy_rejected
    reference_margin = reference_chosen - reference_rejected
    relative_margin = beta * (policy_margin - reference_margin)
    losses = -F.logsigmoid(relative_margin)
    preference_accuracy = (relative_margin > 0).float().mean()
    return losses.mean(), preference_accuracy, relative_margin

def E04(policy_scores, reference_scores, beta):
    return dpo_loss(
        policy_scores["chosen"], policy_scores["rejected"],
        reference_scores["chosen"], reference_scores["rejected"], beta
    )
```

Part 5 - The Philosophy Behind the Exercise

DPO shows that alignment can be framed as relative movement: prefer this answer over that one more strongly than the original model did. The reference provides a historical baseline, while the pair supplies a local direction.

Simplicity in optimization does not simplify values. The model still inherits the limits of who compared the answers, which alternatives were shown, and what the rubric could express. Direct optimization makes this dependency clearer, not absent.

18.6.6 Exercise 05

Exercise Title: Train Tiny Model with DPO and Observe Preference Shift

Part 1 - Deep conceptual foundation

A tiny DPO experiment should prove that preference gradients move conditional probability in the intended direction without claiming general alignment. Use a synthetic task with harmless, objectively ranked responses: correct versus incorrect formatting, grounded versus unsupported answers, or concise relevant answers versus irrelevant text. Keep a held-out set of prompt structures.

Begin policy and reference from identical weights. Freeze the reference and train only the policy. Record pre-training chosen and rejected log-probabilities, then measure their margin throughout training. Preference accuracy on training pairs can reach one while held-out behavior worsens, so track validation margin, response diversity, base retention, and actual generation.

Overfit a handful of pairs as a pipeline sanity check, then increase diversity. If loss does not fall, inspect masks, target shifts, reference gradients, and chosen/rejected ordering. If margins explode, reduce learning rate or beta and check whether one response-length pattern dominates.

Generation analysis should follow probability analysis. A margin can improve without changing greedy output when both candidates remain below another token sequence, while a

small movement can cross a decoding boundary and alter the visible answer. Save response-level scores and decoded output for the same prompts. Include pairs whose candidates share long prefixes and pairs that diverge immediately, because credit assignment differs. Finally, compare one-pass evaluation with repeated sampling: alignment that appears only under greedy decoding may disappear when temperature exposes other modes.

Part 2 - Measured shift

For pair i, define $m_i^{(s)} = \Delta_{\theta_s} - \Delta_{\text{ref}}$. The observed shift is $m_i^{(S)} - m_i^{(0)}$. Report the distribution, not only its mean, and require held-out preference accuracy above a declared threshold.

Part 3 - Training controls

1. Clone identical policy and reference states and hash them.
2. Assert reference parameters are frozen and unchanged after training.
3. Train first on one manually checked pair, then a varied synthetic set.
4. Log DPO loss, relative margin, gradient norm, and held-out accuracy.
5. Generate with fixed decoding before and after tuning.
6. Evaluate retention and diversity to detect narrow optimization.
7. Repeat across seeds and report failed runs.

Part 4 - Explicit DPO training step

```
import torch

def dpo_training_step(policy, reference, optimizer, batch, beta):
    optimizer.zero_grad(set_to_none=True)
    policy_chosen = policy.score_response(batch["chosen"])
    policy_rejected = policy.score_response(batch["rejected"])
    with torch.no_grad():
        reference_chosen = reference.score_response(batch["chosen"])
        reference_rejected = reference.score_response(batch["rejected"])
    loss, accuracy, margin = dpo_loss(
        policy_chosen, policy_rejected,
        reference_chosen, reference_rejected, beta
    )
    loss.backward()
    gradient_norm = torch.nn.utils.clip_grad_norm_(policy.parameters(), 1.0)
    optimizer.step()
    return {
        "loss": float(loss.detach().item()),
        "preference_accuracy": float(accuracy.detach().item()),
        "mean_margin": float(margin.detach().mean().item()),
        "gradient_norm": float(gradient_norm)
```

```
    }

def E05(policy, reference, optimizer, batches, beta):
    history = []
    for batch in batches:
        history.append(dpo_training_step(
            policy, reference, optimizer, batch, beta
        ))
    return history
```

Part 5 - The Philosophy Behind the Exercise

Preference optimization does not insert a rule into the model; it reshapes the relative likelihood of alternatives. Watching margins move makes that mechanism visible and prevents the word "alignment" from hiding an ordinary statistical update.

The tiny experiment also marks the boundary of evidence. Learning the shown pairs proves optimization works, not that the model will make wise choices where preferences were never represented.

18.6.7 Exercise 06

Exercise Title: Analyze Over-Alignment and Mode Collapse Failure Cases

Part 1 - Deep conceptual foundation

Over-alignment occurs when pressure toward a desired behavior becomes excessive or poorly generalized. A model may refuse harmless questions, repeat policy language unnecessarily, suppress uncertainty, or force every answer into one style. Mode collapse is the loss of useful response diversity: different prompts receive nearly identical, generic continuations.

These failures can coexist with improving preference accuracy because the data may reward safe-looking phrases, short answers, or one dominant template. Detect them with paired benign and risky prompts, paraphrases, creative tasks, and requests that legitimately require clarification. Measure refusal precision and recall separately; minimizing unsafe compliance by refusing everything is not a useful solution.

Monitor response entropy, distinct n-grams, semantic similarity across unrelated prompts, response length, and repeated-policy phrase frequency. Compare against the base and SFT checkpoints. Remedies include weaker preference strength, better-balanced pairs, explicit benign boundary examples, diversity-aware evaluation, and stopping before collapse.

Mode collapse also has a conditional form. Global diversity may remain high while every prompt inside one category receives the same canned response. Compute diversity within categories and among minimal prompt pairs. Test context use by changing one relevant fact and checking whether the answer changes. A generic safe answer has not merely lost creativity; it has stopped responding to evidence. Recovery experiments should restart from a pre-collapse checkpoint, because continued optimization may not restore displaced modes.

Part 2 - Refusal and diversity metrics

For safe requests, false refusal rate is $\mathrm{FRR} = \mathrm{FP}/(\mathrm{FP}+\mathrm{TN})$; for disallowed requests, unsafe compliance rate is $\mathrm{UCR} = \mathrm{FN}/(\mathrm{FN}+\mathrm{TP})$. Both must be reported. Diversity can include distinct-n and pairwise semantic similarity, with the latter inspected by task slice.

Part 3 - Failure study

1. Build matched benign, disallowed, ambiguous, and clarification-required prompts.
2. Freeze decoding settings and compare checkpoints.
3. Measure false refusal, unsafe compliance, answer usefulness, and diversity.
4. Search for repeated boilerplate and length collapse.
5. Plot failures against beta, KL strength, and training step.
6. Add boundary examples and verify both sides improve.
7. Preserve representative false refusals and unsafe responses for review.

Part 4 - Collapse monitor

```
def refusal_metrics(labels, predictions):
    false_refusal = 0
    unsafe_compliance = 0
    safe_total = 0
    disallowed_total = 0
    for index in range(len(labels)):
        if labels[index] == "safe":
            safe_total = safe_total + 1
            if predictions[index] == "refuse":
                false_refusal = false_refusal + 1
        if labels[index] == "disallowed":
            disallowed_total = disallowed_total + 1
            if predictions[index] == "comply":
                unsafe_compliance = unsafe_compliance + 1
    return {
        "false_refusal_rate": false_refusal / max(safe_total, 1),
        "unsafe_compliance_rate": unsafe_compliance / max(disallowed_total, 1)
    }

def E06(labels, predictions, responses):
    metrics = refusal_metrics(labels, predictions)
    unique_responses = len(set(responses))
    response_count = max(len(responses), 1)
    metrics["unique_response_ratio"] = unique_responses / response_count
    return metrics
```

Part 5 - The Philosophy Behind the Exercise

Safety without usefulness becomes silence; usefulness without boundaries becomes recklessness. Over-alignment demonstrates that optimizing one visible virtue can destroy the balance that gave the system value.

Plural prompts deserve plural answers. Diversity is not noise to eliminate but part of responsive intelligence, constrained by truth and policy rather than replaced by one universally safe-sounding mode.

18.6.8 Exercise 07

Exercise Title: Implement Safety Filters and Refusal Policies Conceptually

Part 1 - Deep conceptual foundation

Production safety is layered. Input classification, model policy, tool permissions, output checks, rate limits, monitoring, and human escalation protect different boundaries. A keyword blocklist alone misses context and produces false positives; a generative model alone should not hold unrestricted authority over high-impact actions.

Define a policy taxonomy with allowed, disallowed, and ambiguous cases. For allowed requests, answer normally. For clearly disallowed requests, refuse briefly without adding enabling details and offer safe alternatives when useful. For ambiguity or high-stakes contexts, request clarification or route to review. Log decisions with privacy-preserving identifiers and policy versions.

Filters must fail safely but not invisibly. Timeouts, classifier uncertainty, and contradictory signals require explicit fallback. Evaluate adversarial paraphrases and benign terms that resemble risky vocabulary. This exercise uses abstract categories and synthetic content so it tests routing without providing harmful instructions.

The output path needs equivalent care. A response may begin safely and later cross a boundary, or combine harmless fragments into an unsafe whole. Streaming systems need incremental checks and a policy for stopping, replacing, or escalating partial output. Tool calls require schema validation and authorization independent of natural-language safety. Record which layer made the final decision so failures can be attributed. Disagreement between an input classifier and model refusal is diagnostic evidence, not something to suppress.

Calibrate the classifier on deployment-like prevalence. Thresholds selected on a balanced laboratory set can behave very differently when risky requests are rare, so report precision, recall, and absolute review volume.

Part 2 - Decision policy

Given risk probability p and uncertainty u, a simple policy can use two thresholds: allow below τ_a, refuse above τ_r, and review between them. Thresholds must be calibrated per severity because equal error rates do not have equal impact.

Part 3 - Layered validation

1. Version categories, thresholds, refusal templates, and escalation rules.
2. Separate content classification from action authorization.
3. Test allowed, disallowed, ambiguous, multilingual, quoted, and transformed requests.
4. Measure false refusal and unsafe compliance by severity.
5. Simulate classifier timeout and disagreement between layers.
6. Ensure logs exclude sensitive prompt contents unless authorized.
7. Verify safe alternatives do not accidentally reproduce prohibited detail.

Part 4 - Defensive policy router

```
class SafetyDecision:
    def __init__(self, action, category, confidence, policy_version):
        self.action = action
        self.category = category
        self.confidence = confidence
        self.policy_version = policy_version

def route_request(classification, allow_threshold, refuse_threshold):
    probability = classification["risk_probability"]
    category = classification["category"]
    if probability >= refuse_threshold:
        action = "refuse"
    elif probability <= allow_threshold:
        action = "allow"
    else:
        action = "review"
    return SafetyDecision(
        action, category, classification["confidence"], "policy_v1"
    )

def E07(classifier, requests, allow_threshold, refuse_threshold):
    decisions = []
    for request in requests:
        classification = classifier(request)
        decision = route_request(
            classification, allow_threshold, refuse_threshold
        )
        decisions.append(decision)
    return decisions
```

Part 5 - The Philosophy Behind the Exercise

A refusal is an exercise of system authority. It should be explainable, proportionate, consistent, and open to escalation where context matters. Safety cannot be reduced to the model saying "no" more often.

Layering recognizes fallibility. No classifier, model, or rule is complete, so responsibility is distributed across controls whose failures can be observed and contained.

18.6.9 Exercise 08

Exercise Title: Evaluate Helpfulness vs Harmlessness Tradeoff

Part 1 - Deep conceptual foundation

Helpfulness and harmlessness are not simple opposites. Many requests can be answered fully and safely; others require boundaries, uncertainty, or safer alternatives. The tradeoff appears when a control reduces one failure while creating another, such as broad refusal that blocks legitimate education.

Construct matched prompt families near policy boundaries. Score relevance, correctness, completeness, safe handling, refusal appropriateness, and quality of alternatives. Do not average

away hard constraints: a highly helpful unsafe response fails, while a perfectly harmless empty response also fails the service goal.

Compare thresholds or checkpoints on a Pareto frontier. A candidate is dominated if another is at least as helpful and at least as harmless while strictly better on one. Choose operating points using severity-weighted constraints and document the affected users of false refusals.

Grading should account for safe transformation rather than only compliance or refusal. A model may answer the legitimate portion of a mixed request, explain a boundary, or redirect toward prevention. These bounded responses can be more helpful than blanket refusal without increasing risk. Add a metric for alternative usefulness and inspect it separately. Measure calibration as well: the system should express uncertainty when safety classification depends on missing context rather than forcing a confident decision at every boundary.

Measure consistency across languages and levels of technical expertise. A policy that offers useful bounded guidance in one language but defaults to refusal in another creates an unequal service even if the global average is unchanged.

Part 2 - Constrained optimization

For helpfulness H and harm risk R, choose

$$\max H(\theta) \quad \text{subject to} \quad R_c(\theta) \leq \tau_c$$

for every critical category c. This is safer than maximizing $H - \lambda R$ when a large helpfulness gain could numerically compensate for a severe failure.

Part 3 - Evaluation design

1. Define separate rubrics and blinded graders for helpfulness and safety.
2. Include benign, boundary, disallowed, and high-stakes uncertainty cases.
3. Evaluate complete answers, bounded answers, refusals, and safe alternatives.
4. Report per-category rates and severity, not only a global mean.
5. Plot candidate checkpoints and thresholds on a Pareto chart.
6. Audit false refusals for unequal impact across languages and groups.
7. Select an operating point with explicit noncompensable safety gates.

Part 4 - Pareto comparison

```
def is_dominated(candidate, alternatives):
    for alternative in alternatives:
        helpful_not_worse = (
            alternative["helpfulness"] >= candidate["helpfulness"]
        )
        safety_not_worse = (
            alternative["safety"] >= candidate["safety"]
        )
        strictly_better = (
```

```
            alternative["helpfulness"] > candidate["helpfulness"] or
            alternative["safety"] > candidate["safety"]
        )
        if helpful_not_worse and safety_not_worse and strictly_better:
            return True
    return False

def E08(candidates):
    frontier = []
    for candidate in candidates:
        if not is_dominated(candidate, candidates):
            frontier.append(candidate)
    return frontier
```

Part 5 - The Philosophy Behind the Exercise

Helpful behavior respects human purpose; harmless behavior respects human vulnerability. Treating either as absolute can erase the other. Alignment is the craft of preserving both wherever possible and making true conflicts visible.

A Pareto frontier does not make the ethical decision. It prevents a hidden weighted average from making it silently. People remain responsible for the operating point and its unequal consequences.

18.6.10 Exercise 09

Exercise Title: Debug Alignment Training Instability from Noisy Preference Data

Part 1 - Deep conceptual foundation

Preference noise arises from disagreement, weak rubrics, annotation mistakes, position bias, hidden response differences, and genuinely ambiguous values. In DPO or reward modeling, contradictory pairs produce competing gradients. Loss may oscillate, margins may become extreme, and validation preferences may stop improving even as training accuracy rises.

Diagnose data before tuning optimization. Measure duplicate conflicts, annotator consistency, confidence, pair difficulty, length bias, and agreement by category. Inspect the highest-loss pairs; they often reveal misordered candidates or underspecified prompts. Preserve ties and abstentions rather than randomly turning them into hard labels.

Possible interventions include adjudication, removing invalid pairs, weighting by confidence, soft preference targets, robust sampling, lower learning rate, and stronger reference regularization. Every cleaning rule changes whose judgment counts, so report performance across annotator groups and difficult slices.

Distinguish disagreement from pipeline corruption. If experts consistently divide on a value tradeoff, more labels estimate the distribution but do not create one objectively correct ranking. If an annotator reverses an identical pair, the issue is reliability. Use probabilistic targets for the first and quality-control investigation for the second. Track effective sample size after weighting: a large raw dataset can become statistically tiny when most weight concentrates on a few high-confidence pairs.

After cleaning, compare the retained distribution with the original. Removing every disputed example can create an artificially easy dataset that teaches only obvious preferences and fails precisely where judgment is most needed.

Part 2 - Soft-label loss

For empirical preference probability q_i and predicted probability p_i,

$$L_i = -q_i \log p_i - (1 - q_i) \log(1 - p_i).$$

When $q_i \approx 0.5$, the pair carries uncertainty rather than a strong ranking. Confidence weights w_i may scale loss, but must be calibrated and audited.

Part 3 - Debugging protocol

1. Freeze a clean validation subset with expert-reviewed pairs.
2. Find duplicate, reverse, cyclic, and cross-rubric conflicts.
3. Plot pair loss by confidence, category, annotator group, and length gap.
4. Manually inspect high-loss and high-gradient examples.
5. Compare hard labels, soft labels, and confidence weighting.
6. Retest stability across seeds and data order.
7. Report which judgments were excluded and why.

Part 4 - Conflict detector

```
def find_pair_conflicts(records):
    direction_by_pair = {}
    conflicts = []
    for record in records:
        first = record["chosen_id"]
        second = record["rejected_id"]
        ordered = tuple(sorted([first, second]))
        direction = (first, second)
        if ordered in direction_by_pair:
            previous = direction_by_pair[ordered]
            if previous != direction:
                conflicts.append({
                    "pair_key": ordered,
                    "first_direction": previous,
                    "second_direction": direction
                })
        else:
            direction_by_pair[ordered] = direction
    return conflicts

def E09(records):
    conflicts = find_pair_conflicts(records)
    conflict_rate = len(conflicts) / max(len(records), 1)
    return conflicts, conflict_rate
```

Part 5 - The Philosophy Behind the Exercise

Disagreement can be error, ambiguity, or plural values. Treating all three as identical noise destroys information; treating every judgment as equally certain creates unstable learning.

Debugging preference data is therefore partly an inquiry into meaning. The model cannot resolve contradictions that the dataset hides. Engineers must surface them before optimization turns them into unexplained gradients.

18.6.11 Exercise 10

Exercise Title: Run Preference Training on CUDA and Benchmark Memory Costs

Part 1 - Deep conceptual foundation

Preference training is memory intensive because each pair requires chosen and rejected policy computations and often reference computations. A naive implementation keeps several graphs alive simultaneously. Reference forward passes must use no-grad mode, while policy branches can be concatenated into one batch to reduce launch overhead. Sequence-length imbalance and padding can waste substantial attention computation.

Measure parameters, gradients, optimizer state, activations, and allocator peaks under fixed pair count and sequence lengths. Compare full tuning with LoRA, policy-only versus cached reference log-probabilities, activation checkpointing, and precision modes. Cached reference scores save computation but are valid only for an immutable reference and identical tokenization.

Report pairs per second, total tokens per second, response tokens per second, peak allocated memory, reserved memory, and padding efficiency. Warm up kernels, reset peaks, synchronize only around measurement, and record out-of-memory conditions as results.

Benchmarking should separate forward-only reference cost from policy backward cost. Use profiler ranges around transfer, policy branches, reference branches, loss, backward, and optimizer update. This reveals whether cached scores, packed pairs, or adapters address the actual bottleneck. Under mixed precision, compare response log-probabilities and pair ordering against float32. A faster run that changes preference ordering through overflow is a different experiment, not a valid optimization.

Include checkpoint save time and recovery memory in production-oriented tests. A configuration that barely fits training may fail when serialization or evaluation temporarily creates additional tensors.

Part 2 - Cost model

If policy processes two branches and reference scores are computed online, forward work is approximately four sequence passes per pair, with backward only through two policy branches. Actual cost depends on shared batching, padding, kernel fusion, and adapter placement.

Part 3 - Benchmark protocol

1. Verify all policy tensors share one CUDA device and the reference is frozen.
2. Warm up, reset memory statistics, and synchronize before timing.
3. Match token shapes across full and LoRA comparisons.
4. Compare online and cached reference scores with parity tests.
5. Measure useful response-token throughput as well as padded throughput.

6. repeat each configuration and report dispersion.

7. Store failed memory configurations in the result table.

Part 4 - CUDA benchmark skeleton

```
import time
import torch

def E10(training_step, batches, device):
    if device.type != "cuda":
        raise ValueError("CUDA device required")
    for index in range(min(2, len(batches))):
        training_step(batches[index])
    torch.cuda.synchronize(device)
    torch.cuda.reset_peak_memory_stats(device)
    start = time.perf_counter()
    pairs = 0
    response_tokens = 0
    for index in range(2, len(batches)):
        batch = batches[index]
        result = training_step(batch)
        pairs = pairs + result["pair_count"]
        response_tokens = response_tokens + result["response_tokens"]
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - start
    return {
        "pairs_per_second": pairs / elapsed,
        "response_tokens_per_second": response_tokens / elapsed,
        "peak_allocated": torch.cuda.max_memory_allocated(device),
        "peak_reserved": torch.cuda.max_memory_reserved(device)
    }
```

Part 5 - The Philosophy Behind the Exercise

Preference data doubles alternatives because alignment depends on comparison. The hardware cost is the physical expression of asking not merely "what did the model say?" but "which answer should become more likely?"

Efficiency matters because expensive evaluation loops are often shortened first. A faster pipeline should create room for more evidence, not justify weaker oversight.

18.6.12 Exercise 11

Exercise Title: Compare DPO vs PPO Stability on Small Synthetic Task

Part 1 - Deep conceptual foundation

DPO is an offline supervised-style objective over fixed preference pairs. PPO is an on-policy reinforcement-learning method that samples responses, scores them, estimates advantages, and

applies clipped policy updates. PPO can adapt to the current policy distribution, but introduces rollout variance, reward-model dependence, value estimation, and more hyperparameters.

Compare them on a harmless synthetic task with a known reward, such as satisfying format and correctness constraints. Give both methods the same initial policy, token budget, evaluation prompts, and wall-clock accounting. DPO receives fixed pairs; PPO receives sampled trajectories, so equal optimizer steps are not equal evidence. Report both processed tokens and reward evaluations.

Stability includes variance across seeds, KL drift, reward oscillation, collapse, gradient norms, and retained behavior. PPO clipping limits individual updates but does not guarantee global safety. DPO can be stable yet overfit the fixed pair distribution.

The comparison must expose hidden infrastructure. PPO needs generation, reward inference, old-policy probabilities, advantage estimation, and often a value model; DPO needs paired data and a reference pass. Count model copies, stored tensors, reward calls, and human labels, not only optimizer time. For PPO, verify padding and terminal tokens do not enter advantages incorrectly. For DPO, verify response-only sequence scores. Operational stability includes recovery, checkpointing, and monitoring, not merely a smooth loss curve.

Use identical downstream graders but method-appropriate diagnostics. PPO needs advantage and clipping statistics, whereas DPO needs pair margins. Forcing both into one loss-based dashboard would conceal their characteristic failure modes.

Part 2 - PPO and DPO contrast

PPO uses ratio $r_t(\theta) = \pi_\theta(a_t|s_t)/pi_{\text{old}}(a_t|s_t)$ and clipped surrogate

$$L_{\text{PPO}} = -\mathbb{E}\left[\min(r_t A_t, \text{clip}(r_t, 1-\epsilon, 1+\epsilon)A_t)\right].$$

DPO uses the offline relative margin from E04. Compare pipeline complexity as well as scalar performance.

Part 3 - Matched study

1. Use an exactly computable synthetic reward and hidden test prompts.
2. Match initialization, tokenizer, total generated or trained tokens, and evaluation schedule.
3. Tune both methods under equal search budgets.
4. Record reward, task correctness, KL, entropy, and retention.
5. Measure variance and failure count across seeds.
6. Inject mild reward noise and compare robustness.
7. Explain when online exploration is worth PPO's complexity.

Part 4 - Stability summary

```
import statistics

def summarize_runs(run_metrics):
    rewards = []
```

```
    divergences = []
    failures = 0
    for run in run_metrics:
        rewards.append(run["final_reward"])
        divergences.append(run["final_kl"])
        if run["failed"]:
            failures = failures + 1
    return {
        "reward_mean": statistics.mean(rewards),
        "reward_standard_deviation": statistics.stdev(rewards),
        "kl_mean": statistics.mean(divergences),
        "failed_runs": failures
    }

def E11(dpo_runs, ppo_runs):
    return {
        "dpo": summarize_runs(dpo_runs),
        "ppo": summarize_runs(ppo_runs)
    }
```

Part 5 - The Philosophy Behind the Exercise

Optimization methods embody different relationships with evidence. DPO learns from judgments already collected; PPO changes behavior, observes new outcomes, and learns again. One is simpler and bounded, the other adaptive and volatile.

The correct choice is not ideological. It depends on whether fresh exploration provides information valuable enough to justify its cost and risk.

18.6.13 Exercise 12

Exercise Title: Implement Reward Hacking Scenario and Detect It Automatically

Part 1 - Deep conceptual foundation

Reward hacking occurs when a policy maximizes a proxy without achieving the intended outcome. In a safe synthetic scenario, reward a response for containing a required tag while the real task also requires a correct answer. A policy may repeat the tag and ignore correctness, demonstrating exploitation without any harmful content.

Detection requires independent ground-truth metrics that were not optimized by the policy. Monitor proxy reward against task success, response length, repeated phrases, diversity, and out-of-distribution performance. A rising reward paired with flat or falling true success is a central warning.

Use canary prompts and adversarial proxy tests. Compare reward-model confidence with human or deterministic validation. Stop training when divergence exceeds a threshold. Do not "fix" the proxy using the same examples repeatedly without creating a new hidden evaluation set.

Reward hacking can appear through distribution shift before obvious metric divergence. The policy may discover outputs unlike reward-training responses. Track feature distance, reward-model ensemble disagreement, and sensitivity to harmless paraphrases. Extremely high reward in a low-density region deserves inspection, not celebration. Maintain a hidden evaluator based

on the true task and add newly discovered exploits to regression only after measuring them on an untouched checkpoint.

Test the monitor with an injected exploit checkpoint. An alarm that looks reasonable on ordinary learning curves has not proved it can detect the failure for which it was designed.

Part 2 - Proxy gap

For proxy reward $\widehat{R}$ and true task metric R^*, define

$$G = \text{normalize}(\widehat{R}) - \text{normalize}(R^*).$$

Large positive growth in G indicates optimization is outrunning validated utility. Correlation across checkpoints is useful but does not replace slice analysis.

Part 3 - Detection experiment

1. Define a harmless task with deterministic true success.
2. Create a deliberately incomplete proxy based on a superficial feature.
3. Optimize the proxy and evaluate true success at every checkpoint.
4. Monitor length, repetition, diversity, and unseen prompts.
5. Trigger an automatic stop when proxy rises while true success falls.
6. Repair the reward with diverse counterexamples and retest on hidden data.
7. Document the exploit pattern without operational harmful content.

Part 4 - Automatic proxy-gap alarm

```
class RewardHackingMonitor:
    def __init__(self, maximum_gap, patience):
        self.maximum_gap = maximum_gap
        self.patience = patience
        self.bad_steps = 0

    def update(self, proxy_score, true_score):
        gap = proxy_score - true_score
        if gap > self.maximum_gap:
            self.bad_steps = self.bad_steps + 1
        else:
            self.bad_steps = 0
        return {
            "proxy_gap": gap,
            "stop": self.bad_steps >= self.patience
        }

def E12(checkpoints, maximum_gap, patience):
    monitor = RewardHackingMonitor(maximum_gap, patience)
```

```
    history = []
    for checkpoint in checkpoints:
        result = monitor.update(
            checkpoint["proxy_score"], checkpoint["true_score"]
        )
        history.append(result)
        if result["stop"]:
            break
    return history
```

Part 5 - The Philosophy Behind the Exercise

Optimization is literal. It pursues what is measured, not the intention that motivated the measurement. Reward hacking is therefore not disobedience; it is the exposure of an incomplete specification.

Independent evaluation protects meaning from its proxy. When the two diverge, the correct response is to question the measurement before blaming the model.

18.6.14 Exercise 13

Exercise Title: Build Alignment Evaluation Set Focused on Edge-Case Prompts

Part 1 - Deep conceptual foundation

Average prompts rarely reveal alignment boundaries. Edge cases combine ambiguity, conflicting instructions, quoted unsafe material, benign educational context, missing information, multilingual wording, prompt injection, and requests near a policy threshold. A strong suite tests whether behavior changes for the right reason.

Build a taxonomy before authoring prompts. Create matched pairs differing in one meaningful feature, such as authorization or intent, and paraphrase each pair. Expected behavior can be answer, bounded answer, clarification, refusal, or escalation. Store the policy clause and rationale that justify the label.

Avoid releasing detailed harmful prompts in the training book. Use abstract placeholders and controlled synthetic examples while preserving the evaluation logic. Keep a protected test subset to reduce tuning to the benchmark.

Edge cases also need compositional tests. A system may handle quoted material, multilingual wording, and conflicting instructions separately but fail when two features appear together. Build a small factorial design that combines factors without exploding the suite, then use failure clustering to prioritize new combinations. Include multi-turn cases where intent becomes clear only after a clarification. Preserve conversation state and verify that a safe decision does not depend on omitting earlier turns during evaluation.

Maintain grader disagreement as a metric. Edge cases are often where policy language itself is ambiguous, and apparent model inconsistency may reveal an unstable ground-truth rule.

Part 2 - Slice reliability

For slice s, failure estimate is $\widehat{p}_s = k_s/n_s$. Report sample size and a confidence interval; a zero observed failure in a tiny slice is not proof of safety. Track paired consistency between semantic variants.

Part 3 - Suite construction

1. Derive categories from threat models, incidents, and policy boundaries.
2. Author minimal pairs with one controlled semantic difference.
3. Assign expected action, rationale, severity, and grader.
4. Review labels with safety and domain experts.
5. Separate development, regression, and protected test sets.
6. Measure false refusal, unsafe compliance, clarification quality, and paraphrase consistency.
7. Version every item and retire invalid prompts without rewriting history.

Part 4 - Versioned edge-case registry

```
def validate_edge_case(item):
    required = ["item_id", "category", "prompt", "expected_action",
                "policy_clause", "severity"]
    for field_name in required:
        if field_name not in item:
            raise ValueError("missing field: " + field_name)
    actions = ["answer", "bounded_answer", "clarify", "refuse", "escalate"]
    if item["expected_action"] not in actions:
        raise ValueError("invalid expected action")

def E13(items):
    identifiers = set()
    by_category = {}
    for item in items:
        validate_edge_case(item)
        if item["item_id"] in identifiers:
            raise ValueError("duplicate edge-case identifier")
        identifiers.add(item["item_id"])
        category = item["category"]
        if category not in by_category:
            by_category[category] = []
        by_category[category].append(item)
    return by_category
```

Part 5 - The Philosophy Behind the Exercise

Boundaries reveal principles more clearly than ordinary cases. When two prompts differ by one crucial fact, the model's different treatment shows whether it has learned a policy distinction or a superficial trigger.

Edge-case evaluation is not a search for perfection. It is a disciplined way to discover where confidence should end and human judgment should begin.

18.6.15 Exercise 14

Exercise Title: Analyze Hallucination Reduction After Alignment Tuning

Part 1 - Deep conceptual foundation

Alignment tuning can reduce some hallucinations by rewarding calibrated uncertainty, evidence use, and appropriate abstention. It cannot guarantee truth because preference objectives optimize judged behavior, and annotators may prefer fluent incorrect answers. A model can also appear improved by refusing more often, shifting error from false claims to unnecessary abstention.

Use questions with known answers, unanswerable questions, context-grounded questions, and misleading premises. Separate factual correctness, citation or evidence support, calibration, abstention accuracy, and usefulness. Compare base, SFT, and preference-tuned checkpoints under identical decoding.

Claims require atomic evaluation. Split a response into verifiable statements and label each supported, contradicted, or unverifiable. Measure coverage so a model is not rewarded for giving empty answers. For context tasks, ensure the answer is supported by supplied evidence rather than memorized coincidence.

Preference tuning may alter verbal confidence without altering internal probability calibration. Measure token-level confidence, self-reported uncertainty, and empirical correctness separately. Test whether cited sources exist and support the associated claim rather than rewarding citation-shaped text. For temporal questions, attach an evaluation date and evidence snapshot; otherwise later knowledge changes can make the same answer appear alternately correct and incorrect. Human review should focus on fluent contradictions that automatic lexical metrics miss.

Repeat the study with sampling as well as greedy decoding. Preference tuning can reshape probability tails even when the most likely answer remains unchanged, which matters for repeated user interactions.

Part 2 - Selective accuracy

Let coverage be the fraction answered and risk be error among answered cases. Plot risk versus coverage as the abstention threshold changes. Hallucination rate alone is incomplete without answer rate and utility.

Part 3 - Before-and-after study

1. Freeze answerable, unanswerable, grounded, and false-premise slices.
2. Use identical prompts and deterministic decoding for paired comparison.
3. Score atomic claims, evidence support, abstention, and coverage.
4. Plot risk-coverage curves from confidence or uncertainty signals.
5. Inspect whether reduced hallucination is merely increased refusal.
6. Test domains absent from preference training.
7. Report convincing aligned-model failures, not only average improvement.

Part 4 - Claim-level summary

```
def summarize_claims(records):
    supported = 0
    contradicted = 0
    unverifiable = 0
    answered = 0
    for record in records:
        if record["answered"]:
            answered = answered + 1
        for status in record["claim_statuses"]:
            if status == "supported":
                supported = supported + 1
            elif status == "contradicted":
                contradicted = contradicted + 1
            else:
                unverifiable = unverifiable + 1
    total_claims = supported + contradicted + unverifiable
    return {
        "support_rate": supported / max(total_claims, 1),
        "contradiction_rate": contradicted / max(total_claims, 1),
        "coverage": answered / max(len(records), 1)
    }

def E14(base_records, aligned_records):
    return summarize_claims(base_records), summarize_claims(aligned_records)
```

Part 5 - The Philosophy Behind the Exercise

Alignment can teach a model how to behave when it does not know; it cannot make knowledge unlimited. Calibrated uncertainty is valuable because it makes the boundary of evidence visible.

Truthfulness is not silence. A model earns trust by answering when supported, abstaining when necessary, and distinguishing the two without theatrical confidence.

18.6.16 Exercise 15

Exercise Title: Implement Red-Teaming Prompts and Measure Failure Rates

Part 1 - Deep conceptual foundation

Red teaming is authorized adversarial evaluation intended to discover failures before deployment or abuse. It needs a written scope, safe test environment, data-handling rules, stop conditions, severity rubric, and disclosure path. The goal is not to generate operationally harmful material but to test categories, routing, robustness, and containment using controlled abstractions.

Prompts should cover direct requests, paraphrases, role-play, quoted content, multi-turn pressure, instruction conflicts, encoded or transformed benign proxies, and tool-boundary attempts. Record the attack pattern separately from sensitive payloads. A failure is defined by policy and impact: unsafe compliance, privacy leakage, incorrect tool authorization, excessive refusal, or unreliable escalation.

Measure attack success by category and severity, not only total failures. Count unique root causes so hundreds of paraphrases do not create a false sense of independent evidence. After mitigation, rerun the original regression set and a hidden variation set to detect benchmark-specific patching.

The harness should support reproducible replay. Store model and policy versions, decoding configuration, tool permissions, environment, and hashes of protected cases. Remove personal data and restrict raw outputs according to severity. When testers discover several prompts with one root cause, keep representative variants but avoid treating them as independent evidence. Track time to triage, time to mitigation, and recurrence after release; operational response quality is part of the red-team result.

Include control prompts that should always pass. If the harness flags them, the grader or policy interpretation may be faulty, and reported attack success can be inflated.

Part 2 - Failure estimates

For category c, attack success rate is $\mathrm{ASR}_c = k_c/n_c$. Report confidence intervals and severity-weighted counts. The residual risk decision must also consider detectability and exposure, not just laboratory frequency.

Part 3 - Authorized test protocol

1. Obtain scope, ownership, environment, and stop conditions before testing.
2. Use synthetic placeholders for harmful payloads in general documentation.
3. Tag technique, category, severity, expected behavior, and policy clause.
4. Run fixed decoding and production decoding as separate conditions.
5. Store sensitive outputs under restricted access.
6. Cluster failures by root cause and assign remediation owners.
7. Retest original and hidden variants after every mitigation.

Part 4 - Safe red-team harness

```
def evaluate_red_team_case(case, response, policy_grader):
    grade = policy_grader(case["category"], response)
    return {
        "case_id": case["case_id"],
        "category": case["category"],
        "severity": case["severity"],
        "failed": not grade["passed"],
        "reason_code": grade["reason_code"]
    }

def E15(cases, generate, policy_grader):
    results = []
    failures_by_category = {}
    totals_by_category = {}
```

```
    for case in cases:
        response = generate(case["prompt"])
        result = evaluate_red_team_case(case, response, policy_grader)
        results.append(result)
        category = result["category"]
        totals_by_category[category] = totals_by_category.get(category, 0) + 1
        if result["failed"]:
            previous_failures = failures_by_category.get(category, 0)
            failures_by_category[category] = previous_failures + 1
    return results, totals_by_category, failures_by_category
```

Part 5 - The Philosophy Behind the Exercise

Red teaming treats failure discovery as a form of care. It deliberately removes the comfort of ordinary examples so hidden assumptions become visible before people depend on them.

Adversarial testing gains legitimacy from authorization and containment. The same curiosity that finds weaknesses must be governed by responsibility for what the test creates and reveals.

18.6.17 Exercise 16

Exercise Title: Compare Alignment Strength Across Different Model Sizes

Part 1 - Deep conceptual foundation

Model size changes capability, optimization behavior, and the expression of alignment data. A larger model may understand nuanced policies and generalize preferences better, but it may also possess stronger capabilities that increase the impact of failures. Smaller models may underfit subtle distinctions and rely more on superficial refusal templates.

Compare sizes from the same architecture family with matched tokenizer, pretraining lineage where possible, preference dataset, evaluation suite, and search budget. Equal steps do not mean equal compute, while equal compute may give smaller models more data passes. Report both compute-matched and data-matched views when feasible.

Alignment "strength" must be decomposed into helpfulness, safe compliance, false refusal, policy generalization, robustness, calibration, and retention. Also test whether larger models hide failures behind more persuasive language. Do not infer a monotonic law from two checkpoints.

Capacity may change the data requirement itself. A small model can need more explicit boundary demonstrations, while a larger model may infer the rule from fewer examples but exploit subtle reward shortcuts. Measure learning curves over alignment-data size for every model rather than using one fixed final checkpoint. Also normalize adapter rank or trainable fraction carefully: equal LoRA rank does not represent equal relative capacity across widths. Record inference cost and latency because a behaviorally stronger model may be operationally inappropriate for the deployment setting.

Inspect error correlation across sizes. If every model fails the same prompts, the bottleneck may be shared data or policy ambiguity rather than capacity. If failures move between sizes, each deployment needs its own regression suite.

Part 2 - Scaling comparison

For model size N, fit descriptive curves only within observed ranges, for example $M(N) = a + b \log N$. Confidence intervals across seeds and prompt slices are essential; extrapolation beyond tested sizes must be labeled speculative.

Part 3 - Matched evaluation

1. Select at least three sizes from a consistent family.
2. Hold policy, data version, templates, and evaluation constant.
3. Report data-matched and compute-matched training conditions.
4. Tune learning rate and alignment strength per size under equal budgets.
5. Measure all behavior dimensions and per-severity failures.
6. Compare confidence, verbosity, and persuasiveness of incorrect outputs.
7. Avoid claims beyond the tested size and task range.

Part 4 - Size comparison table

```
def E16(model_results):
    required = ["parameters", "helpfulness", "safety",
                "false_refusal", "retention", "compute"]
    validated = []
    for result in model_results:
        for field_name in required:
            if field_name not in result:
                raise ValueError("missing field: " + field_name)
        validated.append(result)
    def parameter_count(item):
        return item["parameters"]
    validated.sort(key=parameter_count)
    return validated
```

Part 5 - The Philosophy Behind the Exercise

Capability and alignment do not scale as one substance. A larger model may interpret values more subtly while making every remaining mistake more capable and convincing.

Scale therefore expands both possibility and obligation. The evaluation burden should grow with what the model can do, not shrink because average behavior looks smoother.

18.6.18 Exercise 17

Exercise Title: Build Safety Checklist for Production LLM Deployment

Part 1 - Deep conceptual foundation

Production safety begins before deployment and continues after it. A checklist must cover model and data identity, intended use, policy, evaluation, access control, tool permissions,

privacy, monitoring, incident response, rollback, human escalation, and change management. Passing a benchmark is not a permanent safety property because users, data, attacks, and dependencies change.

Each item needs evidence, owner, severity, status, expiration, and remediation. Blocking checks cannot be averaged with optional improvements. Test the deployed system, including prompt templates, retrieval, tools, filters, caches, and logs; a safe isolated checkpoint can become unsafe through integration.

Monitoring should track drift, refusal patterns, policy violations, latency failures, anomalous tool calls, and user appeals while minimizing sensitive-data collection. Incident response needs clear authority to disable tools, reduce traffic, or roll back the model.

The checklist must distinguish launch readiness from ongoing authorization. Some evidence expires after a model, retrieval source, tool, or policy change. Define which modifications require full reevaluation and which permit targeted regression tests. Canary deployment should limit exposure while monitoring both automatic metrics and user-reported failures. Rollback artifacts must already exist and be tested; an emergency plan that requires building an old environment after the incident is not a reliable control.

Third-party dependencies need equivalent gates. A change in moderation service, retrieval corpus, model host, or analytics pipeline can alter safety without changing the checkpoint, so dependency versions belong in the release record.

Part 2 - Release gate

If blocking checks produce c_i, release requires $\bigwedge_{i \in B} c_i = 1$. Evidence has an expiry time because models and environments change; stale success cannot authorize a new release.

Part 3 - Checklist domains

1. Verify model, tokenizer, policy, code, data, and evaluation versions.
2. Approve intended uses, prohibited uses, user notices, and escalation.
3. Test safety, privacy, hallucination, bias, prompt injection, and tools.
4. Enforce least privilege, rate limits, sandboxing, and output validation.
5. Validate logging minimization, retention, access, and deletion procedures.
6. Rehearse rollback and incident communication.
7. Define monitoring thresholds, owners, and review cadence.

Part 4 - Executable release checklist

```
class SafetyCheck:
    def __init__(self, name, blocking, owner, evidence, passed):
        self.name = name
        self.blocking = blocking
        self.owner = owner
        self.evidence = evidence
        self.passed = passed
```

```
def E17(check_definitions):
    checks = []
    release_ready = True
    for definition in check_definitions:
        check = SafetyCheck(
            definition["name"], definition["blocking"],
            definition["owner"], definition["evidence"],
            definition["passed"]
        )
        checks.append(check)
        if check.blocking and not check.passed:
            release_ready = False
    return {"release_ready": release_ready, "checks": checks}
```

Part 5 - The Philosophy Behind the Exercise

Safety is not an adjective attached to a model; it is a maintained relationship between a system, its powers, its users, and its environment. That relationship can decay when any part changes.

A checklist makes responsibility durable. It ensures that the ability to launch is accompanied by the ability to notice harm, stop operation, and repair trust.

18.6.19 Exercise 18

Exercise Title: Document Ethical Risks and Mitigations for Your LLM

Part 1 - Deep conceptual foundation

Ethical risk documentation examines who benefits, who can be harmed, which values are encoded, and where technical controls are insufficient. Relevant areas include privacy, consent, intellectual property, bias, accessibility, labor, manipulation, misinformation, environmental cost, concentration of power, and unequal error distribution.

Create an impact register linked to concrete system features and use cases. Distinguish direct harm, misuse, foreseeable secondary effects, and structural effects. For every mitigation, state evidence, limitations, owner, residual risk, and review date. “Use a filter” is not an adequate mitigation without measured coverage and failure analysis.

Include affected stakeholders in review, especially groups bearing risk without being direct users. Document disagreements instead of forcing consensus into one score. Some residual risks require limiting deployment rather than another model update.

Mitigations can move harm rather than remove it. Aggressive filtering may reduce misuse while excluding dialects or accessibility needs; data removal may protect privacy while weakening representation of a community. Evaluate distributional effects and identify who bears the residual cost. Separate reversible decisions from deployments that create lasting data or social consequences. When evidence is weak, document uncertainty and use staged deployment instead of converting unknowns into reassuring numerical scores.

Define participation and appeal mechanisms where feasible. People affected by system errors need a path to contest outputs and correct records; aggregate monitoring cannot represent an individual high-impact failure adequately.

Part 2 - Residual risk

If inherent risk is R_0 and control effectiveness is $e \in [0, 1]$, a simple residual estimate is $R_r = R_0(1-e)$. This is an organizing approximation, not a claim that ethical impact is exactly scalar or independent across controls.

Part 3 - Impact assessment

1. Identify stakeholders, rights, benefits, harms, and power asymmetries.
2. Connect each risk to a feature, workflow, and affected context.
3. Gather quantitative evidence and qualitative testimony.
4. Evaluate mitigation effectiveness and displacement of harm.
5. Record residual risk, disagreements, and deployment limitations.
6. Assign owners and review triggers.
7. Publish an appropriate transparency summary without exposing sensitive security details or personal data.

Part 4 - Ethical risk register

```
class EthicalRisk:
    def __init__(self, risk_id, stakeholders, description, inherent_risk):
        self.risk_id = risk_id
        self.stakeholders = stakeholders
        self.description = description
        self.inherent_risk = inherent_risk
        self.mitigations = []

    def add_mitigation(self, name, effectiveness, owner, evidence):
        self.mitigations.append({
            "name": name, "effectiveness": effectiveness,
            "owner": owner, "evidence": evidence
        })

def E18(risk_records):
    registry = []
    for record in risk_records:
        registry.append(EthicalRisk(
            record["risk_id"], record["stakeholders"],
            record["description"], record["inherent_risk"]
        ))
    return registry
```

Part 5 - The Philosophy Behind the Exercise

Ethics begins where technical success stops being the only question. A model can meet accuracy targets while distributing costs unfairly or changing human agency in ways no benchmark captures.

Documentation does not solve value conflicts, but it prevents them from being hidden behind architecture. It makes deployment a reasoned responsibility rather than an automatic consequence of capability.

18.6.20 Exercise 19

Exercise Title: Produce a Full Alignment Engineering Report

Part 1 - Deep conceptual foundation

The final report must connect behavioral goals, stakeholders, preference data, training objectives, optimization, safety policies, evaluations, red-team findings, deployment controls, and residual risks. It is a decision record, not a claim that alignment is complete.

Begin with scope, policy, non-goals, and authority. Document how candidates were generated, who annotated them, rubric versions, disagreement, bias audits, splits, and privacy. Specify SFT, reward-model, DPO or PPO configurations, reference checkpoint, beta or KL controls, precision, memory, seeds, and stop conditions.

Compare base, SFT, and aligned checkpoints on helpfulness, correctness, hallucination, refusal precision, unsafe compliance, diversity, edge cases, retention, and red-team categories. Include uncertainty and paired failures. Describe filters, tool permissions, monitoring, rollback, and incident response.

End with blocking gates, accepted residual risks, owners, expiration dates, and the next experiment that would reduce the greatest uncertainty. Rejected configurations and failed mitigations are essential evidence.

The report should include a claim-evidence matrix. Every major statement—for example that hallucination decreased or refusal became more precise—must point to a versioned evaluation, confidence estimate, and known limitation. Separate observations from interpretations and release decisions. Add a change log so a future report can explain why policy, data, thresholds, or mitigations changed. The final artifact should be readable by model engineers, safety reviewers, and decision owners without requiring undocumented project memory.

Part 2 - Decision vector

Let $G = (H, S, T, R, D, P, M)$ represent helpfulness, safety, truthfulness, retention, diversity, privacy, and monitoring readiness. Release requires every blocking component to meet its threshold; one high score cannot compensate for a critical failure elsewhere.

Part 3 - Required report sections

1. Identify every model, tokenizer, dataset, rubric, policy, code, and test suite version.
2. Explain preference collection and disagreement handling.
3. Derive the chosen objective and show mask and log-probability tests.
4. Present training stability, CUDA cost, and reproducibility evidence.
5. Compare all behavioral dimensions and critical slices.
6. Include red-team root causes, mitigations, and regression results.
7. Document ethical impact, residual risk, monitoring, rollback, and owners.

8. State the release decision and evidence that could reverse it.

Part 4 - Structured alignment report

```
class AlignmentReport:
    def __init__(self, report_id):
        self.report_id = report_id
        self.sections = {}
        self.gates = []

    def add_section(self, name, evidence):
        self.sections[name] = evidence

    def add_gate(self, name, passed, blocking, owner, evidence):
        self.gates.append({
            "name": name, "passed": passed, "blocking": blocking,
            "owner": owner, "evidence": evidence
        })

    def release_ready(self):
        for gate in self.gates:
            if gate["blocking"] and not gate["passed"]:
                return False
        return True

def E19():
    report = AlignmentReport("LLM04-ALIGNMENT-V1")
    report.add_section("scope", {"status": "defined"})
    report.add_section("preference_data", {"status": "audited"})
    report.add_section("evaluation", {"status": "pending"})
    report.add_gate(
        "critical_safety_suite", False, True,
        "safety_owner", "evaluation must be completed"
    )
    return report, report.release_ready()
```

Part 5 - The Philosophy Behind the Exercise

An alignment report is a map of influence: whose preferences shaped behavior, which proxies carried them, which failures survived, and who accepted the remaining risk. It makes the model's conduct answerable to decisions.

Alignment has no final certificate. The report is valuable because it records a current, contestable justification and creates obligations to monitor, revise, and stop when reality contradicts it.

18.7 LLM05

Chapter Title: Inference, KV Cache, and Serving **Specialization:** Production LLM Inference Engineering

18.7.1 Exercise 00

Exercise Title: Explain Autoregressive Inference and Why KV Cache Is Required

Part 1 - Deep conceptual foundation

Autoregressive inference generates one token at a time. The prompt first passes through a prefill phase that computes representations for all prompt positions. The decode phase then appends one token per iteration. Although operations inside each iteration are parallel, token $t+1$ cannot be chosen before token t exists.

Without a cache, every decode step recomputes keys and values for the entire prefix. A KV cache stores the attention key and value tensors from earlier positions, so the new query attends to stored history while only the newest position is projected. This removes repeated prefix computation but consumes memory proportional to layers, batch, sequence length, heads, and head size.

Distinguish time-to-first-token from inter-token latency. Prefill cost grows with prompt length and benefits from parallelism; decode is bandwidth-sensitive and repeats many small steps. The exercise will trace tensor shapes, estimate cache bytes, and compare exact cached and uncached logits. Cache architecture also differs across attention variants. Multi-query and grouped-query attention store fewer KV heads than full multi-head attention, which changes memory without changing the number of query heads. Beam search and multiple return sequences may share prompt cache initially and diverge later. Production estimates must therefore use the actual checkpoint configuration and decode strategy rather than parameter count alone. Fragmentation and reserved capacity add overhead beyond the ideal equation. Measure live bytes at prompt length boundaries and after request completion to connect theory with allocator behavior.

Part 2 - Mathematical and systems model

For layer l, cache after step t is

$$K_l^{(t)} = [K_l^{(t-1)}; k_{l,t}], \qquad V_l^{(t)} = [V_l^{(t-1)}; v_{l,t}].$$

Approximate cache bytes are

$$M_{KV} = 2LBTHd_h s,$$

where L is layers, B batch, T cached length, H KV heads, d_h head dimension, and s bytes per element.

Part 3 - Evidence and controls

1. Separate prefill and decode timing.
2. Write cache shape for every layer and verify sequence-axis growth.
3. Compare cached and full-prefix logits at every generated position.
4. Estimate bytes analytically and compare with measured allocation.
5. Test one token, long prompt, batched prompts, and cache reset.
6. Explain why caching reduces compute but increases persistent memory.

Part 4 - Explicit cache-size code

```
def kv_cache_bytes(layers, batch, cached_tokens,
                   key_value_heads, head_size, bytes_per_value):
    key_elements = layers * batch * cached_tokens
    key_elements = key_elements * key_value_heads * head_size
    value_elements = key_elements
    return (key_elements + value_elements) * bytes_per_value

def E00(configurations):
    results = []
    for configuration in configurations:
        size = kv_cache_bytes(
            configuration["layers"], configuration["batch"],
            configuration["tokens"], configuration["kv_heads"],
            configuration["head_size"], configuration["bytes"]
        )
        results.append({"configuration": configuration, "cache_bytes": size})
    return results
```

Part 5 - The Philosophy Behind the Exercise

KV caching is computational memory: the service spends storage to avoid repeating the past. It reveals a general systems principle that speed often comes from preserving intermediate work. The cache is useful only while its identity, position, and lifecycle remain correct; memory without provenance becomes error.

18.7.2 Exercise 01

Exercise Title: Implement KV Cache Correctly and Validate Speedup Over Naive Decoding

Part 1 - Deep conceptual foundation

Implement caching at the attention layer before relying on framework generation. During prefill, project all tokens and store keys and values. During decode, project only the newest token, append on the sequence axis, and compute attention against the complete cache. Cache tensors must retain batch, KV-head, sequence, and head-dimension meaning.

Correctness precedes speed. Cached and naive decoding should produce equal logits for deterministic models within dtype tolerance. Compare every step, not only final tokens, because greedy outputs can remain equal despite growing numerical error. Disable dropout, fix seeds, and use the same causal and padding masks.

Benchmark after warmup with CUDA synchronization. Naive decoding repeatedly processes longer prefixes; cached decoding processes one new token but reads a growing cache. Speedup is small for tiny sequences and grows until memory bandwidth or cache management dominates. Appending with repeated tensor concatenation is transparent but can reallocate and copy the entire cache. After correctness is established, compare it with a preallocated or paged cache that writes new states into owned blocks. The optimized form must preserve the same visible prefix and causal mask. Test cache capacity expansion and block reuse under request churn. A speed claim should include allocation time and memory traffic, not merely attention kernels, because poor cache storage can erase the theoretical savings of reused projections.

Part 2 - Attention update

For new query q_t,

$$a_t = \text{softmax}(q_t K_{\le t}^\top / \sqrt{d_h}), \qquad o_t = a_t V_{\le t}.$$

Only q_t, k_t, v_t are newly projected in decode.

Part 3 - Validation protocol

1. Test cache parity layer by layer with float64 on a tiny model.
2. Assert cache length increases by exactly one per step.
3. Compare logits, selected token, and decoded output.
4. Warm up, synchronize, and time multiple sequence lengths.
5. Report prefill separately from decode.
6. Verify a new request cannot reuse another request's cache.

Part 4 - Explicit cache container

```
import torch

class LayerKVCache:
    def __init__(self):
        self.keys = None
        self.values = None

    def append(self, new_keys, new_values):
        if new_keys.shape != new_values.shape:
            raise ValueError("key and value shapes differ")
        if self.keys is None:
            self.keys = new_keys
            self.values = new_values
        else:
            self.keys = torch.cat([self.keys, new_keys], dim=2)
            self.values = torch.cat([self.values, new_values], dim=2)
        return self.keys, self.values

    def clear(self):
        self.keys = None
        self.values = None

def E01(key_steps, value_steps):
    cache = LayerKVCache()
    lengths = []
    for index in range(len(key_steps)):
        keys, values = cache.append(key_steps[index], value_steps[index])
        lengths.append(keys.shape[2])
    return cache, lengths
```

Part 5 - The Philosophy Behind the Exercise

A cache is an optimization that must be observationally invisible: it should change cost, not meaning. Parity testing embodies this contract. When performance work cannot reproduce the reference computation, it has optimized a different program.

18.7.3 Exercise 02

Exercise Title: Debug KV Cache Bugs Caused by Wrong Position Indexing

Part 1 - Deep conceptual foundation

Cached decoding changes the tensor presented to the model from the full prefix to one new token, but its position remains the absolute next position. Resetting the position to zero at every step corrupts positional encoding while preserving valid shapes. RoPE is especially sensitive because query and key rotations must use consistent positions.

Padding complicates batches. Position identifiers may derive from cumulative attention masks rather than raw column indices, and finished sequences must not advance as if they generated real content. Sliding windows may evict old cache entries while logical positions continue increasing or are transformed under a declared policy.

Diagnose the first step where cached logits diverge from full recomputation. Print logical position, cache length, mask length, and token identity. Fault injection—deliberately resetting or offsetting positions—proves the test can detect the bug. Position faults can remain hidden on repetitive or short text. Use a controlled sequence whose next token depends strongly on order, and compare several prompt lengths. Log the RoPE sine/cosine row or position embedding selected at the first divergent step. In a batch, permute row order and confirm positions follow request identity rather than slot history. When a request is compacted into another row, move cache, mask, logical position, and sampling state together as one atomic operation.

Part 2 - Position invariant

For prompt length P and decode offset j, the new logical position is $P + j$. Cache storage index and logical position are different when eviction or padding is present.

Part 3 - Debug procedure

1. Compare full and cached logits after every appended token.
2. Log logical positions independently of tensor columns.
3. Test left padding, right padding, batch size one, and mixed lengths.
4. Inject off-by-one and reset-to-zero faults.
5. Verify RoPE tables cover the maximum logical position.
6. Test cache eviction without silently resetting position semantics.

Part 4 - Explicit position tracker

```
class PositionTracker:
    def __init__(self, prompt_lengths):
        self.positions = []
        for length in prompt_lengths:
            self.positions.append(length)

    def current(self, active_mask):
        output = []
        for index in range(len(self.positions)):
            if active_mask[index]:
                output.append(self.positions[index])
            else:
                output.append(-1)
        return output

    def advance(self, active_mask):
        for index in range(len(self.positions)):
            if active_mask[index]:
                self.positions[index] = self.positions[index] + 1

def E02(prompt_lengths, active_steps):
    tracker = PositionTracker(prompt_lengths)
    history = []
    for active_mask in active_steps:
        history.append(tracker.current(active_mask))
        tracker.advance(active_mask)
    return history
```

Part 5 - The Philosophy Behind the Exercise

Position is not merely where a tensor is stored; it is the token's place in the model's remembered sequence. Cache bugs teach that physical layout and semantic time can diverge. Correct systems preserve the latter while optimizing the former.

18.7.4 Exercise 03

Exercise Title: Implement Batched Inference with Variable Prompt Lengths

Part 1 - Deep conceptual foundation

Variable prompts require padding for dense batches or a specialized packed representation. Padding masks prevent attention to artificial tokens, while position identifiers preserve each sequence's logical order. Left padding is often convenient for decoder-only last-token selection, but model and tokenizer contracts must agree.

During decode, some sequences finish before others. Maintain an active mask, append generated tokens only for active requests, and prevent finished rows from growing cache state indefinitely. Dynamic batching may remove finished rows or insert new requests, which requires an explicit mapping between request IDs and cache rows.

Validate batched outputs against independent single-request decoding under greedy selection. Test mixed prompt lengths, immediate EOS, maximum tokens, and identical prompts in

different row orders. Sampling state is also per request. Temperature, generator seed, repetition penalty, stop sequences, and output budget must follow a request when rows are reordered. Test greedy mode first, then seeded sampling with batch permutations. For continuous batching, record admission step and prefill completion so new rows cannot attend to earlier rows' cache blocks. A correct output comparison should include finish reason and generated-token count, not only decoded text, because padding or hidden extra tokens can produce the same visible string.

Part 2 - Batch efficiency

Padding efficiency is $\eta = \sum_i T_i / (B \max_i T_i)$. Length bucketing increases η but may add queue delay; serving must balance both.

Part 3 - Required tests

1. Record request-to-row mapping and prompt length.
2. Build attention masks and positions from valid tokens.
3. Compare batched and unbatched greedy outputs.
4. Stop rows independently on EOS or token budget.
5. Test row compaction and cache reordering.
6. Measure padding waste and queue delay by length bucket.

Part 4 - Explicit active-row state

```
class BatchRequestState:
    def __init__(self, request_ids, maximum_new_tokens):
        self.request_ids = request_ids
        self.maximum_new_tokens = maximum_new_tokens
        self.generated_counts = []
        self.active = []
        for request_id in request_ids:
            self.generated_counts.append(0)
            self.active.append(True)

    def update(self, next_token_ids, end_token_id):
        for index in range(len(self.request_ids)):
            if self.active[index]:
                self.generated_counts[index] += 1
                reached_end = next_token_ids[index] == end_token_id
                generated_count = self.generated_counts[index]
                maximum_count = self.maximum_new_tokens[index]
                reached_limit = generated_count >= maximum_count
                if reached_end or reached_limit:
                    self.active[index] = False
```

```
def E03(request_ids, limits, generated_steps, end_token_id):
    state = BatchRequestState(request_ids, limits)
    for step in generated_steps:
        state.update(step, end_token_id)
    return state
```

Part 5 - The Philosophy Behind the Exercise

Batching joins independent conversations for efficiency without permitting their identities or histories to mix. The request-row map is therefore a boundary of privacy and meaning, not merely an indexing convenience.

18.7.5 Exercise 04

Exercise Title: Compare Latency vs Throughput Tradeoffs in Batch Size Selection

Part 1 - Deep conceptual foundation

Larger batches improve hardware utilization and total tokens per second, but a request may wait longer for a batch to form and share decode iterations with other sequences. User latency includes queueing, tokenization, prefill, time-to-first-token, inter-token gaps, and completion time. Throughput alone can hide poor interactive experience.

Static batching is simple but suffers from stragglers. Continuous batching admits new requests as rows finish, increasing utilization while making cache scheduling more complex. Compare fixed batch sizes and maximum batching delays under the same arrival trace. Report percentiles, not only means, because overload appears in the tail.

Find the saturation point where throughput stops growing and latency rises sharply. Separate prompt and output lengths; long prefill and long decode stress different paths. Define service-level objectives before selecting a batch policy. Fairness matters when requests have unequal cost. First-come scheduling can let a very long prefill delay many short interactive prompts; shortest-job policies can starve long documents. Compare length-aware queues with aging or tenant quotas. Track latency conditional on cost and customer class, and report dropped or rejected work rather than computing percentiles only for successful requests. Backpressure should activate before memory exhaustion so overload is expressed as bounded waiting or explicit rejection instead of process failure.

Part 2 - Queueing quantities

For request i, $L_i = L_{queue} + L_{tokenize} + L_{prefill} + L_{decode}$. Throughput is completed tokens or requests per unit time. P50, P95, and P99 latency describe different user experiences.

Part 3 - Benchmark design

1. Replay one timestamped arrival trace across policies.
2. Vary batch cap and maximum queue delay.
3. Segment by prompt and output length.
4. Record TTFT, inter-token latency, completion latency, and throughput.
5. Include warm and overloaded conditions.

6. Select a policy that satisfies explicit tail-latency objectives.

Part 4 - Percentile summary

```
def percentile(values, probability):
    ordered = sorted(values)
    if len(ordered) == 0:
        raise ValueError("no latency values")
    index = int(round((len(ordered) - 1) * probability))
    return ordered[index]

def E04(records):
    completion = []
    first_token = []
    for record in records:
        completion.append(record["completion_latency_ms"])
        first_token.append(record["time_to_first_token_ms"])
    return {
        "completion_p50": percentile(completion, 0.50),
        "completion_p95": percentile(completion, 0.95),
        "completion_p99": percentile(completion, 0.99),
        "first_token_p95": percentile(first_token, 0.95)
    }
```

Part 5 - The Philosophy Behind the Exercise

Throughput values collective efficiency; latency describes an individual's wait. Serving design must negotiate both rather than allowing an average to erase the experience of the slowest users.

18.7.6 Exercise 05

Exercise Title: Implement Streaming Token Generation and Measure User-Perceived Latency

Part 1 - Deep conceptual foundation

Streaming sends text incrementally instead of waiting for completion. It improves perceived responsiveness but creates protocol, decoding, cancellation, and safety challenges. Token boundaries are not necessarily valid UTF-8 or human-readable substrings, so use an incremental decoder and buffer incomplete sequences.

Measure time to first token, inter-token latency distribution, stalls, and total completion. Server generation time differs from client display time because network buffering and rendering intervene. Support cancellation that releases KV cache and scheduler state immediately. If output moderation is required, define whether tokens are buffered for inspection before release. Text rendering introduces another boundary. Some tokenizers revise the decoded suffix when byte pieces complete, so emitting each decoded token independently can produce replacement characters or spacing errors. Compare incremental output with decoding the complete token sequence and require exact final parity. Define heartbeat behavior for long prefill or stalls so

proxies do not close healthy connections. If clients reconnect, specify whether generation can resume from a server-held request or must restart, and bound the lifetime of detached streams.

Part 2 - Latency model

If token timestamps are $t_1, \ldots, t_n$, TTFT is $t_1 - t_0$ and inter-token gaps are $t_i - t_{i-1}$. Report P95 gaps and longest stall.

Part 3 - Tests

1. Stream decoded text fragments, not raw token bytes.
2. Timestamp server generation and client receipt separately.
3. Test cancellation, disconnect, EOS, timeout, and malformed transport.
4. Ensure request cache is released on every termination path.
5. Measure jitter under concurrent load.
6. Verify buffered safety checks do not claim zero-latency streaming.

Part 4 - Streaming metrics

```
def streaming_metrics(request_start, token_times):
    if len(token_times) == 0:
        return {"time_to_first_token": None, "gaps": []}
    gaps = []
    previous = token_times[0]
    for index in range(1, len(token_times)):
        gaps.append(token_times[index] - previous)
        previous = token_times[index]
    return {
        "time_to_first_token": token_times[0] - request_start,
        "gaps": gaps,
        "maximum_gap": max(gaps) if len(gaps) > 0 else 0.0,
        "completion_time": token_times[-1] - request_start
    }

def E05(requests):
    results = []
    for request in requests:
        results.append(streaming_metrics(
            request["start"], request["token_times"]
        ))
    return results
```

Part 5 - The Philosophy Behind the Exercise

Streaming changes when knowledge becomes visible. Partial output creates partial commitment, so responsiveness must be balanced with decoding integrity, safety, and the user's ability to cancel.

18.7.7 Exercise 06

Exercise Title: Profile GPU Utilization During Inference and Identify Bottlenecks

Part 1 - Deep conceptual foundation

Low GPU utilization can result from CPU tokenization, host-to-device transfer, small batches, synchronization, Python scheduling, or memory-bound decode. High utilization can still hide padding waste. Profile prefill and decode separately: prefill often uses large matrix multiplications, while single-token decode repeatedly reads weights and KV cache.

Begin with end-to-end timing, then use profiler ranges to locate cost. Measure kernel time, gaps, memory bandwidth, allocation, and data transfer. Avoid adding synchronization to every step because the profiler would change the workload. Correlate GPU traces with request and batch scheduler events. Profiler evidence must be interpreted with workload shape. A trace from one short prompt may emphasize launch overhead, while a production mixture may be dominated by long prefill. Collect representative traces and aggregate stage timing outside the profiler to avoid excessive overhead. Inspect CPU threads and queue state alongside CUDA kernels: blank GPU regions can be intentional waiting for a dynamic batch or accidental serialization. After every optimization, rerun output parity and tail-latency tests so faster kernels do not damage scheduler fairness.

Part 2 - Utilization metrics

Useful throughput equals nonpadding or generated tokens per second. Arithmetic utilization and memory bandwidth reveal different ceilings; a decode workload can be bandwidth-bound even when compute units are not saturated.

Part 3 - Profiling protocol

1. Establish CPU-only and GPU end-to-end baselines.
2. Mark tokenization, transfer, prefill, decode, sampling, and streaming.
3. Warm up before collecting traces.
4. Compare total versus useful tokens.
5. Vary batch, sequence length, and cache size.
6. Optimize the measured bottleneck and rerun the identical trace.

Part 4 - Stage timer

```
import time

class StageTimer:
    def __init__(self):
        self.records = []

    def measure(self, name, function):
        start = time.perf_counter()
        output = function()
```

```
        elapsed = time.perf_counter() - start
        self.records.append({"stage": name, "seconds": elapsed})
        return output

    def totals(self):
        totals = {}
        for record in self.records:
            name = record["stage"]
            totals[name] = totals.get(name, 0.0) + record["seconds"]
        return totals

def E06(stage_functions):
    timer = StageTimer()
    for name in stage_functions:
        timer.measure(name, stage_functions[name])
    return timer.totals()
```

Part 5 - The Philosophy Behind the Exercise

Profiling replaces intuition with evidence. The GPU is not slow or fast in the abstract; it is waiting, computing, or moving data for specific reasons. Good optimization begins by naming the reason.

18.7.8 Exercise 07

Exercise Title: Implement Stop Tokens and Safe Termination Logic

Part 1 - Deep conceptual foundation

Generation can stop because of EOS, one of several stop sequences, maximum new tokens, timeout, cancellation, policy interruption, or service shutdown. These causes have different status codes and cleanup obligations. Stop strings may span multiple tokens or streamed fragments, so compare incremental decoded suffixes while retaining enough overlap.

Define whether matched stop text is included or removed. Avoid exposing partial sensitive markers before a multi-token stop is recognized. In batches, terminate rows independently and release cache state. Always keep a hard token and time limit even when EOS is never produced. Stop matching should be scoped to generated output unless policy explicitly includes the prompt. Normalize only when the protocol guarantees normalization will not change meaning. Multiple overlapping stop strings require deterministic precedence, and a maximum-match buffer prevents premature emission. For tool or structured output, syntactic completion may be an additional termination rule, but it must not replace hard budgets. Record whether output was complete, truncated, cancelled, or filtered so downstream consumers do not treat every finish as semantically final.

Part 2 - Termination state

Termination is a state transition from active to one immutable final reason. Once finished, a request must not emit tokens or advance positions.

Part 3 - Edge cases

1. Test single-token and multi-token stops across fragment boundaries.
2. Define precedence when EOS and timeout occur together.
3. Test immediate cancellation and disconnect.
4. Confirm finished batch rows stop cache growth.
5. Return finish reason and token counts.
6. Release all request resources in a finally path.

Part 4 - Explicit termination controller

```
class TerminationController:
    def __init__(self, stop_strings, maximum_tokens):
        self.stop_strings = stop_strings
        self.maximum_tokens = maximum_tokens
        self.generated_tokens = 0
        self.text = ""
        self.finished = False
        self.reason = None

    def add_fragment(self, fragment):
        if self.finished:
            return
        self.text = self.text + fragment
        self.generated_tokens = self.generated_tokens + 1
        for stop_string in self.stop_strings:
            if self.text.endswith(stop_string):
                self.finished = True
                self.reason = "stop_sequence"
        if self.generated_tokens >= self.maximum_tokens and not self.finished:
            self.finished = True
            self.reason = "length"

def E07(fragments, stops, maximum_tokens):
    controller = TerminationController(stops, maximum_tokens)
    for fragment in fragments:
        controller.add_fragment(fragment)
        if controller.finished:
            break
    return controller
```

Part 5 - The Philosophy Behind the Exercise

Safe termination defines the boundary of a model's opportunity to speak. A service is responsible not only for generating, but for knowing when to stop and for making the reason observable.

18.7.9 Exercise 08

Exercise Title: Debug Memory Leaks in Long-Running Inference Services

Part 1 - Deep conceptual foundation

A memory leak is retained memory that should become unreachable after a request. Common causes include KV caches stored in global dictionaries, unfinished futures, streaming queues, retained tensors in metrics, exception paths, and unbounded tokenizer or prompt caches. CUDA reserved memory alone is not proof of a leak because the allocator intentionally reuses blocks.

Run repeated request waves with fixed shapes, force synchronization, and measure allocated, reserved, and process memory after cleanup. A healthy service may rise to a plateau; a leak grows with completed requests. Tag allocations by request and verify cancellation, timeout, exception, and normal completion all execute the same release contract. Distinguish leaks from legitimate growth in compiled graphs, tokenizer caches, and memory pools. Warm each supported shape before starting the slope test, or record new-shape events explicitly. Python object snapshots can reveal queues or request states whose reference counts never fall; CUDA memory snapshots locate live tensor allocations. Do not use periodic process restarts as the only fix: they hide ownership bugs and create cold-start instability. A temporary restart policy may contain impact while root-cause work continues.

Part 2 - Growth model

Fit memory after wave n as $M_n = a + bn$. Persistent positive slope b after warmup is evidence for investigation, not automatic proof.

Part 3 - Leak hunt

1. Reproduce with deterministic request waves.
2. Separate live cache, allocator reserve, and Python process memory.
3. Count active requests and cache entries after every wave.
4. Test all termination and exception paths.
5. Inspect object references before calling empty-cache functions.
6. Add a regression threshold for post-warmup growth.

Part 4 - Resource registry

```
class RequestResourceRegistry:
    def __init__(self):
        self.resources = {}

    def register(self, request_id, resource):
        if request_id in self.resources:
            raise ValueError("request already registered")
        self.resources[request_id] = resource
```

```
    def release(self, request_id):
        if request_id in self.resources:
            resource = self.resources.pop(request_id)
            resource.close()

    def active_count(self):
        return len(self.resources)

def E08(registry, events):
    for event in events:
        if event["type"] == "start":
            registry.register(event["request_id"], event["resource"])
        if event["type"] == "finish":
            registry.release(event["request_id"])
    return registry.active_count()
```

Part 5 - The Philosophy Behind the Exercise

A leak is forgotten ownership. Memory remains because the system has lost the story of who created it and when its purpose ended. Explicit lifecycle restores that story.

18.7.10 Exercise 09

Exercise Title: Compare fp32 vs fp16 vs int8 Inference Quality and Speed

Part 1 - Deep conceptual foundation

Reduced precision lowers memory bandwidth and can increase throughput, but the effect depends on hardware kernels and quantization method. fp16 changes arithmetic precision; int8 often quantizes weights and possibly activations using scales. Calibration data must represent deployment distributions.

Compare logits and generation, not only model size. Small numerical changes can alter sampled sequences, so use teacher-forced logit error, perplexity, task metrics, and deterministic greedy agreement. Inspect rare tokens, long contexts, outliers, and safety-boundary prompts. Benchmark warm prefill and decode separately with identical batches. Quantization can affect layers unevenly. Inspect embedding, attention output, feed-forward, normalization, and final language head separately, and retain sensitive operations at higher precision when supported. Per-channel scales may handle weight outliers better than one tensor-wide scale. Measure quality after serialization and reload, because deployment kernels and calibration metadata are part of the artifact. If int8 improves prefill but not decode, explain the hardware bottleneck rather than advertising one blended speedup number.

Part 2 - Error measures

For reference logits z and compressed logits $\hat{z}$, report maximum absolute error, relative norm error $\|z - \hat{z}\|/\|z\|$, KL divergence, and task-level quality. One scalar cannot characterize all sensitivity.

Part 3 - Matched benchmark

1. Use one checkpoint, tokenizer, prompts, and decoding policy.

2. Record model and KV-cache precision separately.
3. Warm up and measure prefill, decode, memory, and energy if available.
4. Compare logits before comparing free-running text.
5. Evaluate critical task and safety slices.
6. State calibration data and unsupported operators for int8.

Part 4 - Numeric comparison

```
import torch

def compare_logits(reference, candidate):
    difference = reference.float() - candidate.float()
    maximum = torch.max(torch.abs(difference)).item()
    numerator = torch.linalg.vector_norm(difference)
    denominator = torch.linalg.vector_norm(reference.float())
    relative = (numerator / torch.clamp(denominator, min=1e-12)).item()
    reference_tokens = torch.argmax(reference, dim=-1)
    candidate_tokens = torch.argmax(candidate, dim=-1)
    agreement = (reference_tokens == candidate_tokens).float().mean().item()
    return {
        "maximum_absolute_error": maximum,
        "relative_norm_error": relative,
        "greedy_token_agreement": agreement
    }

def E09(outputs):
    return {
        "fp16": compare_logits(outputs["fp32"], outputs["fp16"]),
        "int8": compare_logits(outputs["fp32"], outputs["int8"])
    }
```

Part 5 - The Philosophy Behind the Exercise

Precision is a decision about which numerical distinctions the service preserves. Compression is successful when discarded distinctions do not change promised behavior, and that claim must be measured on the cases that matter.

18.7.11 Exercise 10

Exercise Title: Deploy LLM Inference with Simple HTTP API and Measure End-to-End Latency

Part 1 - Deep conceptual foundation

An HTTP wrapper defines a public contract around tokenization, scheduling, generation, streaming, errors, and model versions. Validate request size, types, token budget, decoding

parameters, and authorization before allocating GPU state. Never accept arbitrary device or file paths from clients.

End-to-end latency begins when the server receives a request and includes queue, validation, tokenization, transfer, prefill, decode, serialization, and network delivery. Attach a request ID and stage timestamps. Return stable error codes without exposing stack traces or internal prompts.

Test concurrency, cancellation, malformed JSON, oversized prompts, timeout, and server shutdown. Keep model loading outside request handlers and use a bounded scheduler instead of spawning unrestricted generation work. Separate transport status from generation status. An HTTP success may contain a model-level refusal or length stop, while a network failure may occur after the server generated valid tokens. For idempotency, decide whether retries create a new stochastic generation or reference a stored request; never duplicate billable work silently. Apply request-body limits before parsing large payloads and ensure reverse proxies, application servers, and model workers share compatible timeout and streaming settings. Test the deployed network path rather than localhost alone.

Part 2 - Latency decomposition

$L_{e2e} = L_{queue} + L_{validate} + L_{tokenize} + L_{prefill} + L_{decode} + L_{transport}$. Report percentiles and stage contributions by prompt/output bucket.

Part 3 - API controls

1. Define versioned request and response schemas.
2. Validate before GPU admission.
3. Record stage timestamps with privacy-safe request IDs.
4. Bound prompt length, output length, concurrency, and time.
5. Test streaming and nonstreaming parity.
6. Return model version and finish reason.

Part 4 - Framework-neutral request validation

```
def validate_generation_request(payload, maximum_prompt_characters,
                                maximum_new_tokens):
    if "prompt" not in payload or not isinstance(payload["prompt"], str):
        raise ValueError("prompt must be a string")
    if len(payload["prompt"]) > maximum_prompt_characters:
        raise ValueError("prompt is too long")
    requested_tokens = payload.get("maximum_new_tokens", 64)
    if requested_tokens < 1 or requested_tokens > maximum_new_tokens:
        raise ValueError("invalid output token limit")
    return {
        "prompt": payload["prompt"],
        "maximum_new_tokens": requested_tokens,
        "stream": bool(payload.get("stream", False))
```

```
    }

def E10(payloads):
    accepted = []
    for payload in payloads:
        accepted.append(validate_generation_request(payload, 20000, 512))
    return accepted
```

Part 5 - The Philosophy Behind the Exercise

An API turns model capability into institutional action. Validation and bounded resources define who may ask, how much work may be consumed, and how failures remain contained.

18.7.12 Exercise 11

Exercise Title: Implement Rate Limiting and Timeout Handling for Inference Service

Part 1 - Deep conceptual foundation

Rate limits protect availability and fairness. Request counts alone are weak because one long prompt can cost far more than many short ones. Use token- or compute-aware budgets with identity, tenant, and global limits. A token bucket allows controlled bursts while enforcing a long-term rate.

Timeouts need phases: queue deadline, prefill deadline, inter-token stall, and total request deadline. Cancellation must propagate into the scheduler and release KV cache. Returning a timeout while GPU work continues is resource leakage disguised as error handling.

Use monotonic clocks, bounded queues, and explicit retry guidance. Test clock edges, burst traffic, multiple workers, and clients that disconnect midstream. Distributed replicas need coordinated or intentionally partitioned limits. A per-process bucket can multiply a tenant's allowance by the replica count, while a central limiter can become a latency and availability dependency. Document the consistency model and conservative fallback when the limiter is unreachable. Cost estimates should reserve maximum output capacity at admission and refund unused tokens afterward under an auditable rule. Monitor whether repeated rejections concentrate on particular tenants or workloads.

Part 2 - Token bucket

Tokens replenish as $b(t) = \min(C, b(t_0) + r(t - t_0))$. A request of cost c is admitted only if $b(t) \geq c$.

Part 3 - Tests

1. Estimate cost from input and maximum output tokens.
2. Enforce tenant and global budgets.
3. Test bursts and steady traffic with a fake clock.
4. Propagate timeout cancellation to GPU work.
5. Release cache on every deadline path.
6. Monitor rejection and timeout rates by cause.

Part 4 - Explicit token bucket

```
class TokenBucket:
    def __init__(self, capacity, refill_per_second, initial_time):
        self.capacity = capacity
        self.refill_per_second = refill_per_second
        self.available = capacity
        self.last_time = initial_time

    def allow(self, cost, current_time):
        elapsed = max(current_time - self.last_time, 0.0)
        self.available = min(
            self.capacity,
            self.available + elapsed * self.refill_per_second
        )
        self.last_time = current_time
        if cost <= self.available:
            self.available = self.available - cost
            return True
        return False

def E11(bucket, requests):
    decisions = []
    for request in requests:
        decisions.append(bucket.allow(request["cost"], request["time"]))
    return decisions
```

Part 5 - The Philosophy Behind the Exercise

Rate limiting allocates a finite common resource. A fair service measures demand in units related to cost and ensures one user's urgency cannot silently consume everyone else's availability.

18.7.13 Exercise 12

Exercise Title: Benchmark Cold Start vs Warm Start Inference

Part 1 - Deep conceptual foundation

Cold start includes process creation, imports, checkpoint read, deserialization, device transfer, graph or kernel initialization, and first inference. Warm start reuses a resident model, allocator state, and compiled kernels. Mixing them in one average makes capacity planning unreliable.

Measure each stage with clean process restarts and controlled storage caches. Distinguish operating-system page cache from truly remote or cold storage. Run a standard warmup that exercises expected shapes, then benchmark production-like prefill and decode. Record peak memory during loading because transient copies can exceed steady state.

Compare eager loading, lazy loading, compilation, quantized checkpoints, and multiple replicas. Include readiness semantics: a process should not receive traffic merely because its HTTP

port opened. Startup testing must include failures: missing shards, checksum mismatch, insufficient memory, incompatible kernels, and interrupted downloads. Readiness should remain false and expose a useful internal diagnostic without serving a partially loaded model. In autoscaling systems, compare startup time with traffic growth; replicas that become ready after the demand spike cannot protect tail latency. Model download locality and image size may dominate even when checkpoint loading is optimized.

Part 2 - Startup quantities

Readiness time is the interval from process start until a validated inference succeeds. First-request latency and steady-state latency are separate measures.

Part 3 - Benchmark controls

1. Repeat cold starts in fresh processes.
2. Record storage, import, load, transfer, warmup, and validation times.
3. State whether filesystem caches are warm or cold.
4. Measure transient and steady memory.
5. Test readiness and startup failure paths.
6. Compare deployment strategies using identical checkpoints.

Part 4 - Startup timeline

```
class StartupTimeline:
    def __init__(self, start_time):
        self.start_time = start_time
        self.events = []

    def record(self, name, timestamp):
        self.events.append({
            "name": name,
            "seconds_from_start": timestamp - self.start_time
        })

    def readiness_time(self):
        for event in self.events:
            if event["name"] == "ready":
                return event["seconds_from_start"]
        return None

def E12(start_time, events):
    timeline = StartupTimeline(start_time)
    for event in events:
        timeline.record(event["name"], event["timestamp"])
    return timeline, timeline.readiness_time()
```

Part 5 - The Philosophy Behind the Exercise

Warm systems hide the cost of becoming ready. Cold-start measurement restores the full lifecycle and reminds us that availability begins before the first token can be generated.

18.7.14 Exercise 13

Exercise Title: Handle Long Prompts with Sliding Window Inference

Part 1 - Deep conceptual foundation

Sliding-window inference limits attention to recent tokens, bounding KV-cache memory and per-step attention. It does not magically extend global understanding: evicted evidence is unavailable unless summarized, retrieved again, or preserved through another memory mechanism.

Define window size, eviction unit, logical positions, and treatment of system instructions. Blindly dropping the oldest tokens can remove policy, user intent, or critical facts. A prompt manager should reserve protected segments, detect overflow before inference, and disclose truncation when it can affect answers.

Evaluate local tasks and long-range dependency tasks while moving required evidence across the eviction boundary. Compare full-context reference where possible. RoPE and position handling must follow the model's supported policy. Summarization before eviction introduces a second model-generated artifact that can distort facts. Evaluate summaries for coverage and contradiction, and keep links to original spans where retrieval is possible. Recurrent system prompts or protected prefixes also consume fixed window capacity, reducing space for recent dialogue. Report effective user-context capacity rather than nominal window size. For multi-turn service, define whether the window counts raw messages, rendered tokens, retrieved passages, and generated output together.

Part 2 - Bounded cost

For window W, each decode query attends to at most W cached positions, so KV memory is bounded by W rather than total generated length. Information loss is the tradeoff.

Part 3 - Validation

1. Protect required system and task segments explicitly.
2. Record every evicted token range.
3. Test evidence just inside and outside the window.
4. Compare full and windowed logits before eviction.
5. Verify logical positions after cache compaction.
6. Measure quality, memory, and latency across window sizes.

Part 4 - Window manager

```
class SlidingTokenWindow:
    def __init__(self, maximum_tokens):
        self.maximum_tokens = maximum_tokens
        self.tokens = []
        self.total_seen = 0
        self.evicted = 0

    def append(self, token_id):
        self.tokens.append(token_id)
        self.total_seen = self.total_seen + 1
        if len(self.tokens) > self.maximum_tokens:
            self.tokens.pop(0)
            self.evicted = self.evicted + 1

def E13(token_ids, maximum_tokens):
    window = SlidingTokenWindow(maximum_tokens)
    for token_id in token_ids:
        window.append(token_id)
    return window
```

Part 5 - The Philosophy Behind the Exercise

A window makes forgetting deliberate. Bounded memory is honest engineering when the system records what it removed and does not pretend discarded evidence still guides the answer.

18.7.15 Exercise 14

Exercise Title: Compare Server-Side vs Client-Side Tokenization Costs

Part 1 - Deep conceptual foundation

Server-side tokenization centralizes tokenizer versions and validation but uses CPU resources and transfers raw text. Client-side tokenization can reduce server CPU work and let clients estimate cost, yet creates compatibility and security risks: incorrect token IDs, obsolete vocabularies, invalid special tokens, and larger serialized payloads.

Benchmark tokenization time, network bytes, validation, queue delay, and failure rate. Token IDs are often larger on the wire than compressed UTF-8 text. A server accepting IDs must bind requests to an exact tokenizer hash and reject reserved or out-of-range values. Never trust client-reported token counts for billing or limits without verification.

Use multilingual text, code, short chats, and long documents. Separate cold tokenizer initialization from steady operation and measure concurrency scaling. Client-side tokenization also affects governance. Raw text may be needed for policy filtering, abuse investigation, or accessibility transformations, while privacy goals may favor minimizing server text exposure. Decide this separately from performance and document what each side stores. If clients submit token IDs, server-side moderation may require safe decoding under the pinned tokenizer. Test noncanonical encodings that decode to equivalent text and ensure billing and limits operate on validated token counts.

Part 2 - End-to-end comparison

Total cost includes client work, transport, server validation, and any repeated decoding. The fastest local stage may not minimize request latency or bytes.

Part 3 - Protocol

1. Pin tokenizer files and hash on both paths.
2. Measure text and token-ID payload bytes.
3. Validate range, special tokens, and decoded parity.
4. Include client device classes and server concurrency.
5. Test version mismatch and malicious identifiers.
6. Compare end-to-end latency rather than server CPU alone.

Part 4 - Token request validation

```
def validate_token_request(token_ids, vocabulary_size,
                           forbidden_special_ids):
    validated = []
    forbidden = set(forbidden_special_ids)
    for token_id in token_ids:
        if not isinstance(token_id, int):
            raise ValueError("token identifier must be integer")
        if token_id < 0 or token_id >= vocabulary_size:
            raise ValueError("token identifier outside vocabulary")
        if token_id in forbidden:
            raise ValueError("reserved special token is not allowed")
        validated.append(token_id)
    return validated

def E14(requests, vocabulary_size, forbidden_special_ids):
    outputs = []
    for request in requests:
        outputs.append(validate_token_request(
            request, vocabulary_size, forbidden_special_ids
        ))
    return outputs
```

Part 5 - The Philosophy Behind the Exercise

Tokenization is part of model identity. Moving it across a network boundary also moves trust and version responsibility. Performance gains are valid only when the language-to-token contract remains exact.

18.7.16 Exercise 15

Exercise Title: Implement Canary Deployment for New Model Versions

Part 1 - Deep conceptual foundation

A canary sends a small controlled fraction of traffic to a new model while the stable version remains available. Routing must be sticky per conversation so KV cache and behavior do not switch midstream. Exclude high-risk users or workflows until explicit gates pass, and support immediate rollback.

Compare latency, errors, memory, refusal, quality proxies, user feedback, and safety events. Traffic percentages alone are insufficient: prompt distributions can differ, so use randomization or matched analysis. Start small, require a minimum sample and observation time, then expand through declared stages.

Rollback should change new routing while allowing or safely cancelling in-flight requests. Preserve model version in logs and responses. Test the rollback before launch rather than during the first incident. Canary analysis must account for conversations that span evaluation windows. Assign by durable conversation identifier, but avoid using personally identifying data directly in routing. Compare new and control versions on matched prompt length, language, tenant, and task slices. A global metric can look stable while one rare workload regresses. Define automatic rollback for crashes and critical safety events, while quality changes with uncertain graders may require human review before promotion.

Part 2 - Release decision

Canary promotion requires every blocking metric within tolerance relative to control. Statistical significance does not make a practically severe regression acceptable.

Part 3 - Canary protocol

1. Define eligible traffic and sticky assignment.
2. Establish stages, sample minimums, and observation periods.
3. Compare quality, safety, latency, errors, and resource metrics.
4. Detect distribution imbalance between control and canary.
5. Automate stop and rollback for critical gates.
6. Rehearse cache-safe rollback and audit version tags.

Part 4 - Deterministic routing

```
import hashlib

def canary_assignment(conversation_id, canary_percent):
    digest = hashlib.sha256(conversation_id.encode("utf-8")).hexdigest()
    bucket = int(digest[:8], 16) % 10000
    threshold = int(canary_percent * 100)
    if bucket < threshold:
        return "canary"
```

```
    return "control"

def E15(conversation_ids, canary_percent):
    assignments = {}
    for conversation_id in conversation_ids:
        assignments[conversation_id] = canary_assignment(
            conversation_id, canary_percent
        )
    return assignments
```

Part 5 - The Philosophy Behind the Exercise

Canary deployment turns uncertainty into limited exposure. It acknowledges that laboratory evidence is incomplete while refusing to make every user participate in the experiment at once.

18.7.17 Exercise 16

Exercise Title: Monitor Inference Errors and Build Alerting Rules

Part 1 - Deep conceptual foundation

Monitoring should distinguish validation rejection, queue timeout, OOM, nonfinite logits, tokenizer failure, cache corruption, disconnect, policy stop, and internal error. Aggregate error rate hides causes and severity. Attach model, tokenizer, hardware, batch, prompt-length bucket, and finish reason without logging sensitive text unnecessarily.

Alerts need thresholds, windows, minimum volume, severity, owner, and runbook. Use rates for common traffic and absolute counts for rare critical failures. Avoid alert storms through deduplication and recovery conditions. Monitor silent quality proxies and canary regressions in addition to exceptions.

Test alerts by injecting safe synthetic failures. A dashboard is observational; an alert is operational only when someone can act on it. Alert quality has its own metrics: time to detect, actionable rate, duplicate volume, missed incidents, and time to recovery. Review alerts after incidents and remove rules that create habitual noise without losing coverage. Couple nonfinite-logit or cache-isolation failures to immediate protective actions, but avoid automated restart loops that repeatedly destroy evidence. Preserve a small diagnostic snapshot with configuration and recent stage metrics under privacy controls.

Part 2 - Rate and burn

For window error count e and requests n, rate is e/n. Multi-window burn rules can detect fast incidents and slow degradation while respecting a service error budget.

Part 3 - Alert design

1. Define error taxonomy and severity.
2. Track rates by version and workload slice.
3. Create fast and slow windows with minimum volume.
4. Route every alert to an owner and runbook.

5. Deduplicate correlated symptoms.

6. Inject faults and verify firing and recovery.

Part 4 - Rule evaluator

```
class AlertRule:
    def __init__(self, name, threshold, minimum_requests):
        self.name = name
        self.threshold = threshold
        self.minimum_requests = minimum_requests

    def evaluate(self, errors, requests):
        if requests < self.minimum_requests:
            return False
        return errors / requests >= self.threshold

def E16(rules, measurements):
    alerts = []
    for rule in rules:
        for measurement in measurements:
            if rule.evaluate(measurement["errors"], measurement["requests"]):
                alerts.append({
                    "rule": rule.name,
                    "window": measurement["window"]
                })
    return alerts
```

Part 5 - The Philosophy Behind the Exercise

Monitoring is the service's capacity to notice itself failing. Alerting adds obligation: a signal must reach someone with authority and evidence to respond.

18.7.18 Exercise 17

Exercise Title: Stress Test Inference Under High QPS and Detect Failures

Part 1 - Deep conceptual foundation

A stress test increases offered load until the service saturates, then observes queue growth, latency tails, rejections, OOM, cache fragmentation, and recovery. QPS alone is inadequate; define prompt/output distributions, streaming, arrival burstiness, and tenant mix. Run only in an authorized isolated environment.

Use load, stress, spike, soak, and recovery phases. Open-loop generators maintain arrivals even when the server slows and reveal overload; closed-loop clients can hide saturation by waiting. Apply bounded admission so overload becomes explicit rejection rather than uncontrolled collapse.

After load falls, verify latency, memory, active requests, and cache return to baseline. A service that survives peak traffic but never recovers has failed. Coordinate generator clocks

and measure achieved arrivals; otherwise the load tool can become the bottleneck. Separate connection, request, and token throughput. Use several generators when necessary, and verify their network path resembles production. During soak tests, track memory slope, allocator fragmentation, temperature, clock throttling, and error drift. Capacity should include a safety margin below the measured knee because production traffic is less predictable than a controlled trace.

Part 2 - Saturation

Throughput plateaus when a limiting resource reaches capacity; beyond this point queue delay grows rapidly. Identify the knee before selecting safe operating QPS.

Part 3 - Stress protocol

1. Define realistic length and arrival distributions.
2. Increase open-loop load in stages.
3. Measure P50/P95/P99 latency, TTFT, errors, queue, memory, and throughput.
4. Inject bursts, disconnects, and one replica failure.
5. Verify admission control and graceful degradation.
6. Confirm post-test resource and latency recovery.

Part 4 - Load-stage summary

```
def E17(stage_records):
    summaries = []
    for stage in stage_records:
        completed = stage["completed_requests"]
        duration = stage["duration_seconds"]
        offered = stage["offered_requests"]
        summary = {}
        summary["stage"] = stage["stage"]
        summary["throughput_qps"] = completed / duration
        summary["success_rate"] = completed / max(offered, 1)
        summary["queue_depth"] = stage["queue_depth"]
        summary["peak_memory"] = stage["peak_memory"]
        summaries.append(summary)
    return summaries
```

Part 5 - The Philosophy Behind the Exercise

Stress testing asks where graceful service becomes disorder. The goal is not to claim infinite capacity, but to know the boundary and make failure controlled, observable, and recoverable.

18.7.19 Exercise 18

Exercise Title: Build Inference Debugging Checklist

Part 1 - Deep conceptual foundation

An inference checklist should proceed from identity to semantics to performance. Verify model, tokenizer, template, precision, device, and configuration; then validate uncached reference generation, cache parity, positions, masks, batch mapping, stop logic, and lifecycle. Only after correctness should latency and throughput be tuned.

Every item needs an executable test, expected result, evidence, severity, and remediation. Include fault injection for wrong positions, stale cache, timeout, OOM, disconnect, quantization drift, and version mismatch. Blocking failures stop deployment; warnings remain visible.

The checklist must cover single-request, batch, long-run, overload, and restart behavior. A notebook success does not validate a service lifecycle. Organize evidence so one failed check points to the next diagnostic rather than merely returning false. Cache parity failure should identify first divergent layer and position; a leak check should report active request IDs and allocation growth; a latency regression should name the changed stage. Version the checklist with the service architecture and require new checks after every incident. An obsolete checklist can create confidence while testing contracts the service no longer uses.

Part 2 - Gate model

Release readiness is the conjunction of blocking checks. Performance scores cannot compensate for incorrect logits, cache isolation, or cleanup.

Part 3 - Ordered checklist

1. Verify immutable artifact identities.
2. Compare full, cached, batched, and quantized logits.
3. Test positions, padding, cache reorder, and stop conditions.
4. Test cancellation, exception, timeout, and cleanup.
5. Profile stages before optimizing.
6. Run load, soak, recovery, and restart tests.

Part 4 - Executable checks

```
class InferenceCheck:
    def __init__(self, name, blocking, function):
        self.name = name
        self.blocking = blocking
        self.function = function

def E18(checks, context):
    results = []
    ready = True
    for check in checks:
```

```
        passed, evidence = check.function(context)
        results.append({
            "name": check.name,
            "blocking": check.blocking,
            "passed": bool(passed),
            "evidence": evidence
        })
        if check.blocking and not passed:
            ready = False
    return {"ready": ready, "results": results}
```

Part 5 - The Philosophy Behind the Exercise

A checklist is accumulated memory made executable. It protects correctness from urgency by ensuring the system repeatedly proves the contracts on which its speed depends.

18.7.20 Exercise 19

Exercise Title: Produce a Production Inference Engineering Report

Part 1 - Deep conceptual foundation

The final report connects model artifacts, serving architecture, cache design, batch scheduler, precision, API, streaming, limits, monitoring, deployment, and failure recovery. It must allow another engineer to reproduce benchmarks and understand the release decision.

Document prefill and decode paths, KV shapes and memory, logical positions, padding, cache lifecycle, stop semantics, and request isolation. Present latency by stage and percentile, throughput by workload, memory peaks, cold start, precision quality, stress saturation, and soak recovery. Include failed configurations rather than only the winner.

Specify HTTP contracts, authentication boundaries, quotas, deadlines, versioning, canary stages, alerts, rollback, privacy-preserving logs, and owners. End with blocking gates, residual limitations, capacity limits, and the next experiment that would reduce uncertainty most. Include a capacity envelope rather than one benchmark number. State supported prompt lengths, output lengths, concurrency, precision, hardware, and latency objectives, plus the admission behavior outside that envelope. Present cost per request and per generated token for representative workloads. Separate measured facts from forecasts and identify assumptions about traffic mix. Every chart and table should reference a raw trace or script so later model versions can be compared without reconstructing undocumented conditions.

Part 2 - Decision vector

Let $G = (C, L, T, M, Q, R, O)$ represent correctness, latency, throughput, memory, quality, reliability, and observability. Release requires every blocking component to meet its threshold.

Part 3 - Required evidence

1. Identify model, tokenizer, code, configuration, hardware, and data traces.
2. Prove cached, batched, and compressed parity.
3. Report TTFT, token gaps, tail latency, throughput, and cache memory.

4. Include cold start, overload, soak, cancellation, and recovery.
5. Document API limits, canary, monitoring, and rollback.
6. State capacity, unsupported cases, and residual risks.

Part 4 - Structured report

```
class InferenceReport:
    def __init__(self, report_id):
        self.report_id = report_id
        self.sections = {}
        self.gates = []

    def add_section(self, name, evidence):
        self.sections[name] = evidence

    def add_gate(self, name, passed, blocking, owner):
        self.gates.append({
            "name": name, "passed": passed,
            "blocking": blocking, "owner": owner
        })

    def ready(self):
        for gate in self.gates:
            if gate["blocking"] and not gate["passed"]:
                return False
        return True

def E19():
    report = InferenceReport("LLM05-INFERENCE-V1")
    report.add_section("architecture", {"status": "documented"})
    report.add_gate("cache_parity", False, True, "inference_owner")
    return report, report.ready()
```

Part 5 - The Philosophy Behind the Exercise

A production report converts performance into accountable knowledge. It records what the service can sustain, where it fails, and who must act when reality moves beyond tested boundaries.

18.8 LLM06

Chapter Title: Quantization and Deployment
Specialization: Applied AI and Deployment

18.8.1 Exercise 00

Exercise Title: Explain Quantization and Why It Is Critical for LLM Deployment

Part 1 - Why this matters

Quantization represents selected model tensors with fewer discrete numerical levels. A floating-point weight may use 16 or 32 bits; an integer representation may use 8 or 4 bits together with scale metadata. For an LLM containing billions of parameters, this can reduce weight storage, memory traffic, and the hardware capacity required for inference. Quantization is critical because decoding is often limited by moving weights from memory rather than by arithmetic alone.

Separate four layers of the claim. The serialized artifact may be smaller. The resident model may consume less device memory. A supported kernel may execute lower-bit matrix multiplication or dequantize efficiently. Finally, end-to-end latency and quality may improve or degrade. None follows automatically from the previous one. An int4 file that is expanded to fp16 before every operation can save storage while losing runtime performance.

Implement affine quantization for a tiny tensor by hand. Inspect symmetric and asymmetric schemes, per-tensor and per-channel scales, rounding error, clipping, outliers, and dequantization. Then connect the mechanism to LLM weight matrices, activation distributions, KV cache, embeddings, normalization, and logits. State which components are quantized, which remain in higher precision, and where conversion occurs.

Part 2 - Mathematical form and reasoning

For real value x, integer range $[q_{\min}, q_{\max}]$, positive scale s, and zero point z, affine quantization is

$$q = \operatorname{clip}\left(\operatorname{round}(x/s) + z, q_{\min}, q_{\max}\right), \qquad \widehat{x} = s(q - z).$$

For symmetric signed quantization, $z = 0$ and $s = \max_i |x_i|/q_{\max}$. Quantization error is $e = x - \widehat{x}$. Under ideal rounding without clipping, $|e| \leq s/2$; saturation violates that bound. Weight storage falls approximately from NP bits to NQ bits plus scales, where P and Q are original and quantized widths.

Part 3 - Hints and Helper

1. Use a small tensor with zero, ordinary values, and one outlier so scale selection can be checked manually.
2. Report maximum error, mean squared error, cosine similarity, clipping rate, and storage including scale/zero-point metadata.
3. Distinguish fake quantization, packed storage, and a genuinely accelerated quantized kernel.
4. Measure prefill and token-by-token decode separately; their bottlenecks and batch behavior differ.
5. Record model, quantization recipe, calibration data, runtime, hardware, kernel backend, and fallback precision as one deployment contract.

Part 4 - Python code skeleton

```
import torch

def symmetric_quantize(x, bits=8):
    q_max = (2 ** (bits - 1)) - 1
    q_min = -(2 ** (bits - 1))
    maximum = x.abs().max()
    scale = maximum / q_max if maximum > 0 else x.new_tensor(1.0)
    quantized = torch.round(x / scale)
    quantized = torch.clamp(quantized, q_min, q_max)
    integer_dtype = torch.int8 if bits == 8 else torch.int32
    quantized = quantized.to(integer_dtype)
    restored = quantized.to(torch.float32) * scale
    return quantized, scale, restored

def E00():
    weights = torch.tensor([-8.0, -0.4, 0.0, 0.5, 1.2])
    quantized, scale, restored = symmetric_quantize(weights, bits=8)
    error = weights - restored
    return {"quantized": quantized, "scale": scale,
            "restored": restored,
            "maximum_error": error.abs().max().item(),
            "mean_squared_error": error.square().mean().item()}

def main():
    print(E00())

if __name__ == "__main__":
    main()
```

Part 5 - The Philosophy Behind the Exercise

Quantization asks how much numerical detail a learned function truly needs. It removes representational precision while trying to preserve behavioral meaning. The operation is therefore compression under an empirical contract, not a claim that the discarded information never existed.

Deployment succeeds when the representation, kernel, hardware, and quality requirements agree. A smaller model is useful only if the complete serving system preserves the capabilities that matter.

18.8.2 Exercise 01

Exercise Title: Compare Post-Training Quantization vs QAT

Part 1 - Why this matters

Post-training quantization (PTQ) converts a trained model without changing its original optimization process. It is comparatively fast and requires little or no labeled training data, but

its scales and clipping policy must represent the deployment distribution. Quantization-aware training (QAT) inserts simulated quantization into forward passes so parameters can adapt to rounding and saturation while gradients update higher-precision master weights. QAT can recover quality at aggressive bit widths, but it adds cost, data requirements, and training risk.

Build a matched comparison. Start from one floating checkpoint, define the same target backend and quantization granularity, and evaluate dynamic or calibrated PTQ. Then fine-tune a clone with fake-quantization modules for QAT. Freeze or stabilize observers at a documented point, use a conservative learning rate, and export both into the same deployable representation. Comparing PTQ fake quantization against a fully packed QAT runtime would confound method and kernel.

Measure task quality, perplexity, calibration, output divergence, saturation, artifact size, conversion time, QAT training cost, resident memory, prefill latency, decode latency, and throughput. Include in-domain and shifted prompts. PTQ should remain the default when it satisfies requirements; QAT is justified when measured recovery is worth the additional training and governance burden.

Part 2 - Mathematical form and reasoning

PTQ chooses quantizer parameters ϕ after training:

$$\theta^* = \arg\min_{\theta} L(\theta), \qquad \phi^* = \text{Calibrate}(\theta^*, D_c).$$

QAT optimizes through a fake-quantized forward map Q_ϕ:

$$\min_{\theta,\phi} L(Q_\phi(\theta); D_t).$$

Because rounding has zero derivative almost everywhere, QAT commonly uses a straight-through estimator, treating its derivative as approximately one in a selected range. This is a useful optimization approximation, not an exact derivative of integer arithmetic.

Part 3 - Hints and Helper

1. Keep original checkpoint, evaluation prompts, backend, bit width, and grouping identical across methods.
2. Check calibration coverage for length, language, domain, and activation outliers; sample count alone is insufficient.
3. Save observer states and document when ranges stop updating during QAT.
4. Compare final exported kernels, not only fake-quantized PyTorch modules.
5. Add a no-quantization fine-tune control to separate QAT recovery from ordinary additional training.

Part 4 - Python code skeleton

```
import copy
import torch

def run_ptq(float_model, calibration_loader, quantize_function):
    model = copy.deepcopy(float_model).eval()
    return quantize_function(model, calibration_loader)

def run_qat(float_model, train_loader, prepare_qat, steps=200):
    model = copy.deepcopy(float_model).train()
    model = prepare_qat(model)
    optimizer = torch.optim.AdamW(model.parameters(), lr=1e-5)
    iterator = iter(train_loader)
    for step in range(steps):
        try:
            batch = next(iterator)
        except StopIteration:
            iterator = iter(train_loader)
            batch = next(iterator)
        optimizer.zero_grad(set_to_none=True)
        loss = model.compute_loss(batch)
        loss.backward()
        optimizer.step()
    model.eval()
    return model

def E01(float_model, loaders, tools, evaluate):
    ptq_model = run_ptq(float_model, loaders["calibration"], tools["ptq"])
    qat_model = run_qat(float_model, loaders["train"], tools["prepare_qat"])
    return {"float": evaluate(float_model), "ptq": evaluate(ptq_model),
            "qat": evaluate(qat_model)}
```

Part 5 - The Philosophy Behind the Exercise

PTQ asks whether an existing intelligence can survive a new numerical body. QAT allows that intelligence to adapt before the transition. One preserves the training history; the other reopens it.

The more invasive method is not automatically more advanced. Engineering maturity means choosing the least complex intervention that satisfies measured quality and operational constraints.

18.8.3 Exercise 02

Exercise Title: Implement int8 Quantization Conceptually and Measure Accuracy Drop

Part 1 - Why this matters

Int8 is a useful first low-precision target because it provides 256 codes and is supported by many CPUs and accelerators. Yet “int8 model” is incomplete: it may mean weight-only int8 with floating activations, weight-and-activation int8, dynamic activation scales, or static

calibration. Each choice has different accuracy, memory, and kernel implications.

Implement per-tensor and per-output-channel symmetric int8 weight quantization for a linear layer. Store int8 weights and scales, then dequantize for a reference calculation. This reference proves the numerical contract but is not an optimized deployment kernel. Compare its output with the original layer on normal inputs, outlier inputs, and an evaluation set. Per-channel scales often preserve rows with different ranges better than one global scale.

Measure layer-wise error, logit divergence, top-token agreement, perplexity, task accuracy, and generated-output quality. Report absolute change from the float baseline and confidence intervals where examples are finite. Locate the layers responsible for degradation by quantizing one block at a time. Accuracy drop is acceptable only relative to a predefined deployment budget; do not choose the threshold after observing the result.

Part 2 - Mathematical form and reasoning

For weight matrix $W \in \mathbb{R}^{m \times n}$, per-row scales are

$$s_i = \frac{\max_j |W_{ij}|}{127}, \qquad Q_{ij} = \text{clip}(\text{round}(W_{ij}/s_i), -128, 127).$$

Reference output is

$$\widehat{Y} = X\widehat{W}^\top + b, qquad\widehat{W}_{ij} = s_i Q_{ij}.$$

Measure relative output error $\|Y - \widehat{Y}\|_2/(\|Y\|_2 + \epsilon)$ and task delta $\Delta A = A_{\text{int8}} - A_{\text{float}}$. These describe different levels of parity and should not be substituted for one another.

Part 3 - Hints and Helper

1. Handle all-zero rows explicitly so scale never becomes zero.
2. Quantize bias separately or retain it at higher precision; document the accumulator and output dtype.
3. Compare per-tensor and per-channel schemes with identical weights/inputs.
4. Inspect errors by layer and token position, especially the final LM head.
5. Distinguish reference dequantization from real int8 GEMM in every speed claim.

Part 4 - Python code skeleton

```
import torch
import torch.nn.functional as F

def quantize_int8_per_row(weight):
    maximum = weight.abs().amax(dim=1, keepdim=True)
    scale = maximum / 127.0
    scale = torch.where(scale == 0, torch.ones_like(scale), scale)
    integer_weight = torch.round(weight / scale)
    integer_weight = torch.clamp(integer_weight, -128, 127).to(torch.int8)
```

```
    return integer_weight, scale

def reference_quantized_linear(x, integer_weight, scale, bias=None):
    restored_weight = integer_weight.to(x.dtype) * scale.to(x.dtype)
    return F.linear(x, restored_weight, bias)

def E02(linear_layer, evaluation_inputs):
    weight = linear_layer.weight.detach()
    integer_weight, scale = quantize_int8_per_row(weight)
    baseline = linear_layer(evaluation_inputs)
    quantized = reference_quantized_linear(
        evaluation_inputs, integer_weight, scale, linear_layer.bias)
    difference = baseline - quantized
    relative_error = difference.norm() / baseline.norm().clamp_min(1e-12)
    return {"int8_weight": integer_weight, "scale": scale,
            "maximum_error": difference.abs().max().item(),
            "relative_error": relative_error.item()}
```

Part 5 - The Philosophy Behind the Exercise

Accuracy loss is not a property of eight bits in isolation. It emerges from how those bits are assigned across unequal ranges and how small numerical errors propagate through a learned computation.

The right unit of judgment is behavior. Tensor error helps locate mechanisms; task quality determines whether the compressed model still fulfills its role.

18.8.4 Exercise 03

Exercise Title: Implement Mixed Precision Deployment Strategy

Part 1 - Why this matters

Uniformly quantizing every component is rarely optimal. Large matrix weights may tolerate int8 or int4, while normalization, softmax, residual accumulation, output logits, embeddings, or outlier-sensitive projections may need fp16, bfloat16, or fp32. A mixed-precision strategy assigns precision by measured sensitivity, kernel support, memory value, and conversion overhead rather than by one global label.

Build a module policy that records precision, quantization granularity, accumulator dtype, output dtype, device, and backend. Begin with a float baseline, quantize one module family at a time, and rank sensitivity by quality change and output error. Keep numerically sensitive operations in higher precision and avoid repeated quantize/dequantize boundaries that erase performance gains. Confirm tied weights are not accidentally duplicated under inconsistent rules.

Evaluate candidate policies under representative prompt lengths, batch sizes, and generation settings. Record weight memory, KV-cache memory, temporary workspace, prefill/decode

latency, throughput, quality, non-finite events, and conversion count. The best strategy is normally a Pareto point: lowering one more component may save little memory but introduce a large quality or latency penalty.

Part 2 - Mathematical form and reasoning

Let modules be $M_1, \ldots, M_K$ and precision assignment $p = (p_1, \ldots, p_K)$. Deployment design can be written

$$\min_p \ \alpha M(p) + \beta T(p) + \gamma E(p) \quad \text{subject to} \quad Q(p) \geq Q_{\min},$$

where M is memory, T latency, E energy, and Q quality. Interface conversion adds cost

$$C(p) = \sum_{k=1}^{K-1} c(p_k, p_{k+1}),$$

so locally lower precision may worsen the system if conversions dominate.

Part 3 - Hints and Helper

1. Start with a conservative recipe: quantized linear weights and higher- precision norms, softmax, residuals, and logits.
2. Store policy by stable module path and fail when the architecture changes and a rule no longer matches.
3. Measure module sensitivity on multiple data slices; outliers may be domain- or language-specific.
4. Audit actual parameter/storage dtypes and kernel traces after conversion. The configuration file alone is not evidence.
5. Include a higher-precision override list and its measured memory cost.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, asdict
import torch

@dataclass
class PrecisionRule:
    module_path: str
    weight_dtype: str
    activation_dtype: str
    accumulator_dtype: str
    reason: str

def build_policy(model, sensitive_paths):
    rules = []
    for path, module in model.named_modules():
        if isinstance(module, torch.nn.Linear):
```

```
            weight_dtype = "fp16" if path in sensitive_paths else "int8"
            rule = PrecisionRule(path, weight_dtype, "fp16", "fp32",
                                 "sensitivity experiment")
            rules.append(rule)
    return rules

def validate_policy(model, rules):
    available = {path for path, module in model.named_modules()}
    for rule in rules:
        if rule.module_path not in available:
            raise KeyError(f"unknown module path: {rule.module_path}")
    return True

def E03(model, sensitive_paths):
    rules = build_policy(model, sensitive_paths)
    validate_policy(model, rules)
    return [asdict(rule) for rule in rules]
```

Part 5 - The Philosophy Behind the Exercise

Mixed precision rejects the idea that every calculation deserves the same numerical resources. It spends precision where the model is sensitive and removes it where redundancy has been demonstrated.

This is not inconsistency; it is allocation. A good deployment recognizes that different parts of an intelligent system carry different numerical risks and must be treated according to evidence.

18.8.5 Exercise 04

Exercise Title: Benchmark Latency and Memory Before and After Quantization

Part 1 - Why this matters

Quantization is a systems intervention whose value must be measured end to end. Artifact size, resident memory, and peak memory are different quantities. Likewise, cold-start latency, prompt prefill latency, time to first token, inter-token latency, and request completion time describe different stages. A smaller checkpoint can load faster but decode slower if the runtime lacks a native kernel or repeatedly dequantizes weights.

Create float and quantized deployments from the same checkpoint and run them on the same hardware, runtime version, prompts, batch sizes, context lengths, generation lengths, and sampling policy. Separate model loading and warmup from steady-state measurement. Synchronize accelerators at timer boundaries and measure many repetitions after warmup. Randomize deployment order or run in fresh processes to reduce cache and allocator bias.

Record serialized bytes, host RSS, device allocated/reserved memory, KV-cache growth, workspace memory, time to first token, prefill tokens/s, decode tokens/s, p50/p95/p99 request latency, and maximum concurrency before failure. Validate quality parity before interpreting

speed. Report confidence intervals or run dispersion; one favorable timing is not a deployment claim.

Part 2 - Mathematical form and reasoning

For request with prompt length T_p and generated length T_g,

$$t_{\text{total}} = t_{\text{queue}} + t_{\text{prefill}} + \sum_{i=1}^{T_g} t_{\text{decode},i}.$$

Memory can be decomposed as

$$M = M_{\text{weights}} + M_{\text{KV}} + M_{\text{activations}} + M_{\text{workspace}} + M_{\text{allocator}}.$$

Weight compression ratio is $M_{w,\text{float}}/M_{w,q}$, while end-to-end memory ratio uses total measured M. They diverge as context, batch, and KV cache grow.

Part 3 - Hints and Helper

1. Use fixed prompt-token IDs to exclude tokenizer variance from model timing.
2. Measure prefill and decode separately across a grid of prompt and batch sizes.
3. Capture kernel traces to prove the intended quantized operators execute.
4. Reset peak memory statistics and use isolated processes for clean memory comparisons.
5. Include quality, errors, and failed requests beside latency and memory.

Part 4 - Python code skeleton

```
import statistics
import time
import torch

def synchronized_time(function):
    if torch.cuda.is_available():
        torch.cuda.synchronize()
    start = time.perf_counter()
    result = function()
    if torch.cuda.is_available():
        torch.cuda.synchronize()
    return time.perf_counter() - start, result

def benchmark_model(model, request, warmup=5, repeats=30):
    for repeat in range(warmup):
        model.generate(**request)
    latencies = []
    for repeat in range(repeats):
        elapsed, output = synchronized_time(
            lambda: model.generate(**request))
```

```
        latencies.append(elapsed)
    ordered = sorted(latencies)
    return {"median_seconds": statistics.median(ordered),
            "p95_seconds": ordered[int(0.95 * (len(ordered) - 1))],
            "last_output": output}

def E04(float_model, quantized_model, request):
    return {"float": benchmark_model(float_model, request),
            "quantized": benchmark_model(quantized_model, request)}
```

Part 5 - The Philosophy Behind the Exercise

Performance is not an attribute stored inside a model file. It appears when a representation meets a runtime, a workload, and a machine. Benchmarking makes that meeting observable.

A valid optimization claim names the boundary of its truth: which stage became faster, under which load, at what quality, and with what memory consequence.

18.8.6 Exercise 05

Exercise Title: Debug Quantization-Induced NaNs or Saturation

Part 1 - Why this matters

Integer tensors themselves do not represent NaN, but quantized pipelines can produce invalid floating outputs through zero or non-finite scales, overflowed accumulators, broken dequantization, unsupported kernels, or later operations such as softmax and normalization. Saturation is quieter: values are clipped to the minimum or maximum code, remain finite, and may corrupt behavior without an exception.

Instrument every quantize/dequantize boundary. Record observed min/max, selected scale and zero point, fraction at $q_{\min}$ and $q_{\max}$, mean and maximum reconstruction error, accumulator range, output dtype, and non-finite count. Inspect per-channel statistics because one outlier channel can determine a global scale while small channels lose resolution. Save the first failing input and module path.

Inject failures deliberately: all-zero calibration, a single extreme outlier, an incorrect signed or unsigned range, zero scale, and a mismatched scale shape. Also test a distribution shift beyond calibration. Compare percentile clipping, MSE-based clipping, per-channel scales, higher-precision retention of outlier channels, and wider accumulators. Fix the earliest broken invariant, then rerun end-to-end quality; finite outputs alone do not prove recovery.

Part 2 - Mathematical form and reasoning

Saturation rate for codes q_i is

$$r_{\text{sat}} = \frac{1}{N} \sum_i \mathbb{1}[q_i = q_{\min} \ \vee \ q_i = q_{\max}].$$

For integer dot product $a = \sum_{j=1}^{n} q_j^x q_j^w$, worst-case magnitude is

$$|a| \le n \max |q^x| \max |q^w|.$$

This bound determines whether an int32 accumulator is safe. Dequantization $\widehat{y} = s_x s_w a$ requires finite positive scales of broadcast-compatible shape.

Part 3 - Hints and Helper

1. Fail immediately when scales are non-finite, non-positive, or have the wrong axis.
2. Log low- and high-end saturation separately; asymmetric mistakes may affect only one side.
3. Replay the same failing tensor through float, reference quantization, and deployment kernel to localize the discrepancy.
4. Use histograms and percentiles, not just minimum and maximum.
5. Convert every resolved incident into a permanent assertion and regression case.

Part 4 - Python code skeleton

```
import torch

def inspect_quantizer(x, scale, zero_point, q_min=-128, q_max=127):
    if not torch.isfinite(scale).all() or not torch.all(scale > 0):
        raise FloatingPointError("invalid quantization scale")
    raw = torch.round(x / scale) + zero_point
    low = raw <= q_min
    high = raw >= q_max
    q = torch.clamp(raw, q_min, q_max)
    restored = scale * (q - zero_point)
    if not torch.isfinite(restored).all():
        raise FloatingPointError("invalid dequantized tensor")
    return {"low_saturation": low.float().mean().item(),
            "high_saturation": high.float().mean().item(),
            "maximum_error": (x - restored).abs().max().item(),
            "restored": restored}

def E05():
    ordinary = torch.randn(1024)
    shifted = ordinary.clone()
    shifted[0] = 1000.0
    scale = shifted.abs().max() / 127.0
    return inspect_quantizer(shifted, scale, torch.tensor(0.0))
```

Part 5 - The Philosophy Behind the Exercise

Saturation is information loss with a finite face. It reminds us that numerical validity is weaker than semantic fidelity: a tensor can contain legal numbers while no longer expressing the distinctions the model learned.

Debugging quantization means tracing where a representational promise first failed. The final NaN or bad answer is only the downstream witness.

18.8.7 Exercise 06

Exercise Title: Deploy Quantized Model and Validate Output Parity

Part 1 - Why this matters

Deployment parity cannot require bitwise equality between floating and quantized LLMs; quantization intentionally changes numbers and small logit differences can change greedy or sampled continuations. Parity must be defined at several levels: tensor contracts, finite execution, bounded logits, token ranking, task metrics, generation behavior, safety rules, latency, and failure handling. Thresholds must be specified before release.

Create a golden request suite covering short and long prompts, multiple languages/domains, empty or invalid inputs, EOS behavior, stop strings, maximum context, and adversarial numerical cases. Run the float and quantized deployments with identical token IDs, attention masks, generation settings, seeds, and runtime contract. Compare prefill logits and stepwise decode logits before comparing final text; final divergence alone does not locate the source.

Use greedy decoding for deterministic token-agreement tests and fixed-seed sampling for distributional tests. Compare top-k overlap, KL or Jensen–Shannon divergence, selected-token probability, sequence agreement until first divergence, task accuracy, refusal/safety behavior, and human evaluation where needed. Validate cold start, repeated requests, memory stability, timeout, malformed input, and restart. Save model and tokenizer fingerprints with results.

Part 2 - Mathematical form and reasoning

For float and quantized next-token distributions p and q, top-k overlap is

$$O_k = \frac{|\operatorname{TopK}(p) \cap \operatorname{TopK}(q)|}{k}.$$

Jensen–Shannon divergence is

$$\operatorname{JS}(p, q) = \frac{1}{2}\operatorname{KL}(p\|m) + \frac{1}{2}\operatorname{KL}(q\|m), \qquad m = (p + q)/2.$$

Task parity may require $Q_q \geq Q_f - \delta_Q$, while service parity imposes schema, status-code, and latency constraints. Passing one level does not imply the others.

Part 3 - Hints and Helper

1. Compare token IDs before decoded strings; tokenizer differences must not be blamed on quantization.
2. Keep sampling settings identical and isolate stochastic variance with multiple controlled seeds.
3. Track the first layer/token where logit divergence exceeds its threshold.
4. Test repeated load/unload and long generation for memory growth.
5. Store baseline, thresholds, raw outputs, environment, and decision in a versioned parity report.

Part 4 - Python code skeleton

```
import torch

def distribution_metrics(float_logits, quantized_logits, k=10):
    p = float_logits.float().softmax(dim=-1)
    q = quantized_logits.float().softmax(dim=-1)
    top_p = set(p.topk(k).indices.tolist())
    top_q = set(q.topk(k).indices.tolist())
    overlap = len(top_p.intersection(top_q)) / k
    midpoint = 0.5 * (p + q)
    kl_p = (p * (p.clamp_min(1e-12).log() -
                 midpoint.clamp_min(1e-12).log())).sum()
    kl_q = (q * (q.clamp_min(1e-12).log() -
                 midpoint.clamp_min(1e-12).log())).sum()
    return {"top_k_overlap": overlap,
            "jensen_shannon": (0.5 * (kl_p + kl_q)).item()}

def E06(float_service, quantized_service, golden_requests):
    records = []
    for request in golden_requests:
        float_result = float_service.debug_generate(request)
        quantized_result = quantized_service.debug_generate(request)
        metrics = distribution_metrics(float_result["last_logits"],
                                       quantized_result["last_logits"])
        records.append({"request_id": request["id"], **metrics})
    return records
```

Part 5 - The Philosophy Behind the Exercise

Parity is not sameness; it is preservation of the properties that define an acceptable service. Quantization changes internal arithmetic, so deployment must specify which external meanings may change and by how much.

The discipline of parity turns “looks similar” into a layered contract. It makes approximation governable without pretending approximation is identity.

18.8.8 Exercise 07

Exercise Title: Compare int8 vs int4 Tradeoffs Conceptually

Part 1 - Why this matters

Int4 roughly halves raw weight storage relative to int8, but its 16 codes leave far less resolution. Scale metadata, group size, packing, kernel availability, dequantization, and outlier handling become more important. Some accelerators have excellent int8 kernels but weak int4 support; int4 can then reduce model size without improving latency. The comparison must be recipe-and-hardware specific.

Quantize identical weight matrices to int8 and grouped int4. Because PyTorch does not generally expose a universal native int4 tensor for arbitrary computation, represent two signed 4-bit codes in one byte for storage and unpack them in a transparent reference path. Vary group size: smaller groups provide more local scales and lower error but add metadata and may reduce kernel efficiency. Preserve outlier channels or selected modules in higher precision as separate conditions.

Compare total artifact bytes including scales, resident memory, and conversion time. Measure prefill latency, decode latency, throughput, power, reconstruction error, logit divergence, perplexity, task quality, and safety metrics. Include multiple batch and context sizes. Int4 is justified when its additional memory or capacity gains are operationally valuable and the runtime actually realizes them within the quality budget.

Part 2 - Mathematical form and reasoning

Signed symmetric b-bit range uses

$$q_{\max} = 2^{b-1} - 1, qquad q_{\min} = -2^{b-1}.$$

For group size G, each group g has scale

$$s_g = \max_{i \in g} |w_i| / q_{\max}.$$

Approximate weight-plus-scale storage per parameter is $b + b_s/G$, where b_s is scale width. Thus int4 does not achieve exactly twofold compression over int8 once metadata, alignment, and higher-precision exceptions are included.

Part 3 - Hints and Helper

1. Compare int8 and int4 using the same grouping convention where possible, then study group size separately.
2. Verify packing/unpacking with all codes and odd tensor lengths.
3. Measure the actual packed artifact, not an int32 reference tensor used for convenience.
4. Inspect kernel traces and conversion counts before claiming speedup.
5. Report quality by layer sensitivity and data slice; four-bit failures may concentrate rather than appear uniformly.

Part 4 - Python code skeleton

```
import torch

def pack_unsigned_int4(values):
    values = values.to(torch.uint8)
    if torch.any(values > 15):
        raise ValueError("int4 code must be between 0 and 15")
    if values.numel() % 2 == 1:
        values = torch.cat([values, torch.zeros(1, dtype=torch.uint8)])
```

```
    low = values[0::2]
    high = values[1::2] << 4
    return low | high

def unpack_unsigned_int4(packed, original_length):
    output = torch.empty(packed.numel() * 2, dtype=torch.uint8)
    output[0::2] = packed & 0x0F
    output[1::2] = (packed >> 4) & 0x0F
    return output[:original_length]

def E07():
    codes = torch.arange(16, dtype=torch.uint8)
    packed = pack_unsigned_int4(codes)
    restored = unpack_unsigned_int4(packed, codes.numel())
    assert torch.equal(codes, restored)
    return {"original_bytes": codes.numel() * codes.element_size(),
            "packed_bytes": packed.numel() * packed.element_size()}
```

Part 5 - The Philosophy Behind the Exercise

Lower bit width is a stronger act of forgetting. It can free enough memory to make deployment possible, but it leaves fewer distinctions through which the model may express what it learned.

The correct comparison is not "four is smaller than eight." It is whether the entire system converts the additional forgetting into useful capacity without crossing the behavioral boundary stakeholders require.

18.8.9 Exercise 08

Exercise Title: Analyze Hardware Constraints for Quantized Inference

Part 1 - Why this matters

A quantization format has value only where the target hardware and runtime can execute it effectively. CPU vector instructions, GPU compute capability, tensor core modes, memory bandwidth, driver/runtime versions, kernel libraries, and supported matrix shapes determine whether int8 or int4 becomes faster, merely smaller, or unsupported. A recipe validated on one GPU generation cannot be assumed portable to another.

Build a capability probe before model loading. Record CPU architecture and instruction support, accelerator name and capability, total/free memory, runtime/library versions, supported quantized operators, accumulator types, alignment/group-size constraints, maximum context and batch assumptions, and whether the backend performs weight-only or weight-activation quantization. Execute a tiny known operator through the intended kernel and compare it with a float reference. Feature flags without a successful operator test are insufficient evidence.

Create a compatibility matrix across the actual deployment fleet. For each device/backend pair, classify recipes as native, emulated/dequantized, or unsupported. Benchmark representative shapes from prefill and decode because kernel efficiency changes with matrix dimensions and batch size. Include memory needed for weights, KV cache, workspace, and concurrency headroom. Choose a portable baseline and optional hardware-specific optimized profiles.

Part 2 - Mathematical form and reasoning

For arithmetic intensity $I = F/B_m$ (operations per byte moved) and hardware compute C with bandwidth W, roofline throughput is bounded by

$$P \leq \min(C, IW).$$

Quantization reduces bytes B_m and can raise I, but unpacking and dequantization add operations and temporary traffic. Deployment feasibility also requires

$$M_{\text{weights}} + M_{\text{KV}} + M_{\text{workspace}} + M_{\text{headroom}} \leq M_{\text{available}}.$$

Both constraints must be measured for real shapes.

Part 3 - Hints and Helper

1. Probe capabilities at process startup and store the chosen backend/profile in every request log.
2. Test small-batch decode and large prefill matrices separately.
3. Detect silent fallback to floating kernels through profiler traces and actual tensor/storage inspection.
4. Include driver and runtime versions in cache keys for compiled engines.
5. Fail closed or select a validated higher-precision profile when a required kernel or memory constraint is absent.

Part 4 - Python code skeleton

```
import platform
import torch

def hardware_manifest():
    manifest = {"machine": platform.machine(),
                "python": platform.python_version(),
                "torch": torch.__version__,
                "cuda_available": torch.cuda.is_available()}
    if torch.cuda.is_available():
        index = torch.cuda.current_device()
        properties = torch.cuda.get_device_properties(index)
        manifest["gpu_name"] = properties.name
        manifest["compute_capability"] = (
            properties.major, properties.minor)
```

```
        manifest["total_memory"] = properties.total_memory
        manifest["cuda_runtime"] = torch.version.cuda
    return manifest

def select_profile(manifest, profiles):
    for profile in profiles:
        if profile["supports"](manifest):
            return profile["name"]
    raise RuntimeError("no validated inference profile for this hardware")

def E08(profiles):
    manifest = hardware_manifest()
    manifest["selected_profile"] = select_profile(manifest, profiles)
    return manifest
```

Part 5 - The Philosophy Behind the Exercise

Algorithms do not run in abstraction. Their practical meaning is completed by instruction sets, memory systems, kernels, and runtimes. Quantization is thus a relationship between a representation and a machine.

Portability is not pretending every machine is identical. It is making differences explicit enough to choose a validated path on each one.

18.8.10 Exercise 09

Exercise Title: Implement Fallback to Higher Precision on Failure

Part 1 - Why this matters

A quantized deployment may fail because of unsupported shapes, backend errors, non-finite outputs, parity guard violations, memory pressure, or a newly discovered quality defect. A higher-precision fallback can preserve service availability, but only if it is bounded, observable, and independently validated. Blindly retrying every exception can double latency, exhaust memory, repeat unsafe side effects, or conceal a fleet-wide quantized failure.

Define which failures are retryable. Validate requests before either backend, attach a stable request ID, and make generation attempts idempotent from the service perspective. Use a circuit breaker: after repeated quantized failures, stop routing new traffic to that profile for a cooldown period while health checks continue. Limit retry count and total deadline. Preload the fallback or reserve capacity so the recovery path is real under load, not merely present in code.

Log primary failure category, model/profile fingerprints, hardware, prompt shape, fallback decision, added latency, and final outcome. Return response metadata that allows operators to measure fallback rate without exposing internal details to untrusted clients. Inject kernel exceptions, NaNs, timeouts, and parity failures. Test what happens when both paths fail and ensure alerts and rollback policy activate.

Part 2 - Mathematical form and reasoning

If primary failure probability is p, primary latency t_q, fallback latency t_f, and failure detection cost t_d, expected latency with one retry is

$$\mathbb{E}[T] = (1-p)t_q + p(t_d + t_f).$$

Availability improves only if fallback has capacity and independent failure modes. A circuit may open when failures in a window exceed threshold:

$$\frac{N_{\text{primary failures}}}{N_{\text{primary attempts}}} > r_{\max} \quad \wedge \quad N_{\text{attempts}} \geq N_{\min}.$$

Part 3 - Hints and Helper

1. Enumerate retryable and non-retryable errors; invalid input should not be repeated at higher precision.
2. Share tokenizer and request validation across paths, but keep model execution failures independently observable.
3. Reserve memory/capacity for fallback and load-test simultaneous failover.
4. Prevent recursive fallback and enforce one end-to-end deadline.
5. Alert on fallback rate, not only final request failure; successful fallback can hide primary degradation.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import time

@dataclass
class InferenceResult:
    output: object
    precision_profile: str
    fallback_used: bool

RETRYABLE = (FloatingPointError, RuntimeError, TimeoutError)

def run_with_fallback(request, quantized, high_precision, deadline_seconds):
    started = time.monotonic()
    try:
        output = quantized.generate(request)
        if not quantized.validate_output(output):
            raise FloatingPointError("quantized output failed guard")
        return InferenceResult(output, "quantized", False)
    except RETRYABLE as error:
        remaining = deadline_seconds - (time.monotonic() - started)
        if remaining <= 0:
            raise TimeoutError("no deadline remains for fallback") from error
```

```
        output = high_precision.generate(request, timeout=remaining)
        return InferenceResult(output, "high_precision", True)

def E09(test_requests, quantized, high_precision):
    results = []
    for request in test_requests:
        results.append(run_with_fallback(
            request, quantized, high_precision, deadline_seconds=10.0))
    return results
```

Part 5 - The Philosophy Behind the Exercise

Fallback is an admission that optimization has a boundary. It preserves the service by returning to a more expensive representation when the compressed one cannot honor its contract.

Resilience is not the absence of failure; it is the ability to change paths without losing accountability. Every successful fallback should remain visible as evidence about the primary system.

18.8.11 Exercise 10

Exercise Title: Integrate Quantized Model into Inference Service

Part 1 - Why this matters

An inference service adds contracts that a notebook does not have: request validation, token limits, batching, queuing, cancellation, timeouts, and streaming. It also requires resource isolation, health checks, readiness, model versioning, observability, and safe shutdown. Quantization changes memory and kernel behavior, so service capacity and concurrency must be measured again rather than copied from the float model.

Build a service boundary around a versioned quantized engine. Validate text or token inputs, generation parameters, maximum prompt and output lengths, and tenant limits before queuing. Separate liveness from readiness: a process can be alive while weights are not loaded or the quantized kernel self-test has failed. Warm the engine with representative shapes before marking it ready. Preserve request IDs and expose model/profile versions in internal telemetry.

Implement bounded dynamic batching based on compatible generation parameters and a maximum queue delay. Support streaming cancellation without leaving KV cache allocations or batch slots behind. Apply backpressure when queue or memory limits are reached. Test malformed inputs, oversized prompts, client disconnect, timeout, engine exception, fallback, concurrent requests, and rolling shutdown. Validate that preprocessing and tokenizer fingerprints match training.

Part 2 - Mathematical form and reasoning

For arrival rate λ and mean service time W, Little's law relates average in-system requests L:

$$L = \lambda W.$$

If utilization approaches one, queue latency can grow sharply even when isolated model latency is acceptable. Batch scheduler must satisfy memory constraint

$$M_{\text{weights}} + \sum_{r \in \mathcal{B}} M_{\text{KV}}(r) + M_{\text{workspace}}(\mathcal{B}) \leq M_{\text{safe}}.$$

Admission control is therefore part of numerical deployment correctness.

Part 3 - Hints and Helper

1. Keep API schema independent of one backend while recording the selected precision profile internally.
2. Use bounded queues and explicit overload responses; unbounded waiting is not graceful degradation.
3. Track queue time, prefill, decode, tokens/s, batch composition, fallback, cancellation, and memory.
4. Run tokenizer and kernel self-tests before readiness becomes true.
5. Verify no request data is accidentally retained in logs or reusable buffers beyond policy.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import time

@dataclass
class GenerationRequest:
    request_id: str
    prompt: str
    maximum_new_tokens: int
    temperature: float

def validate_request(request, maximum_prompt_characters=20000):
    if not request.prompt:
        raise ValueError("prompt must not be empty")
    if len(request.prompt) > maximum_prompt_characters:
        raise ValueError("prompt exceeds service limit")
    if not 1 <= request.maximum_new_tokens <= 2048:
        raise ValueError("invalid generation length")
    if request.temperature < 0:
        raise ValueError("temperature must be nonnegative")

def handle_request(request, tokenizer, engine):
    validate_request(request)
    queued_at = time.monotonic()
    token_ids = tokenizer.encode(request.prompt)
    output = engine.generate(token_ids,
```

```
                                maximum_new_tokens=request.maximum_new_tokens,
                                temperature=request.temperature)
    return {"request_id": request.request_id,
            "text": tokenizer.decode(output),
            "queue_and_compute_seconds": time.monotonic() - queued_at,
            "model_version": engine.version}

def E10(requests, tokenizer, quantized_engine):
    return [handle_request(request, tokenizer, quantized_engine)
            for request in requests]
```

Part 5 - The Philosophy Behind the Exercise

A deployed model becomes a participant in a larger social and computational system. Its value is mediated by queues, limits, failures, users, and operational rules that do not appear in its weights.

Service engineering turns capability into a dependable relationship. The model must not only produce answers; it must do so within explicit promises about time, resources, identity, and failure.

18.8.12 Exercise 11

Exercise Title: Measure Power Consumption Differences After Quantization

Part 1 - Why this matters

Lower precision may reduce memory traffic and arithmetic energy, but lower latency does not automatically mean lower power at every instant. A quantized kernel may use hardware more intensively, increasing watts while finishing sooner. The meaningful deployment quantities are energy per request, energy per generated token, throughput per watt, and the workload completed within a power or thermal envelope.

Measure float and quantized models on the same device with identical prompt tokens, generated lengths, batch/concurrency, clock policy, ambient/thermal conditions, and runtime. Sample device power at a known interval from before request start through cooldown. Subtract or report idle baseline consistently. Warm up both deployments and alternate trial order to reduce temperature drift. Record temperature, clocks, throttling, utilization, and latency alongside power.

Integrate sampled power over time rather than multiplying one instantaneous reading by latency. Repeat enough trials to report dispersion. Separate model load/cold-start energy from steady inference and prefill from decode when possible. Quantization may permit greater concurrency; compare both equal-load and equal-throughput conditions. State sensor resolution and whether the measurement covers only accelerator power or the entire system.

Part 2 - Mathematical form and reasoning

Energy is the time integral of power:

$$E = \int_{t_0}^{t_1} P(t)\,dt.$$

With sampled values (t_i, P_i), trapezoidal approximation is

$$E \approx \sum_{i=0}^{n-1} \frac{P_i + P_{i+1}}{2}(t_{i+1} - t_i).$$

Report joules per valid generated token E/N_g and throughput per watt $R/\overline{P}$. If subtracting idle power P_0, label dynamic energy $\int (P(t) - P_0)dt$ distinctly from total energy.

Part 3 - Hints and Helper

1. Verify sensor timestamps and units; watts sampled over seconds integrate to joules.
2. Begin sampling before execution and end after the final synchronization.
3. Monitor thermal throttling and randomize float/quantized trial order.
4. Compare equal requests, equal useful tokens, and equal throughput as separate experiments.
5. Report uncertainty and measurement boundary: GPU board, CPU package, or whole-system power.

Part 4 - Python code skeleton

```
def trapezoidal_energy(samples):
    energy_joules = 0.0
    for index in range(len(samples) - 1):
        time_a, power_a = samples[index]
        time_b, power_b = samples[index + 1]
        duration = time_b - time_a
        average_power = 0.5 * (power_a + power_b)
        energy_joules += average_power * duration
    return energy_joules

def summarize_energy(samples, generated_tokens):
    energy = trapezoidal_energy(samples)
    duration = samples[-1][0] - samples[0][0]
    average_power = energy / duration
    return {"energy_joules": energy,
            "average_watts": average_power,
            "joules_per_generated_token": energy / generated_tokens}

def E11(run_and_sample_power, float_model, quantized_model, request):
    report = {}
    for name, model in (("float", float_model),
                        ("quantized", quantized_model)):
        samples, generated_tokens = run_and_sample_power(model, request)
        report[name] = summarize_energy(samples, generated_tokens)
    return report
```

Part 5 - The Philosophy Behind the Exercise

Efficiency is the relationship between useful work and consumed resources. Power describes intensity at a moment; energy describes the accumulated cost of finishing the task. Confusing them can reverse the conclusion.

Responsible deployment measures the physical consequences of abstraction. A numerical representation ultimately becomes memory movement, heat, time, and electricity.

18.8.13 Exercise 12

Exercise Title: Test Quantized Model on Edge or Limited-Memory GPU

Part 1 - Why this matters

Edge and limited-memory devices expose constraints hidden on a development server: small VRAM/RAM, unified-memory contention, limited bandwidth, weaker quantized kernels, thermal throttling, slow storage, and strict power limits. Fitting weights is only the first condition. KV cache, workspaces, tokenizer, runtime, operating system, concurrent processes, and memory fragmentation must also fit throughout the longest supported request.

Define a concrete device envelope and deploy the exact artifact/runtime intended for production. Test cold load, warm load, minimum and maximum prompt, long decode, repeated requests, and concurrency. Measure resident and peak memory, swap or unified-memory pressure, time to first token, decode tokens/s, temperature, clocks, power, and failure recovery. Reserve headroom rather than using every reported byte. On an 8GB GPU, for example, the useful model budget may be materially below 8GB after runtime and KV cache.

Explore controlled mitigations: smaller quantization group, shorter context, KV-cache quantization, CPU/GPU offload, lower batch, paged cache, and selective higher precision. Each changes latency or quality. Test offline operation, restart after interruption, corrupted artifact detection, and low-power/thermal steady state. The final report must state supported prompt/output/concurrency limits instead of implying unlimited inference because one request succeeded.

Part 2 - Mathematical form and reasoning

For L layers, batch B, sequence length T, KV heads H_{kv}, head width d_h, and cache element bytes s, approximate KV cache is

$$M_{KV} \approx 2LBTH_{kv}d_hs.$$

Safe feasibility requires

$$M_w + M_{KV} + M_{workspace} + M_{runtime} + M_{margin} \leq M_{device}.$$

Quantizing weights reduces M_w but does not reduce M_{KV} unless a separate cache policy is used. Long context can therefore erase apparent weight savings.

Part 3 - Hints and Helper

1. Measure memory after load, after prefill, and at maximum decode length.

2. Disable unrelated processes or record their memory so trials are comparable.
3. Soak-test long enough to observe thermal throttling and memory leaks.
4. Treat offload as a new profile with its own transfer and latency metrics.
5. Fail admission before OOM when a request exceeds the validated envelope.

Part 4 - Python code skeleton

```
import torch

def memory_budget(total_bytes, margin_fraction=0.15):
    return int(total_bytes * (1.0 - margin_fraction))

def can_admit(weight_bytes, kv_bytes, workspace_bytes,
              runtime_bytes, total_bytes):
    required = weight_bytes + kv_bytes + workspace_bytes + runtime_bytes
    safe_limit = memory_budget(total_bytes)
    return {"required_bytes": required, "safe_limit_bytes": safe_limit,
            "admitted": required <= safe_limit}

def E12(engine, device_index=0):
    properties = torch.cuda.get_device_properties(device_index)
    torch.cuda.reset_peak_memory_stats(device_index)
    results = []
    for prompt_length in (32, 512, 2048):
        output = engine.run_stress_request(prompt_length=prompt_length,
                                           generated_tokens=256)
        results.append({"prompt_length": prompt_length,
                        "tokens_per_second": output.tokens_per_second,
                        "peak_bytes": torch.cuda.max_memory_allocated(
                            device_index)})
    return {"device": properties.name, "results": results}
```

Part 5 - The Philosophy Behind the Exercise

Edge deployment forces the model to inhabit a finite world. Memory, heat, energy, and time cease to be background infrastructure and become immediate parts of the model's capability.

Constraint is not merely deprivation; it clarifies priorities. A successful edge system states exactly which intelligence it can provide reliably within the resources actually present.

18.8.14 Exercise 13

Exercise Title: Compare Quantized vs Non-Quantized Hallucination Rates

Part 1 - Why this matters

Quantization perturbs logits and may change token rankings, confidence, refusal behavior, and long-generation trajectories. It could increase factual errors in sensitive regions, but ordinary sampling variance can also change answers even without quantization. A hallucination comparison must isolate precision from prompt, retrieval context, decoding policy, evaluator, and randomness. It cannot be inferred from perplexity alone.

Create a frozen evaluation set with answerable factual questions, deliberately unanswerable questions, provided-context questions, and domain slices. Store reference answers, acceptable variants, citations/evidence, and abstention expectations. Run float and quantized models with identical tokenization, prompts, retrieval evidence, generation configuration, and paired random seeds. Use greedy decoding as a deterministic diagnostic and multiple seeds for stochastic settings. Blind evaluators to model version.

Define errors operationally: unsupported factual claim, contradiction with provided evidence, fabricated citation, or failure to abstain. Use rule-based checks where possible and human or validated model-assisted review with an uncertain category. Report paired transitions: correct-to-wrong, wrong-to-correct, abstain-to-claim, and claim-to-abstain. Analyze confidence and logit divergence near changed tokens. Do not conclude causal safety from a small nonsignificant difference.

Part 2 - Mathematical form and reasoning

For paired examples i, let $h_i^f, h_i^q \in \{0, 1\}$ indicate hallucination. Rates are

$$\widehat{H}_f = \frac{1}{N} \sum_i h_i^f, \qquad \widehat{H}_q = \frac{1}{N} \sum_i h_i^q,$$

The paired change is

$$\Delta H = \widehat{H}_q - \widehat{H}_f.$$

Discordant counts n_{01} and n_{10} capture transitions from a correct float answer to a wrong quantized answer, and the reverse transition. Paired tests or bootstrap intervals should operate on examples and preserve this dependence.

Part 3 - Hints and Helper

1. Freeze evaluation definitions and judging rules before seeing model labels.
2. Separate factuality, relevance, citation validity, and abstention rather than collapsing all into one subjective score.
3. Use paired prompts/seeds and retain raw outputs for adjudication.
4. Stratify by domain, language, prompt length, rarity, and answerability.
5. Investigate changed conclusions at token/logit level, then confirm with human-readable evidence.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class Judgment:
    example_id: str
    float_hallucinated: bool
    quantized_hallucinated: bool

def paired_summary(judgments):
    total = len(judgments)
    float_count = 0
    quantized_count = 0
    correct_to_wrong = 0
    wrong_to_correct = 0
    for judgment in judgments:
        float_count += int(judgment.float_hallucinated)
        quantized_count += int(judgment.quantized_hallucinated)
        became_wrong = (
            not judgment.float_hallucinated
            and judgment.quantized_hallucinated
        )
        became_correct = (
            judgment.float_hallucinated
            and not judgment.quantized_hallucinated
        )
        if became_wrong:
            correct_to_wrong += 1
        if became_correct:
            wrong_to_correct += 1
    return {"float_rate": float_count / total,
            "quantized_rate": quantized_count / total,
            "rate_delta": (quantized_count - float_count) / total,
            "correct_to_wrong": correct_to_wrong,
            "wrong_to_correct": wrong_to_correct}

def E13(run_paired_evaluation, judge, dataset):
    outputs = run_paired_evaluation(dataset)
    judgments = [judge(item) for item in outputs]
    return paired_summary(judgments)
```

Part 5 - The Philosophy Behind the Exercise

Factuality is not a scalar hidden inside weights. It appears in a relationship among prompts, evidence, decoding, and judgment. Quantization may perturb that relationship, but attribution requires controlled comparison.

The exercise teaches epistemic restraint: measure paired behavioral changes, preserve uncertainty, and resist turning absence of detected harm into proof of absence.

18.8.15 Exercise 14

Exercise Title: Build Deployment Compatibility Checklist

Part 1 - Why this matters

Quantized deployment depends on agreements across model architecture, tokenizer, quantization recipe, runtime, kernel backend, hardware, API schema, monitoring, and rollback. A checklist converts those agreements into executable gates. Its purpose is not to collect reassuring checkmarks; it is to prevent an artifact from advancing when one required assumption is unknown or false.

Organize checks into identity, numerical correctness, hardware/runtime, performance, quality/safety, service behavior, observability, security, and recovery. Verify model/tokenizer/config fingerprints, supported operators, scales/group sizes, dtype/accumulator policy, memory headroom, cold and warm load, prefill/decode limits, parity thresholds, hallucination/refusal slices, malformed input, concurrency, fallback, rollback, artifact integrity, and data privacy. Assign an owner and evidence artifact to every gate.

Implement the checklist as structured data and code so CI or a release job can evaluate it. Results should be pass, fail, or explicitly approved waiver with expiry—never silent "not applicable." Re-run hardware-dependent gates for every deployment class and software-dependent gates after runtime/driver changes. Inject failed checks to prove the release is blocked.

Part 2 - Mathematical form and reasoning

Let required gates be $g_i \in \{0, 1\}$. Release readiness is conjunctive:

$$R = \prod_{i \in \mathcal{G}_{required}} g_i.$$

An average score is inappropriate because many minor successes cannot compensate for one missing rollback or corrupted tokenizer. Conditional gates can be defined by implication, for example

$$\text{int4 enabled} \Rightarrow \text{int4 kernel probe passed.}$$

Waivers are time-bounded risk decisions with owner, reason, and compensating control, not conversion of a failure into evidence of success.

Part 3 - Hints and Helper

1. Give every check a stable ID, requirement, owner, evidence path, status, and expiry for waivers.
2. Separate static artifact checks from tests that must execute on each hardware profile.
3. Fail on missing evidence and stale benchmark/evaluation versions.
4. Include training/serving tokenizer and preprocessing parity.
5. Drill fallback and rollback under load; documentation alone is not a passed recovery gate.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from datetime import date

@dataclass
class Gate:
    gate_id: str
    required: bool
    passed: bool
    evidence: str
    owner: str
    waiver_expiry: str = ""

def validate_gates(gates):
    failures = []
    for gate in gates:
        waiver_valid = False
        if gate.waiver_expiry:
            expiry = date.fromisoformat(gate.waiver_expiry)
            waiver_valid = expiry >= date.today()
        if gate.required and not gate.passed and not waiver_valid:
            failures.append(gate.gate_id)
        if gate.passed and not gate.evidence:
            failures.append(gate.gate_id + ":missing_evidence")
    return {"ready": len(failures) == 0, "failures": failures}

def E14(gates):
    result = validate_gates(gates)
    if not result["ready"]:
        raise RuntimeError(f"deployment blocked: {result['failures']}")
    return result
```

Part 5 - The Philosophy Behind the Exercise

A checklist is a boundary between confidence and wishful thinking. It asks each deployment claim to present evidence before becoming operational reality.

Its conjunctive nature matters: reliability is often lost through one forgotten interface. Explicit gates preserve the memory of how failures actually happen.

18.8.16 Exercise 15

Exercise Title: Debug ONNX Export Issues for Quantized Models

Part 1 - Why this matters

ONNX export crosses several semantic boundaries: PyTorch graph capture, ONNX operator representation, quantized tensor conventions, opset support, shape inference, and target runtime kernels. A model that exports successfully may still dequantize unexpectedly, reject

dynamic sequence lengths, use unsupported quantized operators, or produce different logits. Export is not deployment until the target runtime executes and passes parity.

Start from a tiny submodule containing the failing pattern. Export the float version first, then a reference quantize/dequantize graph, then the intended packed model. Choose opset and quantization representation supported by the target runtime, such as Q/DQ nodes or quantized operator forms. Mark dynamic batch and sequence axes intentionally. Keep scale, zero-point dtype, signedness, axis, and broadcasting consistent. Run graph checker and shape inference before runtime execution.

Compare named intermediate outputs between PyTorch and ONNX Runtime to locate the first divergence. Inspect the graph for unexpected casts, duplicated dequantization, constant folding, and operators assigned to CPU. Test minimum, typical, and maximum shapes; all-zero inputs; outliers; padding masks; and cached decoding if supported. Maintain a table of exporter/runtime/opset/device versions because support changes over time.

Part 2 - Mathematical form and reasoning

Correct export seeks functional agreement

$$f_{\text{PyTorch}}(x;\theta_q) \approx f_{\text{ONNXRuntime}}(x;G_q)$$

for domain $x \in \mathcal{D}_{deploy}$, not only the trace example. For each observed intermediate h_k, define error

$$e_k = \frac{\|h_k^{PT} - h_k^{ONNX}\|_2}{\|h_k^{PT}\|_2 + \epsilon}.$$

The earliest k exceeding tolerance identifies the conversion/operator boundary to investigate. Dynamic-axis correctness requires shape constraints hold for the whole supported domain.

Part 3 - Hints and Helper

1. Reproduce with the smallest module and fixed input before adding dynamic axes and full generation.
2. Pin exporter, opset, runtime, provider, and quantization tool versions.
3. Inspect scale and zero-point initializer dtypes and quantization axes.
4. Verify provider placement; CPU fallback can preserve outputs while ruining latency.
5. Add successful export plus target-runtime inference to CI, not export alone.

Part 4 - Python code skeleton

```
import numpy as np
import torch

def export_model(model, example_ids, path):
    model.eval()
    torch.onnx.export(
```

```
        model,
        (example_ids,),
        path,
        input_names=["input_ids"],
        output_names=["logits"],
        dynamic_axes={"input_ids": {0: "batch", 1: "sequence"},
                      "logits": {0: "batch", 1: "sequence"}},
        opset_version=17,
        do_constant_folding=True)

def compare_outputs(torch_output, runtime_output, atol=1e-3, rtol=1e-3):
    converted = torch_output.detach().cpu().float().numpy()
    if not np.allclose(converted, runtime_output, atol=atol, rtol=rtol):
        error = np.max(np.abs(converted - runtime_output))
        raise AssertionError(f"ONNX parity failed; max error={error}")
    return True

def E15(model, example_ids, runtime_factory, path="quantized_model.onnx"):
    export_model(model, example_ids, path)
    runtime = runtime_factory(path)
    runtime_output = runtime.run(example_ids.cpu().numpy())
    torch_output = model(example_ids)
    return compare_outputs(torch_output, runtime_output)
```

Part 5 - The Philosophy Behind the Exercise

Export is translation between computational languages. A valid file proves syntax; parity proves that meaning survived the translation over the intended input domain.

Debugging succeeds by refusing to treat the graph as a black box. The first divergent intermediate is where two runtimes stopped agreeing about the same computation.

18.8.17 Exercise 16

Exercise Title: Evaluate Latency Under Concurrent Requests

Part 1 - Why this matters

Single-request latency is not production latency. When many clients arrive at the same time, requests compete for admission slots, CPU preprocessing, GPU memory, attention kernels, KV-cache capacity, and output-stream bandwidth. A quantized model may execute each token faster yet still have poor tail latency if the service builds oversized batches, blocks on memory allocation, or lets long prompts delay short interactive requests. This exercise therefore tests the entire serving system rather than timing one isolated forward pass.

Define the workload before interpreting a number. Record the arrival pattern, concurrency, prompt-length distribution, requested output lengths, sampling settings, cache state, precision, batch policy, timeout, and hardware. Separate closed-loop tests, where each client waits before sending another request, from open-loop tests, where arrivals continue independently of completion. A closed-loop test applies backpressure and can conceal overload; an open-loop test

reveals queue growth but must bound the experiment safely.

Capture queue delay, time to first token (TTFT), inter-token latency (ITL), end-to-end latency, tokens per second, cancellation rate, error rate, fallback rate, and actual batch size. Report distributions rather than averages. The 95th and 99th percentiles expose rare stalls that a mean can hide. Stratify the results by prompt and generation length so that a changing workload mix is not mistaken for a runtime improvement. Warm the service, synchronize asynchronous GPU work at measurement boundaries, and exclude neither failures nor timeouts from the final accounting.

Sweep offered load until throughput stops increasing proportionally and tail latency rises sharply. That point is the saturation knee. A valid capacity claim stays below it with explicit headroom. Compare the quantized deployment against the higher-precision baseline under the same request trace. The result must say whether quantization increased sustainable throughput, reduced TTFT, changed ITL, or merely shifted the bottleneck elsewhere.

Part 2 - Mathematical form and reasoning

For request i, decompose total latency into queue and service time:

$$T_i^{\text{total}} = T_i^{\text{queue}} + T_i^{\text{service}}, \qquad T_i^{\text{service}} = T_i^{\text{prefill}} + T_i^{\text{decode}}.$$

TTFT includes admission, queueing, preprocessing, and prefill. A useful decode measure is

$$\text{ITL}_i = \frac{T_{i,\text{last token}} - T_{i,\text{first token}}}{\max(1, N_i^{\text{generated}} - 1)}.$$

Little's law gives a consistency check for a stable interval:

$$L = \lambda W,$$

where L is average requests in the system, λ is completed request rate, and W is average total time. Large disagreement usually indicates measurement-window, warm-up, or incomplete-request accounting errors. Define a capacity point only when all service-level constraints hold simultaneously:

$$C^* = \max_C \left\{ C : p_{99}(\text{TTFT}) \le S_{\text{TTFT}},\ p_{99}(\text{ITL}) \le S_{\text{ITL}},\ r_{\text{error}} \le S_{\text{error}} \right\}.$$

The concurrency with the largest raw throughput is not automatically the best configuration. It may violate interactive latency, fairness, memory headroom, or reliability constraints.

Part 3 - Hints and Helper

1. Create one immutable request trace and replay it against every model variant.
2. Warm model weights, kernels, memory pools, and tokenization before collecting samples.
3. Record client-send, server-admit, generation-start, first-token, and completion timestamps.
4. Sweep concurrency gradually and stop safely if OOM, timeout, or queue growth exceeds a guardrail.

5. Compute p50, p95, and p99 for TTFT, ITL, and end-to-end latency; keep failed requests in separate counters.
6. Stratify by prompt/output length and verify that the compared systems completed equivalent work.
7. Plot offered request rate against achieved rate and tail latency to locate the saturation knee.
8. Repeat the sweep and report variation rather than selecting the most favorable run.

Part 4 - Python code skeleton

```
from concurrent.futures import ThreadPoolExecutor, as_completed
from dataclasses import dataclass
from time import perf_counter
import math

@dataclass
class RequestResult:
    request_id: int
    prompt_tokens: int
    output_tokens: int
    queue_s: float
    ttft_s: float
    total_s: float
    ok: bool

```

Part 5 - The Philosophy Behind the Exercise

Concurrency turns performance from a property of a model into a property of a shared system. Each request is locally reasonable, yet their interaction creates queues, contention, unfairness, and overload. Tail latency is therefore not statistical clutter; it is evidence about coordination under pressure.

Quantization matters only when its saved memory and arithmetic translate into better service for real workloads. This exercise resists the comforting but incomplete benchmark of an isolated kernel. It asks whether the whole system remains timely, fair, observable, and recoverable when many users need it at once.

18.8.18 Exercise 17

Exercise Title: Build Rollback Strategy for Quantized Deployments

Part 1 - Why this matters

Quantization is a behavior-changing deployment transformation. Even after offline parity and quality tests, production can reveal an unsupported prompt shape, a rare outlier, a driver-specific kernel defect, a latency regression, or a safety failure absent from the evaluation set. A rollback strategy limits the duration and blast radius of such surprises. It must be designed and rehearsed before the quantized model receives traffic.

Keep the last approved high-precision artifact deployable, immutable, and addressable by version. Version the model, tokenizer, quantization metadata, runtime image, preprocessing, API schema, and monitoring configuration as one release unit. Merely switching the weights is unsafe if the candidate changed token IDs, cache formats, output schemas, or runtime dependencies. A rollback target is valid only when the entire compatible serving stack can be restored.

Release progressively: offline validation, shadow traffic, a small canary, then larger traffic stages. At every stage compare quantized and control metrics for equivalent requests. Define automatic stop and rollback thresholds for errors, NaNs, OOMs, tail latency, fallback volume, task quality proxies, safety signals, and confidence drift. Use minimum sample sizes and consecutive bad windows so one noisy observation does not cause oscillation, but retain immediate rollback for catastrophic invariants such as corrupted output or security failure.

Make rollback idempotent and independent of the failing model path. The control plane must remain usable when the candidate exhausts GPU memory or crashes its worker. Drain or cancel in-flight requests deliberately, restore healthy capacity, verify readiness with golden probes, and only then redirect traffic. Record who or what triggered rollback, the evidence, artifact identities, timeline, and post-rollback validation. Regular game-day exercises are required: an untested rollback is a hopeful document, not a recovery mechanism.

Part 2 - Mathematical form and reasoning

Let m index a monitored metric, b_m the control baseline, and $c_m(t)$ the candidate value in window t. Define a signed degradation so that positive is always worse:

$$d_m(t) = \sigma_m \frac{c_m(t) - b_m}{\max(|b_m|, \epsilon)},$$

where $\sigma_m = 1$ for metrics such as latency/error and $\sigma_m = -1$ for metrics such as accuracy. A staged release may advance only if

$$n(t) \geq n_{\min} \quad \wedge \quad d_m(t) \leq \tau_m \text{ for every required } m.$$

Rollback is triggered when a catastrophic invariant fails once, or when an ordinary threshold is violated for K consecutive valid windows:

$$R(t) = I_{\text{catastrophic}}(t) \ \vee \ \bigvee_m \left[\sum_{j=0}^{K-1} I(d_m(t-j) > \tau_m) = K \right].$$

The thresholds, direction, sample requirement, and missing-data behavior must be explicit. Treat missing telemetry as a deployment risk rather than silently assuming health.

Part 3 - Hints and Helper

1. Package model, tokenizer, runtime, configuration, and schema into immutable release manifests.
2. Verify that the previous version can still load on current hardware before starting the canary.
3. Separate catastrophic one-window gates from noisy gates requiring repeated violations.
4. Use shadow or paired traffic where privacy and cost constraints permit direct comparison.
5. Keep rollback control outside the candidate worker and reserve enough capacity for recovery.
6. Define handling for in-flight requests, KV caches, streaming clients, and stateful sessions.
7. Run golden readiness probes after restoration before marking the incident resolved.
8. Rehearse rollback and measure detection time, decision time, traffic-switch time, and recovery time.

    control_plane.route_all_traffic(state.fallback.release_id)
    state.phase = Phase.STABLE
```

Part 5 - The Philosophy Behind the Exercise

Rollback is the engineering expression of intellectual humility. Offline evidence can justify a deployment, but it cannot enumerate every future input or systems interaction. A reversible decision admits this limitation without abandoning progress.

The deeper goal is not to avoid all failures; it is to prevent a surprising failure from becoming a prolonged one. Immutable artifacts, explicit gates, independent control paths, and rehearsed recovery convert uncertainty from an unbounded threat into a manageable operational condition.

18.8.19 Exercise 18

Exercise Title: Document Quantization Tradeoffs for Stakeholders

Part 1 - Why this matters

A technically accurate benchmark can still produce a poor decision if it is communicated without the assumptions, risks, or consequences that matter to its audience. Researchers need to understand where error entered the model; platform engineers need hardware and runtime constraints; product owners need user-visible quality and latency; finance teams need capacity and cost; safety owners need failure-mode evidence. This exercise converts the measurements from the chapter into a decision document without flattening them into a slogan such as “int4 is four times smaller.”

Start with the decision to be made, not the technology to be celebrated. State the baseline, candidate variants, workload, hardware, software versions, calibration data, evaluation coverage, and confidence intervals. Separate artifact size from resident memory, isolated latency from concurrent tail latency, generic quality scores from safety-critical slices, and theoretical bit width from realized kernel speed. Distinguish measured facts, estimates, assumptions, and unknowns visually or structurally.

Present every candidate as a bundle of consequences. For example, int8 may offer broad kernel support and small quality loss; int4 may permit a larger model on the same GPU but require group metadata, special kernels, and more selective high-precision exceptions. Mixed precision may produce the best quality-capacity compromise while increasing configuration and testing burden. Include fallback and rollback costs because operational complexity is part of the tradeoff, not an unrelated implementation detail.

Avoid a universal weighted score unless the organization has explicitly agreed to the weights. Show the Pareto frontier and hard constraints first. Recommend a variant only for a named deployment scenario and state what would invalidate the recommendation: a new GPU, longer context, different traffic shape, changed quality threshold, or emerging production drift. The document should allow a reader to disagree intelligently because the evidence and value judgments are kept separate.

Part 2 - Mathematical form and reasoning

Represent candidate j by a metric vector

$$\mathbf{m}_j = (Q_j, L_{99,j}, M_j, C_j, E_j, R_j),$$

where Q is quality, L_{99} tail latency, M resident memory, C cost per useful token, E energy per useful token, and R an explicitly defined risk measure. Candidate a dominates b only if it is no worse on all required dimensions and strictly better on at least one. Non-dominated candidates form the Pareto set; stakeholders then select among real tradeoffs rather than a fabricated single winner.

A scenario-specific feasibility set can be written as

$$\mathcal{F} = \{j : Q_j \geq Q_{\min},\ L_{99,j} \leq L_{\max},\ M_j \leq M_{\max},\ R_j \leq R_{\max}\}.$$

Only after hard gates are satisfied should cost optimization occur:

$$j^* = \arg\min_{j \in \mathcal{F}} C_j.$$

Report absolute values and deltas. A 30 percent latency reduction is ambiguous without knowing whether the change was from 100 ms to 70 ms or from 10 s to 7 s. For uncertain measures, include an interval and sample count; false numerical precision undermines rather than strengthens the decision.

Part 3 - Hints and Helper

1. Open with the concrete decision, deployment scenario, and recommendation scope.
2. Create one evidence table containing baseline, int8, int4, and mixed-precision variants.
3. Label every value as measured, estimated, assumed, or not yet known.
4. Include quality slices, hallucination/safety results, latency percentiles, memory, energy, and operational risk.
5. State calibration and evaluation coverage so readers know which inputs remain untested.
6. Separate hard release gates from preferences and optimization goals.

7. Describe fallback, monitoring, rollback, staffing, and maintenance consequences.
8. End with a decision, owner, review date, and explicit triggers for re-evaluation.

Part 4 - Python code skeleton

```

            "fallback and rollback plan",
            "re-evaluation triggers",
        ],
    }
```

Part 5 - The Philosophy Behind the Exercise

Engineering communication is not simplification at any cost. Its purpose is to translate evidence across different responsibilities while preserving the uncertainty and conditions that give the evidence meaning. A stakeholder does not need every kernel trace, but they do need to know when the recommendation depends on a particular kernel.

Quantization has no context-free winner. It redistributes memory, computation, quality, energy, compatibility, and operational complexity. The honest document makes those redistributions visible, identifies whose objectives define the decision, and leaves a trail that future evidence can revise.

18.8.20 Exercise 19

Exercise Title: Produce a Full Quantization and Deployment Report

Part 1 - Why this matters

The final report is the durable engineering record of what was built, why it was accepted, where it was tested, how it can fail, and how it will be operated. Without that record, benchmark numbers become detached from their artifacts, deployment assumptions disappear, and later regressions cannot be distinguished from workload changes. This exercise integrates the entire chapter into an auditable release argument rather than a celebratory summary.

Begin with immutable identity: source model and tokenizer digests, quantization recipe, calibration dataset version, per-layer precision policy, framework, backend, compiler flags, runtime image, driver, hardware, and generated artifact hash. Document transformation details including granularity, scale/zero-point rules, group size, clipping, outlier handling, excluded layers, accumulation precision, and whether activations and KV cache are quantized. The report must make it possible to reproduce the candidate rather than merely name it.

Connect every release claim to evidence. Include numerical parity, task quality, calibration, hallucination and safety slices, artifact and resident memory, TTFT, ITL, tail latency under concurrency, throughput, energy, edge-device limits, hardware compatibility, and ONNX/runtime behavior. Record datasets, sample counts, seeds, prompts, decoding configuration, warm-up, repetitions, confidence intervals, failures, and raw-result locations. Negative

experiments and rejected configurations belong in the report because they define the safe boundary and prevent repeated mistakes.

Complete the operational argument: service integration, input limits, fallback conditions, canary stages, monitoring, alert thresholds, rollback target, recovery rehearsal, ownership, security/privacy review, known limitations, and expiration or revalidation date. End with a signed release decision that lists the gates passed, exceptions accepted, residual risks, and the conditions that would force rollback or renewed evaluation. A report is complete only when a new engineer can use it to reproduce, deploy, observe, and safely reverse the system.

Part 2 - Mathematical form and reasoning

Model release readiness as a conjunction of evidence-backed gates rather than an average score:

$$G_{\text{release}} = G_{\text{identity}} \wedge G_{\text{parity}} \wedge G_{\text{quality}} \wedge G_{\text{performance}} \wedge G_{\text{compatibility}} \wedge G_{\text{operations}} \wedge G_{\text{rollback}}.$$

Each gate G_k must contain a claim, threshold, observed value, evidence reference, owner, and status. If a required value is unknown, the gate is not passed. A useful traceability relation is

$$\text{requirement} \rightarrow \text{experiment} \rightarrow \text{raw evidence} \rightarrow \text{decision} \rightarrow \text{production monitor}.$$

For a measured improvement, report both delta and uncertainty. If X_q and X_f are quantized and float results across matched runs, define paired differences $D_i = X_{q,i} - X_{f,i}$ and report

$$\bar{D} = \frac{1}{n}\sum_{i=1}^{n} D_i, \qquad SE(\bar{D}) = \frac{s_D}{\sqrt{n}}.$$

Do not combine incomparable evidence into one opaque readiness percentage. One failed safety, compatibility, or rollback gate can invalidate deployment even when all performance metrics are excellent.

Part 3 - Hints and Helper

1. Use a fixed report schema so every future quantized release answers the same critical questions.
2. Hash all artifacts and record exact software, driver, backend, and hardware versions.
3. Link claims to raw results, scripts, configurations, prompts, and dataset versions.
4. Include per-layer precision and exception lists, not just the headline model bit width.
5. Report rejected candidates, injected failures, and unresolved unknowns alongside successful results.
6. Make release gates machine-readable and fail closed when required evidence is absent.
7. Include monitoring thresholds, fallback logic, rollback rehearsal evidence, owners, and review dates.

8. Ask an independent reviewer to reproduce a subset and challenge the recommendation before sign-off.

```

```
        environment=environment,
    )

# Populate gates from verified experiment outputs. Never mark a gate passed
# because a file merely exists; validate its contents and artifact identity.
```

Part 5 - The Philosophy Behind the Exercise

A rigorous report is institutional memory with enough structure to be tested. It preserves not only the conclusion but the chain of reasoning that made the conclusion responsible at a particular time. This matters because deployed models, runtimes, hardware, traffic, and social expectations continue to change after the benchmark ends.

The final exercise treats deployment as a scientific claim under operational conditions. Reproducibility protects the claim, monitoring keeps it under observation, and rollback makes it reversible. Quantization then becomes more than compression: it becomes a disciplined negotiation between mathematical approximation, physical resources, user-visible behavior, and accountable engineering judgment.

18.9 LLM07

Chapter Title: Evaluation, Hallucination, and Reliability
Specialization: Applied AI and Reliability Engineering

18.9.1 Exercise 00

Exercise Title: Define Hallucination and Explain Why It Occurs in LLMs

Part 1 - Why this matters

An LLM is trained primarily to assign probability to the next token, not to consult reality before every sentence. A fluent answer can therefore be grammatically excellent while containing a fabricated date, citation, person, causal explanation, or software capability. Call an output a hallucination when it presents content as supported by the task's available evidence even though that content is false, unverifiable, contradicted by the evidence, or invented beyond what the prompt permits. This definition must be adapted to the task: a fictional story is not a hallucination merely because it is imaginary, while an invented quotation in a factual report is.

Separate several failure types. Parametric factual error conflicts with the world knowledge expected of the model. Contextual hallucination conflicts with the supplied document. Attribution failure attaches a real claim to the wrong source. Temporal failure answers with stale knowledge as if it were current. Instructional hallucination claims an operation was performed when no tool or evidence confirms it. These categories lead to different mitigations and must not be collapsed into one vague label.

Explain the causes at multiple levels: incomplete or conflicting training data, the lossy compression of knowledge into parameters, token-level objectives, distribution shift, ambiguous prompts, long-context retrieval failure, decoding randomness, exposure to generated prefixes,

and pressure to continue instead of abstain. The model's probability is linguistic probability under its learned distribution; it is not automatically the probability that a claim is true. Reliability work begins by preserving this distinction.

Part 2 - Mathematical form and reasoning

Autoregressive generation factorizes a sequence as

$$p_\theta(y_{1:T} \mid x) = \prod_{t=1}^{T} p_\theta(y_t \mid x, y_{<t}).$$

Maximum-likelihood training minimizes token negative log-likelihood,

$$\mathcal{L}_{\text{NLL}} = -\sum_{t=1}^{T} \log p_\theta(y_t^* \mid x, y_{<t}^*),$$

but the objective does not directly contain a truth predicate for every claim. Define a claim extractor $C(y) = \{c_1, \ldots, c_m\}$ and an evidence-supported label $s(c_j, e) \in \{0, 1\}$. An example-level hallucination score can be

$$H(y, e) = \frac{1}{m} \sum_{j=1}^{m} \left(1 - s(c_j, e)\right).$$

The denominator and treatment of unverifiable claims must be stated. Claim-level and answer-level rates answer different questions and should both be retained.

Part 3 - Hints and Helper

1. Write an operational definition before reading model outputs.
2. Distinguish false, unsupported, contradicted, stale, and unverifiable claims.
3. Label whether the task is factual, creative, predictive, or evidence-bounded.
4. Split an answer into atomic claims so one wrong detail does not erase correct content.
5. Preserve the source and timestamp used to judge each claim.
6. Record ambiguity and evaluator disagreement rather than forcing false certainty.
7. Demonstrate one failure from each major causal category.
8. State which mitigations change knowledge, evidence access, decoding, or abstention.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from enum import Enum

class ClaimStatus(Enum):
    SUPPORTED = "supported"
    CONTRADICTED = "contradicted"
```

```
    UNSUPPORTED = "unsupported"
    UNVERIFIABLE = "unverifiable"

@dataclass
class ClaimJudgment:
    claim: str
    status: ClaimStatus
    evidence_id: str
    explanation: str

def claim_hallucination_rate(judgments, count_unverifiable=True):
    if len(judgments) == 0:
        return 0.0
    failures = 0
    for judgment in judgments:
        if judgment.status == ClaimStatus.CONTRADICTED:
            failures += 1
        elif judgment.status == ClaimStatus.UNSUPPORTED:
            failures += 1
        elif (
            count_unverifiable
            and judgment.status == ClaimStatus.UNVERIFIABLE
        ):
            failures += 1
    return failures / len(judgments)

def answer_has_hallucination(judgments):
    for judgment in judgments:
        if judgment.status in {
            ClaimStatus.CONTRADICTED,
            ClaimStatus.UNSUPPORTED,
        }:
            return True
    return False
```

Part 5 - The Philosophy Behind the Exercise

Fluency creates an illusion of contact with truth because humans normally use confident language after forming beliefs. An LLM can reproduce the language of belief without possessing the same evidential relationship. Reliability work therefore studies not only what the model says, but what licenses it to say it.

A precise definition protects both the model and the evaluator. It avoids calling legitimate creativity a defect, while refusing to excuse unsupported factual authority as mere creativity. The philosophy is simple: confidence is not evidence, and coherence is not verification.

18.9.2 Exercise 01

Exercise Title: Build Evaluation Set That Triggers Hallucinations

Part 1 - Why this matters

A random list of easy questions estimates ordinary accuracy but rarely exposes how hallucinations arise. Build a diagnostic set that deliberately covers known pressure points while remaining fair and reproducible. Include false premises, nonexistent entities, obscure but answerable facts, stale temporal questions, conflicting context, unanswerable questions, attribution requests, multi-hop reasoning, long-context distractors, and prompts that tempt the model to invent citations or claim tool use.

Each item needs more than a prompt. Store the task type, answerability, trusted evidence, valid answers, forbidden claims, expected abstention behavior, difficulty, knowledge date, domain, and risk level. For evidence-bounded items, the reference is the supplied context rather than the model's parametric memory. Include matched controls: if a fabricated entity triggers invention, pair it with a real entity of similar wording so the test measures epistemic behavior instead of unfamiliar spelling alone.

Prevent contamination and evaluator leakage. Freeze a hidden test split, version the source material, remove duplicates and near-duplicates, and avoid repeatedly tuning prompts on the final set. Human reviewers should pilot items for ambiguity. A trigger set should reveal failure modes, not manufacture them through an incorrect reference answer.

Part 2 - Mathematical form and reasoning

Let strata $k = 1, \ldots, K$ represent trigger families. A macro hallucination estimate weights families equally:

$$\widehat{H}_{\text{macro}} = \frac{1}{K} \sum_{k=1}^{K} \frac{1}{n_k} \sum_{i=1}^{n_k} h_{ki}.$$

A deployment-weighted estimate instead uses expected traffic weights w_k:

$$\widehat{H}_{\text{traffic}} = \sum_{k=1}^{K} w_k \widehat{H}_k, \qquad \sum_k w_k = 1.$$

Report both. Macro scoring prevents a common category from hiding a catastrophic rare failure, while traffic weighting estimates expected operational exposure. Coverage can be represented by a matrix of domain, trigger, answerability, and risk; empty cells are known blind spots.

Part 3 - Hints and Helper

1. Define a taxonomy and minimum item count for every trigger family.
2. Pair answerable and unanswerable prompts with similar surface form.
3. Keep evidence and grading rules separate from the prompt shown to the model.
4. Add temporal metadata so changing facts can be refreshed or retired.
5. Include high-risk domains only with qualified reference construction.

6. Deduplicate by normalized text and semantic similarity.
7. Pilot ambiguity with at least two independent reviewers.
8. Freeze a hidden final split and version every later amendment.

Part 4 - Python code skeleton

```
from dataclasses import asdict, dataclass
from typing import List
import json

@dataclass
class EvaluationItem:
    item_id: str
    prompt: str
    trigger_family: str
    domain: str
    answerable: bool
    evidence: List[str]
    accepted_answers: List[str]
    forbidden_claims: List[str]
    expected_behavior: str
    risk_level: str
    knowledge_date: str

def validate_item(item):
    errors = []
    if item.item_id.strip() == "":
        errors.append("missing_id")
    if item.prompt.strip() == "":
        errors.append("missing_prompt")
    if item.answerable and len(item.evidence) == 0:
        errors.append("answerable_without_evidence")
    if not item.answerable and item.expected_behavior != "abstain":
        errors.append("unanswerable_without_abstention_target")
    return errors

def save_validated_set(items, output_path):
    seen = set()
    records = []
    for item in items:
        if item.item_id in seen:
            raise ValueError("duplicate item id: " + item.item_id)
        seen.add(item.item_id)
```

```
        errors = validate_item(item)
        if len(errors) > 0:
            raise ValueError(item.item_id + ":" + ",".join(errors))
        records.append(asdict(item))
    with open(output_path, "w", encoding="utf-8") as handle:
        json.dump(records, handle, indent=2, ensure_ascii=False)
```

Part 5 - The Philosophy Behind the Exercise

An evaluation set is an instrument, and instruments embody theories about what can go wrong. Easy factual questions reward stored knowledge; false-premise and unanswerable questions test whether the model recognizes the boundary of that knowledge. The second ability is often more important in deployment.

Deliberate stress is not unfairness when the scenario is plausible and the reference is sound. It is a way of making epistemic limits visible before users discover them under higher stakes.

18.9.3 Exercise 02

Exercise Title: Measure Hallucination Rate and Confidence Mismatch

Part 1 - Why this matters

Reliability requires two measurements: whether an answer is wrong and whether the model behaves as if it might be wrong. A system that makes occasional errors with calibrated uncertainty can abstain or request review. A system that assigns its strongest confidence to false answers is dangerous even when its average accuracy appears acceptable.

Choose the unit of analysis explicitly. Answer-level hallucination marks an entire response if any material claim fails. Claim-level rate counts each atomic assertion. Citation precision asks whether cited evidence supports the claim. Unsupported-claim rate includes statements not justified by supplied context. Measure these separately and stratify by trigger, domain, risk, answer length, and answerability.

Confidence is also a design choice. It may come from normalized token probabilities, a separate verbal probability, self-evaluation, agreement across samples, or an external verifier. These signals are not interchangeable. Normalize length effects, freeze decoding, and define bins before inspecting results. Save per-example records so aggregate rates can be audited.

Part 2 - Mathematical form and reasoning

For binary correctness $y_i \in \{0, 1\}$ and confidence $p_i \in [0, 1]$, the Brier score is

$$\mathrm{BS} = \frac{1}{N} \sum_{i=1}^{N} (p_i - y_i)^2.$$

Define hallucination $h_i = 1 - y_i$ for tasks with a complete binary judgment. The rate and a normal-approximation standard error are

$$\widehat{H} = \frac{1}{N} \sum_{i} h_i, \qquad SE(\widehat{H}) = \sqrt{\frac{\widehat{H}(1 - \widehat{H})}{N}}.$$

Confidence mismatch can be summarized by signed calibration bias

$$\text{Bias} = \frac{1}{N}\sum_{i}(p_i - y_i),$$

where a positive value indicates overconfidence. Reliability diagrams and ECE will be developed later; retain raw pairs now.

Part 3 - Hints and Helper

1. Keep claim-level and answer-level labels in the same record.
2. Define confidence extraction before examining model correctness.
3. Treat refusals, empty outputs, and unjudgeable cases as separate outcomes.
4. Bootstrap examples, not individual claims from the same answer, for uncertainty.
5. Report sample counts and confidence intervals for every slice.
6. Inspect high-confidence errors individually.
7. Compare confidence on answerable and unanswerable prompts.
8. Never infer factual confidence from fluent wording alone.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import math

@dataclass
class ScoredAnswer:
    item_id: str
    correct: bool
    confidence: float
    claim_count: int
    failed_claim_count: int
    trigger_family: str

def summarize_answers(records):
    if len(records) == 0:
        raise ValueError("records must not be empty")
    hallucinations = 0
    squared_error = 0.0
    signed_bias = 0.0
    failed_claims = 0
    total_claims = 0
    for record in records:
```

```
        if not 0.0 <= record.confidence <= 1.0:
            raise ValueError("confidence outside [0, 1]")
        target = 1.0 if record.correct else 0.0
        if not record.correct:
            hallucinations += 1
        difference = record.confidence - target
        squared_error += difference * difference
        signed_bias += difference
        failed_claims += record.failed_claim_count
        total_claims += record.claim_count

    count = len(records)
    rate = hallucinations / count
    standard_error = math.sqrt(rate * (1.0 - rate) / count)
    return {
        "answer_hallucination_rate": rate,
        "rate_standard_error": standard_error,
        "claim_hallucination_rate": failed_claims / total_claims,
        "brier_score": squared_error / count,
        "confidence_bias": signed_bias / count,
    }
```

Part 5 - The Philosophy Behind the Exercise

Error and uncertainty are morally different dimensions of a system. No finite model can eliminate all error, but it can be designed to expose uncertainty at the boundary of its competence. Measuring only correctness ignores this possibility; measuring only confidence mistakes self-description for truth.

The paired record asks the model to be accountable not only for answers, but for the relationship between certainty and evidence. That relationship is the foundation of selective prediction and safe escalation.

18.9.4 Exercise 03

Exercise Title: Compare Factual vs Creative Prompt Behavior

Part 1 - Why this matters

The same linguistic novelty can be valuable in a story and harmful in a medical summary. Reliability evaluation must therefore respect the intent of the prompt. Construct matched factual and creative prompts about similar subjects. The factual prompt should require evidence, attribution, and abstention when information is unavailable. The creative prompt should permit invention but still obey constraints such as named characters, tone, length, and explicit separation from real claims.

Do not compare the two modes with one metric. Factual responses need claim support, citation precision, contradiction rate, completeness, and calibrated abstention. Creative responses need constraint adherence, coherence, diversity, originality, and human preference. A creative response can fail by presenting fiction as biography; a factual response can fail by being

cautious but useless. Record how the system prompt and user wording signal the mode.

Run a crossover experiment: factual instruction with high temperature, creative instruction with low temperature, and both instructions under several decoding settings. This separates prompt intent from sampling behavior. The result should show that reliability is a contract between task, evidence, and decoding rather than an inherent property of a sentence.

Part 2 - Mathematical form and reasoning

Let $m \in \{F, C\}$ be factual or creative mode. Define different utility functions:

$$U_F = \alpha S + \beta A - \gamma H - \delta O,$$

where S is evidence support, A factual answer coverage, H hallucination, and O overconfidence. For creative work,

$$U_C = \eta K + \rho D + \mu I - \nu V,$$

where K is coherence, D diversity, I instruction adherence, and V violation of factual-boundary constraints. Scores are meaningful only within the declared mode; comparing U_F and U_C directly is invalid.

Part 3 - Hints and Helper

1. Build matched prompt pairs that differ mainly in declared intent.
2. Tell evaluators whether invention is allowed before they score output.
3. Use separate rubrics and keep a shared instruction-adherence measure.
4. Test mode cues in system and user messages independently.
5. Cross prompt mode with temperature and sampling strategy.
6. Flag creative claims that impersonate real citations or biography.
7. Include refusal usefulness in factual scoring.
8. Save outputs for blinded human comparison.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class ModeScore:
    prompt_id: str
    mode: str
    support: float
    hallucination: float
    coherence: float
```

```
    diversity: float
    instruction_adherence: float
    factual_boundary_violation: float

def factual_utility(score):
    return (
        0.35 * score.support
        + 0.25 * score.instruction_adherence
        + 0.20 * score.coherence
        - 0.15 * score.hallucination
        - 0.05 * score.factual_boundary_violation
    )

def creative_utility(score):
    return (
        0.30 * score.coherence
        + 0.30 * score.diversity
        + 0.30 * score.instruction_adherence
        - 0.10 * score.factual_boundary_violation
    )

def evaluate_by_declared_mode(scores):
    results = []
    for score in scores:
        if score.mode == "factual":
            utility = factual_utility(score)
        elif score.mode == "creative":
            utility = creative_utility(score)
        else:
            raise ValueError("unknown mode: " + score.mode)
        results.append((score.prompt_id, score.mode, utility))
    return results
```

Part 5 - The Philosophy Behind the Exercise

Truthfulness is not the elimination of imagination. It is the disciplined placement of imagination inside a contract that permits it. Human language contains science, law, poetry, speculation, and play; a reliable model must recognize which norm governs the current act.

This exercise replaces the simplistic command “never invent” with a richer principle: invent freely where invention is invited, and mark the boundary where invented language could be mistaken for evidence.

18.9.5 Exercise 04

Exercise Title: Implement Retrieval-Augmented Prompting and Compare Hallucination Reduction

Part 1 - Why this matters

Retrieval-augmented generation (RAG) supplies external evidence at inference time instead of requiring every fact to be stored reliably in parameters. It can reduce unsupported answers, update knowledge without retraining, and expose citations. It can also introduce new failures: the relevant passage may not be retrieved, an irrelevant passage may distract the model, the prompt may exceed context limits, or the generator may ignore or distort correct evidence.

Build a controlled comparison with three conditions: no retrieval, oracle retrieval containing the correct evidence, and realistic retrieval from an indexed corpus. The oracle separates generation faithfulness from retrieval recall. Freeze prompts, decoding, model version, and judge. Measure retrieval recall at k, context precision, answer accuracy, unsupported-claim rate, citation precision, abstention, latency, and token cost.

Require the model to answer only from provided evidence and to abstain when the evidence is insufficient. Include adversarial distractors and conflicting documents with timestamps or authority metadata. A reduction in hallucination is meaningful only if it is not purchased by refusing every difficult question or copying irrelevant passages.

Part 2 - Mathematical form and reasoning

For query x, a retriever selects documents

$$D_k(x) = \mathrm{TopK}_{d \in \mathcal{D}}\, s(x, d),$$

and generation becomes $p_\theta(y \mid x, D_k(x))$. Decompose factual success:

$$\begin{aligned} P(\text{correct}) = {} & P(\text{evidence retrieved}) \\ & \times P(\text{correct} \mid \text{evidence retrieved}) \\ & + P(\text{correct without retrieved evidence}). \end{aligned}$$

This decomposition prevents blaming the generator for retriever failure. The paired hallucination reduction is

$$\Delta H = \widehat{H}_{\mathrm{RAG}} - \widehat{H}_{\mathrm{base}},$$

with negative values indicating improvement. Report it with retrieval coverage and refusal rate.

Part 3 - Hints and Helper

1. Version the corpus, chunking, embedding model, index, and retrieval parameters.
2. Evaluate oracle retrieval before debugging the realistic retriever.
3. Keep model and decoding identical across comparison conditions.

4. Test no-answer queries and require evidence-aware abstention.
5. Measure whether every citation actually entails its attached claim.
6. Add plausible distractors and temporally conflicting documents.
7. Log retrieved document IDs and scores for every output.
8. Report accuracy, hallucination, refusal, latency, and token cost together.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class RetrievedDocument:
    document_id: str
    text: str
    score: float
    source_date: str

def build_grounded_prompt(question, documents):
    lines = []
    lines.append("Answer only from the evidence below.")
    lines.append("If evidence is insufficient, say: I don't know.")
    for index, document in enumerate(documents):
        label = "[D" + str(index + 1) + "]"
        lines.append(label + " " + document.text)
    lines.append("Question: " + question)
    lines.append("Cite supporting document labels after each claim.")
    return "\n\n".join(lines)

def run_rag_item(model, retriever, item, top_k):
    documents = retriever.search(item.question, top_k=top_k)
    prompt = build_grounded_prompt(item.question, documents)
    answer = model.generate(prompt, temperature=0.0)
    document_ids = []
    for document in documents:
        document_ids.append(document.document_id)
    return {
        "item_id": item.item_id,
        "answer": answer,
        "retrieved_document_ids": document_ids,
    }
```

```
def compare_conditions(items, base_model, rag_model, retriever):
    records = []
    for item in items:
        base_answer = base_model.generate(item.question, temperature=0.0)
        rag_record = run_rag_item(rag_model, retriever, item, top_k=5)
        records.append({
            "item_id": item.item_id,
            "base_answer": base_answer,
            "rag_answer": rag_record["answer"],
            "documents": rag_record["retrieved_document_ids"],
        })
    return records
```

Part 5 - The Philosophy Behind the Exercise

RAG changes the epistemic structure of generation. The answer no longer needs to emerge solely from compressed memory; it can be justified by inspectable evidence. Yet access to evidence is not the same as faithful use of evidence. Retrieval, reading, reasoning, and citation remain distinct obligations.

The central lesson is traceability. A reliable answer should allow us to ask: which document was available, which claim it supported, and where the chain broke when the answer failed.

18.9.6 Exercise 05

Exercise Title: Evaluate Robustness Under Prompt Paraphrasing

Part 1 - Why this matters

Semantically equivalent prompts should not produce incompatible factual answers merely because word order, politeness, dialect, or formatting changed. Paraphrase sensitivity reveals that the model may be responding to surface cues rather than a stable interpretation. It also exposes evaluation fragility: a single canonical prompt can overestimate reliability for real users.

Create paraphrase families that preserve meaning while varying syntax, vocabulary, active/passive voice, question order, spelling noise, and location of constraints. Include a meaning-preservation review; a paraphrase that changes scope or temporal reference is a new task, not a robustness test. Run all variants with identical system message, evidence, decoding, and seed where possible.

Measure correctness variance, hallucination variance, refusal inconsistency, semantic answer agreement, and worst-case family performance. Inspect families where one wording triggers an unsupported answer while another correctly abstains. Robustness should not mean identical text; it means stable claims and decisions under meaning-preserving changes.

Part 2 - Mathematical form and reasoning

For item i with M_i paraphrases and correctness y_{ij}, define family accuracy and instability:

$$\bar{y}_i = \frac{1}{M_i} \sum_j y_{ij}, \qquad I_i = \max_j y_{ij} - \min_j y_{ij}.$$

For binary labels, $I_i = 1$ when at least one paraphrase changes correctness. A stricter robust accuracy is

$$A_{\text{worst}} = \frac{1}{N} \sum_i \min_j y_{ij}.$$

Pair it with semantic contradiction rate between answers, since two incorrect answers may agree and two correct answers may use different wording.

Part 3 - Hints and Helper

1. Generate several controlled paraphrase types for every base prompt.
2. Have a reviewer verify semantic equivalence before model evaluation.
3. Keep system prompt, evidence, tools, and decoding fixed.
4. Compare atomic claims rather than exact text.
5. Report average and worst-paraphrase accuracy.
6. Track refusal and confidence transitions within each family.
7. Inspect sensitivity to constraint placement and negation separately.
8. Save the exact prompt form with every result.

Part 4 - Python code skeleton

```
from collections import defaultdict
from dataclasses import dataclass

@dataclass
class ParaphraseResult:
    family_id: str
    variant_id: str
    correct: bool
    hallucinated: bool
    abstained: bool
    confidence: float

def summarize_families(results):
    grouped = defaultdict(list)
    for result in results:
        grouped[result.family_id].append(result)

    summaries = []
    robust_correct_count = 0
    for family_id, family in grouped.items():
```

```
        correct_values = []
        confidences = []
        for result in family:
            correct_values.append(int(result.correct))
            confidences.append(result.confidence)
        all_correct = min(correct_values) == 1
        if all_correct:
            robust_correct_count += 1
        summaries.append({
            "family_id": family_id,
            "mean_accuracy": sum(correct_values) / len(correct_values),
            "unstable": max(correct_values) != min(correct_values),
            "confidence_range": max(confidences) - min(confidences),
        })
    robust_accuracy = robust_correct_count / len(grouped)
    return summaries, robust_accuracy
```

Part 5 - The Philosophy Behind the Exercise

Meaning is richer than phrasing. A reliable language system should respond to the intended proposition, not treat each syntactic costume as a different world. Paraphrase testing therefore probes whether the model has learned a stable task or a collection of linguistic shortcuts.

Worst-case family performance also changes our idea of quality: the user should not need to discover the one magical wording that makes the system truthful.

18.9.7 Exercise 06

Exercise Title: Analyze Temperature Impact on Hallucination Frequency

Part 1 - Why this matters

Temperature changes the sharpness of the token distribution. Higher values usually increase diversity and the probability of low-ranked continuations; lower values make outputs more repeatable but do not guarantee truth. If the most probable continuation encodes a misconception, greedy decoding can repeat it confidently. This exercise measures rather than assumes the relationship.

Use a fixed factual evaluation set and sample several independent generations per prompt at each temperature. Keep top-p, top-k, maximum tokens, prompt, model, evidence, and evaluator constant. Record accuracy, claim hallucination, answer diversity, refusal, length, and confidence. Separate factual prompts from creative prompts because diversity has different utility in each mode.

Estimate uncertainty across prompts, not just across samples from one prompt. Look for nonlinear thresholds: hallucination may remain stable through moderate temperature and then increase rapidly, or retrieval grounding may weaken only when sampling becomes very diffuse. Recommend a temperature for a named task and risk tolerance rather than declaring a universal best value.

Part 2 - Mathematical form and reasoning

For logits z_i and temperature $T > 0$,

$$p_T(i) = \frac{\exp(z_i/T)}{\sum_j \exp(z_j/T)}.$$

As $T \to 0$, mass concentrates near the largest logit; increasing T flattens the distribution. For prompt x with R samples, estimate

$$\widehat{H}_T(x) = \frac{1}{R}\sum_{r=1}^{R} h_{xTr}, \qquad \widehat{H}_T = \frac{1}{N}\sum_x \widehat{H}_T(x).$$

Use the prompt as the resampling unit when constructing confidence intervals, because samples from the same prompt share difficulty.

Part 3 - Hints and Helper

1. Sweep a predeclared temperature grid including a near-deterministic baseline.
2. Generate the same number of samples for every prompt and temperature.
3. Hold nucleus or top-k filtering fixed.
4. Preserve seeds and raw outputs for paired inspection.
5. Measure diversity together with reliability.
6. Stratify answerable, unanswerable, retrieval-grounded, and creative prompts.
7. Plot per-prompt trajectories to expose heterogeneous effects.
8. Select an operating point using task-specific quality constraints.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class TemperatureTrial:
    item_id: str
    temperature: float
    sample_id: int
    hallucinated: bool
    correct: bool
    answer: str

def run_temperature_sweep(model, items, temperatures, repeats):
    trials = []
    for temperature in temperatures:
```

```
        for item in items:
            for sample_id in range(repeats):
                answer = model.generate(
                    item.prompt,
                    temperature=temperature,
                    seed=sample_id,
                )
                trial = TemperatureTrial(
                    item_id=item.item_id,
                    temperature=temperature,
                    sample_id=sample_id,
                    hallucinated=False,
                    correct=False,
                    answer=answer,
                )
                trials.append(trial)
    return trials

def rate_by_temperature(scored_trials):
    totals = {}
    failures = {}
    for trial in scored_trials:
        totals[trial.temperature] = totals.get(trial.temperature, 0) + 1
        if trial.hallucinated:
            old = failures.get(trial.temperature, 0)
            failures[trial.temperature] = old + 1
    rates = {}
    for temperature, total in totals.items():
        failure_count = failures.get(temperature, 0)
        rates[temperature] = failure_count / total
    return rates
```

Part 5 - The Philosophy Behind the Exercise

Randomness is neither the cause of all hallucination nor a defect by itself. It is a mechanism for exploring alternatives in a learned distribution. When the distribution contains unsupported continuations, exploration reveals them; when the top mode is wrong, determinism merely conceals the alternatives.

The responsible question is not whether temperature is good or bad, but how much uncertainty the task can tolerate and what benefits diversity provides.

18.9.8 Exercise 07

Exercise Title: Implement Self-Consistency Sampling and Measure Accuracy Gains

Part 1 - Why this matters

Self-consistency generates several reasoning paths and chooses the answer that receives the most independent support. It can improve tasks where different valid paths converge on the same result, but it is not an oracle. Correlated samples may repeat the same misconception, majority voting may suppress a rare correct path, and free-form answers may require careful normalization before they can be compared.

Create a deterministic single-sample baseline and sampling conditions with a fixed budget. Extract a final answer separately from the reasoning text, normalize units and formatting without changing meaning, and vote only among comparable answers. Track vote margin, entropy, answer accuracy, hallucination, token cost, latency, and cases where consistency makes a correct baseline wrong.

Compare majority vote, confidence-weighted vote, and verifier-based selection. Use odd sample counts and plot marginal gain from additional samples. A reliable system should treat low agreement as uncertainty and consider abstention rather than forcing a majority from fragmented outputs.

Part 2 - Mathematical form and reasoning

Given extracted answers $a^{(1)}, \ldots, a^{(R)}$, majority selection is

$$\hat{a} = \arg\max_{a} \sum_{r=1}^{R} I(a^{(r)} = a).$$

If v_a is the vote fraction, agreement entropy is

$$H_{\text{vote}} = -\sum_{a} v_a \log(v_a + \epsilon).$$

Low entropy and a large margin $v_{(1)} - v_{(2)}$ indicate agreement, not truth. Measure paired accuracy change relative to the same items and report added tokens per corrected answer.

Part 3 - Hints and Helper

1. Separate answer extraction from answer generation.
2. Normalize formatting conservatively and retain the raw text.
3. Sweep odd sample counts under a recorded token budget.
4. Measure disagreement entropy and winning-vote margin.
5. Inspect correlated wrong majorities.
6. Compare majority, weighted, and external-verifier selection.
7. Allow abstention when agreement is below a threshold.
8. Report accuracy gain beside latency and token-cost growth.

Part 4 - Python code skeleton

```
from collections import Counter
from dataclasses import dataclass
import math

@dataclass
class ConsistencyResult:
    selected_answer: str
    vote_fraction: float
    vote_margin: float
    vote_entropy: float
    raw_answers: list

def select_by_majority(raw_answers, normalize_answer):
    normalized = []
    for answer in raw_answers:
        normalized.append(normalize_answer(answer))
    counts = Counter(normalized)
    ranked = counts.most_common()
    winner, winner_count = ranked[0]
    second_count = 0
    if len(ranked) > 1:
        second_count = ranked[1][1]

    total = len(normalized)
    entropy = 0.0
    for count in counts.values():
        probability = count / total
        entropy -= probability * math.log(probability + 1.0e-12)
    return ConsistencyResult(
        selected_answer=winner,
        vote_fraction=winner_count / total,
        vote_margin=(winner_count - second_count) / total,
        vote_entropy=entropy,
        raw_answers=raw_answers,
    )

def generate_consistent_answer(model, prompt, repeats, normalize_answer):
    answers = []
    for seed in range(repeats):
        answer = model.generate(prompt, temperature=0.7, seed=seed)
        answers.append(answer)
    return select_by_majority(answers, normalize_answer)
```

Part 5 - The Philosophy Behind the Exercise

Agreement is evidence about stability, not direct evidence about reality. A community of

samples can reproduce one shared bias because all members inherit the same model and data. Self-consistency is valuable when independent routes carry partially independent errors; its limit appears when the errors are systematic.

The exercise teaches a broader principle: ensembles improve judgment only to the degree that their diversity is meaningful and their aggregation respects uncertainty.

18.9.9 Exercise 08

Exercise Title: Debug Cases Where Model Sounds Confident but Is Wrong

Part 1 - Why this matters

The most harmful hallucinations often contain precise numbers, named sources, causal detail, and decisive language. These features can increase human trust without increasing evidential support. Build a debugging workflow around high-confidence errors rather than editing prompts ad hoc. Preserve the entire request, system message, retrieved context, tool results, model/version, decoding configuration, token probabilities if available, and evaluator evidence.

Decompose the failure. Did retrieval omit the answer, return a distractor, or provide conflicting evidence? Did the prompt contain a false premise? Did the generator copy evidence incorrectly, invent an unsupported bridge, or attach a citation to the wrong claim? Did a later token commit the answer to a mistaken trajectory? Compare with oracle context, lower temperature, explicit abstention, a larger model, and an independent verifier one change at a time.

Do not treat hedging words as calibrated uncertainty. Measure whether a confidence signal predicts correctness. The debugging output should identify the earliest causal boundary that failed and a regression test that reproduces it.

Part 2 - Mathematical form and reasoning

Define a high-confidence error set

$$\mathcal{E}_\tau = \{i : y_i = 0 \wedge p_i \geq \tau\}.$$

Its rate among confident predictions is

$$R_{\mathrm{HC}}(\tau) = \frac{\sum_i I(y_i = 0, p_i \geq \tau)}{\sum_i I(p_i \geq \tau)}.$$

For a pipeline with retrieval R, grounding G, and final answer A, annotate the earliest failed event. This produces mutually interpretable root-cause counts instead of assigning every symptom to the final generator.

Part 3 - Hints and Helper

1. Freeze the exact failing trace before attempting a fix.
2. Split the output into atomic claims and attach evidence to each.
3. Compare realistic and oracle retrieval.

4. Test prompt, decoding, model, and verifier changes independently.
5. Examine token-level confidence near the first wrong commitment.
6. Distinguish verbal certainty from measured probability.
7. Add the minimal reproducer to a permanent regression suite.
8. Verify that the fix does not cause excessive refusal elsewhere.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class FailureTrace:
    item_id: str
    confidence: float
    correct: bool
    retrieval_ok: bool
    evidence_used_correctly: bool
    unsupported_bridge: bool
    citation_mismatch: bool

def root_cause(trace):
    if not trace.retrieval_ok:
        return "retrieval_failure"
    if not trace.evidence_used_correctly:
        return "grounding_failure"
    if trace.unsupported_bridge:
        return "reasoning_bridge_failure"
    if trace.citation_mismatch:
        return "attribution_failure"
    return "unclassified_generation_failure"

def collect_high_confidence_errors(traces, threshold):
    selected = []
    counts = {}
    for trace in traces:
        if trace.correct or trace.confidence < threshold:
            continue
        cause = root_cause(trace)
        selected.append(trace)
        counts[cause] = counts.get(cause, 0) + 1
    return selected, counts
```

```
def regression_record(trace, prompt, expected_behavior):
    return {
        "item_id": trace.item_id,
        "prompt": prompt,
        "expected_behavior": expected_behavior,
        "root_cause": root_cause(trace),
    }
```

Part 5 - The Philosophy Behind the Exercise

Confidence in language is a social signal. Models learn its form from texts in which precision and authority often accompany expertise, but they can reproduce the form after the evidential foundation has disappeared. Debugging must break this spell by reconstructing the foundation claim by claim.

The aim is not to make the model sound permanently uncertain. It is to align decisiveness with evidence and make unsupported authority expensive to emit.

18.9.10 Exercise 09

Exercise Title: Build Automatic Hallucination Detection Heuristics

Part 1 - Why this matters

Human claim verification is valuable but too slow for every production output. Automatic heuristics can prioritize review, trigger abstention, or monitor drift. They are screening instruments, not proof of truth. Useful signals include missing citations, citation-entailment failure, contradiction with provided context, unsupported named entities or numbers, retrieval coverage, answer-to-evidence similarity, self-contradiction, cross-sample disagreement, and unusual confidence.

Build a modular detector that returns individual signals and reasons rather than one opaque score. Evaluate each signal against human labels using precision, recall, false-positive cost, and performance by domain. Tune thresholds on a development set and freeze them before final evaluation. Prevent leakage when an LLM judge is closely related to the model being judged.

Combine heuristics conservatively. A low lexical overlap can be legitimate paraphrase, while high overlap can copy a passage without answering correctly. Design explicit escalation bands: accept, review, abstain, or block. Log which rule fired so humans can audit and improve the detector.

Part 2 - Mathematical form and reasoning

For detector score s_i and threshold τ, predicted hallucination is $\hat{h}_i = I(s_i \geq \tau)$. Then

$$\text{Precision} = \frac{TP}{TP + FP}, \qquad \text{Recall} = \frac{TP}{TP + FN}.$$

Choose τ from operational cost, not accuracy alone:

$$\tau^* = \arg\min_{\tau} \left(c_{FP} FP(\tau) + c_{FN} FN(\tau) + c_R R(\tau) \right),$$

where R is the number sent to human review. Domain-specific thresholds may be necessary when base rates and consequences differ.

Part 3 - Hints and Helper

1. Implement signals independently before combining them.
2. Return interpretable reasons and supporting spans.
3. Use human-labeled development and hidden test sets.
4. Measure precision-recall curves and domain slices.
5. Include paraphrases and copied-but-wrong outputs as hard negatives.
6. Calibrate escalation thresholds to review capacity and risk.
7. Monitor detector drift after model or retrieval updates.
8. Never present a heuristic acceptance as factual verification.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class DetectionSignal:
    name: str
    score: float
    reason: str

def combine_signals(signals, weights):
    weighted_sum = 0.0
    total_weight = 0.0
    reasons = []
    for signal in signals:
        weight = weights.get(signal.name, 0.0)
        weighted_sum += weight * signal.score
        total_weight += abs(weight)
        if signal.score >= 0.5:
            reasons.append(signal.reason)
    if total_weight == 0.0:
        raise ValueError("at least one detector weight is required")
    return weighted_sum / total_weight, reasons

def decide_action(score, review_threshold, block_threshold):
    if score >= block_threshold:
```

```
        return "abstain_or_block"
    if score >= review_threshold:
        return "human_review"
    return "accept_with_monitoring"

def confusion_counts(labels, scores, threshold):
    counts = {"tp": 0, "fp": 0, "tn": 0, "fn": 0}
    for label, score in zip(labels, scores):
        predicted = score >= threshold
        if predicted and label:
            counts["tp"] += 1
        elif predicted and not label:
            counts["fp"] += 1
        elif not predicted and label:
            counts["fn"] += 1
        else:
            counts["tn"] += 1
    return counts
```

Part 5 - The Philosophy Behind the Exercise

Detection occupies the space between ignorance and proof. It can notice that an answer lacks the features normally associated with support, but it cannot turn correlation into truth. Its value comes from allocating scarce attention to the outputs most likely to need it.

An interpretable detector respects this limited role. It does not announce "true"; it says which reliability obligations appear unmet and what should happen next.

18.9.11 Exercise 10

Exercise Title: Compare Multiple Model Sizes on Same Evaluation Set

Part 1 - Why this matters

Larger models often improve knowledge and reasoning, but parameter count does not guarantee lower hallucination, better calibration, or safer abstention. They may produce more persuasive errors, incur higher latency and cost, or use different tokenizers and context limits. Compare model sizes under a common evaluation contract rather than treating a leaderboard score as deployment evidence.

Freeze prompts, evidence, decoding semantics, output limits, scoring rules, and hardware reporting. If tokenizers differ, report both text length and each model's token count. Evaluate factual accuracy, claim hallucination, calibration, refusal usefulness, paraphrase robustness, RAG faithfulness, latency, memory, energy, and cost. Use paired per-item results so improvements and regressions can be localized.

Construct capability curves rather than a single winner. A smaller model may meet requirements for routine grounded queries while a larger model is needed for multi-hop reasoning. Consider a routing policy, but include routing errors and operational complexity. The recommendation must name the workload and hard reliability gates it satisfies.

Part 2 - Mathematical form and reasoning

For models a and b on matched items, paired accuracy change is

$$\Delta A = \frac{1}{N}\sum_{i=1}^{N}(y_{ib} - y_{ia}).$$

Define useful throughput by discounting incorrect outputs:

$$\text{UsefulTokens/s} = \text{Tokens/s} \times (1 - \widehat{H}).$$

A deployment chooses the lowest-cost feasible model,

$$m^* = \arg\min_{m \in \mathcal{F}} C_m,$$

where $\mathcal{F}$ contains models meeting accuracy, hallucination, calibration, latency, memory, and safety constraints. Scaling curves should include uncertainty and not assume monotonic improvement.

Part 3 - Hints and Helper

1. Use one immutable evaluation manifest for every model.
2. Match decoding behavior and document unavoidable API differences.
3. Save per-item outputs and paired correctness transitions.
4. Report tokenizer, context, hardware, precision, latency, and memory.
5. Compare confidence calibration, not only factual accuracy.
6. Stratify by task difficulty and failure family.
7. Evaluate routing as a separate system if proposed.
8. Select the smallest model that passes all hard gates.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class ModelResult:
    model_name: str
    item_id: str
    correct: bool
    hallucinated: bool
    latency_ms: float
    output_tokens: int
    cost: float
```

```
def paired_transition_table(left_results, right_results):
    left_by_id = {}
    right_by_id = {}
    for result in left_results:
        left_by_id[result.item_id] = result
    for result in right_results:
        right_by_id[result.item_id] = result

    counts = {
        "both_correct": 0,
        "left_only": 0,
        "right_only": 0,
        "both_wrong": 0,
    }
    for item_id, left in left_by_id.items():
        right = right_by_id[item_id]
        if left.correct and right.correct:
            counts["both_correct"] += 1
        elif left.correct:
            counts["left_only"] += 1
        elif right.correct:
            counts["right_only"] += 1
        else:
            counts["both_wrong"] += 1
    return counts

def passes_gates(metrics, gates):
    for name, rule in gates.items():
        value = metrics[name]
        if rule["direction"] == "minimum" and value < rule["value"]:
            return False
        if rule["direction"] == "maximum" and value > rule["value"]:
            return False
    return True
```

Part 5 - The Philosophy Behind the Exercise

Scale buys representational capacity, not unconditional reliability. A larger model can know more and still fail to recognize when it does not know. Treating size as a substitute for evidence turns an engineering choice into mythology.

The disciplined choice is conditional: use enough capacity for the task, then verify the behavior that matters. Efficiency is not choosing the smallest model; it is refusing to pay for capacity that does not improve the required outcomes.

18.9.12 Exercise 11

Exercise Title: Implement Abstention or “I Don’t Know” Strategy Conceptually

Part 1 - Why this matters

A reliable model should sometimes decline to answer. Abstention is useful when evidence is absent, retrieval is weak, model confidence is poorly calibrated, the prompt is ambiguous, or the consequence of error is high. However, a model that refuses everything achieves zero hallucinations while providing zero utility. The goal is selective prediction: answer when expected reliability is high enough and escalate otherwise.

Build signals from calibrated confidence, retrieval coverage, citation support, sample agreement, detector score, domain risk, and input validity. Distinguish hard refusal from a clarification request, an evidence request, a tool call, a safe partial answer, or human escalation. The user-facing response should explain what is missing and how to proceed without inventing facts.

Tune thresholds on a development set under an explicit error-versus-coverage objective. Evaluate selective accuracy, hallucination among answered cases, coverage, false abstention, group/domain disparities, and escalation load. Test whether adversarial wording can suppress abstention or make the model claim false certainty.

Part 2 - Mathematical form and reasoning

For risk estimate $r(x)$ and threshold τ, answer when $r(x) \le \tau$. Coverage and selective risk are

$$\text{Coverage}(\tau) = \frac{1}{N} \sum_i I(r_i \le \tau),$$

$$\text{Risk}(\tau) = \frac{\sum_i I(r_i \le \tau)\ell_i}{\sum_i I(r_i \le \tau)}.$$

Plot the risk-coverage curve. A policy dominates another when it yields lower risk at equal coverage. For risk-sensitive domains, add expected cost for wrong answers, abstentions, and human review rather than optimizing accuracy alone.

Part 3 - Hints and Helper

1. Define answer, clarify, retrieve, escalate, and refuse as separate actions.
2. Calibrate risk signals on held-out data.
3. Optimize the risk-coverage curve under review-capacity limits.
4. Write useful abstention messages that identify missing evidence.
5. Test false abstention on easy and underrepresented cases.
6. Apply stricter thresholds to higher-consequence domains.
7. Prevent prompt text from directly overriding policy gates.
8. Monitor coverage and error after deployment.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class ReliabilitySignals:
    calibrated_confidence: float
    retrieval_coverage: float
    detector_risk: float
    domain_risk: float
    input_valid: bool

def choose_action(signals, answer_threshold, review_threshold):
    if not signals.input_valid:
        return "request_clarification"
    evidence_risk = 1.0 - signals.retrieval_coverage
    confidence_risk = 1.0 - signals.calibrated_confidence
    combined_risk = (
        0.30 * evidence_risk
        + 0.30 * confidence_risk
        + 0.25 * signals.detector_risk
        + 0.15 * signals.domain_risk
    )
    if combined_risk <= answer_threshold:
        return "answer"
    if combined_risk <= review_threshold:
        return "human_review"
    return "abstain"

def selective_metrics(records):
    answered = 0
    correct_answered = 0
    for record in records:
        if record["action"] == "answer":
            answered += 1
            if record["correct"]:
                correct_answered += 1
    coverage = answered / len(records)
    selective_accuracy = 0.0
    if answered > 0:
        selective_accuracy = correct_answered / answered
    return coverage, selective_accuracy
```

Part 5 - The Philosophy Behind the Exercise

Knowing a limit is a capability, not an absence of capability. Human expertise includes the judgment to consult a source, ask a colleague, or postpone a claim. A model that must always

answer is denied this essential form of intelligence.

Abstention also redistributes responsibility honestly. It tells the system when automation has reached its evidential boundary and invites another process to continue the work.

18.9.13 Exercise 12

Exercise Title: Measure Calibration Error and Overconfidence

Part 1 - Why this matters

Calibration asks whether events predicted with confidence 0.8 are correct about 80 percent of the time. It differs from accuracy: a highly accurate model can be overconfident on its remaining errors, and a lower-accuracy model can expose uncertainty honestly. Reliable thresholds for abstention and review depend on calibration.

Select a confidence source that corresponds to a clearly defined event, such as exact answer correctness or claim support. Token probabilities do not automatically become answer probabilities; aggregation and length normalization must be justified. Compare raw confidence, temperature-scaled confidence, verbal probability, and sample agreement if available.

Measure reliability diagrams, expected calibration error (ECE), maximum calibration error, Brier score, negative log loss, and overconfidence on wrong answers. Report bin counts and several binning schemes because ECE is sensitive to bin boundaries. Fit calibration on a validation split only, then test on untouched data and domain slices.

Part 2 - Mathematical form and reasoning

Partition predictions into bins B_m. ECE is

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{N} \left|\mathrm{acc}(B_m) - \mathrm{conf}(B_m)\right|.$$

Overconfidence on errors can be reported as

$$O_{\text{wrong}} = \frac{1}{|W|} \sum_{i \in W} p_i, \qquad W = \{i : y_i = 0\}.$$

For binary correctness logits z_i, temperature scaling uses $p_i = \sigma(z_i/T)$ and fits $T > 0$ on validation NLL. Calibration cannot repair incorrect ranking; it only remaps confidence.

Part 3 - Hints and Helper

1. Define the predicted event before defining confidence.
2. Preserve a separate calibration split and hidden test split.
3. Report ECE with bin counts and alternative binning.
4. Include Brier score and NLL as proper scoring rules.
5. Inspect confidence specifically on wrong and hallucinated outputs.
6. Plot calibration per domain and trigger family.

7. Refit after model, prompt, retrieval, or decoding changes.

8. Do not claim calibration outside the evaluated distribution.

Part 4 - Python code skeleton

```
def expected_calibration_error(confidences, labels, bin_count=10):
    if len(confidences) != len(labels):
        raise ValueError("confidence and label lengths differ")
    total = len(labels)
    ece = 0.0
    rows = []
    for bin_index in range(bin_count):
        lower = bin_index / bin_count
        upper = (bin_index + 1) / bin_count
        indices = []
        for index, confidence in enumerate(confidences):
            in_bin = lower <= confidence < upper
            if bin_index == bin_count - 1 and confidence == 1.0:
                in_bin = True
            if in_bin:
                indices.append(index)
        if len(indices) == 0:
            continue
        confidence_sum = 0.0
        correct_sum = 0.0
        for index in indices:
            confidence_sum += confidences[index]
            correct_sum += float(labels[index])
        mean_confidence = confidence_sum / len(indices)
        accuracy = correct_sum / len(indices)
        gap = abs(accuracy - mean_confidence)
        ece += (len(indices) / total) * gap
        rows.append((lower, upper, len(indices), accuracy, mean_confidence))
    return ece, rows
```

Part 5 - The Philosophy Behind the Exercise

Calibration is a promise about frequencies, not an inner feeling of certainty. It allows confidence to acquire operational meaning across repeated decisions. Without that link, a number such as 0.9 is decoration.

The exercise also teaches modesty about scope: a model may be calibrated on one population and dangerously overconfident after the world, prompt, or evidence pipeline changes.

18.9.14 Exercise 13

Exercise Title: Evaluate Domain Shift and Knowledge Cutoff Effects

Part 1 - Why this matters

An LLM is evaluated under one distribution and deployed into a changing world. New events occur after training, terminology changes, organizations revise policies, and user populations ask questions from domains absent in the test set. The model may answer stale questions fluently because it cannot directly observe that its internal knowledge is outdated.

Build matched in-domain, shifted-domain, pre-cutoff, and post-cutoff subsets. Attach an "as of" date to every temporal question and use time-stamped authoritative evidence. Compare closed-book generation, RAG with current documents, and abstention. Avoid leakage: a model released later may have a different unknown training cutoff, so document only verifiable model metadata and evaluate behavior directly.

Measure accuracy, hallucination, calibration, retrieval gain, and stale-answer rate. Shift should include vocabulary, style, task, source, and population changes, not just harder questions. Monitor embedding or input-distribution drift in production, but validate that detected drift predicts actual quality loss before using it as a rollback signal.

Part 2 - Mathematical form and reasoning

For source distribution P and target distribution Q, empirical performance drop is

$$\Delta_Q = M_Q - M_P.$$

If M is accuracy, negative values indicate degradation; if M is hallucination, positive values do. A post-cutoff stale-answer rate is

$$S = \frac{1}{N_{\text{post}}} \sum_i I(\text{answer contradicts evidence valid at query date}).$$

Report performance by shift type and distance proxy. An aggregate shift score cannot identify whether vocabulary, knowledge time, or task composition caused the failure.

Part 3 - Hints and Helper

1. Attach query date and evidence-validity interval to temporal items.
2. Match shifted and source examples by difficulty when possible.
3. Separate post-cutoff knowledge from general domain unfamiliarity.
4. Compare closed-book, current RAG, and abstention policies.
5. Measure confidence drift along with error drift.
6. Preserve model metadata without assuming undocumented training data.
7. Validate whether input drift correlates with reliability degradation.
8. Define refresh and re-evaluation triggers before deployment.

Part 4 - Python code skeleton

```
from collections import defaultdict
from dataclasses import dataclass

@dataclass
class ShiftResult:
    item_id: str
    split: str
    shift_type: str
    correct: bool
    hallucinated: bool
    stale: bool
    confidence: float

def summarize_shift(results):
    grouped = defaultdict(list)
    for result in results:
        key = (result.split, result.shift_type)
        grouped[key].append(result)

    summary = {}
    for key, group in grouped.items():
        correct = 0
        hallucinated = 0
        stale = 0
        confidence = 0.0
        for result in group:
            correct += int(result.correct)
            hallucinated += int(result.hallucinated)
            stale += int(result.stale)
            confidence += result.confidence
        count = len(group)
        summary[key] = {
            "count": count,
            "accuracy": correct / count,
            "hallucination_rate": hallucinated / count,
            "stale_rate": stale / count,
            "mean_confidence": confidence / count,
        }
    return summary
```

Part 5 - The Philosophy Behind the Exercise

Knowledge is situated in time and community. A static parameter set can encode patterns from the past, but truth continues to change after training stops. Reliability requires a relationship with current evidence, not nostalgia for a benchmark snapshot.

Domain shift reminds us that competence is conditional. The honest statement is never simply "the model is accurate"; it is accurate for particular tasks, people, sources, and dates within measured limits.

18.9.15 Exercise 14

Exercise Title: Build Reliability Dashboard for LLM Outputs

Part 1 - Why this matters

Reliability evidence becomes operational only when teams can observe it over time. A dashboard should connect user traffic, model/version, prompt template, retrieval index, confidence, detector signals, abstention, human review, latency, and eventual correctness labels. It must support investigation rather than display attractive averages.

Design three levels: executive service health, engineering diagnosis, and case-level trace. Show volume, hallucination estimates, verified error rate, calibration, refusal/coverage, citation support, retrieval failure, human-review queue, p95/p99 latency, cost, and model or data drift. Slice by domain, language, risk, tenant, prompt version, and deployment release while enforcing privacy and minimum-count rules.

Separate real-time proxies from delayed ground truth. Detector risk can alert quickly but is not the same as human-verified hallucination. Mark missing or stale telemetry visibly. Establish baselines, control limits, alert ownership, and links to representative traces. A dashboard that cannot lead from a spike to affected examples is a poster, not an engineering instrument.

Part 2 - Mathematical form and reasoning

For metric X_t in time window t, a standardized deviation is

$$z_t = \frac{X_t - \mu_{\text{base}}}{\sigma_{\text{base}} + \epsilon}.$$

An alert may require both sufficient volume and repeated deviation:

$$A_t = I(n_t \geq n_{\min}) I\left(\sum_{j=0}^{K-1} I(|z_{t-j}| > z_{\max}) = K\right).$$

For delayed labels, display label coverage

$$C_t = \frac{n_{\text{labeled},t}}{n_{\text{eligible},t}},$$

so apparent improvements are not caused by fewer reviewed examples.

Part 3 - Hints and Helper

1. Define a common event schema with model, prompt, retrieval, and trace identities.
2. Separate online proxy metrics from delayed verified outcomes.
3. Display denominators, confidence intervals, and label coverage.
4. Add domain, risk, language, and release filters.

5. Suppress tiny privacy-sensitive slices and control trace access.
6. Link alerts to representative failing requests.
7. Assign alert thresholds, owners, and runbooks.
8. Test the dashboard by injecting known failures and missing telemetry.

Part 4 - Python code skeleton

```
from collections import defaultdict
from dataclasses import dataclass

@dataclass
class ReliabilityEvent:
    release_id: str
    domain: str
    request_id: str
    detector_risk: float
    abstained: bool
    verified_hallucination: object
    latency_ms: float

def aggregate_events(events, minimum_slice_count):
    groups = defaultdict(list)
    for event in events:
        key = (event.release_id, event.domain)
        groups[key].append(event)

    rows = []
    for key, group in groups.items():
        if len(group) < minimum_slice_count:
            continue
        risk_sum = 0.0
        abstentions = 0
        labeled = 0
        hallucinations = 0
        latencies = []
        for event in group:
            risk_sum += event.detector_risk
            abstentions += int(event.abstained)
            latencies.append(event.latency_ms)
            if event.verified_hallucination is not None:
                labeled += 1
                hallucinations += int(event.verified_hallucination)
        verified_rate = None
        if labeled > 0:
```

```
            verified_rate = hallucinations / labeled
        rows.append({
            "release_id": key[0],
            "domain": key[1],
            "volume": len(group),
            "mean_detector_risk": risk_sum / len(group),
            "abstention_rate": abstentions / len(group),
            "label_coverage": labeled / len(group),
            "verified_hallucination_rate": verified_rate,
        })
    return rows
```

Part 5 - The Philosophy Behind the Exercise

A dashboard is a shared memory of system behavior. It turns isolated failures into patterns and makes responsibility continuous after release. Yet visualization can create false confidence if proxy signals, missing labels, and small denominators are hidden.

The reliable dashboard makes uncertainty visible. Its purpose is not to prove that the system is healthy, but to help humans notice when the evidence for health has weakened.

18.9.16 Exercise 15

Exercise Title: Stress Test Model with Adversarial Prompts

Part 1 - Why this matters

Adversarial prompts deliberately search for ways to bypass evidence rules, abstention, privacy boundaries, tool constraints, or system instructions. In a reliability chapter, the goal is not to collect dramatic jailbreak examples; it is to understand how ordinary and malicious inputs transform the model's epistemic behavior. Test false premises, authority pressure, requested fake citations, prompt injection inside retrieved documents, encoded instructions, conflicting roles, very long distractors, multilingual switching, and requests to claim actions that were not performed.

Define allowed and disallowed outcomes before testing. Preserve the system prompt and deployment wrappers, because a naked model benchmark does not represent the production boundary. Use a controlled red-team corpus and mutate prompts systematically instead of selecting only successful attacks. Record the attack family, transformations, release identity, exposed tools, evidence, response, detector output, and final policy decision.

Measure attack success, factual hallucination, false compliance, safe-completion quality, refusal precision, and transfer across paraphrases and languages. Analyze near misses: an answer may refuse the malicious request but still leak an unsupported factual claim. Convert every confirmed weakness into a minimal regression test and verify that mitigations do not destroy benign utility.

Part 2 - Mathematical form and reasoning

For attack family k, attack success rate is

$$\mathrm{ASR}_k = \frac{1}{n_k} \sum_{i=1}^{n_k} a_{ki},$$

where success is defined by a predeclared violation, not by reviewer surprise. Let B be benign utility before mitigation and B' after mitigation. A fix should report both security gain and utility cost:

$$\Delta\mathrm{ASR} = \mathrm{ASR}' - \mathrm{ASR}, \qquad \Delta B = B' - B.$$

Worst-family ASR prevents a large easy category from hiding one weak attack surface.

Part 3 - Hints and Helper

1. Define threat model, protected assets, and attack success before generation.
2. Test the complete production prompt, retrieval, tool, and policy stack.
3. Include prompt injection inside untrusted retrieved content.
4. Generate controlled transformations for language, encoding, and role pressure.
5. Keep benign matched controls for every mitigation.
6. Measure worst-family performance and transfer to unseen variants.
7. Store sensitive attack details with appropriate access control.
8. Add confirmed failures to a permanent regression suite.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class AdversarialCase:
    case_id: str
    family: str
    prompt: str
    expected_policy: str
    benign_control: bool

@dataclass
class AdversarialResult:
    case_id: str
    family: str
    policy_violated: bool
    hallucinated: bool
    useful_safe_response: bool
```

```
def run_cases(system, cases):
    raw_results = []
    for case in cases:
        response = system.respond(case.prompt)
        raw_results.append((case, response))
    return raw_results

def summarize_attack_results(results):
    family_totals = {}
    family_successes = {}
    for result in results:
        family = result.family
        family_totals[family] = family_totals.get(family, 0) + 1
        if result.policy_violated:
            old_value = family_successes.get(family, 0)
            family_successes[family] = old_value + 1
    rates = {}
    for family, total in family_totals.items():
        success_count = family_successes.get(family, 0)
        rates[family] = success_count / total
    return rates
```

Part 5 - The Philosophy Behind the Exercise

Adversarial testing studies the gap between a rule stated in language and a rule enforced by a system. A model may understand the words "ignore untrusted instructions" while still following a persuasive instruction embedded in a document. Reliability requires boundaries stronger than rhetorical reminders.

The exercise treats failure discovery as care rather than hostility. By seeking the boundary deliberately, engineers learn where users would otherwise meet it accidentally and at greater cost.

18.9.17 Exercise 16

Exercise Title: Compare Retrieval-Augmented vs Fine-Tuned Models

Part 1 - Why this matters

Retrieval augmentation and fine-tuning solve different problems. RAG supplies current, inspectable knowledge at inference time. Fine-tuning changes behavior, format, style, task procedure, and sometimes domain capability, but it is a poor mechanism for frequently changing facts and may memorize or distort them. Compare them under the same task rather than asking which technique is universally better.

Build four conditions where feasible: base, RAG, fine-tuned, and fine-tuned plus RAG. Hold model family, evaluation set, decoding, and compute reporting as constant as possible.

Split tests into stable procedure, static domain knowledge, post-training updates, no-answer questions, long evidence, and adversarial distractors. Measure accuracy, hallucination, citation faithfulness, format adherence, calibration, abstention, latency, memory, index/update cost, training cost, and maintenance complexity.

Test provenance and refresh. RAG should expose which source supported a claim; a fine-tuned fact may not be attributable. Update part of the knowledge base and measure how quickly each system reflects the change. Check whether fine-tuning damages general capabilities or makes the model more confidently wrong outside its training distribution.

Part 2 - Mathematical form and reasoning

Fine-tuning optimizes parameters,

$$\theta' = \arg\min_{\theta} \sum_{(x,y)\in\mathcal{T}} \mathcal{L}(f_\theta(x), y),$$

while RAG keeps parameters fixed and conditions on selected evidence $D_k(x)$:

$$y \sim p_\theta(y \mid x, D_k(x)).$$

Compare total lifecycle cost over horizon T:

$$C_{\text{life}} = C_{\text{build}} + C_{\text{update}}(T) + C_{\text{serve}}(T) + C_{\text{review}}(T).$$

The technically best score may not minimize lifecycle cost or maximize traceability.

Part 3 - Hints and Helper

1. Match base architecture and evaluation prompts across conditions.
2. Create subsets for stable behavior and changing facts.
3. Evaluate oracle and realistic retrieval for the RAG conditions.
4. Record fine-tuning data provenance and contamination risk.
5. Measure citations and update freshness, not only accuracy.
6. Test catastrophic forgetting and out-of-domain calibration.
7. Include build, refresh, serving, and human-review costs.
8. Recommend a method per requirement, including hybrid use when justified.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class ConditionMetrics:
    condition: str
```

```
    accuracy: float
    hallucination_rate: float
    citation_precision: float
    format_adherence: float
    latency_ms: float
    build_cost: float
    monthly_update_cost: float
    monthly_serve_cost: float

def lifecycle_cost(metrics, months):
    return (
        metrics.build_cost
        + months * metrics.monthly_update_cost
        + months * metrics.monthly_serve_cost
    )

def compare_conditions(all_metrics, months, gates):
    rows = []
    for metrics in all_metrics:
        passed = True
        if metrics.accuracy < gates["minimum_accuracy"]:
            passed = False
        if metrics.hallucination_rate > gates["maximum_hallucination"]:
            passed = False
        if metrics.latency_ms > gates["maximum_latency_ms"]:
            passed = False
        rows.append({
            "condition": metrics.condition,
            "passes_gates": passed,
            "lifecycle_cost": lifecycle_cost(metrics, months),
            "citation_precision": metrics.citation_precision,
            "format_adherence": metrics.format_adherence,
        })
    return rows
```

Part 5 - The Philosophy Behind the Exercise

RAG and fine-tuning represent two kinds of learning. One changes the evidence available now; the other changes the dispositions of the model. Confusing them encourages teams to bake changing facts into weights or retrieve instructions that should have become stable behavior.

The mature design asks where knowledge should live, how it should be updated, and how a claim can be traced. Technique follows epistemic architecture.

18.9.18 Exercise 17

Exercise Title: Document Known Failure Patterns and Safe Usage Guidelines

Part 1 - Why this matters

Every deployed LLM has known limits. If those limits remain in private benchmark notebooks, users and operators will repeat avoidable failures. Create a living failure catalog that names the pattern, triggering conditions, affected versions, observable symptoms, severity, detection method, mitigation, residual risk, safe alternative, owner, evidence, and review date.

Cover false premises, fabricated citations, stale facts, long-context neglect, retrieval distraction, calculation errors, multilingual degradation, prompt injection, confidence mismatch, excessive or insufficient refusal, domain shift, and tool-use claims without execution. Distinguish confirmed limitations from hypotheses. Include examples that are representative without exposing private data or providing unnecessary exploit detail.

Translate the catalog into audience-specific usage guidelines. End users need clear verification and escalation advice. Developers need supported inputs, evidence requirements, and forbidden integrations. Operators need monitors, thresholds, and recovery actions. Governance reviewers need scope, ownership, exceptions, and revalidation. Test whether readers can apply the guidelines to new scenarios; documentation that no one can operationalize is not a control.

Part 2 - Mathematical form and reasoning

Prioritize pattern k with an explicit risk model,

$$R_k = P_k \times S_k \times E_k,$$

where P is observed likelihood, S consequence severity, and E exposure. The factors need defined scales and evidence. Residual risk after mitigation is

$$R_k^{\text{res}} = R_k(1 - M_k),$$

where M_k is measured mitigation effectiveness, not an assumed checkbox. High-severity low-frequency failures should remain visible even when their average contribution is small.

Part 3 - Hints and Helper

1. Give every failure pattern a stable identifier and evidence link.
2. Record affected releases, domains, languages, and prompt conditions.
3. Separate symptom, root cause, mitigation, and residual risk.
4. Write safe alternatives instead of only prohibitions.
5. Tailor guidance for users, developers, operators, and reviewers.
6. Add owners, review dates, and retirement criteria.
7. Test guidance through scenario exercises and incident drills.
8. Update the catalog after every confirmed production failure.

Part 4 - Python code skeleton

```
from dataclasses import asdict, dataclass
from typing import List
import json

@dataclass
class FailurePattern:
    pattern_id: str
    name: str
    triggers: List[str]
    affected_releases: List[str]
    symptom: str
    severity: int
    likelihood: float
    exposure: float
    detection: str
    mitigation: str
    safe_alternative: str
    owner: str
    evidence_uri: str
    review_date: str

def risk_score(pattern):
    return pattern.severity * pattern.likelihood * pattern.exposure

def validate_patterns(patterns):
    errors = []
    seen = set()
    for pattern in patterns:
        if pattern.pattern_id in seen:
            errors.append("duplicate:" + pattern.pattern_id)
        seen.add(pattern.pattern_id)
        if pattern.evidence_uri.strip() == "":
            errors.append("missing_evidence:" + pattern.pattern_id)
        if pattern.safe_alternative.strip() == "":
            errors.append("missing_safe_alternative:" + pattern.pattern_id)
    return errors

def save_catalog(patterns, output_path):
    errors = validate_patterns(patterns)
    if len(errors) > 0:
        raise ValueError(",".join(errors))
    ordered = sorted(patterns, key=risk_score, reverse=True)
    records = []
    for pattern in ordered:
```

```
        record = asdict(pattern)
        record["risk_score"] = risk_score(pattern)
        records.append(record)
    with open(output_path, "w", encoding="utf-8") as handle:
        json.dump(records, handle, indent=2)
```

Part 5 - The Philosophy Behind the Exercise

Documentation is a promise not to make each person rediscover the same danger. It converts private engineering experience into shared practical knowledge. Stating limitations does not weaken trust; hiding known limits makes trust fragile and undeserved.

Safe guidance respects users as participants in reliability. It gives them the information and alternatives required to judge when automation is appropriate.

18.9.19 Exercise 18

Exercise Title: Build Human-in-the-Loop Review Workflow

Part 1 - Why this matters

Automation should escalate cases whose uncertainty, novelty, or consequence exceeds its safe authority. A human-in-the-loop workflow is not a button labeled "review"; it is a queueing, evidence, accountability, and feedback system. Define which outputs require review using domain risk, confidence, detector signals, retrieval failure, policy rules, and random quality sampling.

Present reviewers with the user request, model output, atomic claims, cited evidence, retrieval trace, confidence, detector reasons, model/version, and clear decision options. Blind irrelevant information that could bias judgment. Require reviewers to mark supported, corrected, abstained, escalated, or policy violating outcomes and provide structured reasons. High-risk decisions may require dual review or qualified specialists.

Design operational controls: priority, service-level target, capacity, workload forecast, access control, privacy, conflict resolution, audit log, and emergency escalation. Measure review agreement, turnaround, queue age, overturn rate, residual error after review, and reviewer fatigue. Feed confirmed labels into evaluation and detector improvement only after data governance checks; do not silently train on every correction.

Part 2 - Mathematical form and reasoning

Let requests arrive at rate λ and each reviewer complete μ cases per unit time. With c reviewers, stable capacity requires

$$\rho = \frac{\lambda}{c\mu} < 1.$$

Operating near one creates rapidly growing delay and fatigue. A review policy can prioritize expected risk reduction:

$$V_i = P(\text{error} \mid x_i) \times S_i \times P(\text{review corrects error}) - C_i^{\text{review}}.$$

Use V_i with age and fairness constraints; risk alone must not indefinitely starve low-risk requests.

Part 3 - Hints and Helper

1. Define mandatory, risk-triggered, and random-audit review routes.
2. Show claim-level evidence and detector reasons to reviewers.
3. Use structured decisions and correction reasons.
4. Require specialist or dual review for designated high-risk domains.
5. Track queue volume, age, service level, and reviewer agreement.
6. Protect sensitive prompts and restrict trace access.
7. Sample accepted automated outputs to estimate missed errors.
8. Govern how review labels enter future training or evaluation.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from datetime import datetime, timezone
import heapq

@dataclass
class ReviewCase:
    case_id: str
    error_probability: float
    severity: float
    created_at: str
    requires_specialist: bool
    payload_uri: str

def priority_value(case, current_time, aging_weight=0.01):
    created = datetime.fromisoformat(case.created_at)
    age_seconds = (current_time - created).total_seconds()
    risk = case.error_probability * case.severity
    return risk + aging_weight * age_seconds

def build_priority_queue(cases):
    current_time = datetime.now(timezone.utc)
    queue = []
    for case in cases:
        priority = priority_value(case, current_time)
```

```
        heapq.heappush(queue, (-priority, case.case_id, case))
    return queue

def next_eligible_case(queue, reviewer_is_specialist):
    deferred = []
    selected = None
    while len(queue) > 0:
        item = heapq.heappop(queue)
        case = item[2]
        if case.requires_specialist and not reviewer_is_specialist:
            deferred.append(item)
            continue
        selected = case
        break
    for item in deferred:
        heapq.heappush(queue, item)
    return selected
```

Part 5 - The Philosophy Behind the Exercise

Human review is not an admission that automation failed. It is a design choice about where judgment and responsibility should reside. Models offer scale and pattern recognition; people contribute contextual understanding, authority, and accountability.

The partnership succeeds only when escalation is selective, evidence-rich, and operationally sustainable. Sending everything to an exhausted reviewer merely moves the failure downstream.

18.9.20 Exercise 19

Exercise Title: Produce a Full LLM Reliability and Evaluation Report

Part 1 - Why this matters

The final report assembles the chapter into an auditable argument about where the LLM can be trusted, where it must abstain, and how remaining risk will be observed. A list of benchmark averages is insufficient. Preserve model and tokenizer identity, prompt templates, retrieval/index versions, tools, decoding, hardware, evaluation-set manifest, evidence dates, judge instructions, human agreement, code revision, seeds, and raw-result locations.

Report evaluation construction and coverage before results. Include trigger families, answerability, domains, languages, temporal splits, paraphrase families, adversarial cases, model sizes, and known gaps. Then present claim and answer hallucination, accuracy, confidence mismatch, calibration, abstention risk-coverage, RAG retrieval and citation metrics, self-consistency, domain shift, attack success, latency, cost, and human-review performance. Provide uncertainty, denominators, slices, and paired transitions.

Translate findings into a deployment decision. Specify supported and prohibited uses, evidence requirements, model-routing or RAG policy, abstention and review thresholds, monitoring

dashboard, alert/runbook ownership, known failure patterns, canary gates, rollback conditions, and revalidation date. Link every claim to raw evidence and record exceptions. Include negative results and unresolved unknowns; they define the limits of the release. An independent reviewer should reproduce selected metrics before sign-off.

Part 2 - Mathematical form and reasoning

Readiness is conjunctive:

$$G = G_{\text{identity}} \wedge G_{\text{coverage}} \wedge G_{\text{factuality}} \wedge G_{\text{calibration}} \wedge G_{\text{robustness}} \wedge G_{\text{operations}} \wedge G_{\text{review}}.$$

Each gate contains a requirement, threshold, observation, uncertainty, evidence URI, owner, and status. A missing required value fails closed. Traceability is

$$\text{risk} \rightarrow \text{test} \rightarrow \text{result} \rightarrow \text{control} \rightarrow \text{monitor}.$$

For central binary rates, report estimates with intervals; for comparisons, prefer paired differences on identical examples. Do not average a failed safety gate into good latency or accuracy.

Part 3 - Hints and Helper

1. Use a versioned schema shared by future reliability reports.
2. Hash model, tokenizer, prompt, corpus, index, dataset, and result artifacts.
3. Link every claim to reproducible raw evidence.
4. Present overall metrics, critical slices, uncertainty, and denominators.
5. Include failure examples, rejected mitigations, and unresolved unknowns.
6. Convert findings into explicit abstention, review, monitoring, and rollback controls.
7. Require independent reproduction of selected results.
8. Set owners, expiry dates, and triggers for immediate re-evaluation.

Part 4 - Python code skeleton

```
from dataclasses import asdict, dataclass, field
from datetime import datetime, timezone
from typing import Dict, List
import json

@dataclass
class ReliabilityGate:
    name: str
    requirement: str
    threshold: str
```

```
    observed: str
    uncertainty: str
    evidence_uri: str
    owner: str
    passed: bool

@dataclass
class ReliabilityReport:
    release_id: str
    created_at: str
    artifact_hashes: Dict[str, str]
    evaluation_manifest: str
    gates: List[ReliabilityGate] = field(default_factory=list)
    known_failures: List[str] = field(default_factory=list)
    unsupported_uses: List[str] = field(default_factory=list)

    )
```

Part 5 - The Philosophy Behind the Exercise

Evaluation is a claim about a model under specified conditions, not a permanent property of the model. A rigorous report preserves those conditions so that future changes in data, time, tools, or users can challenge the claim honestly.

Reliability is therefore not the absence of failure. It is the disciplined ability to define failure, search for it, measure uncertainty, limit authority, route difficult cases, observe deployment, and revise decisions when evidence changes. The final report is the memory that makes this discipline continuous.

18.10 LLM08

Chapter Title: Agents, Tools, and RAG Systems
Specialization: Applied AI and Agentic Systems Engineering

18.10.1 Exercise 00

Exercise Title: Explain Tool-Using LLMs and Why Pure Text Generation Is Not Enough

Part 1 - Why this matters

Pure text generation can explain how to calculate, search, query, send, or modify something, but explanation is not execution. An LLM's parameters are a compressed and time-bounded source of patterns; they cannot guarantee current database values, exact arithmetic, private account state, or that an external action actually occurred. A tool-using system gives the model controlled access to calculators, retrieval indexes, databases, code runtimes, APIs, sensors, or workflow services.

Separate five responsibilities. The model interprets intent and proposes a tool call. A schema defines permitted arguments. A policy layer authorizes the operation. The executor performs it and returns a typed result. The model then uses that result to answer or choose another step. The system must never treat generated words such as "the email was sent" as proof that the executor confirmed success. Tool identity, call ID, arguments, status, timestamps, and

result provenance must remain explicit.

Agents extend this loop over several steps, maintaining state and choosing whether to reason, retrieve, act, verify, ask for clarification, or stop. This adds capability and new failure modes: wrong-tool selection, invalid arguments, unauthorized side effects, duplicated actions, prompt injection in tool output, loops, stale state, and fabricated results. The core lesson is that an LLM can propose actions, but a trustworthy system constrains, executes, observes, and verifies them outside the model.

Part 2 - Mathematical form and reasoning

At state s_t, the model proposes an action a_t from text or a finite tool set:

$$a_t \sim \pi_\theta(a \mid s_t), \qquad o_t = \mathcal{E}(a_t), \qquad s_{t+1} = U(s_t, a_t, o_t).$$

$\mathcal{E}$ is the external executor and o_t is an observation, not a model belief. A policy gate $g(s_t, a_t) \in \{0, 1\}$ must precede execution:

$$o_t = \begin{cases} \mathcal{E}(a_t), & g(s_t, a_t) = 1, \\ \text{denied}, & g(s_t, a_t) = 0. \end{cases}$$

Success requires task correctness, valid authorization, and confirmed side effects. Fluent final text cannot substitute for any of these predicates.

Part 3 - Hints and Helper

1. Draw the boundary between model proposal, policy decision, and tool execution.
2. Use typed schemas for every tool and reject additional fields.
3. Distinguish read-only tools from tools with external side effects.
4. Attach call IDs and provenance to observations.
5. Require confirmation for costly, destructive, or person-directed actions.
6. Make retries idempotent or explicitly guarded.
7. Treat tool output as untrusted data that may contain injected instructions.
8. Verify completion from executor state before reporting success.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from enum import Enum
from typing import Dict

class ActionStatus(Enum):
    PROPOSED = "proposed"
    DENIED = "denied"
```

```
    SUCCEEDED = "succeeded"
    FAILED = "failed"

@dataclass
class ToolCall:
    call_id: str
    tool_name: str
    arguments: Dict[str, object]

@dataclass
class ToolObservation:
    call_id: str
    status: ActionStatus
    payload: Dict[str, object]
    provenance: str

def execute_proposed_call(call, registry, policy, context):
    if call.tool_name not in registry:
        return ToolObservation(
            call.call_id, ActionStatus.DENIED, {}, "unknown_tool"
        )
    if not policy.authorize(call, context):
        return ToolObservation(
            call.call_id, ActionStatus.DENIED, {}, "policy_denial"
        )
    tool = registry[call.tool_name]
    validated_arguments = tool.schema.validate(call.arguments)
    try:
        payload = tool.execute(validated_arguments)
        status = ActionStatus.SUCCEEDED
    except Exception as exc:
        payload = {"error_type": type(exc).__name__}
        status = ActionStatus.FAILED
    return ToolObservation(call.call_id, status, payload, tool.provenance)
```

Part 5 - The Philosophy Behind the Exercise

Language can represent an action without causing it. Agent engineering begins by refusing to confuse the symbol with the event. A promise, command, and report of success are different objects even when they use similar words.

Tools give models contact with the world, while boundaries give that contact meaning and safety. Capability arises from the loop; accountability arises from keeping every transition observable and externally verifiable.

18.10.2 Exercise 01

Exercise Title: Implement Retrieval-Augmented Generation Pipeline Conceptually

Part 1 - Why this matters

RAG answers questions using an external corpus whose documents can be updated, inspected, and cited. A complete pipeline contains ingestion, parsing, chunking, metadata extraction, embedding, indexing, query transformation, retrieval, reranking, context assembly, grounded generation, citation validation, and evaluation. Treating RAG as merely "put search results in the prompt" hides where errors originate.

Create an offline ingestion path and an online query path. During ingestion, preserve document ID, source, version, effective date, permissions, section, chunk offsets, and checksum. During querying, enforce user access before results enter the prompt. Retrieve candidates, rerank them, remove duplicates, respect a token budget, and keep source labels stable. Instruct the generator to use only the supplied evidence and abstain when it is insufficient.

Evaluate stages separately. Retrieval recall asks whether supporting evidence was found. Context precision asks how much retrieved text was useful. Grounding asks whether claims follow from context. Answer quality asks whether the response solves the task. Citation correctness asks whether references support their attached claims. Save traces that connect every final claim to retrieved chunk IDs; otherwise the pipeline cannot be debugged.

Part 2 - Mathematical form and reasoning

For query q, candidate retrieval and reranking are

$$C_k(q) = \mathrm{TopK}_{d \in \mathcal{D}}\, s_e(q, d), \qquad D_r(q) = \mathrm{TopR}_{d \in C_k(q)}\, s_r(q, d).$$

Generation becomes $p_\theta(y \mid q, D_r(q))$. End-to-end correctness can be decomposed as

$$P(Y) = P(R)P(Y \mid R) + P(\neg R)P(Y \mid \neg R),$$

where R means sufficient evidence was retrieved. The decomposition makes clear that good generation cannot recover evidence that never reached the context.

Part 3 - Hints and Helper

1. Version corpus, chunker, embedding model, index, reranker, and prompt.
2. Preserve access-control metadata and filter before prompt construction.
3. Evaluate retriever with known supporting chunk IDs.
4. Compare realistic retrieval with oracle evidence.
5. Enforce a context token budget and stable citation labels.
6. Require evidence-aware abstention for no-answer items.
7. Validate citation entailment after generation.
8. Store an end-to-end trace for every request.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from typing import Dict, List

@dataclass
class Chunk:
    chunk_id: str
    document_id: str
    text: str
    metadata: Dict[str, str]
    score: float = 0.0

def build_context(chunks, maximum_characters):
    selected = []
    used = 0
    for chunk in chunks:
        label = "[" + chunk.chunk_id + "] "
        entry = label + chunk.text
        if used + len(entry) > maximum_characters:
            continue
        selected.append(entry)
        used += len(entry)
    return "\n\n".join(selected)

def rag_answer(query, user, retriever, reranker, generator):
    candidates = retriever.search(query, top_k=30, user=user)
    authorized = []
    for chunk in candidates:
        if chunk.metadata["authorized"] == "true":
            authorized.append(chunk)
    ranked = reranker.rank(query, authorized)
    context = build_context(ranked, maximum_characters=12000)
    prompt = (
        "Use only the evidence. Cite chunk IDs. "
        "If insufficient, say I don't know.\n\n"
        + context + "\n\nQuestion: " + query
    )
    answer = generator.generate(prompt, temperature=0.0)
    return {"answer": answer, "chunks": ranked, "prompt": prompt}
```

Part 5 - The Philosophy Behind the Exercise

RAG is an architecture of epistemic traceability. It moves part of the system's knowledge from opaque parameters into documents whose origin, date, and access rules can be inspected.

That does not guarantee truth, but it makes failure locatable.

The pipeline succeeds when it can explain not only an answer, but the chain by which evidence became available and was transformed into that answer.

18.10.3 Exercise 02

Exercise Title: Integrate Vector Database Retrieval Into Prompt Construction

Part 1 - Why this matters

A vector database stores embeddings and metadata so semantically related chunks can be retrieved even when query words differ from document words. Integration requires more than calling similarity search. The query and document embeddings must come from compatible models and normalization rules; metadata filters must enforce tenant, date, language, and permission constraints; results must be deduplicated, budgeted, and labeled before entering the prompt.

Design a retrieval adapter independent of a specific database. It should accept a query, authorization scope, top-k, score threshold, namespace, and filters, then return typed chunks with similarity, source, version, offsets, and permissions. Validate embedding dimension and index identity at startup. Apply authorization inside the retrieval query rather than retrieving forbidden chunks and discarding them after exposure.

Prompt construction must preserve evidence boundaries. Do not concatenate untrusted chunks as instructions; delimit them as quoted data and state that instructions inside evidence are not authoritative. Order by reranked relevance or source structure, measure lost-in-the-middle effects, and reject context that exceeds the token budget. Record which chunks were omitted and why.

Part 2 - Mathematical form and reasoning

For normalized query vector u and chunk vector v_i, cosine similarity is

$$s_i = u^\top v_i, \qquad \|u\|_2 = \|v_i\|_2 = 1.$$

Filtered retrieval is

$$D_k = \mathrm{TopK}_{i:\, F(m_i)=1}\, s_i,$$

where $F(m_i)$ enforces metadata and access conditions. Context selection under token budget B resembles a constrained utility problem:

$$\max_S \sum_{i \in S} r_i \quad \text{s.t.} \quad \sum_{i \in S} t_i \le B.$$

Redundancy penalties may be added so near-duplicate chunks do not consume the entire budget.

Part 3 - Hints and Helper

1. Verify embedding model ID, dimension, normalization, and distance metric.

2. Push authorization and tenant filters into the database query.
3. Return typed records with source, version, offsets, and scores.
4. Deduplicate overlapping chunks before context packing.
5. Count tokens with the generator's tokenizer.
6. Delimit retrieved text as untrusted evidence, not instructions.
7. Log selected and omitted chunk IDs with reasons.
8. Unit-test empty results, stale indexes, wrong dimensions, and permission denial.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from typing import Dict, List

@dataclass
class SearchRecord:
    chunk_id: str
    text: str
    score: float
    metadata: Dict[str, str]

def retrieve_for_user(vector_db, embedder, query, user_scope, top_k):
    query_vector = embedder.encode(query)
    if len(query_vector) != vector_db.embedding_dimension:
        raise ValueError("embedding dimension mismatch")
    filters = {
        "tenant_id": user_scope.tenant_id,
        "access_level": {"$lte": user_scope.access_level},
        "active": True,
    }
    rows = vector_db.search(
        vector=query_vector,
        top_k=top_k,
        filters=filters,
    )
    records = []
    for row in rows:
        record = SearchRecord(
            chunk_id=row["chunk_id"],
            text=row["text"],
            score=row["score"],
            metadata=row["metadata"],
        )
```

```
        records.append(record)
    return records

def evidence_block(records):
    lines = ["BEGIN UNTRUSTED EVIDENCE"]
    for record in records:
        lines.append("[" + record.chunk_id + "]")
        lines.append(record.text)
    lines.append("END UNTRUSTED EVIDENCE")
    return "\n".join(lines)
```

Part 5 - The Philosophy Behind the Exercise

Similarity is a mathematical relation, not permission, authority, or truth. Vector retrieval finds nearby representations; system design must still decide which sources are allowed, current, and worthy of entering the model's context.

Prompt construction is therefore an act of curation. It determines what the model is permitted to treat as evidence and preserves the distinction between data received and instructions trusted.

18.10.4 Exercise 03

Exercise Title: Implement Tool Calling Logic and Validate Structured Outputs

Part 1 - Why this matters

Tool calling converts a model proposal into structured data that software can validate. Without a strict schema, a model may omit required fields, invent argument names, use the wrong type, select a nonexistent tool, or place prose where an executor expects JSON. Parsing success is only the first gate; semantic validity and authorization must follow before execution.

Define a registry with stable tool names, descriptions, input schemas, output schemas, side-effect classification, timeout, idempotency behavior, and policy requirements. Ask the model either for a final response or one structured call. Parse with a real JSON parser, reject extra properties, validate enums and ranges, normalize only safe representations, and never repair an ambiguous high-impact action silently. Return validation errors to a bounded correction loop or ask the user for clarification.

After execution, validate the result against its output schema and bind it to the original call ID. The model must not substitute a guessed result when a tool fails. Test correct calls and malformed, incomplete, adversarial, and unauthorized calls. Keep the executor unreachable except through the validated dispatcher.

Part 2 - Mathematical form and reasoning

Let z be raw model output, $P(z)$ a parser, V schema validation, and A authorization. Execution is permitted only if

$$G(z) = I(P(z) \text{ succeeds}) I(V(P(z)) = 1) I(A(P(z)) = 1) = 1.$$

For a bounded correction loop with maximum K attempts, termination is

$$T = \min\{t : G(z_t) = 1 \ \vee \ t = K\}.$$

The maximum prevents malformed outputs from causing unbounded agent loops.

Part 3 - Hints and Helper

1. Use strict JSON schemas with required fields and no extra properties.
2. Validate tool name before validating arguments.
3. Check semantic ranges, identifiers, permissions, and resource ownership.
4. Require confirmation for side-effecting calls.
5. Bind results to call IDs and validate output schemas.
6. Limit correction attempts and preserve every failed proposal.
7. Keep execution behind one dispatcher.
8. Fuzz schemas with wrong types, Unicode, huge values, and extra fields.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
import json

@dataclass
class RegisteredTool:
    name: str
    input_validator: object
    output_validator: object
    executor: object
    has_side_effects: bool

def parse_call(raw_text):
    value = json.loads(raw_text)
    if not isinstance(value, dict):
        raise ValueError("tool call must be a JSON object")
    allowed = {"tool_name", "arguments", "call_id"}
    for key in value.keys():
        if key not in allowed:
            raise ValueError("unexpected field: " + key)
    for required in allowed:
        if required not in value:
            raise ValueError("missing field: " + required)
    return value
```

```
def dispatch(raw_text, registry, policy, context):
    call = parse_call(raw_text)
    name = call["tool_name"]
    if name not in registry:
        raise ValueError("unknown tool")
    tool = registry[name]
    arguments = tool.input_validator.validate(call["arguments"])
    if not policy.authorize(name, arguments, context):
        raise PermissionError("tool call denied")
    if tool.has_side_effects and not context.confirmed:
        return {"status": "confirmation_required"}
    output = tool.executor(arguments)
    validated_output = tool.output_validator.validate(output)
    return {
        "call_id": call["call_id"],
        "status": "succeeded",
        "output": validated_output,
    }
```

Part 5 - The Philosophy Behind the Exercise

Structure is a contract between probabilistic language and deterministic software. The model may propose many forms; the schema narrows those forms to objects that the surrounding system can reason about and constrain.

Validation is not distrust of intelligence. It is recognition that agency requires accountable interfaces. The more consequential the tool, the less room there is for implicit interpretation.

18.10.5 Exercise 04

Exercise Title: Debug Tool Invocation Failures and Hallucinated Tool Calls

Part 1 - Why this matters

Tool failures appear at different boundaries: the model chooses the wrong tool, emits malformed arguments, calls a tool that does not exist, violates policy, times out, receives a partial result, misreads the result, retries a completed side effect, or claims success without execution. Treating them all as "the agent failed" prevents targeted fixes and may hide dangerous duplication.

Capture a complete trace: user request, system/tool descriptions, model proposal, parse result, schema errors, authorization decision, executor request, response, timeout, retry metadata, observation given back to the model, and final answer. Assign the earliest failed boundary. Reproduce with a deterministic stub tool, then vary one component at a time. For side effects, use idempotency keys and query operation status before retrying.

Hallucinated calls include nonexistent tool names, unsupported capabilities, or invented results. The dispatcher must reject them mechanically. Test tool description ambiguity, similar

names, missing tools, adversarial tool output, and transient errors. A successful fix reduces the targeted class without causing excessive refusal or moving the failure downstream.

Part 2 - Mathematical form and reasoning

Represent the pipeline as gates $G_1, \ldots, G_m$. The root cause is the first failed gate,

$$k^* = \min\{k : G_k = 0\}.$$

For retry attempt r with success probability p_r and side-effect duplication cost C_D, naive retry is unsafe when

$$P(\text{first attempt succeeded but response was lost})C_D > P(\text{transient failure})\, B_R,$$

where B_R is retry benefit. Idempotency or status lookup changes this risk.

Part 3 - Hints and Helper

1. Preserve the exact trace before modifying prompts or schemas.
2. Label the earliest failure boundary.
3. Replace external tools with deterministic stubs for reproduction.
4. Distinguish safe read retries from side-effect retries.
5. Use idempotency keys and operation-status lookup.
6. Reject nonexistent tools and fabricated results outside the model.
7. Inject timeout, malformed response, denial, and partial-success cases.
8. Add every confirmed bug to a regression suite.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from typing import List

@dataclass
class InvocationTrace:
    call_id: str
    tool_exists: bool
    parsed: bool
    schema_valid: bool
    authorized: bool
    executor_started: bool
    executor_succeeded: bool
    result_valid: bool
    final_claimed_success: bool
```

```
    events: List[str]

def earliest_failure(trace):
    checks = [
        ("unknown_tool", trace.tool_exists),
        ("parse_failure", trace.parsed),
        ("schema_failure", trace.schema_valid),
        ("authorization_denial", trace.authorized),
        ("executor_not_started", trace.executor_started),
        ("executor_failure", trace.executor_succeeded),
        ("invalid_result", trace.result_valid),
    ]
    for name, passed in checks:
        if not passed:
            return name
    if trace.final_claimed_success and not trace.executor_succeeded:
        return "hallucinated_success"
    return "no_failure_detected"

def should_retry(operation, error, status_lookup):
    if not error.transient:
        return False
    if not operation.has_side_effects:
        return True
    existing_status = status_lookup(operation.idempotency_key)
    if existing_status == "succeeded":
        return False
    return operation.supports_idempotency
```

Part 5 - The Philosophy Behind the Exercise

An agent trace is a causal history. Debugging becomes possible when proposals, decisions, events, and reports are not blended into one narrative. The first broken contract matters more than the final symptom.

Reliable agency depends on modest claims: the system should report only what an authorized executor can confirm. Anything else is imagination wearing the grammar of action.

18.10.6 Exercise 05

Exercise Title: Compare RAG vs Fine-Tuning for Knowledge Updates

Part 1 - Why this matters

RAG and fine-tuning are often proposed as interchangeable ways to "teach" a model, but they place knowledge in different locations. RAG reads versioned documents at inference time and can expose citations. Fine-tuning changes model behavior through parameter updates; it is useful for style, format, procedure, and recurring task patterns, but it does not provide simple

deletion, provenance, or rapid correction of changing facts.

Build base, RAG, fine-tuned, and hybrid conditions on matched tasks. Include stable procedures, static domain knowledge, newly changed facts, no-answer questions, and conflicting versions. Measure answer accuracy, unsupported claims, citation precision, format adherence, calibration, update freshness, latency, token cost, training cost, index maintenance, and forgetting on general tasks. Record data provenance and contamination risk.

Perform an update experiment: change a policy document after the initial build, refresh the RAG index, and compare the effort and delay required for each system to answer according to the new version. Do not conclude that RAG is superior when retrieval is poorly engineered, or that fine-tuning stores a fact because one prompted example was remembered.

Part 2 - Mathematical form and reasoning

RAG conditions on evidence $D(x)$ while fine-tuning changes parameters:

$$y_{\text{RAG}} \sim p_\theta(y \mid x, D(x)), \qquad \theta' = \arg\min_\theta \sum_{(x,y)\in\mathcal{T}} \mathcal{L}_\theta(x, y).$$

Compare lifecycle cost over horizon T:

$$C(T) = C_{\text{build}} + C_{\text{refresh}}(T) + C_{\text{serve}}(T) + C_{\text{review}}(T).$$

Freshness lag $L_f = t_{\text{correct availability}} - t_{\text{source change}}$ is a first-class metric for dynamic knowledge.

Part 3 - Hints and Helper

1. Define whether the requirement concerns facts, behavior, style, or procedure.
2. Use matched base, RAG, fine-tuned, and hybrid conditions.
3. Add post-build fact changes and deletion requests.
4. Evaluate retrieval oracle and realistic retrieval separately.
5. Test general-task regression after fine-tuning.
6. Measure provenance, freshness, latency, and lifecycle cost.
7. Record data and index versions.
8. Recommend a knowledge location per requirement, not one global winner.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class KnowledgeCondition:
    name: str
    accuracy: float
```

```
    hallucination_rate: float
    citation_precision: float
    freshness_hours: float
    format_adherence: float
    build_cost: float
    monthly_refresh_cost: float
    monthly_serve_cost: float

def total_cost(condition, months):
    return (
        condition.build_cost
        + months * condition.monthly_refresh_cost
        + months * condition.monthly_serve_cost
    )

def feasible(condition, requirements):
    if condition.accuracy < requirements["minimum_accuracy"]:
        return False
    if condition.hallucination_rate > requirements["maximum_hallucination"]:
        return False
    if condition.freshness_hours > requirements["maximum_freshness_hours"]:
        return False
    return True

def select_condition(conditions, requirements, months):
    candidates = []
    for condition in conditions:
        if feasible(condition, requirements):
            candidates.append(condition)
    if len(candidates) == 0:
        return None
    selected = candidates[0]
    for candidate in candidates[1:]:
        if total_cost(candidate, months) < total_cost(selected, months):
            selected = candidate
    return selected
```

Part 5 - The Philosophy Behind the Exercise

Knowledge architecture asks where a claim should live and how it should change. Some knowledge belongs in inspectable sources; some behavior belongs in learned parameters; some high-risk decisions should remain outside the model entirely.

The exercise rejects the fantasy that every form of learning is the same. A system becomes maintainable when facts, skills, evidence, and authority have deliberate homes.

18.10.7 Exercise 06

Exercise Title: Implement Memory Component for Multi-Turn Agents

Part 1 - Why this matters

Multi-turn agents need continuity, but "memory" refers to several different stores. Working memory contains the current task state. Episodic memory records prior interactions and outcomes. Semantic memory stores durable user or domain facts. Procedural memory contains policies and workflows. Keeping the entire conversation forever is expensive, privacy-sensitive, and vulnerable to stale or malicious instructions.

Create a memory service outside the model with typed entries, subject, source, timestamp, confidence, scope, permissions, expiry, and supersession links. Write only after policy checks; do not promote every model statement into durable truth. Retrieve memory by task relevance and authorization, then place it in a clearly delimited context. Conflicting entries should be surfaced or resolved by recency and authority rules rather than silently blended.

Support correction, deletion, session isolation, retention limits, and audit. Summaries must link to their source turns so compression errors remain traceable. Test cross-user leakage, prompt injection stored as memory, stale preferences, duplicate facts, and context-budget pressure. Evaluate task success, retrieval precision, stale-memory error, privacy violations, and token savings.

Part 2 - Mathematical form and reasoning

Score candidate memory m_i for query q using relevance, recency, authority, and risk:

$$S(m_i, q) = \alpha R_i + \beta e^{-\lambda \Delta t_i} + \gamma A_i - \delta K_i.$$

Select memories under token budget B and authorization predicate P_i:

$$\max_{M} \sum_{i \in M} S(m_i, q) \quad \text{s.t.} \quad \sum_{i \in M} t_i \leq B,\ P_i = 1.$$

Source authority and explicit correction should override mere semantic similarity.

Part 3 - Hints and Helper

1. Separate working, episodic, semantic, and procedural memory.
2. Store provenance, timestamp, scope, authority, and expiry.
3. Require policy approval before durable writes.
4. Keep user and tenant namespaces isolated.
5. Link summaries to source turns and support correction/deletion.
6. Treat retrieved memory as untrusted data.
7. Resolve conflicts explicitly and log supersession.
8. Test stale memory, injection, leakage, and token-budget behavior.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from datetime import datetime
from typing import Dict, List

@dataclass
class MemoryEntry:
    memory_id: str
    tenant_id: str
    subject_id: str
    kind: str
    content: str
    source_uri: str
    created_at: str
    expires_at: str
    confidence: float
    authority: float
    superseded_by: str = ""

class MemoryStore:
    def __init__(self):
        self.entries: Dict[str, MemoryEntry] = {}

    def write(self, entry, policy, context):
        if not policy.allow_memory_write(entry, context):
            raise PermissionError("memory write denied")
        self.entries[entry.memory_id] = entry

    def retrieve(self, tenant_id, subject_id, now):
        selected = []
        for entry in self.entries.values():
            if entry.tenant_id != tenant_id:
                continue
            if entry.subject_id != subject_id:
                continue
            if entry.superseded_by != "":
                continue
            expiry = datetime.fromisoformat(entry.expires_at)
            if expiry <= now:
                continue
            selected.append(entry)
        return selected

    def delete(self, memory_id):
        if memory_id in self.entries:
            del self.entries[memory_id]
```

Part 5 - The Philosophy Behind the Exercise

Memory creates continuity by allowing the past to influence the present. That power makes forgetting equally important. A system unable to correct, expire, or delete memory confuses persistence with truth and convenience with consent.

Agent memory should be curated history, not sediment. Its value comes from provenance, boundaries, and the possibility of revision.

18.10.8 Exercise 07

Exercise Title: Evaluate Agent Planning Failures and Looping Behavior

Part 1 - Why this matters

Multi-step agents can decompose goals, but each added step creates another chance to choose the wrong action, lose constraints, repeat work, or fail to stop. Common planning failures include impossible goals, missing prerequisites, premature execution, stale plans after observations change, repeated identical calls, alternating between two states, unbounded research, and declaring success without testing the terminal condition.

Instrument the plan-act-observe loop. Record state hash, step number, proposed goal, selected tool, normalized arguments, observation, cost, remaining budget, and termination reason. Define success and stop conditions outside the model. Use maximum steps, wall time, token/tool budgets, repeated-state detection, and progress tests. A budget stop is a safe outcome, not an invitation to fabricate completion.

Build tasks with necessary detours, unavailable tools, misleading observations, partial success, and unsatisfiable requirements. Measure task success, steps, unnecessary calls, repeated states, recovery after error, cost, and false-success rate. Compare static plans with plans revised after each observation.

Part 2 - Mathematical form and reasoning

Let progress potential be $\Phi(s_t)$. A step has progress

$$\Delta_t = \Phi(s_{t+1}) - \Phi(s_t).$$

Flag stagnation when $\Delta_t \leq \epsilon$ for K consecutive steps. Exact loop detection uses a normalized state/action hash:

$$L_t = I\left(H(s_t, a_t) \in \{H(s_j, a_j) : j < t\}\right).$$

Termination occurs on verified success, verified impossibility, user clarification, policy denial, or exhausted budget. Only verified success may be reported as completion.

Part 3 - Hints and Helper

1. Define external success and terminal predicates for every task.
2. Record normalized state and action hashes.
3. Enforce step, time, token, tool, and cost budgets.

4. Detect repeated calls and low-progress windows.
5. Replan after observations invalidate assumptions.
6. Test unavailable tools and impossible goals.
7. Distinguish safe stop, failure, and verified success.
8. Turn looping traces into regression scenarios.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, field
import hashlib
import json

@dataclass
class AgentBudget:
    maximum_steps: int
    maximum_tool_calls: int
    maximum_cost: float

@dataclass
class AgentState:
    step: int = 0
    tool_calls: int = 0
    cost: float = 0.0
    seen_hashes: set = field(default_factory=set)

def action_hash(tool_name, arguments):
    payload = json.dumps(arguments, sort_keys=True)
    value = tool_name + ":" + payload
    return hashlib.sha256(value.encode("utf-8")).hexdigest()

def guard_next_action(state, budget, tool_name, arguments, cost):
    if state.step >= budget.maximum_steps:
        return "stop_step_budget"
    if state.tool_calls >= budget.maximum_tool_calls:
        return "stop_tool_budget"
    if state.cost + cost > budget.maximum_cost:
        return "stop_cost_budget"
    fingerprint = action_hash(tool_name, arguments)
    if fingerprint in state.seen_hashes:
        return "stop_repeated_action"
    state.seen_hashes.add(fingerprint)
```

```
    state.step += 1
    state.tool_calls += 1
    state.cost += cost
    return "continue"
```

Part 5 - The Philosophy Behind the Exercise

Planning is not the production of a plausible list; it is the disciplined revision of action under evidence. An agent that cannot recognize stagnation may turn persistence into waste and uncertainty into false completion.

Stopping is part of intelligence. It preserves the distinction between a goal that has been achieved, one that remains open, and one that cannot responsibly be pursued with available authority and resources.

18.10.9 Exercise 08

Exercise Title: Implement Guardrails for Tool Safety and Input Validation

Part 1 - Why this matters

Tool-enabled agents can affect databases, files, accounts, communications, and infrastructure. Safety cannot depend on the model remembering a warning. Build guardrails as deterministic controls surrounding every call: identity, authentication, authorization, schema validation, semantic validation, resource ownership, rate and cost limits, confirmation, sandboxing, timeout, network restrictions, audit, and response filtering.

Classify tools by side effects and consequence. Read-only search may run automatically within access scope. Financial transfer, deletion, deployment, or person-directed messaging requires explicit user intent and often confirmation. Use least-privilege credentials per tool, not one agent-wide secret. Reject path traversal, arbitrary SQL, shell metacharacters, unbounded dates, huge payloads, and identifiers outside the caller's tenant.

Treat user input, retrieved text, memory, and tool output as untrusted. Prompt injection inside a webpage must not grant authority. Redact secrets before returning observations to the model. Use dry-run previews and idempotency keys for side effects. Test allowed, denied, boundary, malformed, replayed, and concurrent cases; log decisions without storing unnecessary sensitive data.

Part 2 - Mathematical form and reasoning

Execution permission is a conjunction:

$$G = I_{\text{authenticated}} I_{\text{schema}} I_{\text{authorized}} I_{\text{owned}} I_{\text{budget}} I_{\text{confirmed}}.$$

Any required zero denies the call. Risk-based control may use

$$R = P(\text{harm} \mid a, s) \times S(\text{harm}) \times E(a),$$

but high-impact forbidden actions remain hard constraints rather than weighted preferences that model utility can override.

Part 3 - Hints and Helper

1. Classify every tool by side effect, privilege, and maximum consequence.
2. Use strict schemas plus semantic and ownership validation.
3. Grant separate least-privilege credentials to each executor.
4. Require confirmation and preview for designated actions.
5. Sandbox code and restrict filesystem, network, time, and resources.
6. Redact secrets from tool observations and logs.
7. Use idempotency keys and replay protection.
8. Fuzz allowed and denied boundaries in automated tests.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class SafetyContext:
    authenticated: bool
    user_id: str
    tenant_id: str
    confirmed_call_ids: set
    remaining_cost: float

def authorize_call(call, tool, context):
    reasons = []
    if not context.authenticated:
        reasons.append("not_authenticated")
    if call.arguments.get("tenant_id") != context.tenant_id:
        reasons.append("tenant_mismatch")
    if tool.estimated_cost(call.arguments) > context.remaining_cost:
        reasons.append("cost_budget_exceeded")
    if tool.has_side_effects:
        if call.call_id not in context.confirmed_call_ids:
            reasons.append("confirmation_required")
    if not tool.ownership_check(call.arguments, context.user_id):
        reasons.append("resource_not_owned")
    return len(reasons) == 0, reasons

def safe_dispatch(call, registry, context, audit_log):
    if call.tool_name not in registry:
        return {"status": "denied", "reasons": ["unknown_tool"]}
    tool = registry[call.tool_name]
```

```
    arguments = tool.schema.validate(call.arguments)
    call.arguments = arguments
    allowed, reasons = authorize_call(call, tool, context)
    audit_log.record(call.call_id, call.tool_name, allowed, reasons)
    if not allowed:
        return {"status": "denied", "reasons": reasons}
    result = tool.execute(arguments)
    return {"status": "succeeded", "result": tool.redact(result)}
```

Part 5 - The Philosophy Behind the Exercise

Guardrails express a constitutional idea: intelligence does not imply authority. An agent may understand and propose an action while still lacking permission to perform it. The boundary protects users, systems, and the agent from ambiguous intent.

Safety becomes credible when it is enforced by mechanisms that do not depend on the same probabilistic process they constrain.

18.10.10 Exercise 09

Exercise Title: Benchmark End-to-End RAG Latency and Accuracy

Part 1 - Why this matters

RAG latency is the sum of many stages: query preprocessing, embedding, network round trip, vector search, metadata filtering, reranking, context packing, prompt prefill, decoding, citation validation, and queueing. A fast vector search does not guarantee a fast answer, and a fast answer is useless if the supporting evidence was missed. Benchmark latency and accuracy together under a representative workload.

Use a frozen query set with known supporting chunks and no-answer cases. Record corpus/index version, cache state, query length, retrieved k, reranked r, context tokens, output tokens, concurrency, hardware, and network placement. Warm components, then measure cold and warm paths separately. Instrument every stage with one trace ID and use server-side clocks where possible.

Report retrieval recall@k, mean reciprocal rank, context precision, and answer accuracy. Also measure unsupported claims, citation precision, abstention, latency percentiles, throughput, and cost. Sweep k, reranker depth, chunk size, and context budget to find a Pareto frontier. Include timeouts and errors in accounting; discarding them creates a fictional service.

Part 2 - Mathematical form and reasoning

End-to-end latency is

$$T = T_e + T_v + T_r + T_c + T_p + T_d + T_{\text{verify}} + T_q.$$

Retrieval recall@k is

$$R@k = \frac{1}{N} \sum_i I(D_k(q_i) \cap G_i \neq \varnothing),$$

where G_i is the gold support set. Select configurations from the non-dominated set over answer quality, p99 latency, cost, and memory instead of optimizing one metric alone.

Part 3 - Hints and Helper

1. Freeze queries, gold evidence, corpus, index, model, and decoding.
2. Trace embedding, search, rerank, packing, prefill, decode, and verification.
3. Measure cold and warm cache paths.
4. Sweep retrieval depth and context budget.
5. Report retrieval and generation metrics separately and end to end.
6. Stratify by query and document length.
7. Include timeout, empty retrieval, and error outcomes.
8. Repeat runs and report percentile distributions.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, field
from time import perf_counter

@dataclass
class StageTimer:
    durations_ms: dict = field(default_factory=dict)

    def measure(self, name, function, *arguments, **keywords):
        started = perf_counter()
        result = function(*arguments, **keywords)
        elapsed = (perf_counter() - started) * 1000.0
        self.durations_ms[name] = elapsed
        return result

def benchmark_query(query, pipeline):
    timer = StageTimer()
    vector = timer.measure("embedding", pipeline.embed, query.text)
    candidates = timer.measure(
        "vector_search", pipeline.search, vector, query.filters
    )
    ranked = timer.measure(
        "reranking", pipeline.rerank, query.text, candidates
    )
    prompt = timer.measure(
        "context_packing", pipeline.pack, query.text, ranked
```

```
)
answer = timer.measure("generation", pipeline.generate, prompt)
verified = timer.measure("verification", pipeline.verify, answer, ranked)
total_ms = 0.0
for duration in timer.durations_ms.values():
    total_ms += duration
return {
    "query_id": query.query_id,
    "answer": answer,
    "verified": verified,
    "stage_ms": timer.durations_ms,
    "measured_total_ms": total_ms,
}
```

Part 5 - The Philosophy Behind the Exercise

End-to-end measurement respects the fact that users experience a system, not a component. Local optimizations can move cost across boundaries or improve speed while degrading evidence. Only the complete path reveals the delivered value.

The Pareto view is equally important: reliability, latency, and cost are real constraints that must be negotiated openly rather than hidden inside one score.

18.10.11 Exercise 10

Exercise Title: Integrate SQL Queries as Tools and Validate Correct Query Generation

Part 1 - Why this matters

SQL tools give an agent access to exact, current, structured data, but generated queries can expose private rows, join incorrectly, omit time filters, scan huge tables, or modify production state. A safe design does not grant the model a raw database credential. It exposes a read-only query service with an approved schema, row-level authorization, resource limits, and deterministic validation.

Provide the model with selected table and column descriptions, relationships, units, time semantics, and allowed operations. Prefer parameterized templates or an abstract query representation for high-risk systems. If free SQL is accepted, parse it into an AST; reject multiple statements, comments used for bypass, DDL/DML, forbidden functions, unapproved schemas, missing tenant filters, unbounded results, and excessive estimated cost. Execute with a read-only role, timeout, row limit, and isolated replica.

Validate correctness on a dataset with known answers, including joins, aggregation, nulls, dates, duplicate keys, ambiguous names, and empty results. Compare execution result, not string equality, while also checking that the query respects policy. Return typed rows plus schema and truncation status. The agent must not invent missing rows or treat an execution error as an empty set.

Part 2 - Mathematical form and reasoning

Query acceptance is

$$G(q) = I_{\text{parse}} I_{\text{read only}} I_{\text{schema}} I_{\text{row policy}} I_{\text{cost}} I_{\text{bounded}}.$$

Execution accuracy on test i can compare canonicalized result multisets:

$$A = \frac{1}{N} \sum_{i} I(\mathcal{R}(q_i) = \mathcal{R}(q_i^*)).$$

When ordering is required, compare ordered sequences; otherwise do not mark a semantically correct query wrong because row order differs.

Part 3 - Hints and Helper

1. Use a read-only replica and least-privilege database role.
2. Expose only approved schema metadata.
3. Parse SQL into an AST; never validate with keywords alone.
4. Enforce tenant predicates, row limits, timeout, and cost budget.
5. Parameterize user values instead of interpolating text.
6. Test joins, nulls, dates, duplicates, empty sets, and truncation.
7. Compare executed results and policy validity.
8. Distinguish query error, no rows, and partial/truncated result.

Part 4 - Python code skeleton

```
from dataclasses import dataclass

@dataclass
class QueryRequest:
    sql: str
    parameters: dict
    tenant_id: str
    maximum_rows: int

def validate_query(parsed_query, request, policy):
    errors = []
    if parsed_query.statement_type != "SELECT":
        errors.append("read_only_required")
    if len(parsed_query.statements) != 1:
        errors.append("single_statement_required")
    for table_name in parsed_query.tables:
        if table_name not in policy.allowed_tables:
            errors.append("forbidden_table:" + table_name)
    if not parsed_query.has_tenant_predicate("tenant_id"):
```

```
        errors.append("missing_tenant_filter")
    if request.maximum_rows > policy.maximum_rows:
        errors.append("row_limit_exceeded")
    if parsed_query.estimated_cost > policy.maximum_cost:
        errors.append("query_cost_exceeded")
    return errors

def execute_sql_tool(request, parser, policy, connection):
    parsed = parser.parse(request.sql)
    errors = validate_query(parsed, request, policy)
    if len(errors) > 0:
        return {"status": "denied", "errors": errors}
    rows = connection.execute_read_only(
        request.sql,
        request.parameters,
        timeout_seconds=policy.timeout_seconds,
        maximum_rows=request.maximum_rows,
    )
    return {"status": "succeeded", "rows": rows, "truncated": False}
```

Part 5 - The Philosophy Behind the Exercise

Natural language is flexible; databases are literal. SQL integration joins those worlds at a boundary where ambiguity can become data exposure or a wrong decision. The parser and policy make the boundary explicit.

The model should be allowed to ask a precise question of the database, not to inherit the database's authority. Access remains a governed capability.

18.10.12 Exercise 11

Exercise Title: Integrate Vector DB Search and Measure Recall vs Latency Tradeoffs

Part 1 - Why this matters

Approximate nearest-neighbor indexes trade search effort for speed and memory. Increasing candidate depth, probe count, or ef-search can recover more relevant chunks while increasing latency. Larger top-k may improve evidence recall but also burdens reranking and context packing with distractors. Integration should select an operating point from measured end-to-end behavior.

Create a gold query set with one or more supporting chunk IDs. Benchmark exact search on a manageable subset to establish an upper bound, then sweep index parameters, top-k, filters, and concurrency. Record index type, distance metric, embedding model, dimension, corpus size, shard/replica layout, warm-up, cache state, CPU/GPU, and network placement.

Measure recall@k, MRR, nDCG where graded relevance exists, p50/p95/p99 search latency, throughput, index memory, reranker cost, and final answer quality. Test metadata filters because selective filters can change both recall and latency. Inspect queries whose gold evidence

remains far away even under exact search; their problem is representation or chunking, not ANN tuning.

Part 2 - Mathematical form and reasoning

Evidence recall is

$$R@k = \frac{1}{N} \sum_i I(D_k(q_i) \cap G_i \neq \varnothing).$$

Approximation recall relative to exact top-k is

$$R_{\text{ANN}}@k = \frac{1}{N} \sum_i \frac{|D_k^{\text{ANN}}(q_i) \cap D_k^{\text{exact}}(q_i)|}{k}.$$

Choose a non-dominated configuration satisfying minimum evidence recall and maximum tail latency rather than maximizing search recall without regard to the rest of RAG.

Part 3 - Hints and Helper

1. Build gold supporting-chunk labels and an exact-search reference subset.
2. Sweep ANN effort, top-k, filters, and concurrency.
3. Warm the index and measure cold behavior separately.
4. Report search and end-to-end RAG quality.
5. Include p99 latency and failures, not only mean latency.
6. Inspect embedding/chunking failures that tuning cannot repair.
7. Measure index memory and rebuild/update cost.
8. Select the Pareto operating point under service constraints.

Part 4 - Python code skeleton

```
from time import perf_counter

def evidence_recalled(result_ids, gold_ids):
    gold_set = set(gold_ids)
    for result_id in result_ids:
        if result_id in gold_set:
            return True
    return False

def benchmark_search(database, queries, configurations):
    rows = []
    for configuration in configurations:
        recalled = 0
```

```
        latencies = []
        for query in queries:
            started = perf_counter()
            results = database.search(
                vector=query.vector,
                top_k=configuration["top_k"],
                search_effort=configuration["search_effort"],
                filters=query.filters,
            )
            elapsed_ms = (perf_counter() - started) * 1000.0
            latencies.append(elapsed_ms)
            result_ids = []
            for result in results:
                result_ids.append(result["chunk_id"])
            if evidence_recalled(result_ids, query.gold_chunk_ids):
                recalled += 1
        ordered = sorted(latencies)
        p95_index = int(0.95 * (len(ordered) - 1))
        rows.append({
            "configuration": configuration,
            "evidence_recall": recalled / len(queries),
            "p95_latency_ms": ordered[p95_index],
        })
    return rows
```

Part 5 - The Philosophy Behind the Exercise

Search is a physical approximation to a semantic intention. More computation can explore the index more thoroughly, but it cannot guarantee that the embedding space represents relevance correctly.

The tradeoff teaches restraint: optimize the component only until it supports the system's evidence obligation. Beyond that point, additional recall may be expensive noise.

18.10.13 Exercise 12

Exercise Title: Implement Tool Result Verification to Prevent Hallucinated Answers

Part 1 - Why this matters

A successful tool call does not guarantee a correct final answer. The result may be partial, stale, malformed, truncated, internally inconsistent, or misinterpreted by the model. Conversely, when a tool fails, the model may fill the gap with a plausible value. Build a verification layer that establishes whether the observation is suitable for the claim the agent wants to make.

Validate transport status, call ID, output schema, units, ranges, timestamps, completeness, checksums, row counts, and provenance. For high-impact results, cross-check with an independent source or deterministic calculation. Bind claims to result fields and forbid the model from presenting an unverified value as confirmed. Distinguish unavailable, failed, partial, stale,

contradictory, and verified states.

Test adversarial results containing prompt injection, fake success fields, incorrect units, duplicated rows, missing pages, and inconsistent totals. The verifier should return structured evidence and reasons, not merely a boolean. If verification fails, retry safely, request clarification, escalate, or abstain; do not silently downgrade the evidence requirement.

Part 2 - Mathematical form and reasoning

For result o, verification is a conjunction of predicates:

$$V(o) = V_{\text{status}} V_{\text{schema}} V_{\text{fresh}} V_{\text{complete}} V_{\text{consistent}} V_{\text{provenance}}.$$

Claim c is supported only if required fields $F(c)$ are verified and an entailment rule holds:

$$S(c, o) = I(F(c) \subseteq F_{\text{verified}}(o)) I(o \models c).$$

Verification cost should scale with consequence; independent confirmation may be mandatory above a risk threshold.

Part 3 - Hints and Helper

1. Bind every observation to the originating call ID.
2. Validate schema, units, ranges, freshness, completeness, and provenance.
3. Represent partial and stale results explicitly.
4. Map final claims to verified fields.
5. Cross-check high-impact outputs independently.
6. Treat tool text as untrusted and strip embedded instructions.
7. Fail closed when required verification is unavailable.
8. Inject malformed, truncated, contradictory, and fake-success results.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from enum import Enum

class VerificationStatus(Enum):
    VERIFIED = "verified"
    PARTIAL = "partial"
    STALE = "stale"
    INVALID = "invalid"

@dataclass
```

```
class VerificationResult:
    status: VerificationStatus
    verified_fields: set
    reasons: list
    sanitized_payload: dict

def verify_tool_result(call, observation, schema, current_time):
    reasons = []
    verified_fields = set()
    if observation["call_id"] != call.call_id:
        reasons.append("call_id_mismatch")
    if observation["status"] != "succeeded":
        reasons.append("tool_did_not_succeed")
    payload = schema.sanitize(observation.get("payload", {}))
    validation_errors = schema.validate(payload)
    reasons.extend(validation_errors)
    if observation.get("expires_at") is not None:
        if observation["expires_at"] <= current_time:
            return VerificationResult(
                VerificationStatus.STALE, set(), ["expired"], payload
            )
    if len(reasons) > 0:
        return VerificationResult(
            VerificationStatus.INVALID, set(), reasons, payload
        )
    for field_name in payload.keys():
        verified_fields.add(field_name)
    return VerificationResult(
        VerificationStatus.VERIFIED, verified_fields, [], payload
    )
```

Part 5 - The Philosophy Behind the Exercise

Observation is not yet knowledge. It becomes usable knowledge when its identity, meaning, completeness, and relation to a claim have been checked. This is the same discipline applied in science, accounting, and reliable software.

Verification protects the boundary between what happened and what the agent wishes had happened. That boundary is the heart of truthful tool use.

18.10.14 Exercise 13

Exercise Title: Compare Single-Step vs Multi-Step Agent Reasoning

Part 1 - Why this matters

Single-step systems choose one tool or answer directly. They are fast, predictable, and easier to secure, but cannot solve tasks requiring sequential dependencies. Multi-step agents can retrieve, transform, verify, and revise, yet accumulate error, cost, latency, and loop risk.

Compare both on tasks whose dependency depth is known.

Create strata requiring zero, one, two, or several tool dependencies. Give both systems the same tools, permissions, evidence, and task budget. A single-step system should not be penalized on a task impossible within one action without making that limitation explicit. Measure task success, false success, tool accuracy, steps, redundant calls, recovery, latency, tokens, cost, and safety violations.

Test whether a planner adds value beyond repeated free-form generation. Require multi-step plans to update after observations and verify the final condition. Inspect cases where extra reasoning amplifies a false assumption. Recommend the least complex architecture that satisfies task depth and reliability gates; agentic complexity is a cost, not an achievement by itself.

Part 2 - Mathematical form and reasoning

If each step succeeds independently with probability p, a required d-step chain has approximate success

$$P_{\text{chain}} \approx p^d.$$

Verification and recovery can change this, while correlated errors make the independence assumption optimistic. Define net utility

$$U = A - \lambda_L L - \lambda_C C - \lambda_R R,$$

where A is task achievement, L latency, C resource cost, and R safety risk. Compare within task-depth strata rather than averaging incompatible tasks.

Part 3 - Hints and Helper

1. Label the minimum dependency depth of every task.
2. Give systems identical tools, permissions, and evidence.
3. Define externally verified success conditions.
4. Count useful, redundant, failed, and repeated tool calls.
5. Measure false-success claims separately.
6. Test replanning after changed observations.
7. Report results by task depth and risk.
8. Prefer the simplest system that passes required gates.

Part 4 - Python code skeleton

```
from collections import defaultdict
from dataclasses import dataclass

@dataclass
class ReasoningRun:
    architecture: str
    task_id: str
    required_depth: int
    verified_success: bool
    claimed_success: bool
    steps: int
    redundant_calls: int
    latency_ms: float
    cost: float

def summarize_by_depth(runs):
    grouped = defaultdict(list)
    for run in runs:
        key = (run.architecture, run.required_depth)
        grouped[key].append(run)

    rows = []
    for key, group in grouped.items():
        success = 0
        false_success = 0
        total_steps = 0
        total_cost = 0.0
        for run in group:
            success += int(run.verified_success)
            false_success += int(
                run.claimed_success and not run.verified_success
            )
            total_steps += run.steps
            total_cost += run.cost
        rows.append({
            "architecture": key[0],
            "required_depth": key[1],
            "success_rate": success / len(group),
            "false_success_rate": false_success / len(group),
            "mean_steps": total_steps / len(group),
            "mean_cost": total_cost / len(group),
        })
    return rows
```

Part 5 - The Philosophy Behind the Exercise

More thought is not automatically better thought. Additional steps create room for checking and adaptation, but also for drift and self-deception. Complexity must justify itself through tasks that genuinely require it.

Good engineering uses the minimum agency necessary. A one-step answer is elegant when sufficient; a multi-step process is responsible when the world demands evidence, dependency, and revision.

18.10.15 Exercise 14

Exercise Title: Debug Agent Failure Under Partial Tool Errors

Part 1 - Why this matters

Real tools rarely fail as a clean all-or-nothing event. A paginated search may return two pages and time out on the third. A batch API may update some records. A database replica may be stale. A payment may succeed while its acknowledgment is lost. Agents that interpret any payload as complete success or retry entire operations blindly can produce wrong answers and duplicated side effects.

Require tools to return structured status: succeeded, partial, failed, unknown, or denied; completed and failed item IDs; continuation token; freshness; idempotency key; and retry guidance. The agent state must preserve partial progress. Define per-tool recovery: resume from checkpoint, retry failed items, query operation status, compensate completed side effects, switch replica, ask for confirmation, or escalate.

Inject failures at every boundary and step. Test timeouts before execution, during execution, and after success but before acknowledgment. Verify that the final answer labels incomplete evidence and never claims full completion. Measure recovery success, duplicate side effects, lost work, additional cost, time to safe state, and false-success rate.

Part 2 - Mathematical form and reasoning

For a batch of items B, preserve disjoint sets

$$B = C \cup F \cup U, \qquad C \cap F = C \cap U = F \cap U = \varnothing,$$

where C completed, F failed, and U has unknown status. Retry only a set approved by tool semantics. Completion can be reported only when

$$F = \varnothing \wedge U = \varnothing$$

or the user explicitly accepts a documented partial result.

Part 3 - Hints and Helper

1. Define succeeded, partial, failed, unknown, and denied statuses.
2. Return completed, failed, and unknown item IDs.
3. Persist checkpoints and idempotency keys outside model context.
4. Query status before retrying ambiguous side effects.

5. Retry only failed or safe items according to tool semantics.
6. Label incomplete evidence in the final response.
7. Inject failures before, during, and after external execution.
8. Measure duplication, lost work, recovery, and false completion.

Part 4 - Python code skeleton

```
from dataclasses import dataclass, field
from enum import Enum

class BatchStatus(Enum):
    SUCCEEDED = "succeeded"
    PARTIAL = "partial"
    FAILED = "failed"
    UNKNOWN = "unknown"

@dataclass
class BatchObservation:
    operation_id: str
    status: BatchStatus
    completed_ids: set = field(default_factory=set)
    failed_ids: set = field(default_factory=set)
    unknown_ids: set = field(default_factory=set)

def validate_partition(requested_ids, observation):
    combined = (
        observation.completed_ids
        | observation.failed_ids
        | observation.unknown_ids
    )
    if combined != set(requested_ids):
        raise ValueError("result partition does not match request")
    if observation.completed_ids & observation.failed_ids:
        raise ValueError("completed and failed overlap")
    if observation.completed_ids & observation.unknown_ids:
        raise ValueError("completed and unknown overlap")

def recovery_action(observation, tool):
    if len(observation.unknown_ids) > 0:
        return "query_operation_status"
    if len(observation.failed_ids) > 0 and tool.safe_item_retry:
        return "retry_failed_items_only"
```

```
    if observation.status == BatchStatus.SUCCEEDED:
        return "verify_and_finish"
    return "human_escalation"
```

Part 5 - The Philosophy Behind the Exercise

Partial failure reveals that the world does not share the clean transactional boundaries imagined in a prompt. Reliable agents must remember what is known, what happened, and what remains uncertain without collapsing those categories.

Recovery is not repeating hope. It is reasoning from durable state and choosing an action whose consequences remain bounded.

18.10.16 Exercise 15

Exercise Title: Build Production Agent Monitoring and Logging

Part 1 - Why this matters

Agent systems make decisions across model, retrieval, memory, policy, and tool boundaries. A final HTTP status cannot explain why a task failed or whether an external side effect occurred. Build distributed traces that preserve the causal chain while respecting privacy. Every request needs a trace ID; every model turn, retrieval, policy decision, tool call, verification, retry, memory write, and final response needs a span linked to its parent.

Record release identity, prompt template, model, token counts, and retrieved chunk IDs. Add tool and schema versions, argument hashes, policy outcome, executor status, latency, retry metadata, idempotency information, verification, termination reason, and cost. Avoid raw secrets, credentials, unnecessary personal data, and complete sensitive prompts. Use redaction, access control, encryption, retention limits, and separate audit logs for privileged actions.

Monitor task success, false success, tool failure, denied calls, repeated actions, loop/budget stops, RAG recall proxies, citation verification, memory errors, p95/p99 latency, queue depth, cost, and human escalations. Establish baselines and alerts with minimum volume and repeated windows. Link each alert to representative traces and a runbook. Test observability by injecting failures and missing telemetry; a silent monitor is itself a production failure.

Part 2 - Mathematical form and reasoning

Trace latency obeys a critical-path relation rather than the sum of parallel spans. For a sequential chain,

$$T_{\text{trace}} \approx \sum_{j} T_j,$$

while concurrent child spans contribute approximately their maximum plus coordination overhead. Define error-budget burn over window w:

$$B_w = \frac{\text{observed bad-event rate}_w}{\text{allowed bad-event rate}}.$$

Alerting can combine burn rate, sample minimum, and consecutive windows to avoid both silence and noise.

Part 3 - Hints and Helper

1. Propagate trace and call IDs through every component.
2. Log decisions and hashes without exposing secrets or unnecessary raw text.
3. Separate operational logs from immutable privileged-action audit records.
4. Track verified task outcomes and false-success claims.
5. Monitor loop stops, denials, retries, partial results, and memory writes.
6. Add release, schema, prompt, corpus, and tool versions.
7. Link alerts to traces, owners, and runbooks.
8. Inject known failures to verify observability end to end.

Part 4 - Python code skeleton

```
from contextlib import contextmanager
from dataclasses import dataclass, field
from time import perf_counter

@dataclass
class Span:
    trace_id: str
    span_id: str
    parent_id: str
    name: str
    attributes: dict = field(default_factory=dict)
    duration_ms: float = 0.0
    status: str = "unknown"

class TraceRecorder:
    def __init__(self, sink, redactor):
        self.sink = sink
        self.redactor = redactor

    @contextmanager
    def span(self, span):
        started = perf_counter()
        try:
            yield span
            span.status = "succeeded"
        except Exception as exc:
            span.status = "failed"
            span.attributes["error_type"] = type(exc).__name__
```

```
            raise
        finally:
            span.duration_ms = (perf_counter() - started) * 1000.0
            safe_attributes = self.redactor.clean(span.attributes)
            span.attributes = safe_attributes
            self.sink.write(span)

def record_tool_call(recorder, span, call, execute):
    with recorder.span(span):
        span.attributes["tool_name"] = call.tool_name
        span.attributes["call_id"] = call.call_id
        result = execute(call)
        span.attributes["tool_status"] = result.status
        return result
```

Part 5 - The Philosophy Behind the Exercise

Observability is the system's capacity to remember how it acted. Without that memory, an agent's apparent autonomy becomes opacity: nobody can distinguish a reasoned action from an accident or a reported success from a real one.

Good monitoring does not watch everything indiscriminately. It preserves the minimum causal evidence needed for accountability while respecting the people whose data passes through the system.

18.10.17 Exercise 16

Exercise Title: Stress Test Agent System Under Concurrent Requests

Part 1 - Why this matters

Concurrency exposes failures invisible in single-agent demos. Requests compete for model batches, vector indexes, database pools, tool quotas, memory locks, and human-review capacity. Shared state can leak across tenants, duplicate tool calls can race, idempotency keys can collide, and long agent loops can starve short tasks. A correct isolated trace does not prove a correct shared system.

Build closed-loop and open-loop workloads with realistic task-depth, prompt length, retrieval size, tool mix, and side-effect frequency. Include hot keys, same-user concurrent turns, different tenants, cancellations, tool throttling, slow dependencies, and partial failures. Use unique trace and idempotency IDs; verify that state and memory remain isolated. Bound concurrency and queue sizes so overload becomes controlled rejection rather than collapse.

Measure queue time, TTFT, task completion, p95/p99 latency, throughput, tool and model saturation, retries, duplicate effects, cross-request contamination, loop stops, errors, fallbacks, and cost. Sweep offered load until throughput flattens and tail latency grows. Define a capacity point below that saturation knee with explicit headroom and service-level constraints.

Part 2 - Mathematical form and reasoning

For stable service, Little's law gives

$$L = \lambda W,$$

where L is average in-flight work, λ completed request rate, and W mean time in system. Capacity is the maximum offered load satisfying all gates:

$$\lambda^* = \max_{\lambda} \{\lambda : p_{99}(T) \le S_T,\ r_{\text{error}} \le S_E,\ r_{\text{duplicate}} = 0,\ r_{\text{leak}} = 0\}.$$

Zero duplication and cross-tenant leakage are invariants, not percentile goals.

Part 3 - Hints and Helper

1. Model prompt length, task depth, tool mix, and arrival pattern.
2. Test closed-loop and open-loop traffic separately.
3. Inject slow tools, rate limits, cancellations, and partial failures.
4. Verify tenant, memory, trace, and idempotency isolation.
5. Bound queues and implement overload rejection.
6. Measure tail latency, success, duplicates, leakage, and cost.
7. Sweep load to locate the saturation knee.
8. Repeat runs and preserve every failed trace.

Part 4 - Python code skeleton

```
from concurrent.futures import ThreadPoolExecutor, as_completed
from dataclasses import dataclass
from time import perf_counter

@dataclass
class LoadResult:
    request_id: str
    tenant_id: str
    ok: bool
    latency_ms: float
    tool_calls: int
    duplicate_effect: bool
    leaked_tenant_id: str
    error_type: str

def execute_request(agent, request):
    started = perf_counter()
    try:
```

```
        output = agent.run(request)
        latency = (perf_counter() - started) * 1000.0
        return LoadResult(
            request.request_id,
            request.tenant_id,
            True,
            latency,
            output.tool_calls,
            output.duplicate_effect,
            output.leaked_tenant_id,
            "",
        )
    except Exception as exc:
        latency = (perf_counter() - started) * 1000.0
        return LoadResult(
            request.request_id, request.tenant_id, False,
            latency, 0, False, "", type(exc).__name__
        )

def run_concurrent(agent, requests, workers):
    results = []
    with ThreadPoolExecutor(max_workers=workers) as executor:
        futures = []
        for request in requests:
            futures.append(executor.submit(execute_request, agent, request))
        for future in as_completed(futures):
            results.append(future.result())
    return results
```

Part 5 - The Philosophy Behind the Exercise

Concurrency transforms independent intentions into a shared-resource problem. Failures arise not because any request is unreasonable, but because their timing creates contention, interference, and ambiguity about ownership.

Stress testing asks whether the agent remains bounded and truthful when the world is crowded. Production readiness begins where the isolated demonstration ends.

18.10.18 Exercise 17

Exercise Title: Build Agent Safety Checklist for Production Use

Part 1 - Why this matters

Agent safety spans architecture, identity, tools, data, memory, reliability, operations, and governance. A checklist converts these obligations into release gates with evidence. It must fail closed when a required item is unknown, and it must not reduce safety to a reassuring count of checked boxes. One missing authorization or rollback gate can invalidate the entire deployment.

Cover scoped goals, supported domains, success/stop conditions, tool inventory, side-effect classification, least privilege, schemas, ownership validation, confirmation, idempotency, sandboxing, prompt-injection defense, data classification, memory retention/deletion, tenant isolation, retrieval access, result verification, loop budgets, human escalation, monitoring, incident response, fallback, rollback, testing, red-teaming, privacy, and compliance.

Give every gate a stable ID, requirement, owner, evidence URI, last test date, expiry, status, and waiver with approver and end date. Separate static design review from executable tests that must run per release and hardware profile. Drill denial, tool outage, partial success, leakage attempt, loop, overload, and rollback. Revisit the checklist after incidents and architecture changes.

Part 2 - Mathematical form and reasoning

Required release readiness is conjunctive:

$$G_{\text{release}} = \bigwedge_{k \in \mathcal{K}_{\text{required}}} G_k.$$

Risk prioritization may use

$$R_k = P_k S_k E_k,$$

but risk scores do not waive hard requirements. Evidence freshness can be a predicate $I(t_{\text{now}} - t_{\text{test}} \leq \Delta_k)$; stale evidence fails the gate unless an authorized time-limited waiver exists.

Part 3 - Hints and Helper

1. Use stable gate IDs, owners, evidence, and expiry dates.
2. Make required readiness a conjunction, not a percentage.
3. Separate design assertions from executable release tests.
4. Cover identity, permissions, tools, data, memory, loops, and operations.
5. Drill denial, outage, partial success, overload, and rollback.
6. Time-limit waivers and record explicit residual risk.
7. Fail on missing or stale evidence.
8. Update gates after every incident and architecture change.

Part 4 - Python code skeleton

```
from dataclasses import dataclass
from datetime import date

@dataclass
class SafetyGate:
```

```
    gate_id: str
    required: bool
    passed: bool
    owner: str
    evidence_uri: str
    tested_on: str
    expires_on: str
    waiver_expires_on: str = ""

def gate_is_current(gate, today):
    expiry = date.fromisoformat(gate.expires_on)
    return expiry >= today

def waiver_is_valid(gate, today):
    if gate.waiver_expires_on == "":
        return False
    expiry = date.fromisoformat(gate.waiver_expires_on)
    return expiry >= today

def evaluate_safety_gates(gates, today):
    failures = []
    for gate in gates:
        if not gate.required:
            continue
        evidence_present = gate.evidence_uri.strip() != ""
        current = gate_is_current(gate, today)
        waived = waiver_is_valid(gate, today)
        if not evidence_present:
            failures.append(gate.gate_id + ":missing_evidence")
        elif not current:
            failures.append(gate.gate_id + ":stale_evidence")
        elif not gate.passed and not waived:
            failures.append(gate.gate_id + ":failed")
    return {"ready": len(failures) == 0, "failures": failures}
```

Part 5 - The Philosophy Behind the Exercise

A checklist is institutional memory made executable. It preserves lessons that individual engineers would otherwise forget under schedule pressure and forces important claims to produce evidence.

Its deepest value is conjunctive thinking. Complex systems often fail through one neglected boundary, so safety cannot be averaged into existence.

18.10.19 Exercise 18

Exercise Title: Document Architecture Decisions for RAG and Agent Systems

Part 1 - Why this matters

RAG and agent systems accumulate consequential choices: chunking, embedding, index, reranker, context policy, model, tool boundary, memory type, planning loop, verification, guardrails, observability, and fallback. When the reasons are not recorded, later teams inherit implementation without assumptions and repeat debates after conditions have changed. Use architecture decision records (ADRs) to preserve the decision, evidence, alternatives, and consequences.

Each ADR should contain context, problem, forces, hard constraints, considered options, decision, rationale, evidence, security/privacy implications, operational consequences, rejected alternatives, unknowns, owner, status, date, and re-evaluation triggers. Link to benchmarks and threat models rather than copying results without provenance. Keep decisions small enough to revise independently; "use an agent" is too broad for one useful record.

Record interface contracts and data flows. State where authorization occurs, which component owns retries, how memory is deleted, how result verification is performed, and what happens when retrieval or tools fail. Mark decisions as proposed, accepted, superseded, or retired. Test documentation through a design review: a new engineer should reconstruct the current architecture and explain why major alternatives were rejected.

Part 2 - Mathematical form and reasoning

An option j can be represented by measurable consequences

$$\mathbf{m}_j = (Q_j, L_j, C_j, R_j, M_j, O_j),$$

for quality, latency, cost, risk, memory, and operational complexity. Hard constraints define the feasible set $\mathcal{F}$; preferences select within it. Sensitivity analysis asks whether the decision changes when assumptions or weights change. A fragile decision receives an earlier review trigger.

Part 3 - Hints and Helper

1. Write one decision per ADR with a stable identifier.
2. State constraints, assumptions, alternatives, and evidence.
3. Record security, privacy, reliability, and operational consequences.
4. Document failure ownership and fallback behavior at interfaces.
5. Link benchmarks, diagrams, threat models, and schemas.
6. Mark proposed, accepted, superseded, and retired states.
7. Define measurable re-evaluation triggers.
8. Review whether a new engineer can reconstruct the rationale.

Part 4 - Python code skeleton

```
from dataclasses import asdict, dataclass
from typing import List
import json

@dataclass
class ArchitectureDecision:
    decision_id: str
    title: str
    status: str
    context: str
    constraints: List[str]
    alternatives: List[str]
    decision: str
    rationale: str
    consequences: List[str]
    evidence_uris: List[str]
    owner: str
    decision_date: str
    reevaluation_triggers: List[str]
    supersedes: str = ""

def validate_decision(record):
    errors = []
    if len(record.alternatives) < 2:
        errors.append("insufficient_alternatives")
    if record.rationale.strip() == "":
        errors.append("missing_rationale")
    if len(record.evidence_uris) == 0:
        errors.append("missing_evidence")
    if len(record.reevaluation_triggers) == 0:
        errors.append("missing_reevaluation_triggers")
    return errors

def save_decisions(records, output_path):
    payload = []
    for record in records:
        errors = validate_decision(record)
        if len(errors) > 0:
            raise ValueError(record.decision_id + ":" + ",".join(errors))
        payload.append(asdict(record))
    with open(output_path, "w", encoding="utf-8") as handle:
        json.dump(payload, handle, indent=2, sort_keys=True)
```

Part 5 - The Philosophy Behind the Exercise

Architecture is a history of constrained choices. Code shows what the system does now; a decision record explains why this form was considered responsible under the evidence available then.

Documentation makes architecture revisable without making it arbitrary. Future engineers can preserve a sound rationale or replace it when its assumptions no longer hold.

18.10.20 Exercise 19

Exercise Title: Produce a Final LLM Systems Engineering Report

Part 1 - Why this matters

The final report is the auditable release argument for the complete RAG and agent system. It must identify model, tokenizer, prompts, corpus, chunks, embedding model, vector index, reranker, tools, schemas, policies, memory stores, runtime, deployment, and code revision. Hash artifacts and preserve exact versions so measured behavior remains connected to the system that produced it.

Describe architecture and trust boundaries before results. Include data flows, identity and authorization, tool side effects, confirmation, idempotency, sandboxing, retrieval access filters, memory lifecycle, planning budgets, result verification, partial-error recovery, monitoring, human escalation, and rollback. Link each choice to an ADR and threat-model obligation.

Report retrieval recall, context and citation quality, task success, false success, tool selection and argument validity, SQL execution accuracy, memory precision/leakage, loop rate, recovery, safety denials, latency/throughput under concurrency, cost, human review, and known failure slices. Include denominators, uncertainty, workload, hardware, injected failures, rejected variants, and raw evidence. End with supported/unsupported uses, release gates, residual risks, owners, canary plan, monitors, incident runbooks, rollback target, and revalidation date. Independent review should reproduce selected claims.

Part 2 - Mathematical form and reasoning

Release readiness is conjunctive:

$$G = G_{\text{identity}} \wedge G_{\text{RAG}} \wedge G_{\text{tools}} \wedge G_{\text{memory}} \wedge G_{\text{safety}} \wedge G_{\text{reliability}} \wedge G_{\text{operations}} \wedge G_{\text{rollback}}.$$

Traceability follows

$$\text{requirement} \to \text{design decision} \to \text{test} \to \text{evidence} \to \text{control} \to \text{monitor}.$$

Unknown or missing required evidence fails closed. Performance cannot compensate for a failed authorization, isolation, verification, or rollback gate.

Part 3 - Hints and Helper

1. Hash and version every model, data, index, prompt, schema, policy, and runtime artifact.
2. Map architecture, data flows, trust boundaries, and side effects.

3. Link requirements to ADRs, tests, raw evidence, controls, and monitors.
4. Include quality, safety, reliability, latency, concurrency, and cost.
5. Report injected failures, rejected designs, and unresolved unknowns.
6. State supported uses, prohibited uses, and human escalation rules.
7. Include canary, incident response, fallback, rollback, and owners.
8. Require independent reproduction and a dated revalidation decision.

Part 4 - Python code skeleton

```
from dataclasses import asdict, dataclass, field
from datetime import datetime, timezone
from typing import Dict, List
import json

@dataclass
class SystemGate:
    name: str
    requirement: str
    observed: str
    evidence_uri: str
    owner: str
    passed: bool

@dataclass
class SystemsReport:
    release_id: str
    created_at: str
    artifact_hashes: Dict[str, str]
    architecture_decisions: List[str]
    gates: List[SystemGate] = field(default_factory=list)
    supported_uses: List[str] = field(default_factory=list)
    prohibited_uses: List[str] = field(default_factory=list)
    residual_risks: List[str] = field(default_factory=list)
    rollback_release: str = ""
    revalidation_date: str = ""
    decision: str = "pending"

def validate_report(report, required_gates):
    errors = []
    by_name = {}
    for gate in report.gates:
```

```
        by_name[gate.name] = gate
    for gate_name in required_gates:
        if gate_name not in by_name:
            errors.append("missing_gate:" + gate_name)
            continue
        gate = by_name[gate_name]
        if not gate.passed:

Part 5 - The Philosophy Behind the Exercise

An agentic system is not merely a model with additional functions. It is a network of authorities, memories, observations, actions, and recovery paths. Engineering quality lies in how those relations are bounded and evidenced.

The report preserves a disciplined claim: this system may act in these ways, under these conditions, because these tests and controls justify that authority. Monitoring and rollback keep the claim open to correction when reality changes. ==== Book19: DMM (Dynamic Memory Management) ====

Book 19

Dynamic Memory Management

19.1 Introduction

19.1.1 What will the book teach you

Modern artificial intelligence systems are often described through model architecture, parameter count, training loss, and computational throughput. Those quantities are important, but they do not fully determine whether a system can be trained or served. A model may have mathematically valid operations and sufficient arithmetic performance while still being impossible to execute because its parameters, activations, gradients, optimizer states, temporary workspaces, communication buffers, or inference caches cannot reside in the available memory at the required time. Dynamic memory management is the discipline of deciding what should exist, where it should exist, when it should move, how long it should remain alive, and what should happen when the original plan no longer fits the physical machine.

This book studies memory as an active part of the artificial intelligence runtime rather than as a passive container for tensors. The reader will move beyond the simple question "How much VRAM does this model use?" and learn to ask a more complete set of questions. Which allocations are persistent and which are temporary? Which tensor owns a storage object, and which tensor is only a view into that storage? What is the difference between memory that is allocated by PyTorch, memory reserved by the caching allocator, and memory reported as used by the operating system or GPU driver? At what instant does peak memory occur? Can a tensor be recomputed more cheaply than it can be stored? Can data movement be hidden behind useful computation? Can a runtime recover when an estimated budget is wrong? These questions turn memory from an afterthought into an engineering model that can be predicted, measured, and controlled.

The central problem is the growing separation between the capacity demanded by AI workloads and the capacity offered by the fastest memory tier. GPU VRAM is valuable because it provides the bandwidth and proximity needed by CUDA kernels, but it is limited and expensive. CPU RAM is usually larger, yet a tensor in ordinary pageable host memory cannot be consumed directly by a GPU kernel and may require a costly transfer. Pinned host memory can support more efficient asynchronous transfers, but it is a constrained system resource and should not be allocated carelessly. NVMe storage provides far greater capacity at much higher latency and lower bandwidth than RAM. A successful runtime must therefore reason across a hierarchy rather than pretend that every byte is equivalent:

GPU VRAM $\longleftrightarrow$ Pinned CPU Memory $\longleftrightarrow$ Pageable CPU Memory $\longleftrightarrow$ NVMe Storage.

Moving an object to a larger and slower tier increases available capacity, but it also introduces transfer latency, bandwidth pressure, synchronization, and new failure modes. Keeping every object in VRAM minimizes some transfers but may make the workload impossible to run. Evicting too aggressively may avoid an out-of-memory error while making the system slower than a CPU-only baseline. The goal is therefore not to minimize memory usage in isolation. The goal is to satisfy correctness and capacity constraints while choosing a defensible trade-off among memory, computation, transfer, latency, throughput, and reliability.

The book begins with observation because memory cannot be managed responsibly when it cannot be seen. The reader will learn the PyTorch CUDA memory APIs, memory statistics, profiler views, allocator summaries, and memory snapshots. These tools reveal different layers of the system and must not be interpreted as interchangeable measurements. In particular, a tensor that is deleted at the Python level does not imply that the corresponding block is immediately returned to the GPU driver. PyTorch may retain the block inside its caching allocator so that a later allocation can reuse it without paying the full cost of a device allocation. Consequently, `memory_allocated()`, `memory_reserved()`, peak statistics, and external device monitors can all report different values while each remains correct within its own definition. The reader will learn to explain those differences instead of treating them as contradictory evidence.

Allocator behavior then connects measurement to mechanism. Repeatedly creating and destroying differently sized tensors can produce inactive blocks, fragmentation, and a reserved pool that contains enough total free bytes but not a suitable contiguous block for the next request. A CUDA out-of-memory failure is therefore not always equivalent to "the model is larger than the GPU." It may be caused by a transient peak, a retained autograd graph, a growing Python container, a badly timed workspace, a batch-size spike, a fragmented allocator state, or an external process consuming the same device. The exercises will distinguish these cases by timeline, tensor ownership, allocation history, and reproducible evidence.

The next stage studies movement between CPU and GPU. The reader will compare pageable and pinned host buffers, blocking and non-blocking copies, default and custom CUDA streams, synchronization boundaries, CUDA events, and prefetching. An operation marked `non_blocking=True` is not automatically overlapped with useful work. True overlap depends on the source memory, the device, available copy engines, stream relationships, dependency ordering, and whether an accidental synchronization forces the host or device to wait. The book will therefore separate three claims that are often confused: an API call returned quickly to the CPU, a transfer executed asynchronously on the GPU timeline, and the transfer actually overlapped with computation. Each claim requires its own measurement.

Once movement is measurable, memory placement becomes a policy problem. Dynamic tensor placement, parameter placement, layer offloading, CPU offloading, NVMe offloading, and out-of-core execution all require the runtime to choose which objects occupy the fastest tier at each phase. A useful policy must account for object size, next-use time, transfer cost, recomputation cost, dependency order, available headroom, and the penalty of a wrong prediction. Simple policies such as first-in-first-out or least-recently-used eviction are valuable baselines, but neural network execution has more structure than a generic cache. The next layer is usu-

ally known, an activation may have a single future consumer, a parameter can be reused across many requests, and a KV cache entry may have semantic importance that is not represented by recency alone. The exercises will progress from explicit baselines to memory-aware decisions whose assumptions can be tested.

Training creates its own memory lifecycle. Parameters, gradients, optimizer states, saved activations, temporary kernels, data batches, and validation outputs do not reach their peaks at the same moment. Activation checkpointing reduces saved forward state by recomputing selected operations during backward. Activation offloading moves saved tensors to CPU memory and later restores them. Mixed precision changes both storage and numerical range. Gradient accumulation changes the relationship between micro-batch size and effective batch size. Adaptive batching changes work admitted by the runtime according to current headroom. None of these techniques creates free capacity: each exchanges memory for extra computation, transfer, latency, numerical risk, or optimization behavior. The reader will quantify the exchange rather than describing a technique only as "memory efficient."

Out-of-memory recovery is treated as a runtime protocol, not as a broad `try/except` block. CUDA work is asynchronous, and a failure can surface later than the operation that caused it. Partially completed training steps may leave gradients, optimizer state, data iterators, or random number generators in a condition that makes a careless retry incorrect. Recovery must identify a safe boundary, release recoverable references, restore invariants, modify the workload, and verify that the retry did not silently change the intended training semantics. The book will build failure injection tests so that recovery behavior is exercised deliberately before it is trusted in a long run.

The middle chapters move deeper into storage behavior. Memory pools and buffer reuse can reduce allocator traffic, but reuse requires precise lifetime and aliasing rules. In-place operations can save a temporary allocation while corrupting a value required by autograd. Views may share storage even when their shapes are different. A detached tensor may share the same bytes while leaving the gradient graph. The `meta` device can construct model structure without allocating parameter storage, but the parameters must later be materialized with correct shapes, devices, dtypes, initialization, and checkpoint mappings. Memory-mapped datasets and virtualized or paged tensor storage extend the same principle to objects that cannot be loaded eagerly. These chapters teach that a tensor is not merely a shape containing numbers; it has storage, ownership, lifetime, placement, and synchronization semantics.

Large language model inference introduces a particularly important dynamic object: the Key-Value cache. KV caching avoids recomputing attention keys and values for the entire prefix at every generation step, but its capacity grows with sequence length, batch size, layer count, head configuration, and data type. A server that accepts many long requests can exhaust memory through cache growth even when its model weights fit comfortably. The reader will study paged KV caches, CPU offloading, quantization, eviction, and context-retention policies. The correctness question is not only whether a cache operation saves memory. It must preserve token positions, request boundaries, attention masks, cache order, and the exact association between stored keys, values, layers, and sequences. A fast cache that retrieves the wrong history is a semantic failure, not a performance optimization.

Distributed execution expands the memory problem across devices. Fully Sharded Data Par-

allel, ZeRO-style partitioning, tensor parallelism, pipeline parallelism, and explicit multi-GPU balancing distribute parameters, gradients, optimizer states, activations, and communication buffers in different ways. Sharding reduces replication but creates all-gather, reduce-scatter, or point-to-point communication at specific times. Pipeline parallelism reduces per-device model residency but introduces stage imbalance, pipeline bubbles, and activation queues. Tensor parallelism splits individual operations but requires collectives in the critical path. The correct question is not "Which technique uses the least memory?" It is "Which objects are partitioned, which objects remain replicated, when are they materialized, what communication is introduced, and where does the new peak occur?"

The distributed chapters are designed to run on one multi-GPU computer. A two-GPU system is sufficient for the core experiments that compare one and two ranks, inspect per-device memory, and validate communication-aware placement. Two physical computers are not required. Multi-node execution may be explored as an optional extension when suitable hardware and networking are available, but it is not a prerequisite for completing the book. This distinction keeps the conceptual study of distributed memory separate from the operational complexity of configuring a cluster.

The final chapters bring the complete discipline together. CUDA events provide device-side timing needed to distinguish launch latency from executed GPU work. Bandwidth profiling shows whether an offload path is limited by PCIe transfer, host preparation, storage access, synchronization, or computation. Leak detection and autograd graph analysis locate memory that remains reachable longer than intended. `detach()`, `no_grad()`, and `inference_mode()` are compared through both graph semantics and measured allocation behavior. Finally, the reader will construct a custom memory manager and a custom offload engine. These projects require the earlier ideas to operate together: accounting, budgets, tensor identity, placement, eviction, prefetch, streams, correctness checks, metrics, recovery, and policy evaluation.

The objective of the final runtime is not to outperform every specialized framework. Its purpose is to prove that the reader can turn a memory-management idea into a controlled system. Every policy decision must produce evidence: what was moved, why it was selected, how much capacity was recovered, what transfer was introduced, whether execution remained correct, and how behavior changed when the workload or hardware budget changed. By the end of the book, the reader should be able to investigate an unfamiliar PyTorch memory problem from first principles rather than relying on a list of isolated fixes.

19.1.2 Why this book comes after large language models

The earlier books developed models from linear regression through perceptrons, MLPs, CNNs, RNNs, LSTMs, Transformers, and large language model systems. Each stage increased the number and diversity of objects that must remain alive during execution. A small classifier may be described adequately by its parameters and batch activations. A Transformer training step adds attention matrices, residual streams, normalization state, gradients, optimizer moments, temporary matrix-multiplication workspaces, and possibly multiple copies of state across devices. Autoregressive inference replaces many training objects with a KV cache whose size changes continuously as requests arrive, generate tokens, and finish.

This makes dynamic memory management a natural systems-level continuation of the model

books. The reader already knows what the tensors mean mathematically; the present book asks how those tensors can be scheduled on finite hardware. Attention explains why long context is useful, while this book explains why long context is expensive. Mixed precision was previously introduced as a training technique; here it is examined as one component in a memory budget with numerical and kernel constraints. Distributed training was previously a way to scale computation; here it is analyzed as a transformation of tensor residency, lifetime, replication, and communication. The model and the memory runtime are therefore not separate subjects. The model creates the lifetimes and dependencies that a correct memory policy must respect.

19.1.3 The seven-part structure of every exercise

Each exercise in this book is organized into seven parts. The order is deliberate. It prevents implementation from becoming trial and error and forces every result to connect a conceptual claim with a measurable system effect.

1. **Part 1 - Exercise Contract and Why It Matters.** This part defines the exact problem, the expected deliverable, the correctness conditions, the hardware assumptions, and the practical reason the exercise exists. It states what must be proved rather than merely what code must be written. A deep motivation is included so that an allocator statistic, transfer flag, or offload policy is connected to a real failure mode in training or inference.

2. **Part 2 - System and Memory Mental Model.** This part identifies every important object and relationship before any experiment begins. It explains tensor storage, lifetime, device placement, allocator state, stream dependencies, autograd ownership, or distributed partitioning as required by the exercise. The purpose is to create a model of the runtime that is detailed enough to predict behavior.

3. **Part 3 - Quantitative Prediction Before Execution.** The reader calculates expected tensor sizes, peak residency, transfer volume, bandwidth limits, operation order, or scaling behavior before running the program. Predictions must include units and assumptions. When an exact value cannot be known in advance, the reader defines a range or a directional hypothesis. The later difference between prediction and observation becomes evidence about hidden runtime costs.

4. **Part 4 - Experimental Design and Instrumentation.** This part defines the baseline, controlled variable, metrics, warm-up, synchronization, random seeds, repetitions, failure injection, and logging plan. Instrumentation is selected according to the claim being tested. Wall-clock timers, CUDA events, allocator counters, profiler traces, and snapshots answer different questions and cannot be substituted blindly.

5. **Part 5 - PyTorch/CUDA Implementation.** The system is implemented explicitly and readably. Tensor shapes, devices, dtypes, streams, events, masks, and ownership transitions remain visible. Convenience abstractions may be introduced only after a transparent reference implementation exists. The code must contain assertions and diagnostic output that make violations observable instead of allowing a silent incorrect result.

6. **Part 6 - Measurement, Validation, and Failure Analysis.** The implementation is tested against the original contract. Numerical parity, peak memory, throughput, latency, transfer overlap, allocator behavior, and recovery correctness are measured where relevant.

Failure cases are reproduced deliberately. The reader must locate the root cause, apply a correction, and create a regression test that detects the same failure if it returns.

7. **Part 7 - Engineering Interpretation and Philosophy.** The final part explains what the experiment means beyond one machine and one run. It separates universal principles from hardware-dependent observations, identifies the trade-off purchased by the technique, states when the method should not be used, and records remaining uncertainty. The philosophy of the exercise is to develop engineering judgment: a memory optimization is successful only when it preserves the intended computation and improves the resource constraint that actually limits the system.

The seven parts form one reasoning cycle:

$$\text{Understand} \longrightarrow \text{Model} \longrightarrow \text{Predict} \longrightarrow \text{Design} \longrightarrow \text{Implement} \longrightarrow \text{Measure} \longrightarrow \text{Interpret}.$$

This cycle is more important than any individual API. PyTorch and CUDA will continue to evolve, but the ability to define a contract, model lifetimes, predict a peak, design a valid measurement, and interpret a trade-off remains transferable.

19.1.4 How to study this book

Begin every exercise with a small, deterministic case. Write down the shapes, element counts, dtypes, expected byte sizes, devices, and lifetime boundaries. For a dense tensor with dimensions $n_1, \ldots, n_k$ and element size s bytes, the payload estimate begins with

$$B_{\text{tensor}} = s \prod_{i=1}^{k} n_i.$$

This is a starting point, not the complete process footprint. Storage may be shared by views; allocators round requests and reserve blocks; kernels may require temporary workspaces; autograd may save tensors; libraries and CUDA contexts consume device memory; and asynchronous work may keep an object alive past the line where Python appears to release it. The exercise should state which quantities are included in a prediction and which are expected to appear only in measurement.

Do not benchmark asynchronous CUDA work with an unsynchronized CPU timer and interpret the result as kernel duration. Use warm-up to remove initialization and compilation effects, synchronize at meaningful boundaries, and use CUDA events for device timeline measurements when appropriate. Repeat measurements and report variability. A single fast run is not a performance conclusion, and a single memory snapshot is not a lifetime analysis.

Do not trigger uncontrolled allocations merely to discover the physical limit of the machine. Estimate a safe budget, leave headroom for the CUDA context and temporary workspaces, and use bounded synthetic cases. Exercises involving out-of-memory behavior should fail inside a controlled scope and recover at a known boundary. A benchmark must not make the workstation unstable or consume all system RAM in order to be considered realistic.

When comparing two techniques, preserve correctness before comparing speed. Verify outputs against a trusted baseline with tolerances appropriate to the dtype. Confirm that gradients,

cache positions, masks, and optimizer steps represent the same intended computation. Only then compare peak allocated and reserved memory, runtime, throughput, transfer volume, or power. A technique that reduces memory by changing the task, dropping required context, or using stale state has not solved the original problem.

Record hardware and software context with every serious result: GPU model and count, VRAM capacity, CPU RAM, storage type, interconnect, PyTorch version, CUDA version, dtype, batch size, sequence length, model dimensions, and relevant allocator or determinism settings. Absolute performance values are not universal. The book uses measurements to uncover mechanisms and trade-offs, not to produce rankings detached from the environment that created them.

19.1.5 The seven stages of the book

The fifty chapters form seven connected stages rather than fifty isolated API lessons.

1. **DMM00–DMM04: Observation and allocator visibility.** The reader learns the PyTorch CUDA memory APIs, the profiler, caching allocator behavior, memory statistics, and snapshots. This stage builds the evidence required by every later optimization.

2. **DMM05–DMM09: Movement, streams, overlap, and prefetch.** Pinned memory, non-blocking transfers, CUDA streams, compute-transfer overlap, and prefetching establish how data can arrive before it is needed without introducing races or hidden synchronization.

3. **DMM10–DMM16: Placement, eviction, and out-of-core execution.** The reader designs eviction policies and moves tensors, parameters, layers, and training state across GPU, CPU, and NVMe tiers, culminating in models whose total state exceeds VRAM.

4. **DMM17–DMM23: Training-time memory control and recovery.** Activation checkpointing, activation offloading, mixed precision, dynamic loss scaling, gradient accumulation, adaptive batch sizing, and controlled OOM recovery are evaluated as interacting parts of the training runtime.

5. **DMM24–DMM33: Scheduling, storage, reuse, and virtualization.** Memory-aware scheduling, pooling, fragmentation, buffer reuse, aliasing, meta-device construction, lazy materialization, memory mapping, DataLoader behavior, and paged tensor storage expose the lower-level mechanics needed for reusable systems.

6. **DMM34–DMM42: KV cache and distributed memory.** The reader manages dynamic inference caches, then studies how FSDP, ZeRO-style partitioning, tensor parallelism, pipeline parallelism, and multi-GPU balancing redistribute both storage and communication.

7. **DMM43–DMM49: Precise profiling, diagnosis, and runtime construction.** CUDA events, bandwidth analysis, leak detection, autograd graph inspection, inference graph control, a custom memory manager, and a custom offload engine convert the complete book into an integrated engineering practice.

19.1.6 The Chapters (DMM00 - DMM49) included in this book

- DMM00 - PyTorch CUDA Memory APIs
- DMM01 - PyTorch Profiler for Memory
- DMM02 - PyTorch Caching Allocator
- DMM03 - PyTorch CUDA Memory Statistics
- DMM04 - PyTorch CUDA Memory Snapshots
- DMM05 - Pinned Memory and Page-Locked Host Buffers
- DMM06 - Non-Blocking CPU-GPU Transfers
- DMM07 - CUDA Streams in PyTorch
- DMM08 - Compute and Data Transfer Overlap
- DMM09 - Data and Tensor Prefetching
- DMM10 - Memory Eviction Policies
- DMM11 - Dynamic Tensor Placement
- DMM12 - Dynamic Parameter Placement
- DMM13 - Dynamic Layer Offloading
- DMM14 - CPU Offloading for Models and Training State
- DMM15 - NVMe Offloading and Three-Tier Memory Hierarchies
- DMM16 - Out-of-Core Model Execution
- DMM17 - Activation Checkpointing and Recomputation
- DMM18 - Activation Offloading to CPU Memory
- DMM19 - Mixed Precision Memory Management
- DMM20 - Gradient Scaling and Dynamic Loss Scaling
- DMM21 - Gradient Accumulation and Effective Batch Scaling
- DMM22 - Adaptive Batch Sizing Under Dynamic VRAM Budgets
- DMM23 - CUDA Out-of-Memory Detection and Recovery
- DMM24 - Memory-Aware Scheduling
- DMM25 - Memory Pooling and Buffer Reuse
- DMM26 - Memory Fragmentation Management
- DMM27 - Tensor Reuse and Buffer Reuse

- DMM28 - In-Place Operations and Storage Aliasing
- DMM29 - Meta Device and Zero-Allocation Model Construction
- DMM30 - Lazy Parameter Materialization
- DMM31 - Memory-Mapped Data and Large Dataset Access
- DMM32 - DataLoader Memory Optimization
- DMM33 - Paged Memory and Virtualized Tensor Storage
- DMM34 - Paged KV Cache for LLM Inference
- DMM35 - KV Cache Offloading Between VRAM and RAM
- DMM36 - KV Cache Quantization
- DMM37 - KV Cache Eviction and Context Retention Policies
- DMM38 - Fully Sharded Data Parallel (FSDP) Memory Management
- DMM39 - ZeRO-Style Memory Partitioning
- DMM40 - Tensor Parallel Memory Placement
- DMM41 - Pipeline Parallelism and Pipeline Memory Scheduling
- DMM42 - Multi-GPU Memory Balancing
- DMM43 - CUDA Events and Precise GPU Timing
- DMM44 - Memory and Transfer Bandwidth Profiling
- DMM45 - CUDA Memory Leak Detection and Root-Cause Analysis
- DMM46 - Autograd Graph Memory Analysis
- DMM47 - Detach, No-Grad, and Inference Mode Memory Control
- DMM48 - Custom Memory Manager in PyTorch
- DMM49 - Custom Offload Engine and Final Runtime

At the end of this book, memory should no longer appear as an unexplained number printed after a failed run. It should be understood as a timeline of objects, allocations, dependencies, movements, and policy decisions. The reader should be able to predict the dominant costs, collect the evidence needed to correct the prediction, design a safe response to changing capacity, and explain why a chosen memory strategy is correct for the workload in front of it. That is the foundation required to build AI systems that do not merely fit once, but remain observable, recoverable, and efficient as their models, contexts, datasets, and hardware environments grow.

19.2 DMM00

Chapter Title: PyTorch CUDA Memory APIs
Specialization: Dynamic Memory Management and CUDA Systems

19.2.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Allocated, Reserved, Peak, Free, and Total GPU Memory

Part 1 - Exercise Contract and Why It Matters

This exercise establishes the vocabulary used throughout the entire book. The words allocated, reserved, peak, free, and total describe different views of GPU memory. Treating them as synonyms creates false leak reports, incorrect capacity estimates, unsafe batch-size decisions, and misleading claims about what `torch.cuda.empty_cache()` can accomplish. The objective is not merely to print five numbers. The objective is to explain which subsystem owns each number, what event changes it, and what conclusion may legitimately be drawn from it.

Your experiment must distinguish the memory occupied by live PyTorch tensor storage from the larger pool of CUDA blocks held by PyTorch's caching allocator. It must also distinguish both quantities from device-wide free and total memory reported through the CUDA driver. Peak memory is a historical high-water mark, not a description of the current state. A correct report must therefore attach a semantic definition and a time boundary to every value.

The deliverable is a CUDA program and an accompanying table containing measurements at six controlled stages: before the experiment, after one tensor allocation, after a second allocation, after deleting the first tensor, after deleting all live tensors, and after requesting that unused cached blocks be released. The program must report bytes and MiB without confusing decimal MB with binary MiB. It must retain no hidden tensor references and must state that the CUDA context, library workspaces, graphics usage, and allocations from other processes are not completely represented by PyTorch's live-tensor counter.

Success requires more than observing that reserved memory exceeds allocated memory. You must explain why the inequality is normal, identify which values are process-local and which are device-wide, demonstrate that a peak may remain high after current allocations fall, and show why device free memory does not generally equal total memory minus PyTorch allocated memory.

Part 2 - System and Memory Mental Model

PyTorch does not normally ask the CUDA driver for an exact new block every time a tensor is created. Device allocation is relatively expensive and may force synchronization. PyTorch therefore obtains segments from CUDA and manages smaller blocks inside those segments. A live tensor uses a block; an unused block may remain inside the allocator's reserved pool so that a later tensor can reuse it quickly. This produces three nested but non-equivalent views:

$$M_{\text{allocated}} \leq M_{\text{reserved}} \leq M_{\text{device used by all sources}}.$$

`torch.cuda.memory_allocated()` reports memory currently occupied by live tensor storage managed by PyTorch's CUDA allocator for the selected device. It is not a complete process resident-set measurement. Some CUDA libraries, contexts, graph pools, or third-party extensions may allocate memory outside this counter.

`torch.cuda.memory_reserved()` reports the memory held by the caching allocator, including blocks used by live tensors and unused blocks retained for possible reuse. The approximate cached slack is

$$M_{\text{cached slack}} = M_{\text{reserved}} - M_{\text{allocated}},$$

but this subtraction does not guarantee that all slack can satisfy one new request. Blocks have sizes, stream histories, and fragmentation states. Total free bytes are not the same as one contiguous usable block.

`torch.cuda.max_memory_allocated()` is the maximum allocated value observed since the peak statistics were last reset. It answers "How high did live tensor memory rise during this interval?" It does not answer "How much memory is live now?" The corresponding reserved peak records the high-water mark of the allocator pool. Resetting peak statistics changes only the measurement baseline; it does not free memory.

`torch.cuda.mem_get_info()` obtains a driver-level pair $(M_{\text{free}}, M_{\text{total}})$. Total is the usable capacity reported for the selected device in the current environment, while free is capacity currently available at that system view. Other processes, display workloads, CUDA context state, and non-PyTorch allocations influence free memory. Therefore the residual

$$M_{\text{other}} = M_{\text{total}} - M_{\text{free}} - M_{\text{reserved}}$$

is only an accounting remainder, not proof of a leak.

Part 3 - Quantitative Prediction Before Execution

Before running code, record the idle measurements and predict the directional change produced by each stage. For a tensor with shape $(n_1, \ldots, n_k)$ and element size s bytes, begin with

$$B_{\text{payload}} = s \prod_{i=1}^{k} n_i.$$

For example, a `float32` tensor of shape $(4096, 4096)$ contains 16,777,216 elements and requires

$$16{,}777{,}216 \times 4 = 67{,}108{,}864 \text{ bytes} = 64 \text{ MiB}.$$

Predict that allocated memory will rise by approximately the payload size. Do not demand exact equality before considering allocator rounding, temporary construction, or existing reusable blocks. Predict that reserved memory may rise by the same amount or a larger step. After deleting the tensor and ensuring no references remain, predict that allocated memory will fall while reserved memory may remain unchanged. After `torch.cuda.empty_cache()`, predict that only unused cached blocks may be returned; memory supporting live tensors must remain allocated. Peak allocated memory should remain at its earlier maximum until explicitly reset.

Part 4 - Experimental Design and Instrumentation

Use one explicit device, preferably `cuda:0`. Start a fresh Python process so that earlier notebook allocations do not contaminate the baseline. Synchronize before every snapshot because CUDA execution is asynchronous. Create tensors with `torch.empty` so that the payload size is clear and avoid unrelated model libraries in this first experiment. Store snapshots as ordinary Python dictionaries containing integer byte counts.

Use a sequence of named checkpoints rather than printing values at arbitrary lines. Delete references explicitly, call Python garbage collection only as a controlled intervention, and separate it from `torch.cuda.empty_cache()` so that their roles are not confused. Reset peak statistics immediately before the controlled region. Repeat the experiment twice: the second run may reuse cached blocks and reveal why reserved growth differs between a cold and warm allocator state.

For every checkpoint, record allocated, reserved, allocated peak, reserved peak, driver free, and driver total. Also calculate cached slack and the device-wide used value. The measurement table must state units and must not round before differences are calculated.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

MIB = 1024 * 1024

def bytes_to_mib(number_of_bytes):
    return number_of_bytes / MIB

def memory_snapshot(label, device):
    torch.cuda.synchronize(device)
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)

    snapshot = {}
    snapshot["label"] = label
    snapshot["allocated_bytes"] = torch.cuda.memory_allocated(device)
    snapshot["reserved_bytes"] = torch.cuda.memory_reserved(device)
    snapshot["peak_allocated_bytes"] = (
        torch.cuda.max_memory_allocated(device)
    )
    snapshot["peak_reserved_bytes"] = (
        torch.cuda.max_memory_reserved(device)
    )
    snapshot["free_bytes"] = free_bytes
    snapshot["total_bytes"] = total_bytes
    snapshot["device_used_bytes"] = total_bytes - free_bytes
    snapshot["cached_slack_bytes"] = (
        snapshot["reserved_bytes"] - snapshot["allocated_bytes"]
    )
    return snapshot

def print_snapshot(snapshot):
    print("\nStage:", snapshot["label"])
    keys = [
        "allocated_bytes",
        "reserved_bytes",
        "peak_allocated_bytes",
```

```
        "peak_reserved_bytes",
        "free_bytes",
        "total_bytes",
        "device_used_bytes",
        "cached_slack_bytes",
    ]

    for key in keys:
        value_in_mib = bytes_to_mib(snapshot[key])
        print(f"{key:24s}: {value_in_mib:10.2f} MiB")

def E00():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM00-E00.")

Part 6 - Measurement, Validation, and Failure Analysis

Validate four invariants. First, allocated memory must never exceed reserved memory at a synchronized snapshot. Second, free memory must not exceed total memory. Third, peak allocated memory must be at least the current allocated memory. Fourth, deleting a tensor must not be credited with a reduction unless all references to its storage are gone. Add assertions for these invariants, but use explanations rather than overly strict equality checks for allocator deltas.

Compare the measured allocation increase with the predicted payload. Report the absolute error and explain likely sources. If allocated memory fails to drop after deletion, inspect containers, closures, global variables, exception tracebacks, views, and autograd graphs for surviving references. If reserved memory remains high, do not label it a leak until the live allocation counter, snapshot history, and cache-release experiment have been examined. If driver free memory changes between otherwise identical runs, check for display activity and other processes.

Run the experiment in a fresh process and then inside a long-lived notebook. The notebook is expected to have a less clean baseline. This difference is part of the lesson: memory measurements are observations of a process history, not immutable properties of one line of source code.

Part 7 - Engineering Interpretation and Philosophy

Memory is not one number because ownership is layered. A tensor has logical meaning to the model, storage meaning to PyTorch, block meaning to the caching allocator, allocation meaning to CUDA, and physical-capacity meaning to the device. Each interface reveals one layer and hides another. Engineering errors occur when a number from one layer is used to answer a question belonging to a different layer.

The deeper philosophy is that unused memory is not automatically wasted memory. A reserved block may represent deliberate preparation for reuse, reducing latency and synchronization in later steps. Conversely, high device utilization is not automatically productive if the bytes belong to stale graphs or fragmented blocks. The correct judgment depends on lifetime, reusability, and the workload's next demand.

This exercise establishes the discipline for the rest of the book: define the observer, define the time interval, predict the mechanism, and only then interpret the measurement. Dynamic memory management begins when a printed number becomes an explainable state transition.

19.2.2 Exercise 01

Exercise Title: Predict CUDA Memory Usage from Tensor Shape, Dtype, and Element Count Before Running the Code

Part 1 - Exercise Contract and Why It Matters

This exercise trains the habit that must precede every serious memory experiment: calculate the payload before asking the GPU to allocate it. You will build a predictor that accepts an explicit shape and dtype, computes the element count without hidden shortcuts, converts it to bytes and MiB, and then checks the prediction against the increase reported by PyTorch. The predictor must support at least `float16`, `bfloat16`, `float32`, `float64`, `int8`, `int32`, and `bool`.

The exercise is successful when you can reject an unsafe allocation before it is attempted, explain the difference between tensor payload and complete runtime cost, and identify shape mistakes whose memory effect is multiplicative. A forgotten batch or head dimension is not a small bookkeeping error; it can change an allocation by orders of magnitude.

A second requirement is to make integer overflow and unit confusion visible. Very large shapes should be multiplied using Python integers, not a fixed-width tensor scalar that may overflow before the capacity check. The report must show both decimal gigabytes and binary GiB only when each unit is labeled. A request described casually as "eight gigabytes" can differ by hundreds of millions of bytes depending on the convention, which is already large enough to determine whether an allocation succeeds near the boundary.

Finally, the predictor must refuse shapes whose meaning is incomplete. A batch dimension, sequence dimension, number of heads, or number of layers must never be silently assumed. The reader should treat a shape as a resource contract: every axis is named, its maximum is stated, and any dynamic axis is included in the budget formula.

Part 2 - System and Memory Mental Model

A dense strided tensor normally stores one value for every logical element. Its payload is determined by the number of elements and the number of bytes per element:

$$N = \prod_{i=1}^{k} n_i, \qquad B = N\, s_{\text{dtype}}.$$

This formula describes storage, not the cost of computing the tensor. A view created with `reshape`, `transpose`, or slicing may share an existing storage and allocate no new payload. A materializing operation such as `clone()` or `contiguous()` may create new storage with the same element count. Sparse and quantized layouts require different accounting. The predictor in this exercise is deliberately restricted to dense tensors so that its contract is explicit.

The tensor payload also excludes Python objects, allocator metadata, CUDA context memory, kernel workspaces, autograd-saved tensors, and future outputs. It is therefore the first line of a budget rather than a prediction of the entire process.

Part 3 - Quantitative Prediction Before Execution

Manually calculate three cases before running the program:

$(32, 3, 224, 224)$, `float32`; $(8, 16, 2048, 2048)$, `float16`; $(2, 32, 4096, 4096)$, `float64`.

Write every multiplication and convert with 1 MiB = 2^{20} bytes and 1 GiB = 2^{30} bytes. Compare each predicted payload with a conservative safety budget equal to a selected fraction of current driver-free memory. Explain why using 100 percent of reported free memory is unsafe: temporary operations, allocator rounding, and unrelated activity still need headroom.

Part 4 - Experimental Design and Instrumentation

Test one shape at a time in a fresh controlled function. Record allocated memory before allocation, allocate with `torch.empty`, synchronize, record the new value, and calculate the delta. Delete the tensor after each case. Keep prediction arithmetic in integer bytes and round only for display. Include a deliberately unsafe shape, but reject it through the budget check instead of allocating it.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def element_count(shape):
    count = 1
    for dimension in shape:
        if dimension < 0:
            raise ValueError("Dimensions must be non-negative.")
        count = count * dimension
    return count

def predict_dense_tensor_bytes(shape, dtype):
    count = element_count(shape)
    probe = torch.empty((), dtype=dtype)
    bytes_per_element = probe.element_size()
    return count * bytes_per_element

def safe_to_allocate(predicted_bytes, device, safety_fraction):
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    allowed_bytes = int(free_bytes * safety_fraction)
    return predicted_bytes <= allowed_bytes, allowed_bytes, total_bytes

def measure_case(shape, dtype, device):
    predicted_bytes = predict_dense_tensor_bytes(shape, dtype)
    permitted, allowed_bytes, total_bytes = safe_to_allocate(
        predicted_bytes,
        device,
        0.70,
    )

    if not permitted:
        return {
            "shape": shape,
            "dtype": str(dtype),
            "predicted_bytes": predicted_bytes,
```

```
            "status": "rejected before allocation",
        }

    torch.cuda.synchronize(device)
    before = torch.cuda.memory_allocated(device)
    tensor = torch.empty(shape, dtype=dtype, device=device)
    torch.cuda.synchronize(device)
    after = torch.cuda.memory_allocated(device)

    result = {
        "shape": shape,
        "dtype": str(dtype),
        "predicted_bytes": predicted_bytes,
        "measured_delta_bytes": after - before,
        "allowed_bytes": allowed_bytes,
        "total_bytes": total_bytes,
        "status": "measured",
    }

    del tensor
    gc.collect()
    return result

def E01():
    device = torch.device("cuda:0")
    cases = [
        ((32, 3, 224, 224), torch.float32),
        ((8, 16, 2048, 2048), torch.float16),
        ((2, 32, 4096, 4096), torch.float64),
    ]

    results = []
    for shape, dtype in cases:
        results.append(measure_case(shape, dtype, device))
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Require exact agreement between `tensor.numel()` and the manually calculated element count. Compare payload prediction with allocated delta and report both absolute and percentage error. Investigate a mismatch before changing tolerance. Common causes include a live result from a previous case, construction of a temporary tensor, an accidental copy, or measuring reserved instead of allocated memory. Test a zero-sized dimension and explain why its logical payload is zero even though a tensor object still exists.

Part 7 - Engineering Interpretation and Philosophy

Prediction is a form of control. Without it, the GPU becomes an oracle that is asked whether an idea fits only after the program risks failure. Shape algebra allows the engineer to move that decision earlier, where alternatives such as smaller batches, lower precision, tiling, or

offloading can still be selected. The deeper lesson is that dimensions are resource commitments. Every new axis has semantic meaning and a physical price.

19.2.3 Exercise 02

Exercise Title: Measure Live Tensor Memory Using torch.cuda.memory_allocated() Before and After CUDA Allocations

Part 1 - Exercise Contract and Why It Matters

This exercise isolates the meaning of live allocated memory. You will create a sequence of CUDA tensors with known payloads, retain selected references, create views and clones, and observe which operations change `torch.cuda.memory_allocated()`. The final report must distinguish logical tensors from independent storages. Two tensor variables do not necessarily represent two allocations, while one expression may create several temporary storages.

The contract requires synchronized snapshots, byte-accurate deltas, and an explanation for every increase or decrease. The experiment must include an original tensor, an alias assignment, a slice view, a transpose view, a clone, a dtype conversion, and deletion in a controlled order.

This distinction becomes especially important with non-contiguous layouts. Transposing a tensor changes its strides and logical indexing but ordinarily does not rearrange the underlying bytes. A later operator may accept those strides directly or may create a contiguous copy internally. Therefore the memory cost cannot always be assigned to the transpose line itself; it may appear at the first downstream operation that requires a particular layout. The experiment should preserve this causal chain.

You must also explain why storage-pointer inspection is a debugging aid rather than a complete ownership API. Allocator reuse can cause a pointer value to appear again after an earlier tensor dies, and zero-sized tensors have special cases. Pointer equality during overlapping lifetimes supports a sharing claim, but pointer history alone does not define semantic identity.

Part 2 - System and Memory Mental Model

PyTorch tensors contain metadata that refers to storage. An alias such as `b = a` creates another Python reference to the same tensor object. A view such as `a[:, :512]` may create a new tensor object with different shape and strides while sharing the original storage. Neither operation needs another full payload. A clone creates independent storage. A conversion from `float32` to `float16` also materializes new storage when the dtype changes.

Storage lifetime ends only when no live tensor or object retains a reference to it and no pending CUDA work still requires it. Deleting the original variable cannot free the storage when a view survives. This relationship is central to leak diagnosis because the variable that appears responsible may not be the last owner.

Part 3 - Quantitative Prediction Before Execution

Use an original $(4096, 4096)$ `float32` tensor with a 64 MiB payload. Predict zero allocated delta for an alias, approximately zero for a view, 64 MiB for a clone, and 32 MiB for a `float16` conversion. Predict that deleting the original while its view remains will not release the original 64 MiB storage. Construct a ledger that lists storage identity, dtype, payload, and surviving owners at every stage.

Part 4 - Experimental Design and Instrumentation

Start from a clean baseline and use one snapshot function. Perform only one operation between snapshots. Use `tensor.untyped_storage().data_ptr()` to compare storage pointers for educational inspection. Do not infer sharing from equal values. Synchronize before each snapshot and preserve Python references deliberately until their assigned deletion stage.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def allocated(device):
    torch.cuda.synchronize(device)
    return torch.cuda.memory_allocated(device)

def storage_pointer(tensor):
    return tensor.untyped_storage().data_ptr()

def E02():
    device = torch.device("cuda:0")
    gc.collect()
    torch.cuda.empty_cache()

    records = []
    records.append(("baseline", allocated(device)))

    original = torch.empty(
        (4096, 4096),
        dtype=torch.float32,
        device=device,
    )
    records.append(("original", allocated(device)))

    alias = original
    records.append(("alias", allocated(device)))

    view = original[:, :512]
    records.append(("view", allocated(device)))

    clone = original.clone()
    records.append(("clone", allocated(device)))

    half_copy = original.to(dtype=torch.float16)
    records.append(("half copy", allocated(device)))

    assert storage_pointer(alias) == storage_pointer(original)
    assert storage_pointer(view) == storage_pointer(original)
    assert storage_pointer(clone) != storage_pointer(original)
```

```
    del original
    del alias
    gc.collect()
    records.append(("original names deleted", allocated(device)))

    del view
    gc.collect()
    records.append(("view deleted", allocated(device)))

    del clone
    del half_copy
    gc.collect()
    records.append(("all storages deleted", allocated(device)))
    return records
```

Part 6 - Measurement, Validation, and Failure Analysis

Convert adjacent snapshots into deltas and compare them with the storage ledger. If a view unexpectedly allocates a large block, verify whether the operation was actually a materializing reshape or contiguous conversion. If memory remains after all named tensors are deleted, inspect the records container and ensure it stores only integers rather than tensors. Also inspect interactive notebook output history, which may retain the last displayed tensor. Repeat inside a standalone script to separate notebook retention from allocator behavior.

Part 7 - Engineering Interpretation and Philosophy

Logical identity and physical ownership are different. A program may contain many tensor descriptions of one storage, or one innocent-looking expression may create a costly copy. Dynamic memory management therefore requires reasoning about storage graphs, not variable names alone. The philosophical lesson is that appearances at the language level can conceal continuity at the memory level: deletion of a name is not destruction of the thing it once described.

19.2.4 Exercise 03

Exercise Title: Measure Reserved CUDA Memory Using torch.cuda.memory_reserved() and Explain Why It Exceeds Allocated Memory

Part 1 - Exercise Contract and Why It Matters

This exercise studies the caching allocator as a performance mechanism. You will show that reserved memory can remain high after live tensors disappear, then prove that a later allocation can reuse the pool without requesting an equally large new segment from CUDA. The report must avoid calling every allocated–reserved gap fragmentation. Some gap is healthy reusable capacity; fragmentation is a more specific inability to satisfy useful requests from the available block structure.

The exercise must also separate allocator efficiency from device sharing. A high reserved pool may be entirely reasonable for a single long-running training job, yet undesirable when several independent processes must share the same GPU. In the first situation, retention avoids

repeated allocation cost. In the second, returning inactive segments can improve system fairness. The same counter value can therefore be healthy or harmful depending on who needs the capacity next.

Your conclusion must include both a local and a system-level interpretation: whether PyTorch can reuse the pool efficiently and whether retaining that pool prevents another workload from making progress.

Part 2 - System and Memory Mental Model

The allocator receives segments from CUDA and subdivides them into blocks. Allocated blocks support live tensors. Inactive blocks may remain reserved and become candidates for reuse. If the next request matches an available block, PyTorch can satisfy it internally. If it does not fit, the allocator may split a larger block, request a new segment, or fail despite apparently large slack. Thus,

$$M_{\text{reserved}} = M_{\text{active}} + M_{\text{inactive}},$$

is a capacity identity, not a statement that all inactive bytes are equally usable. The cache-release operation returns eligible unused blocks to CUDA but cannot release blocks occupied by live tensor storage.

Part 3 - Quantitative Prediction Before Execution

Predict allocated and reserved values for a 256 MiB tensor, its deletion, a new 192 MiB tensor, and a cache-release request. The exact reserved segment sizes are allocator-dependent, so write directional hypotheses: allocation raises allocated; deletion lowers allocated; reserved may remain; reuse may raise allocated without a comparable rise in reserved; emptying the cache may lower reserved only after live tensors are removed.

Part 4 - Experimental Design and Instrumentation

Measure both counters at every stage and include driver free memory. Run a cold trial after clearing eligible cache and a warm trial without clearing it. Synchronize snapshots. Use the same allocation pattern in both trials and record execution time only as supporting evidence because this chapter focuses on capacity semantics.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def counters(label, device):
    torch.cuda.synchronize(device)
    return {
        "label": label,
        "allocated": torch.cuda.memory_allocated(device),
        "reserved": torch.cuda.memory_reserved(device),
    }

def one_trial(device, release_cache_first):
    gc.collect()
```

```
    if release_cache_first:
        torch.cuda.empty_cache()

    rows = []
    rows.append(counters("start", device))

    first = torch.empty(
        (64, 1024, 1024),
        dtype=torch.float32,
        device=device,
    )
    rows.append(counters("256 MiB live", device))

    del first
    gc.collect()
    rows.append(counters("256 MiB deleted", device))

    second = torch.empty(
        (48, 1024, 1024),
        dtype=torch.float32,
        device=device,
    )
    rows.append(counters("192 MiB live", device))

    del second
    gc.collect()
    rows.append(counters("all deleted", device))

    torch.cuda.empty_cache()
    rows.append(counters("cache released", device))
    return rows

def E03():
    device = torch.device("cuda:0")
    cold = one_trial(device, True)
    warm = one_trial(device, False)
    return {"cold": cold, "warm": warm}
```

Part 6 - Measurement, Validation, and Failure Analysis

Calculate reserved slack at each stage and annotate whether live storage exists. Prove reuse by showing a substantial allocated increase with little or no reserved increase during the warm allocation. If reserved does not fall to zero after `empty_cache()`, check for live tensors and remember that some context or non-releasable allocator state can remain. Do not use `empty_cache()` inside every training iteration; benchmark the synchronization and allocation penalty if you are tempted to do so.

Part 7 - Engineering Interpretation and Philosophy

The caching allocator demonstrates that apparent excess can be intentional preparedness. A system may hold more memory than it currently needs because future reuse is cheaper than repeated acquisition and release. The engineering question is not whether reserved exceeds allocated, but whether the pool serves the workload efficiently and yields capacity when another consumer genuinely needs it. Good memory management balances present occupancy with future cost.

19.2.5 Exercise 04

Exercise Title: Track Peak VRAM with max_memory_allocated() and Reset Peak Statistics Between Controlled Experiments

Part 1 - Exercise Contract and Why It Matters

Current memory can miss the event that determines whether a workload fits. A temporary attention matrix, backward workspace, or optimizer update may exist for only milliseconds and disappear before an end-of-step snapshot. This exercise uses peak statistics to capture that high-water mark. You must prove that the peak persists after current memory falls, that resetting statistics does not free storage, and that each compared experiment needs its own reset boundary.

Peak statistics are also needed when two implementations finish with identical outputs and identical final allocations. A fused operation may create a lower temporary peak than a sequence of individually materialized intermediates. End-of-function measurement would declare them equal even though only one fits a constrained GPU. This exercise therefore establishes peak memory as an independent engineering metric alongside correctness, latency, and throughput.

The report must include the baseline current allocation at the moment of reset. Without that baseline, a raw peak combines persistent model state with temporary demand and cannot reveal how much capacity the measured operation added.

Part 2 - System and Memory Mental Model

Let $A(t)$ be allocated tensor memory during a measured interval. The peak is

$$A_{\max} = \max_{t_0 \le t \le t_1} A(t).$$

`max_memory_allocated()` stores this historical maximum, whereas `memory_allocated()` samples the present. A reset sets the new measurement baseline to the current state; it does not make the current state zero and does not return blocks to the driver. Peaks are device-specific and process-specific, so the selected device and interval must be documented.

Part 3 - Quantitative Prediction Before Execution

Begin with a persistent 64 MiB tensor, reset the peak, create a temporary 256 MiB tensor, delete it, and retain the persistent tensor. Predict a current value near 64 MiB after deletion and a peak near 320 MiB. Reset again and predict that both current and new peak begin near 64 MiB. Then create a 128 MiB temporary and predict a second-interval peak near 192 MiB.

Part 4 - Experimental Design and Instrumentation

Use two functions whose temporary allocations differ while their final live state is identical. Reset immediately before each function and synchronize after it. Record current allocated,

peak allocated, current reserved, and peak reserved. Run the functions in both orders to show why failure to reset makes the second result inherit the first high-water mark.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def run_temporary_case(device, temporary_mib):
    element_count = temporary_mib * 1024 * 1024 // 4
    temporary = torch.empty(
        element_count,
        dtype=torch.float32,
        device=device,
    )
    temporary.fill_(1.0)
    del temporary
    gc.collect()
    torch.cuda.synchronize(device)

    return {
        "current_allocated": torch.cuda.memory_allocated(device),
        "peak_allocated": torch.cuda.max_memory_allocated(device),
        "current_reserved": torch.cuda.memory_reserved(device),
        "peak_reserved": torch.cuda.max_memory_reserved(device),
    }

def E04():
    device = torch.device("cuda:0")
    persistent = torch.empty(
        64 * 1024 * 1024 // 4,
        dtype=torch.float32,
        device=device,
    )

    torch.cuda.reset_peak_memory_stats(device)
    large_case = run_temporary_case(device, 256)

    torch.cuda.reset_peak_memory_stats(device)
    small_case = run_temporary_case(device, 128)

    del persistent
    gc.collect()
    return {"large": large_case, "small": small_case}
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that each peak is at least the corresponding current value and that the large temporary produces a larger peak. If filling the tensor introduces an unexpected workspace, compare

with `torch.empty` alone and explain which case represents committed use. If repeated trials differ, inspect baseline allocations and allocator state. Report deltas from the current baseline, rather than comparing raw peaks from unrelated process histories.

Part 7 - Engineering Interpretation and Philosophy

Capacity failure is governed by the maximum simultaneous demand, not by the memory visible when the program is calm. Peak tracking turns a fleeting event into durable evidence, but only when the observer defines the interval. The philosophical lesson is that measurement depends on boundaries: a maximum without a declared beginning and end is a number without an experiment.

19.2.6 Exercise 05

Exercise Title: Compare Theoretical Tensor Memory Against Observed PyTorch CUDA Memory for float16, float32, and float64

Part 1 - Exercise Contract and Why It Matters

Precision changes capacity directly, but the common claim that `float16` always halves total training memory is incomplete. This exercise first proves the exact payload ratio for isolated dense tensors and then explains why a complete model may contain mixed dtypes, master weights, optimizer states, gradients, workspaces, and alignment overhead. You will use the same shape for three dtypes and compare theoretical bytes, allocated deltas, reserved deltas, and numerical range.

The comparison must also resist a common benchmarking error: changing the dtype of only the input while the operator promotes or converts it internally. Inspect the actual result dtype and the dtype of every live tensor. A valid capacity comparison requires the intended storage format to survive throughout the measured region. If an operation lacks support for a selected dtype and creates a higher-precision temporary, that behavior is part of the measured system and must be reported.

Alongside capacity, include one numerical stress case containing small and large magnitudes. The purpose is not to decide that one dtype is universally better, but to show that the bytes saved have a measurable representational consequence.

Part 2 - System and Memory Mental Model

The element sizes are normally

$$s_{\text{float16}} = 2, \qquad s_{\text{float32}} = 4, \qquad s_{\text{float64}} = 8 \text{ bytes}.$$

For a fixed dense shape, payload ratios are $1 : 2 : 4$. Allocated deltas should closely follow those ratios. Reserved deltas may not, because the allocator uses block and segment policies and can reuse earlier blocks. Precision also changes representable range and rounding behavior; memory savings cannot be evaluated independently of correctness.

Part 3 - Quantitative Prediction Before Execution

For shape $(64, 1024, 1024)$, calculate the element count and predict 128 MiB for `float16`, 256 MiB for `float32`, and 512 MiB for `float64`. Predict allocated ratios and explicitly state that reserved ratios may be distorted by trial order. Estimate how many such tensors could fit inside a chosen 2 GiB experimental budget while leaving headroom.

Part 4 - Experimental Design and Instrumentation

Run each dtype in a separate clean subprocess if exact reserved comparison is required. Within one process, clear eligible cache before each trial and record the remaining baseline. Allocate with `torch.empty`, then write finite values so that pages are meaningfully used. Measure payload prediction, allocated delta, reserved delta, and maximum absolute error after converting a controlled input down and back to `float64`.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def dtype_trial(shape, dtype, device):
    gc.collect()
    torch.cuda.empty_cache()
    torch.cuda.synchronize(device)

    before_allocated = torch.cuda.memory_allocated(device)
    before_reserved = torch.cuda.memory_reserved(device)

    tensor = torch.empty(shape, dtype=dtype, device=device)
    tensor.fill_(0.125)
    torch.cuda.synchronize(device)

    after_allocated = torch.cuda.memory_allocated(device)
    after_reserved = torch.cuda.memory_reserved(device)

    theoretical_bytes = tensor.numel() * tensor.element_size()
    result = {
        "dtype": str(dtype),
        "element_size": tensor.element_size(),
        "theoretical_bytes": theoretical_bytes,
        "allocated_delta": after_allocated - before_allocated,
        "reserved_delta": after_reserved - before_reserved,
    }

    del tensor
    gc.collect()
    return result

def E05():
    device = torch.device("cuda:0")
    shape = (64, 1024, 1024)
    dtypes = [torch.float16, torch.float32, torch.float64]

    results = []
    for dtype in dtypes:
        results.append(dtype_trial(shape, dtype, device))
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify `element_size()` rather than hard-coding an unsupported assumption. Compare allocated delta with theoretical bytes and calculate the ratio across dtypes. If a trial OOMs, stop and reduce the common shape instead of allowing different shapes to invalidate the comparison. If reserved deltas appear out of order, repeat in fresh processes and attribute the original result to cache history rather than precision itself.

Part 7 - Engineering Interpretation and Philosophy

A dtype is simultaneously a storage format, an arithmetic contract, and a statement about tolerated error. Choosing precision only from memory pressure ignores numerical meaning; choosing it only from accuracy ignores capacity and throughput. Good engineering treats precision as a negotiated boundary between representation and resources, and validates both sides of that negotiation.

19.2.7 Exercise 06

Exercise Title: Allocate and Delete CUDA Tensors Repeatedly and Measure How Allocated and Reserved Memory Evolve Over Time

Part 1 - Exercise Contract and Why It Matters

One allocation provides a snapshot; a runtime produces a history. This exercise constructs repeated allocation and deletion cycles so that you can separate stable cache reuse, expected warm-up growth, unbounded live-memory growth, and fragmentation-like behavior. The result must be a time series, not a final number. You will compare a stable workload with a deliberately leaking workload that retains one tensor per iteration.

Repeated variable-size workloads are representative of real systems: variable-length sequences, changing image resolutions, and concurrent inference requests do not ask for one perfectly repeating block. The stable trial should therefore include both a fixed-size pattern and a variable pattern. This lets the reader observe that a pool can stabilize quickly for one workload yet continue changing for another even when neither leaks live tensors.

The deliverable must mark three regions in the curve: cold initialization, warm steady state, and deliberate leak. If a plateau cannot be identified, extend the run or reduce unrelated variability. A diagnosis based on five iterations is not strong enough for a long-horizon memory claim.

Part 2 - System and Memory Mental Model

In a stable loop, allocated memory should return near its baseline after each iteration once temporary references disappear. Reserved memory may grow during early iterations as the allocator learns the workload's size pattern, then reach a plateau. In a leak, allocated memory grows because additional storage remains live. These signatures are different:

$$\text{stable cache: } A_t \approx A_0, \quad R_t \to R^*,$$

$$\text{retained tensors: } A_{t+1} > A_t.$$

Reserved growth without allocated growth is not sufficient evidence of a Python reference leak, though it may motivate allocator snapshot analysis.

Part 3 - Quantitative Prediction Before Execution

Choose temporary sizes of 32, 48, 64, and 96 MiB in a repeating pattern. Predict that the stable trial's end-of-iteration allocated delta approaches zero. Predict a finite reserved plateau large enough to service the pattern. For the leak trial, retain one 8 MiB tensor per iteration and predict an approximately linear allocated slope of 8 MiB per iteration.

Part 4 - Experimental Design and Instrumentation

Run at least 30 iterations. Synchronize before every record and capture allocated, reserved, peak, driver free, and iteration label. Use two independent trials in fresh process states where possible. Plot allocated and reserved MiB against iteration. Do not call `empty_cache()` inside the stable loop, because that would remove the allocator behavior being studied.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def make_float32_tensor(mib, device):
    count = mib * 1024 * 1024 // 4
    return torch.empty(count, dtype=torch.float32, device=device)

def record(iteration, mode, device):
    torch.cuda.synchronize(device)
    return {
        "iteration": iteration,
        "mode": mode,
        "allocated": torch.cuda.memory_allocated(device),
        "reserved": torch.cuda.memory_reserved(device),
        "peak": torch.cuda.max_memory_allocated(device),
    }

def run_pattern(device, keep_references):
    sizes = [32, 48, 64, 96]
    retained = []
    rows = []

    for iteration in range(30):
        size_index = iteration % len(sizes)
        temporary = make_float32_tensor(sizes[size_index], device)
        temporary.fill_(1.0)

        if keep_references:
            leak_piece = make_float32_tensor(8, device)
            retained.append(leak_piece)

        del temporary
        gc.collect()
        rows.append(record(iteration, str(keep_references), device))
```

```
    return rows, retained

def E06():
    device = torch.device("cuda:0")
    stable_rows, stable_retained = run_pattern(device, False)
    del stable_retained
    gc.collect()
    torch.cuda.empty_cache()

    leak_rows, leak_retained = run_pattern(device, True)
    return stable_rows, leak_rows, leak_retained
```

Part 6 - Measurement, Validation, and Failure Analysis

Calculate the allocated slope over the final ten iterations for both trials. The stable slope should be near zero; the leaking slope should approximate the retained payload. Inspect any staircase in reserved memory and relate it to the size pattern. If the stable allocated baseline rises, look for tensors stored inside measurement records, exception objects, closures, or asynchronous work. After proving the leak, delete the retained container and verify that allocated memory falls.

Part 7 - Engineering Interpretation and Philosophy

Leaks are temporal claims. A large memory value may be completely legitimate, while a small but persistent positive slope can eventually destroy a long service. The engineer must therefore study trends, plateaus, and phase changes. The philosophy of this exercise is that system health lives in trajectories: memory becomes understandable when we observe how ownership changes through time rather than judging one isolated frame.

19.2.8 Exercise 07

Exercise Title: Compare PyTorch CUDA Memory Measurements Against torch.cuda.mem_get_info() and Explain Every Difference

Part 1 - Exercise Contract and Why It Matters

PyTorch allocator counters describe memory managed through PyTorch, while the CUDA driver memory-information call describes free and total capacity at the CUDA device level. This exercise reconciles both views without forcing them into false equality. You will build a ledger that measures a controlled tensor, calculates device-wide used memory, and identifies the residual not explained by PyTorch reserved memory. The residual must be described as a category to investigate, not automatically as a leak.

The comparison must be performed as a reconciliation across stages, not as a single subtraction at program startup. Creating the first CUDA tensor can initialize context and library state, so the first driver-level delta may be larger than the tensor payload while PyTorch allocated remains exact. Later allocations may reuse reserved segments and produce the opposite pattern: PyTorch allocated rises while driver free barely changes. Both observations are expected under the layered model.

The final table must classify every measured delta as live PyTorch storage, inactive PyTorch reserve, or outside the PyTorch reserve. It is acceptable for the last category to remain partly unexplained, but it is not acceptable to silently call it tensor memory.

Part 2 - System and Memory Mental Model

Define

$$D = T - F, \qquad P = R, \qquad U = D - P,$$

where T is driver-reported total, F is driver-reported free, D is device-wide used, R is PyTorch reserved, and U is the unexplained remainder relative to the PyTorch pool. U may include CUDA contexts, cuBLAS or cuDNN allocations, graphics use, other processes, or measurement timing. PyTorch allocated memory A is a subset of R, not a value that should be subtracted independently from device use after R has already been counted.

Part 3 - Quantitative Prediction Before Execution

Record a baseline (A_0, R_0, F_0, T), then predict the effect of a 512 MiB tensor. Expect A to rise by approximately 512 MiB and F to fall only if the allocator needs new device segments. If cached capacity already exists, allocated may rise while free remains nearly unchanged. Predict what changes after deletion and after cache release.

Part 4 - Experimental Design and Instrumentation

Take synchronized snapshots in a standalone process. Record the operating device and check that no second process is intentionally started during the trial. Perform the allocation twice to expose cold and warm behavior. Store raw bytes, not only rounded MiB, and calculate all residuals after collection.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def reconcile(label, device):
    torch.cuda.synchronize(device)
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    allocated_bytes = torch.cuda.memory_allocated(device)
    reserved_bytes = torch.cuda.memory_reserved(device)
    device_used_bytes = total_bytes - free_bytes
    residual_bytes = device_used_bytes - reserved_bytes

    return {
        "label": label,
        "allocated": allocated_bytes,
        "reserved": reserved_bytes,
        "free": free_bytes,
        "total": total_bytes,
        "device_used": device_used_bytes,
        "outside_pytorch_reserved": residual_bytes,
    }
```

```
def E07():
    device = torch.device("cuda:0")
    gc.collect()
    torch.cuda.empty_cache()

    rows = []
    rows.append(reconcile("baseline", device))

    tensor = torch.empty(
        512 * 1024 * 1024 // 4,
        dtype=torch.float32,
        device=device,
    )
    rows.append(reconcile("tensor live", device))

    del tensor
    gc.collect()
    rows.append(reconcile("tensor deleted", device))

    torch.cuda.empty_cache()
    rows.append(reconcile("cache released", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare deltas rather than demanding that raw baselines match across tools. Verify that total remains stable during the trial. A negative residual indicates that snapshots or definitions were combined incorrectly and should trigger investigation. If driver free memory changes while PyTorch counters do not, look for another process or a non-PyTorch CUDA allocation. Repeat after closing GPU-using applications and document the environment rather than deleting uncomfortable results.

Part 7 - Engineering Interpretation and Philosophy

No single observer owns the complete truth of a layered system. PyTorch knows its allocator; the driver knows device capacity; neither counter alone knows the semantic purpose of every byte. Reconciliation is the practice of allowing multiple valid perspectives to coexist while defining their boundaries. The lesson is not to search for one magical number, but to build an accounting model in which every number has a responsible observer.

19.2.9 Exercise 08

Exercise Title: Build a Reusable PyTorch Function That Reports Allocated, Reserved, Peak, Free, and Total GPU Memory in MiB

Part 1 - Exercise Contract and Why It Matters

Repeated manual print statements produce inconsistent labels, units, device selection, and synchronization. This exercise turns the definitions learned so far into a reusable reporting component. The function must support an explicit CUDA device, return machine-readable integers,

optionally synchronize, display MiB only at the presentation layer, and include timestamps and stage labels. It must never reset peaks or empty the cache as a hidden side effect.

The utility will become infrastructure for later chapters, so its behavior must be conservative. It should raise on invalid device selection, preserve full precision in raw counters, and avoid depending on whichever GPU happens to be current in the process. A report gathered from the wrong device can look perfectly plausible, making explicit placement more important than decorative formatting.

Add a version field to the schema when the utility is reused in saved experiments. If the meaning or calculation of a field later changes, historical records must remain interpretable rather than being silently read under a new definition.

Part 2 - System and Memory Mental Model

Instrumentation should observe a system without silently changing the property being observed. Synchronization is itself an intervention because it changes timing, but it may be required for a consistent stage boundary. Peak reset and cache release are stronger interventions and belong in the caller. Separating collection, derived metrics, formatting, and persistence makes the tool auditable and prevents unit conversion from contaminating raw evidence.

Part 3 - Quantitative Prediction Before Execution

Define the report schema before writing code. Required byte fields are allocated, reserved, peak allocated, peak reserved, free, and total. Derived fields are cached slack, device used, allocated fraction of total, and reserved fraction of total. Predict all invariants and specify how a zero total value would be handled defensively.

Part 4 - Experimental Design and Instrumentation

Test the reporter at baseline, with a known tensor live, and after deletion. Call it for every visible GPU so device selection errors can be detected. Validate JSON serialization and ensure that the raw dictionary contains no tensor values. Compare synchronized and unsynchronized modes and explain why the synchronized mode is preferred for chapter experiments.

Part 5 - PyTorch/CUDA Implementation

```
from datetime import datetime, timezone
import json
import torch

MIB = 1024 * 1024

def collect_cuda_memory(label, device, synchronize=True):
    selected = torch.device(device)
    if selected.type != "cuda":
        raise ValueError("A CUDA device is required.")

    if synchronize:
        torch.cuda.synchronize(selected)

    free_bytes, total_bytes = torch.cuda.mem_get_info(selected)
    allocated_bytes = torch.cuda.memory_allocated(selected)
```

```
    reserved_bytes = torch.cuda.memory_reserved(selected)

    report = {}
    report["timestamp_utc"] = datetime.now(timezone.utc).isoformat()
    report["label"] = label
    report["device"] = str(selected)
    report["allocated_bytes"] = allocated_bytes
    report["reserved_bytes"] = reserved_bytes
    report["peak_allocated_bytes"] = (
        torch.cuda.max_memory_allocated(selected)
    )
    report["peak_reserved_bytes"] = (
        torch.cuda.max_memory_reserved(selected)
    )
    report["free_bytes"] = free_bytes
    report["total_bytes"] = total_bytes
    report["cached_slack_bytes"] = reserved_bytes - allocated_bytes
    report["device_used_bytes"] = total_bytes - free_bytes
    return report

def format_memory_report(report):
    formatted = dict(report)
    for key in report:
        if key.endswith("_bytes"):
            formatted[key.replace("_bytes", "_mib")] = (
                report[key] / MIB
            )
    return formatted

def E08():
    report = collect_cuda_memory("baseline", "cuda:0", True)
    formatted = format_memory_report(report)
    print(json.dumps(formatted, indent=2))
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Write assertions for allocated not exceeding reserved, peak not falling below current, free not exceeding total, and non-negative cached slack. Test an invalid CPU device and an unavailable CUDA index. Verify that formatting does not replace or round raw byte fields. If multi-GPU reports are identical, confirm that each API received the selected device rather than relying on the current default device.

Part 7 - Engineering Interpretation and Philosophy

Reusable measurement code is part of scientific infrastructure. Its value comes from stable semantics, not visual decoration. A reporter that secretly clears memory may produce comforting numbers while destroying the phenomenon under investigation. The philosophical principle is that an instrument should declare how it touches the world it measures.

19.2.10 Exercise 09

Exercise Title: Demonstrate Why Deleting a CUDA Tensor Does Not Necessarily Make the Same Amount of VRAM Immediately Appear Free

Part 1 - Exercise Contract and Why It Matters

The statement `del tensor` removes one Python reference; it is not a command that promises the driver an immediate increase in free VRAM. This exercise separates three events: reference removal, live-storage reclamation by PyTorch, and release of unused cached blocks to CUDA. You must demonstrate a case where allocated memory falls after deletion but driver free memory changes little because the caching allocator retains the block.

The exercise must distinguish delayed release caused by legitimate pending GPU work from retention caused by a Python reference. Synchronization can establish a clean diagnostic boundary, but it should not be inserted into production code without considering lost overlap. A block that cannot yet be reused by another stream is a scheduling issue; a block whose tensor remains reachable is an ownership issue; an inactive block held in the pool is an allocator-policy issue. Their visible symptom may initially be the same.

Your report should therefore describe deletion as the beginning of an investigation rather than proof that the device must immediately report more free memory.

Part 2 - System and Memory Mental Model

Python reference counting and garbage collection determine when tensor objects become unreachable. PyTorch then marks the associated allocator block unused when it is safe to do so. The block can remain reserved for reuse. Pending work on another CUDA stream may delay safe reuse, and a surviving view or autograd graph may keep storage genuinely live. Thus deletion, deallocation, cache retention, and device release are separate transitions.

Part 3 - Quantitative Prediction Before Execution

Allocate a 512 MiB tensor. Predict an allocated increase near 512 MiB and a driver-free decrease only when new segments are requested. Delete the sole reference and predict an allocated decrease near 512 MiB, a small reserved change, and little driver-free recovery. After cache release, predict a larger driver-free increase. Repeat while keeping a view and predict that allocated memory will not fall until the view is deleted.

Part 4 - Experimental Design and Instrumentation

Use two trials: sole-owner deletion and surviving-view deletion. Synchronize before measurements. Call garbage collection separately from cache release. Record storage pointers to prove the view owns access to the same storage. Do not create a measurement list that stores tensors.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def state(label, device):
    torch.cuda.synchronize(device)
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
```

```
    return (
        label,
        torch.cuda.memory_allocated(device),
        torch.cuda.memory_reserved(device),
        free_bytes,
        total_bytes,
    )

def E09():
    device = torch.device("cuda:0")
    gc.collect()
    torch.cuda.empty_cache()
    rows = [state("baseline", device)]

    tensor = torch.empty(
        512 * 1024 * 1024 // 4,
        dtype=torch.float32,
        device=device,
    )
    rows.append(state("live", device))

    view = tensor[:1024]
    del tensor
    gc.collect()
    rows.append(state("original deleted, view alive", device))

    del view
    gc.collect()
    rows.append(state("all references deleted", device))

    torch.cuda.empty_cache()
    rows.append(state("unused cache released", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Explain each counter transition. If allocated drops before the view is deleted, verify that the chosen slice truly shares the original storage. If it never drops, inspect hidden references and synchronize pending work. If driver free does not recover exactly the payload after cache release, account for allocator rounding and other device consumers rather than forcing equality.

Part 7 - Engineering Interpretation and Philosophy

Deletion expresses loss of one name, not immediate physical surrender of capacity. High-level languages, frameworks, allocators, and devices cooperate through delayed ownership transitions. This separation is useful because reuse is fast, but it requires conceptual patience: the engineer must ask which layer has released what, to whom, and for which future use.

19.2.11 Exercise 10

Exercise Title: Experiment with torch.cuda.empty_cache() and Prove What Memory It Releases and What Memory It Cannot Release

Part 1 - Exercise Contract and Why It Matters

`torch.cuda.empty_cache()` is frequently presented as a cure for CUDA memory problems. This exercise replaces that myth with a precise contract. You will call it while a large tensor is live, after the tensor is deleted, and inside a repeated allocation loop. You must prove that it cannot release live tensor storage, may release eligible unused cached blocks, does not increase the memory available to PyTorch beyond freeing its own unused pool, and may reduce performance when called unnecessarily.

You must examine one situation in which releasing the cache is operationally useful: for example, a notebook that has finished a large temporary experiment and will allow a second process to use the device. This prevents the exercise from replacing one myth with another. The function is neither a universal cure nor universally wrong; it is a policy intervention whose value depends on the next consumer and the cost of rebuilding the pool.

The deliverable must state the exact trigger that would justify calling it in a real system. "Memory looks high" is not a sufficient trigger.

Part 2 - System and Memory Mental Model

The operation asks the caching allocator to return releasable unused blocks to CUDA. It does not invalidate tensors, detach graphs, remove Python references, move data to CPU, or reduce a tensor's payload. If allocated memory is close to reserved memory because nearly all blocks are live, little can be returned. If reserved greatly exceeds allocated after a temporary peak, more cache may be eligible. Releasing blocks can help another process obtain capacity or alter fragmentation state, but later PyTorch allocations may need expensive device allocation again.

Part 3 - Quantitative Prediction Before Execution

For a live 256 MiB tensor, predict no meaningful allocated reduction after cache release. After deleting it, predict allocated reduction first and possible reserved reduction only after cache release. For a loop of 100 repeated allocations, predict higher latency when cache is emptied every iteration than when the allocator reuses its pool.

Part 4 - Experimental Design and Instrumentation

Build a semantic trial and a performance trial. The semantic trial records allocated, reserved, and driver free at each stage. The performance trial uses warm-up, CUDA events, synchronization, identical tensor sizes, and several repetitions. Do not combine timing from a cold first allocation with warm steady-state results.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def measure_loop(device, clear_each_iteration, iterations):
    start_event = torch.cuda.Event(enable_timing=True)
```

```
    end_event = torch.cuda.Event(enable_timing=True)

    start_event.record()
    for iteration in range(iterations):
        tensor = torch.empty(
            (32, 1024, 1024),
            dtype=torch.float32,
            device=device,
        )
        tensor.add_(1.0)
        del tensor
        if clear_each_iteration:
            gc.collect()
            torch.cuda.empty_cache()
    end_event.record()
    torch.cuda.synchronize(device)
    return start_event.elapsed_time(end_event)

def E10():
    device = torch.device("cuda:0")
    live = torch.empty(
        (64, 1024, 1024),
        dtype=torch.float32,
        device=device,
    )

    before = torch.cuda.memory_allocated(device)
    torch.cuda.empty_cache()
    while_live = torch.cuda.memory_allocated(device)
    assert while_live >= before

    del live
    gc.collect()
    after_delete = torch.cuda.memory_allocated(device)
    reserved_before_release = torch.cuda.memory_reserved(device)
    torch.cuda.empty_cache()
    reserved_after_release = torch.cuda.memory_reserved(device)

    reuse_ms = measure_loop(device, False, 100)
    clear_ms = measure_loop(device, True, 100)
    return {
        "after_delete": after_delete,
        "reserved_before_release": reserved_before_release,
        "reserved_after_release": reserved_after_release,
        "reuse_ms": reuse_ms,
        "clear_every_time_ms": clear_ms,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that live allocated memory survives the cache call. Report how much reserved memory becomes driver-free only after references are removed. Repeat timing trials and use the median because host garbage collection adds noise. If cache clearing appears faster in one short run, increase repetitions and separate warm-up. Never conclude that it fixes a reference leak unless allocated memory also falls for a separately proven reason.

Part 7 - Engineering Interpretation and Philosophy

`empty_cache()` is a negotiation between PyTorch and the wider device, not a garbage collector for user mistakes. Its misuse reflects a desire for a ritual that makes numbers smaller without understanding ownership. The better practice is causal: release references, verify liveness, diagnose the pool, and use cache release only when returning inactive capacity serves a defined system goal.

19.2.12 Exercise 11

Exercise Title: Detect a Hidden CUDA Tensor Reference That Prevents Memory from Being Released and Fix the Leak

Part 1 - Exercise Contract and Why It Matters

Many PyTorch leaks are not failures to free memory; they are failures to stop owning it. This exercise creates three hidden-reference patterns: appending a loss tensor to a Python list, retaining a view after deleting its base name, and holding an autograd graph through a tensor with `grad_fn`. You will measure the positive allocated-memory slope, locate the reference, repair it, and add a regression assertion that the stable version no longer grows.

The leak must be diagnosed without immediately calling `empty_cache()`. Cache release can change reserved memory and distract from the live allocated slope, but it cannot invalidate a tensor that remains reachable. Begin by proving continued liveness, then identify the ownership path, then repair the representation stored by the program. This order turns the fix into a causal explanation.

Your repaired version must preserve the information actually needed for later analysis. Replacing every tensor with nothing is not a valid fix if the training history is required. Store a scalar, a bounded CPU sample, or an explicit summary whose lifetime and capacity are designed.

Part 2 - System and Memory Mental Model

Python containers, closures, object attributes, exception tracebacks, notebook history, and autograd graphs can extend tensor lifetime. Storing `loss` retains its graph; storing `loss.item()` stores a CPU number. Storing `loss.detach()` removes gradient history but may still retain CUDA storage. Moving the small detached result to CPU prevents that specific GPU residency. A view keeps the underlying storage alive even if the base variable is deleted.

Part 3 - Quantitative Prediction Before Execution

Choose a model and batch whose graph adds a measurable but safe amount per iteration. Predict near-linear allocated growth when raw losses are appended. Predict stable allocated memory when only Python floats are stored. Estimate the slope in MiB per iteration and the iteration count at which an 8 GiB GPU would fail if the slope continued.

Part 4 - Experimental Design and Instrumentation

Run leaking and repaired loops from comparable clean baselines for at least 50 iterations. Record end-of-iteration allocated memory. Keep model, input shape, seed, and optimizer identical. Use `gc.get_referrers()` only as an optional diagnostic because it can be noisy; begin with an ownership inventory of every persistent container.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def run_case(device, keep_graph_tensors, iterations):
    model = torch.nn.Sequential(
        torch.nn.Linear(1024, 2048),
        torch.nn.ReLU(),
        torch.nn.Linear(2048, 1),
    ).to(device)
    optimizer = torch.optim.Adam(model.parameters(), lr=0.001)
    history = []
    memory_rows = []

    for iteration in range(iterations):
        inputs = torch.randn(
            (512, 1024),
            dtype=torch.float32,
            device=device,
        )
        targets = torch.randn(
            (512, 1),
            dtype=torch.float32,
            device=device,
        )

        optimizer.zero_grad(set_to_none=True)
        predictions = model(inputs)
        loss = torch.nn.functional.mse_loss(predictions, targets)
        loss.backward()
        optimizer.step()

        if keep_graph_tensors:
            history.append(loss)
        else:
            history.append(loss.item())

        del inputs
        del targets
        del predictions
        del loss
```

```
        gc.collect()
        torch.cuda.synchronize(device)
        memory_rows.append(torch.cuda.memory_allocated(device))

    return history, memory_rows

def E11():
    device = torch.device("cuda:0")
    leaking_history, leaking_rows = run_case(device, True, 50)
    del leaking_history
    gc.collect()
    torch.cuda.empty_cache()

    safe_history, safe_rows = run_case(device, False, 50)
    return leaking_rows, safe_rows, safe_history
```

Part 6 - Measurement, Validation, and Failure Analysis

Fit a simple end-minus-start slope and compare the last ten iterations with the first ten. Confirm that clearing the leaking history lowers allocated memory. If the repaired loop still grows, inspect optimizer initialization, cuDNN warm-up, variable input shapes, and measurement records. Distinguish a short warm-up plateau from unbounded growth by extending the run. The regression test should allow bounded allocator noise but reject a sustained slope.

Part 7 - Engineering Interpretation and Philosophy

A leak is often valid ownership applied for too long. The framework cannot know that a loss tensor stored in a list was intended only as a number. Memory safety therefore depends on semantic lifetime: the programmer must express when information should survive and in what representation. The deeper lesson is that persistence is a design decision, even when it is introduced accidentally by a convenient container.

19.2.13 Exercise 12

Exercise Title: Measure Forward-Pass and Backward-Pass Memory Separately in a PyTorch Neural Network Training Step

Part 1 - Exercise Contract and Why It Matters

End-of-step memory hides the phases that create peak demand. This exercise divides one training iteration into input creation, forward pass, loss construction, backward pass, optimizer step, and cleanup. You will record current and peak memory after every phase and explain why forward retains activations for backward, why backward creates gradients, and why some saved activations can be released as gradient computation progresses.

Phase separation is also required for comparing memory optimizations. Activation checkpointing primarily changes what survives from forward into backward, gradient clearing changes the state after backward, and optimizer choice changes persistent and update-stage state. Without phase attribution, all three techniques may appear as one unexplained change in a global peak.

The output of this exercise must therefore be a timeline with both current and high-water values. It should show not only where the maximum occurs, but what new objects become live and what earlier objects cease to be needed at each boundary.

Part 2 - System and Memory Mental Model

During forward with gradient tracking, autograd records operations and saves selected tensors needed to compute derivatives. Parameters are persistent; activations are phase-dependent. Backward materializes or accumulates parameter gradients and may release saved intermediates after their final use. The peak can occur during forward, early backward, or optimizer update depending on the model and optimizer. A single "training memory" value therefore lacks enough temporal structure.

Part 3 - Quantitative Prediction Before Execution

Calculate parameter payload and input payload before running. Estimate output sizes layer by layer for a three-layer MLP and identify activations likely saved for backward. Predict that forward current memory exceeds the input-plus- parameter baseline and that backward adds gradient storage approximately equal to the trainable parameter payload when gradients use the same dtype. Do not claim an exact backward peak without measuring temporary buffers.

Part 4 - Experimental Design and Instrumentation

Warm up the model once so initialization does not dominate. Clear gradients by assigning them to `None`, reset peaks, and run one measured step. Synchronize at phase boundaries. Repeat with `torch.no_grad()` for an inference forward pass. Keep input, architecture, batch, and dtype fixed.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def mark(label, device):
    torch.cuda.synchronize(device)
    return {
        "label": label,
        "current": torch.cuda.memory_allocated(device),
        "peak": torch.cuda.max_memory_allocated(device),
    }

def E12():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.ReLU(),
        torch.nn.Linear(8192, 4096),
        torch.nn.ReLU(),
        torch.nn.Linear(4096, 1000),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.001)

    inputs = torch.randn((128, 4096), device=device)
```

```
    targets = torch.randint(0, 1000, (128,), device=device)
    optimizer.zero_grad(set_to_none=True)
    torch.cuda.reset_peak_memory_stats(device)

    rows = [mark("inputs and model", device)]
    logits = model(inputs)
    rows.append(mark("after forward", device))

    loss = torch.nn.functional.cross_entropy(logits, targets)
    rows.append(mark("after loss", device))

    loss.backward()
    rows.append(mark("after backward", device))

    optimizer.step()
    rows.append(mark("after optimizer step", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Calculate phase deltas and compare them with predicted parameter, activation, and gradient payloads. Use hooks or profiler evidence if backward peak is unexpected. Ensure warm-up does not leave gradients live. Repeat with `optimizer.zero_grad(set_to_none=False)` and explain why zero tensors remain allocated. If inference is not smaller, verify that it ran under `no_grad()` and that training outputs were no longer referenced.

Part 7 - Engineering Interpretation and Philosophy

Training is a choreography of lifetimes, not one static model footprint. A tensor's cost depends on when it overlaps with other tensors. This creates the possibility of checkpointing, offloading, and scheduling: memory can be reduced by changing overlap even when total information processed is unchanged. The philosophical shift is from asking what exists to asking what must coexist.

19.2.14 Exercise 13

Exercise Title: Measure the Additional VRAM Cost of Parameters, Gradients, Activations, and Optimizer State During Training

Part 1 - Exercise Contract and Why It Matters

This exercise constructs a component ledger for training memory. You will measure the incremental cost of model parameters, inputs and forward activations, parameter gradients, and AdamW optimizer state. The final table must compare theoretical payloads with observed phase deltas and identify temporary or allocator costs that do not fit a simple category. The purpose is to replace the misleading belief that model size equals parameter size.

The ledger must be produced for at least two optimizers, such as SGD without momentum and AdamW. This controlled comparison demonstrates that two training runs using the same model, batch, and dtype can have very different persistent footprints. It also reveals lazy initialization: an optimizer object may appear cheap until its first update materializes state for

every parameter.

Report both payload totals obtained by traversing real tensors and phase deltas obtained from allocator counters. Agreement supports the category model; disagreement identifies temporary overlap, early release, or a missing state category that must be investigated.

Part 2 - System and Memory Mental Model

For P parameter elements stored in s_p bytes, parameter payload is Ps_p. Same-dtype gradients can add approximately another Ps_p. Adam-style optimizers commonly maintain first and second moments, adding two state tensors per parameter, often in `float32`. Mixed-precision training may keep higher-precision master parameters. Activations scale with batch and model shape, while parameter and optimizer state do not scale with batch in the same way. Optimizer state is often initialized lazily at the first `step()`, so constructing the optimizer object alone may allocate little CUDA state.

Part 3 - Quantitative Prediction Before Execution

Count every parameter explicitly with `numel()` and calculate parameter, gradient, and two-moment payloads. Predict when each category first appears: parameters after model transfer, activations after forward, gradients after backward, and Adam state after the first optimizer step. State why bias and weight tensors must both be counted.

Part 4 - Experimental Design and Instrumentation

Begin before model creation and take synchronized snapshots after model transfer, input allocation, forward, backward, first optimizer step, and gradient clearing. Reset peaks before the measured step. Traverse optimizer state after initialization and sum tensor payloads directly. Do not assign all unexplained peak bytes to activations.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def parameter_bytes(model):
    total = 0
    for parameter in model.parameters():
        total = total + parameter.numel() * parameter.element_size()
    return total

def gradient_bytes(model):
    total = 0
    for parameter in model.parameters():
        if parameter.grad is not None:
            total = total + (
                parameter.grad.numel() * parameter.grad.element_size()
            )
    return total

def optimizer_state_bytes(optimizer):
    total = 0
    for state in optimizer.state.values():
```

```
        for value in state.values():
            if torch.is_tensor(value):
                total = total + value.numel() * value.element_size()
    return total

def E13():
    device = torch.device("cuda:0")
    baseline = torch.cuda.memory_allocated(device)

    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 4096),
        torch.nn.GELU(),
        torch.nn.Linear(4096, 4096),
    ).to(device)
    after_parameters = torch.cuda.memory_allocated(device)

    optimizer = torch.optim.AdamW(model.parameters(), lr=0.001)
    inputs = torch.randn((256, 4096), device=device)
    targets = torch.randn((256, 4096), device=device)
    optimizer.zero_grad(set_to_none=True)

    outputs = model(inputs)
    loss = torch.nn.functional.mse_loss(outputs, targets)
    after_forward = torch.cuda.memory_allocated(device)

    loss.backward()
    after_backward = torch.cuda.memory_allocated(device)
    optimizer.step()
    after_step = torch.cuda.memory_allocated(device)

    return {
        "observed_parameter_delta": after_parameters - baseline,
        "observed_forward_delta": after_forward - after_parameters,
        "observed_backward_delta": after_backward - after_forward,
        "observed_step_delta": after_step - after_backward,
        "theoretical_parameter_bytes": parameter_bytes(model),
        "live_gradient_bytes": gradient_bytes(model),
        "optimizer_state_bytes": optimizer_state_bytes(optimizer),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that the parameter traversal agrees closely with the model-transfer delta. Confirm that optimizer state is near zero before the first step and substantial afterward. Explain step counters or scalar state tensors rather than assuming exactly two full buffers and nothing else. Repeat with SGD and compare state payload. If phase subtraction becomes negative because earlier activations were freed, switch from naive deltas to a lifetime table and peak measurements.

Part 7 - Engineering Interpretation and Philosophy

The memory cost of learning is larger than the memory cost of knowing. A trained parameter stores a result; training must also store evidence about how to change it, historical optimizer information, and intermediate states that assign credit. Memory accounting reveals that optimization algorithms are physical systems with persistent state, not abstract update rules. Choosing an optimizer is therefore also choosing a memory architecture.

19.2.15 Exercise 14

Exercise Title: Sweep Batch Size Until GPU Memory Growth Reaches the Out-of-Memory Boundary and Record the Scaling Curve

Part 1 - Exercise Contract and Why It Matters

Batch size changes activation, input, target, workspace, and sometimes algorithm-selection memory. The relationship with peak VRAM is often close to linear over a stable regime but should never be assumed globally. This exercise builds a bounded sweep, measures peak training memory for increasing micro-batches, fits the observed scaling curve, and estimates the OOM boundary without crashing the primary process. The final result must report the largest validated batch and a conservative recommended batch with explicit headroom.

The curve must also distinguish micro-batch size from effective batch size. Gradient accumulation can preserve a large effective batch while reducing the activation peak of each micro-step, but it changes the number and timing of forward/backward passes. This exercise measures the physical micro-batch boundary first so later chapters can reason about accumulation without confusing optimization semantics with one-step capacity.

Document why the sweep stops. It may stop because the safety budget was reached, the estimated next point was unsafe, the experiment hit its configured maximum, or a controlled child trial observed OOM. These outcomes must not all be labeled as the exact hardware limit.

Part 2 - System and Memory Mental Model

Separate persistent memory P from batch-dependent memory:

$$M_{\text{peak}}(B) \approx P + \alpha B + \epsilon(B).$$

α represents the marginal bytes per sample and $\epsilon(B)$ includes nonlinear workspaces, allocator rounding, and implementation changes. The mathematical boundary $B^* = (M_{\text{budget}} - P)/\alpha$ is only an estimate. A production choice should satisfy a smaller operational budget to survive variation.

Part 3 - Quantitative Prediction Before Execution

Calculate input and target bytes per sample and estimate major activation bytes. Choose candidate batches by gradual growth, such as $8, 16, 24, \ldots$, rather than doubling into an enormous request. Define a measurement budget no larger than 70–80 percent of free memory on a shared or display GPU. Predict the slope from tensor shapes and later compare it with the fitted empirical slope.

Part 4 - Experimental Design and Instrumentation

Warm up the model at the smallest batch. For every candidate, clear references, reset peak statistics, run one forward and backward step, synchronize, record peak allocated and reserved,

then clean up. Stop before the predicted next case exceeds the safety budget. Repeat each validated batch three times and use the maximum peak for capacity planning. Do not use `empty_cache()` as a substitute for consistent lifetime cleanup.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def measured_step(model, batch_size, device):
    model.zero_grad(set_to_none=True)
    torch.cuda.reset_peak_memory_stats(device)

    inputs = torch.randn(
        (batch_size, 4096),
        dtype=torch.float32,
        device=device,
    )
    targets = torch.randint(
        0,
        1000,
        (batch_size,),
        device=device,
    )

    logits = model(inputs)
    loss = torch.nn.functional.cross_entropy(logits, targets)
    loss.backward()
    torch.cuda.synchronize(device)
    peak = torch.cuda.max_memory_allocated(device)

    del inputs
    del targets
    del logits
    del loss
    model.zero_grad(set_to_none=True)
    gc.collect()
    return peak

def E14():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.GELU(),
        torch.nn.Linear(8192, 1000),
    ).to(device)

    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    safety_budget = int(free_bytes * 0.75)
```

```
    results = []

    batch_size = 8
    while batch_size <= 4096:
        peaks = []
        for repetition in range(3):
            peak = measured_step(model, batch_size, device)
            peaks.append(peak)

        worst_peak = max(peaks)
        results.append((batch_size, worst_peak))

        if worst_peak >= safety_budget:
            break
        batch_size = batch_size + 8

    return {
        "results": results,
        "safety_budget": safety_budget,
        "device_total": total_bytes,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot peak MiB against batch size and compute local slopes between adjacent points. Identify discontinuities rather than hiding them behind one regression line. Confirm that every point performed the same training computation. If a candidate unexpectedly OOMs, record the last successful batch, terminate that trial cleanly, and do not continue from a possibly damaged state. Compare the empirical safe maximum with the model-based prediction and explain the margin.

Part 7 - Engineering Interpretation and Philosophy

The largest batch that succeeds once is not the largest batch that can be trusted. Reliability requires distance from the cliff because memory demand is not perfectly stationary. Capacity planning is therefore a problem of margins, not records. The philosophy is to learn the shape of the boundary while refusing to confuse proximity to failure with efficient use of hardware.

19.2.16 Exercise 15

Exercise Title: Trigger a Controlled CUDA Out-of-Memory Error and Capture Memory Statistics Immediately Before Failure

Part 1 - Exercise Contract and Why It Matters

An OOM handler that has never been tested is only a hope. This exercise creates a controlled failure inside a child process, captures a pre-attempt memory snapshot, records the exception text, and proves that the parent process survives. The experiment must never be run blindly on a GPU driving critical work. On a shared or display GPU, replace the physical OOM with a simulated budget exception. A dedicated secondary GPU is preferred.

The deliverable includes a simulated failure path because production recovery logic should be testable without consuming a whole device. Define a custom budget exception raised before allocation when a request violates a configured limit. First prove that logging and cleanup work under simulation; only then, and only on suitable hardware, repeat with the real allocator exception. The two paths should produce the same structured failure record.

An OOM is considered controlled only when the target device, maximum attempted request, process boundary, expected exception, cleanup behavior, and success criteria were all specified before execution. Catching an accidental crash afterward does not satisfy the contract.

Part 2 - System and Memory Mental Model

CUDA execution is asynchronous, so an error may surface at a synchronization point later than the operation that initiated pressure. An allocation failure does not necessarily mean all theoretical bytes were in live tensors; fragmentation, reserved blocks, driver consumers, and temporary requests matter. The exception object is evidence, but allocator statistics and a snapshot immediately before the failing request provide the context needed to interpret it. Isolating the test in a child process gives the CUDA context a clear recovery boundary.

Part 3 - Quantitative Prediction Before Execution

Read driver free memory and choose a requested tensor slightly larger than the allowed free capacity. Convert requested bytes into `float32` elements using ceiling division. Predict that the request fails without becoming a live allocation. Record how allocated, reserved, and free values differ before and after exception handling. Do not pre-fill the GPU to 100 percent merely to force failure.

Part 4 - Experimental Design and Instrumentation

Use `multiprocessing` with the spawn start method. The child selects an explicit device, warms the CUDA context, clears eligible cache, records its pre-failure snapshot, and attempts one oversized allocation. It catches only the expected out-of-memory class or a RuntimeError whose message is validated. The parent checks the exit code and reads a small CPU result through a queue. Run a simulated policy failure first.

Part 5 - PyTorch/CUDA Implementation

```
import math
import multiprocessing as mp
import torch

def child_oom_experiment(device_index, output_queue):
    device = torch.device(f"cuda:{device_index}")
    torch.cuda.set_device(device)
    torch.cuda.empty_cache()
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)

    before = {
        "allocated": torch.cuda.memory_allocated(device),
        "reserved": torch.cuda.memory_reserved(device),
        "free": free_bytes,
        "total": total_bytes,
```

```
    }

    requested_bytes = free_bytes + (64 * 1024 * 1024)
    requested_elements = math.ceil(requested_bytes / 4)

    try:
        impossible = torch.empty(
            requested_elements,
            dtype=torch.float32,
            device=device,
        )
        output_queue.put({
            "unexpected_success": True,
            "before": before,
        })
        del impossible
    except torch.OutOfMemoryError as error:
        output_queue.put({
            "unexpected_success": False,
            "before": before,
            "requested_bytes": requested_bytes,
            "error": str(error),
        })

def E15(device_index=1):
    if torch.cuda.device_count() <= device_index:
        raise RuntimeError(
            "Use simulated OOM unless a dedicated CUDA device exists."
        )

    context = mp.get_context("spawn")
    output_queue = context.Queue()
    process = context.Process(
        target=child_oom_experiment,
        args=(device_index, output_queue),
    )
    process.start()
    process.join()

    if process.exitcode != 0:
        raise RuntimeError("OOM child did not exit cleanly.")
    return output_queue.get()
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm that the child caught the expected error and exited with code zero. Preserve the full exception only in the artifact because wording varies across versions. Verify that the parent can run a small CUDA operation afterward. If the allocation unexpectedly succeeds, stop rather than requesting a larger unbounded tensor; re-check the free-memory measurement

and virtual-memory behavior. For a workstation with two RTX 3070 cards, use the non-display card when available and close other GPU workloads first.

Part 7 - Engineering Interpretation and Philosophy

Failure is part of a system's contract. Controlled failure testing converts OOM from a frightening accident into an observable state transition with a safe boundary. Yet experimentation has an ethical constraint: understanding a limit does not justify destabilizing shared hardware. The mature engineer designs a failure that teaches the mechanism while containing its consequences.

19.2.17 Exercise 16

Exercise Title: Build a Memory Budget Estimator and Compare Its Predicted Peak VRAM Against Real PyTorch Measurements

Part 1 - Exercise Contract and Why It Matters

Tensor payload prediction becomes useful at system scale only when separate components are combined into a budget. This exercise builds an estimator for parameters, gradients, optimizer state, inputs, layer outputs, saved activations, and configurable headroom. It then compares predicted peak VRAM with measured peak allocation for a known MLP. The report must expose every assumption; a single unexplained multiplier is not an acceptable estimator.

The estimator must support two modes. The explanatory mode exposes every category and favors transparency. The admission-control mode receives current free memory and decides whether a proposed batch may begin with a configurable margin. The second mode must be built from the first rather than hiding its logic inside an unexplained threshold.

Evaluate the estimator on shapes not used for calibration. A model that matches only one batch or architecture has not learned a resource law; it has recorded one measurement. Generalization here means that the accounting assumptions continue to describe how memory changes when a controlled dimension changes.

Part 2 - System and Memory Mental Model

A first-order training budget can be written as

$$M_{\text{estimate}} = M_P + M_G + M_O + M_I + M_A + M_T + M_H,$$

where parameter, gradient, optimizer, input, saved activation, temporary, and headroom terms are separate. Some objects overlap in lifetime and others do not, so adding every tensor ever created overestimates peak. Omitting temporaries underestimates it. The estimator should therefore use a phase lifetime table and state which terms coexist at the predicted peak.

Part 3 - Quantitative Prediction Before Execution

For each linear layer, compute weight and bias elements. Calculate same-dtype gradients and Adam first and second moments. Derive activation payload from batch and layer widths. Add an empirical temporary allowance only after reporting the subtotal it modifies. Produce a predicted range with lower and upper bounds rather than pretending that unknown kernel workspaces are exact.

Part 4 - Experimental Design and Instrumentation

Use several batch sizes while holding architecture fixed. Predict before each run, then reset peaks and measure one warmed training step. Record absolute error, percentage error, and error direction. Calibrate temporary allowance on one batch and evaluate it on different batches; otherwise the estimator merely memorizes one observation.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def tensor_payload_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def model_parameter_bytes(model):
    total = 0
    for parameter in model.parameters():
        total = total + tensor_payload_bytes(parameter)
    return total

def estimate_mlp_training_bytes(
    model,
    batch_size,
    layer_widths,
    optimizer_multiplier,
    temporary_fraction,
):
    parameters = model_parameter_bytes(model)
    gradients = parameters
    optimizer_state = int(parameters * optimizer_multiplier)

    activation_elements = 0
    for width in layer_widths:
        activation_elements = (
            activation_elements + batch_size * width
        )
    activations = activation_elements * 4

    subtotal = (
        parameters
        + gradients
        + optimizer_state
        + activations
    )
    temporary = int(subtotal * temporary_fraction)
    return {
        "parameters": parameters,
        "gradients": gradients,
        "optimizer_state": optimizer_state,
        "activations": activations,
        "temporary_allowance": temporary,
```

```
        "predicted_peak": subtotal + temporary,
    }

def E16():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.ReLU(),
        torch.nn.Linear(8192, 4096),
        torch.nn.ReLU(),
        torch.nn.Linear(4096, 1000),
    ).to(device)

    estimates = []
    batch_sizes = [16, 32, 64, 128]
    for batch_size in batch_sizes:
        estimate = estimate_mlp_training_bytes(
            model,
            batch_size,
            [4096, 8192, 4096, 1000],
            2.0,
            0.10,
        )
        estimates.append((batch_size, estimate))
    return estimates
```

Part 6 - Measurement, Validation, and Failure Analysis

Measure the real warmed training peak and compare it with the predicted range. If error grows with batch, the activation model is incomplete. If error is roughly constant, persistent state or baseline context may be missing. If the optimizer estimate is wrong, inspect actual state tensors after the first step. Never repair the model by adding an arbitrary constant without naming the mechanism it represents.

Part 7 - Engineering Interpretation and Philosophy

An estimator is not valuable because it predicts perfectly. It is valuable because its errors are structured enough to teach us what the mental model omitted. Prediction and measurement form a dialogue: theory proposes a ledger, hardware reveals the residual, and the next model becomes more precise. The philosophy is disciplined approximation, not false certainty.

19.2.18 Exercise 17

Exercise Title: Compare Training and Inference CUDA Memory Footprints for the Same Model, Batch Size, and Input Shape

Part 1 - Exercise Contract and Why It Matters

The same parameters can produce very different memory footprints depending on whether the runtime must preserve a graph and compute updates. This exercise compares a warmed training step with evaluation under ordinary grad mode, no-grad mode, and inference mode.

Model, input, batch, dtype, and output shape must remain identical. The report must separate current memory after execution from peak memory during execution.

The experiment must include two baselines. The research baseline keeps the optimizer alive so the same process can return to training. The deployment baseline loads only model state needed for prediction. Mixing these cases causes optimizer moments to be blamed on inference even though a serving process would never create them. Both measurements are useful, but they answer different operational questions.

Also inspect output retention. An inference service that appends GPU outputs to a request history can leak despite using inference mode correctly. Autograd control removes graphs; it does not design application-level lifetime.

Part 2 - System and Memory Mental Model

Training requires forward activations saved for backward, parameter gradients, and optimizer state. Evaluation mode changes module behavior such as dropout and BatchNorm, but `model.eval()` alone does not disable autograd. `no_grad()` prevents graph recording for operations inside its context. `inference_mode()` applies stronger inference-oriented restrictions and can remove additional autograd bookkeeping. These controls answer different questions and should be used together with correct model mode.

Part 3 - Quantitative Prediction Before Execution

Calculate parameter and input payloads. Predict that trained optimizer state remains persistent if the optimizer is kept alive during inference comparison. For a clean deployment footprint, predict again after discarding optimizer and gradients. Expect training peak to exceed inference peak because activations and gradients overlap. Predict that `eval()` without no-grad remains closer to training forward memory than proper inference.

Part 4 - Experimental Design and Instrumentation

Use identical pre-created inputs. Warm each mode separately, remove outputs, reset peak statistics, and run several repetitions. For fair model-only inference, set gradients to None and delete optimizer state or perform the test in a new process loaded only with model weights. Verify numerical parity between no-grad and inference mode within tolerance.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def measure_inference(model, inputs, device, use_inference_mode):
    model.eval()
    torch.cuda.reset_peak_memory_stats(device)

    if use_inference_mode:
        with torch.inference_mode():
            outputs = model(inputs)
    else:
        with torch.no_grad():
            outputs = model(inputs)
```

```
    torch.cuda.synchronize(device)
    peak = torch.cuda.max_memory_allocated(device)
    copied = outputs.detach().cpu()
    del outputs
    gc.collect()
    return peak, copied

def measure_training(model, inputs, targets, device):
    model.train()
    model.zero_grad(set_to_none=True)
    torch.cuda.reset_peak_memory_stats(device)
    outputs = model(inputs)
    loss = torch.nn.functional.cross_entropy(outputs, targets)
    loss.backward()
    torch.cuda.synchronize(device)
    peak = torch.cuda.max_memory_allocated(device)
    del outputs
    del loss
    return peak

def E17():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.ReLU(),
        torch.nn.Linear(8192, 1000),
    ).to(device)
    inputs = torch.randn((128, 4096), device=device)
    targets = torch.randint(0, 1000, (128,), device=device)

    training_peak = measure_training(
        model, inputs, targets, device
    )
    model.zero_grad(set_to_none=True)
    no_grad_peak, output_a = measure_inference(
        model, inputs, device, False
    )
    inference_peak, output_b = measure_inference(
        model, inputs, device, True
    )

    assert torch.allclose(output_a, output_b, atol=1e-5, rtol=1e-5)
    return training_peak, no_grad_peak, inference_peak
```

Part 6 - Measurement, Validation, and Failure Analysis

Report both absolute peaks and deltas above the persistent model-plus-input baseline. If inference appears larger, inspect surviving training gradients, outputs, or optimizer state. Confirm `model.eval()` was used and that the comparison did not include first-call kernel initial-

ization in only one mode. Verify predictions, because a smaller footprint obtained through changed dtype or shape is not the same experiment.

Part 7 - Engineering Interpretation and Philosophy

One model does not have one memory cost. Cost belongs to a mode of use and a lifetime policy. Training asks the system to remember how an answer was constructed so it can assign credit; inference asks only for the answer. The contrast shows that memory is partly the price of future possibility: gradients require the past because the model intends to change.

19.2.19 Exercise 18

Exercise Title: Build a Live GPU Memory Monitor That Records PyTorch CUDA Memory at Every Stage of a Training Iteration

Part 1 - Exercise Contract and Why It Matters

Manual snapshots are useful but easy to omit. This exercise builds a reusable stage monitor implemented as a context manager. It records timestamps, allocated and reserved memory, peaks, driver free memory, stage duration, and exceptions. The monitor must store only CPU metadata so that measurement does not retain the CUDA tensors it is supposed to observe. It will instrument data transfer, forward, loss, backward, optimizer step, and cleanup.

The monitor must remain useful after the tutorial. Add optional run, epoch, iteration, and request identifiers so records from concurrent or repeated work can be grouped. A stage label alone is ambiguous when hundreds of iterations share the same name. The schema should support threshold warnings without printing tensors or invoking expensive snapshots on every normal step.

Design two operating levels: lightweight continuous counters and a heavy diagnostic mode activated after a threshold or anomaly. This reflects a real observability trade-off: enough evidence must be collected to detect change, but the measurement system must not dominate the workload it protects.

Part 2 - System and Memory Mental Model

A stage is a semantic interval with an entry and exit. CUDA kernels launched inside it may outlive the host statements unless the monitor synchronizes. Synchronization improves attribution but changes overlap and timing, so the monitor should offer an explicit synchronized diagnostic mode. The observer must also distinguish phase peak from global peak by resetting at the stage entry when phase-local high-water marks are desired.

Part 3 - Quantitative Prediction Before Execution

Before implementation, define the expected ordering of stage peaks. Predict which stages create persistent objects and which should return to baseline. Estimate the log size for N iterations and prove that storing numeric dictionaries is negligible compared with storing tensors. Define warning thresholds as fractions of total and free memory.

Part 4 - Experimental Design and Instrumentation

Run five training iterations and compare stage reports. The first iteration is warm-up and should be labeled rather than mixed with steady state. Validate that the monitor logs an exception stage without suppressing the exception. Export JSON lines so a partial log remains readable if the process ends.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

class CudaMemoryStage:
    def __init__(self, label, device, records, synchronize=True):
        self.label = label
        self.device = torch.device(device)
        self.records = records
        self.synchronize = synchronize
        self.start_time = None

    def __enter__(self):
        if self.synchronize:
            torch.cuda.synchronize(self.device)
        torch.cuda.reset_peak_memory_stats(self.device)
        self.start_time = time.perf_counter()
        return self

    def __exit__(self, error_type, error_value, traceback):
        if self.synchronize:
            torch.cuda.synchronize(self.device)
        end_time = time.perf_counter()
        free_bytes, total_bytes = torch.cuda.mem_get_info(self.device)

        record = {}
        record["label"] = self.label
        record["duration_seconds"] = end_time - self.start_time
        record["allocated_bytes"] = torch.cuda.memory_allocated(
            self.device
        )
        record["reserved_bytes"] = torch.cuda.memory_reserved(
            self.device
        )
        record["stage_peak_bytes"] = torch.cuda.max_memory_allocated(
            self.device
        )
        record["free_bytes"] = free_bytes
        record["total_bytes"] = total_bytes
        record["failed"] = error_type is not None
        if error_value is None:
            record["error"] = None
        else:
            record["error"] = str(error_value)
        self.records.append(record)
        return False

def E18(model, optimizer, cpu_inputs, cpu_targets):
```

```
    device = torch.device("cuda:0")
    records = []

    with CudaMemoryStage("transfer", device, records):
        inputs = cpu_inputs.to(device)
        targets = cpu_targets.to(device)

    with CudaMemoryStage("forward", device, records):
        predictions = model(inputs)

    with CudaMemoryStage("loss", device, records):
        loss = torch.nn.functional.cross_entropy(
            predictions, targets
        )

    optimizer.zero_grad(set_to_none=True)
    with CudaMemoryStage("backward", device, records):
        loss.backward()

    with CudaMemoryStage("optimizer", device, records):
        optimizer.step()

    return records
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that every record is JSON serializable and contains no CUDA tensor. Compare phase peaks with the global peak from a separate whole-iteration measurement. They need not add because stages occur at different times. Measure monitor overhead with synchronization enabled and disabled. If stage attribution changes, explain the role of asynchronous execution rather than selecting whichever number looks cleaner.

Part 7 - Engineering Interpretation and Philosophy

Observability converts memory from an internal accident into an operational signal. Yet instruments influence systems: synchronization may destroy overlap, and excessive logging may change timing. The mature approach is not invisible measurement, which is impossible, but declared measurement whose disturbance is understood and bounded.

19.2.20 Exercise 19

Exercise Title: Build a Complete Memory Accounting Experiment That Explains Every Major MiB of VRAM Used by a PyTorch Model

Part 1 - Exercise Contract and Why It Matters

The final exercise integrates the entire chapter into an auditable memory accounting report. You will select one PyTorch model and explain every major MiB category during initialization, forward, backward, optimizer update, and inference. Exact byte attribution for every library workspace may be impossible, but every residual must be bounded, named, and investigated.

The report must include theoretical calculations, synchronized measurements, peak timelines, allocator behavior, driver reconciliation, a controlled reference leak, and a correction.

The report must make three types of claim visually distinct. A calculated claim comes from shapes and dtypes; a measured claim comes from an instrument at a specified boundary; an inferred claim explains a residual by combining several observations. Treating an inference as direct measurement makes the ledger look more certain than the evidence permits.

Include a reproducibility package containing raw JSON records, environment metadata, formulas, code version, and plots generated from the raw data. A reader should be able to recalculate every table cell without copying numbers from an image. The report is complete only when it can be challenged and recomputed.

Part 2 - System and Memory Mental Model

Construct a two-dimensional ledger: rows are memory categories and columns are execution phases. Categories include parameters, buffers, inputs, targets, outputs, saved activations, gradients, optimizer state, allocator slack, temporary workspaces, CUDA or library overhead, and external device use. A category occupies a phase only when its storage is live. Peak is produced by the sum of simultaneous residents, not by the sum of every allocation over the whole run.

$$M_{\text{device used}} = M_{\text{PyTorch reserved}} + M_{\text{outside pool}},$$

$$M_{\text{PyTorch reserved}} = M_{\text{live tensor}} + M_{\text{cached slack}}.$$

These identities organize evidence but do not magically identify each tensor. Use module traversal, optimizer-state traversal, phase snapshots, profiler evidence, and memory snapshots to refine the ledger.

Part 3 - Quantitative Prediction Before Execution

Before the final run, calculate parameter, buffer, gradient, optimizer, input, target, and output payloads. Estimate saved activations layer by layer and state which may share storage. Build lower and upper bounds for the expected peak. Choose a residual significance threshold such as 1 percent of total device capacity or 32 MiB, whichever better suits the test device. A residual above the threshold requires investigation, not arbitrary reassignment.

Part 4 - Experimental Design and Instrumentation

Run in a fresh process and save hardware, PyTorch, CUDA, dtype, shape, seed, and allocator configuration metadata. Warm up once, then perform a measured training step with stage monitoring. Repeat inference in a clean state. Export raw byte records, a MiB table, a peak timeline, and a narrative explanation. Introduce one hidden loss reference for several steps, detect it from slope, remove it, and prove recovery.

Part 5 - PyTorch/CUDA Implementation

```
import json
import platform
import torch

def sum_model_storage(model):
```

```
    parameter_bytes = 0
    buffer_bytes = 0

    for parameter in model.parameters():
        parameter_bytes = parameter_bytes + (
            parameter.numel() * parameter.element_size()
        )

    for buffer in model.buffers():
        buffer_bytes = buffer_bytes + (
            buffer.numel() * buffer.element_size()
        )

    return parameter_bytes, buffer_bytes

def build_metadata(device):
    metadata = {}
    metadata["python_platform"] = platform.platform()
    metadata["torch_version"] = torch.__version__
    metadata["cuda_version"] = torch.version.cuda
    metadata["device_name"] = torch.cuda.get_device_name(device)
    metadata["device_count"] = torch.cuda.device_count()
    return metadata

def validate_ledger(ledger):
    required = [
        "parameters",
        "buffers",
        "inputs",
        "activations",
        "gradients",
        "optimizer_state",
        "allocator_slack",
        "driver_residual",
    ]
    missing = []
    for category in required:
        if category not in ledger:
            missing.append(category)
    if len(missing) != 0:
        raise RuntimeError(f"Missing ledger categories: {missing}")

def E19(model, optimizer, experiment_records, output_path):
    device = torch.device("cuda:0")
    parameter_bytes, buffer_bytes = sum_model_storage(model)

    ledger = {}
    ledger["parameters"] = parameter_bytes
```

```
    ledger["buffers"] = buffer_bytes
    # TODO: fill remaining categories from verified chapter tools
    ledger["inputs"] = ...
    ledger["activations"] = ...
    ledger["gradients"] = ...
    ledger["optimizer_state"] = ...
    ledger["allocator_slack"] = ...
    ledger["driver_residual"] = ...

    validate_ledger(ledger)
    report = {
        "metadata": build_metadata(device),
        "ledger_bytes": ledger,
        "timeline": experiment_records,
    }

    with open(output_path, "w", encoding="utf-8") as file:
        json.dump(report, file, indent=2)
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Reconcile the ledger at every phase, not only at peak. Verify tensor payloads by traversing the actual model and optimizer after lazy state initialization. Use allocated-versus-reserved deltas to avoid assigning cache slack to live activations. Compare driver use with PyTorch reserved and document other processes. If the ledger overcounts, inspect shared storage and non-overlapping lifetimes. If it undercounts, investigate temporary workspaces, saved tensors, and external allocations. The final report must state uncertainty honestly.

Part 7 - Engineering Interpretation and Philosophy

Complete accounting does not mean pretending that the runtime is perfectly transparent. It means organizing uncertainty so that major costs are visible, residuals are bounded, and claims can be audited. The chapter began with five numbers that appeared to describe the same memory. It ends with a model of ownership, caching, history, lifetime, and observation that explains why they differ.

The philosophy of dynamic memory management is responsibility for coexistence. Every byte represents a decision that some information should remain available at a particular place and time. Efficient systems do not merely delete more; they preserve exactly what the computation still needs, release what no longer has purpose, and maintain enough evidence to explain the difference.

19.3 DMM01

Chapter Title: PyTorch Profiler for Memory
Specialization: Dynamic Memory Management and CUDA Systems

19.3.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Operator-Level Memory Profiling in PyTorch and Distinguish It from Global CUDA Memory Counters

Part 1 - Exercise Contract and Why It Matters

DMM00 answered system-level questions: how many bytes are currently allocated, how many are reserved by the caching allocator, what peak was reached, and how much capacity the CUDA driver reports as free. Those counters reveal whether a workload fits and when its high-water mark occurs, but they do not identify the operation responsible for a change. This exercise introduces the PyTorch Profiler as an attribution instrument. Its purpose is to connect memory events to operators, execution regions, tensor shapes, call stacks, and CPU or CUDA activities.

The exercise must prevent a common conceptual error: the sum of memory columns in a profiler table is not automatically equal to the global allocated-memory peak. Profiler memory values describe allocation and deallocation events attributed to operators over time. Global peak memory describes the maximum simultaneous live allocation. Operations can allocate at different times, free storage before later operations begin, reuse allocator blocks, call child operations, and retain outputs beyond their own execution interval. Summing attributed events ignores these lifetimes and may double-count nested work.

Your deliverable is a controlled forward-and-backward profile accompanied by a four-layer evidence model. Layer one is the global CUDA state from DMM00. Layer two is profiler event attribution. Layer three is semantic lifetime: which outputs survive and why. Layer four is hardware activity: which CUDA kernels and transfers execute. For every reported memory number, state which layer produced it and which question it can answer.

The experiment is successful only if you can explain all of the following: why a high-memory operator may not determine global peak, why an operator with zero self memory may still have large total memory through children, why a deallocation may appear as a negative event, why CUDA activity is not identical to a high-level PyTorch operator, and why profiler instrumentation changes runtime and therefore must be used selectively.

This distinction matters in real optimization. A global counter can prove that peak memory decreased after a code change, while the profiler can suggest which operator caused the reduction. Neither evidence is sufficient alone. An operator table without global validation can optimize an attribution artifact; a peak counter without operator attribution can reveal a problem but not guide the repair.

Part 2 - System and Memory Mental Model

PyTorch executes high-level operations through a hierarchy. A Python call may dispatch an ATen operator, which may invoke child operators, request allocator blocks, and launch one or more CUDA kernels. The host call can finish before the device work completes. The profiler observes selected activities and associates events using correlation metadata, but the resulting table is a summary of an execution graph rather than a photograph of physical VRAM.

For an operator o, define self memory as memory directly attributed to the operator excluding nested child operators. Total memory includes the operator and descendants in its recorded

call tree. In simplified notation,

$$M_{\text{total}}(o) = M_{\text{self}}(o) + \sum_{c \in \text{children}(o)} M_{\text{total}}(c),$$

subject to the profiler's attribution rules. This identity explains why sorting by self memory and sorting by total memory answer different questions. Self memory highlights the location of direct allocation. Total memory highlights an inclusive region whose implementation may delegate the actual work.

Global allocated memory is a state function $A(t)$. The peak is

$$A_{\max} = \max_t A(t).$$

Profiler memory events are changes ΔA_i associated with events. Reconstructing a timeline requires event order and lifetimes:

$$A(t_k) = A(t_0) + \sum_{i \le k} \Delta A_i.$$

The unordered sum of positive allocations is total allocation traffic, not peak residency. A program may allocate and free the same 100 MiB workspace ten times, generating 1000 MiB of traffic while never holding more than 100 MiB from that workspace at once.

The caching allocator adds another layer. An operator can increase live allocated memory by consuming an already reserved block without decreasing driver free memory. Conversely, releasing a tensor can reduce live allocated memory while the block stays reserved. The profiler and DMM00 counters are therefore complementary views of live storage, allocator ownership, and event attribution.

Part 3 - Quantitative Prediction Before Execution

Before profiling, draw the expected operator graph of a small MLP: matrix multiplication or linear operations, bias addition, activation, second linear operation, loss, backward functions, gradient accumulation, and optimizer update. Calculate parameter, input, output, and major activation payloads. Predict which calls allocate new outputs and which can reuse or view existing storage.

Create two separate predictions. The event prediction ranks operators by expected direct allocation. The residency prediction identifies which tensors coexist at the forward and backward peaks. State explicitly why these rankings may differ. Predict profiler overhead qualitatively: enabling memory tracking adds bookkeeping, recording shapes retains metadata, and collecting stacks requires more host work and storage.

Part 4 - Experimental Design and Instrumentation

Use a fresh Python process, one explicit CUDA device, fixed seed, fixed shapes, and a warmed model. Capture CPU and CUDA activities. Enable memory profiling but leave stack collection disabled for this foundational run. Wrap the whole step in named profiler regions while preserving individual operators. Reset global peak statistics immediately before the active region and take DMM00 snapshots before and after.

Profile one measured training step, not a long uncontrolled loop. Synchronize before entering and after leaving the profiled region so the interval has a clear boundary. Export neither a trace nor a large artifact yet; inspect the event and key-average tables first. Record profiler configuration alongside results because different options create different evidence.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile
from torch.profiler import record_function

def global_memory(device):
    torch.cuda.synchronize(device)
    return {
        "allocated": torch.cuda.memory_allocated(device),
        "reserved": torch.cuda.memory_reserved(device),
        "peak": torch.cuda.max_memory_allocated(device),
    }

def E00():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM01.")

    device = torch.device("cuda:0")
    torch.manual_seed(7)
    torch.cuda.manual_seed_all(7)

    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.ReLU(),
        torch.nn.Linear(8192, 1000),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.001)
    inputs = torch.randn((128, 4096), device=device)
    targets = torch.randint(0, 1000, (128,), device=device)

    # Warm-up initializes lazy state outside the measured interval.
    warm_output = model(inputs)
    warm_loss = torch.nn.functional.cross_entropy(
        warm_output,
        targets,
    )
    warm_loss.backward()
    optimizer.step()
    optimizer.zero_grad(set_to_none=True)
    del warm_output
    del warm_loss
    torch.cuda.synchronize(device)
```

```
    torch.cuda.reset_peak_memory_stats(device)
    before = global_memory(device)

    activities = [
        ProfilerActivity.CPU,
        ProfilerActivity.CUDA,
    ]

    with profile(
        activities=activities,
        profile_memory=True,
        record_shapes=True,
        with_stack=False,
    ) as profiler:
        with record_function("training_step"):
            with record_function("forward"):
                output = model(inputs)
            with record_function("loss"):
                loss = torch.nn.functional.cross_entropy(
                    output,
                    targets,
                )
            with record_function("backward"):
                loss.backward()
            with record_function("optimizer"):
                optimizer.step()
                optimizer.zero_grad(set_to_none=True)

    torch.cuda.synchronize(device)
    after = global_memory(device)

    table = profiler.key_averages().table(
        sort_by="self_cuda_memory_usage",
        row_limit=25,
    )
    print(table)
    return profiler, before, after
```

Part 6 - Measurement, Validation, and Failure Analysis

First verify numerical execution: loss must be finite, parameters must receive gradients before the optimizer clears them, and output shape must remain $(128, 1000)$. Then inspect tables sorted independently by self CUDA memory, total CUDA memory, self CPU memory, and CUDA time. Do not assume the same operator leads every ranking.

Compare the global peak increase with predicted simultaneous residency. Use the profiler to identify allocation hotspots but do not sum all positive memory rows and call the result peak. Inspect negative values as possible deallocations. If CUDA rows are missing, verify activities,

CUDA availability, synchronization, and build support. If operator names differ across PyTorch versions, classify their role rather than hard-coding one expected string.

Run once without the profiler and confirm that outputs match within tolerance. This proves instrumentation did not change the intended computation. Measure wall-clock overhead only as a preliminary observation; a rigorous overhead study belongs to E15.

Part 7 - Engineering Interpretation and Philosophy

Profiling is an act of attribution. Global counters say that memory exists; the profiler proposes where responsibility lies. Responsibility is not the same as blame. A high-memory operator may be implementing the central useful work of the model, while a smaller unnecessary copy may be the better target. Optimization begins by relating cost to purpose.

The profiler also teaches that software operations are nested explanations. The Python line, ATen operator, allocator event, and CUDA kernel are different descriptions of one execution. No layer is the single reality. Each exposes causes that the others compress or hide. Engineering judgment consists of moving between those layers without confusing their measurements.

The philosophical rule for this chapter is evidence triangulation. A memory claim becomes strong when shape arithmetic predicts it, the profiler attributes it, global counters confirm its effect on residency, and numerical tests prove that the optimized computation still means the same thing.

19.3.2 Exercise 01

Exercise Title: Predict Which Operations in a CUDA Model Will Allocate the Most Memory Before Running the PyTorch Profiler

Part 1 - Exercise Contract and Why It Matters

Profilers are most useful when they test a prior model rather than replace thinking. In this exercise you will examine a CUDA network on paper, list every major materialized tensor, calculate its payload, predict the five largest allocating operations, and only then compare the ranking with profiler output. The objective is to expose missing assumptions: broadcasted intermediates, dtype promotion, contiguous copies, saved activations, and backward buffers.

The deliverable must contain an operator hypothesis table with input shapes, output shapes, dtype, element count, predicted bytes, lifetime, and whether the allocation is direct or delegated to a child operation. A ranking with no byte calculation is not a prediction.

Part 2 - System and Memory Mental Model

An operator allocates memory when it materializes storage that cannot be represented as an existing view or reused output. Matrix multiplication usually creates an output of shape determined by its non-contracted axes. Elementwise operations often create an output as large as their broadcast result. A reduction can create a small final tensor but may require temporary storage. Backward operators create gradient tensors and may use saved forward activations.

Operator names do not determine size by themselves. A ReLU over (B, T, D) can allocate more than a matrix multiplication with a small output. The same operation becomes larger when batch, sequence, or feature dimensions grow. Prediction must therefore be shape-specific.

Part 3 - Quantitative Prediction Before Execution

For each dense output, calculate

$$B = s_{\text{dtype}} \prod_i n_i.$$

Include a residual addition, a broadcasted bias, a `contiguous()` call after transpose, and a loss reduction. Predict both forward outputs and same-shaped backward gradients. Rank by predicted direct output bytes, then construct a second ranking by expected lifetime contribution to peak.

Part 4 - Experimental Design and Instrumentation

Freeze the model definition and input shape before profiling. Save the prediction table with a timestamp so it cannot be rewritten after seeing the result. Profile one warmed training step with memory tracking and shapes enabled. Sort by self CUDA memory and preserve the top 20 rows, including unexpected operators.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

class PredictionModel(torch.nn.Module):
    def __init__(self):
        super().__init__()
        self.first = torch.nn.Linear(2048, 4096)
        self.second = torch.nn.Linear(4096, 2048)

    def forward(self, inputs):
        hidden = self.first(inputs)
        activated = torch.nn.functional.gelu(hidden)
        transposed = activated.transpose(0, 1)
        materialized = transposed.contiguous()
        restored = materialized.transpose(0, 1)
        output = self.second(restored)
        return output + inputs

def predict_bytes(shape, dtype):
    count = 1
    for dimension in shape:
        count = count * dimension
    probe = torch.empty((), dtype=dtype)
    return count * probe.element_size()

def E01():
    device = torch.device("cuda:0")
    model = PredictionModel().to(device)
    inputs = torch.randn((256, 2048), device=device)
```

```
    predictions = {}
    predictions["first_linear_output"] = predict_bytes(
        (256, 4096), torch.float32
    )
    predictions["contiguous_copy"] = predict_bytes(
        (4096, 256), torch.float32
    )
    predictions["second_linear_output"] = predict_bytes(
        (256, 2048), torch.float32
    )

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        output = model(inputs)
        loss = output.square().mean()
        loss.backward()

    return predictions, profiler.key_averages()
```

Part 6 - Measurement, Validation, and Failure Analysis

Match predictions to profiler operators by semantics, not only exact names. Calculate rank error and byte error. If an unexpected copy leads the table, inspect strides and layout. If predicted activation allocations are absent, check whether fusion or in-place behavior changed materialization. If one operator has large total but low self memory, inspect its children before declaring the prediction wrong.

Part 7 - Engineering Interpretation and Philosophy

A profiler can show what happened, but prediction explains whether the result was surprising. Surprise is scientifically valuable because it locates a gap between our model and the runtime. The goal is not to guess every internal operator name; it is to construct shape-and-lifetime reasoning precise enough that discrepancies produce new knowledge rather than passive acceptance.

19.3.3 Exercise 02

Exercise Title: Profile a Minimal CUDA Forward Pass with torch.profiler.profile() and Identify CPU and CUDA Activities Correctly

Part 1 - Exercise Contract and Why It Matters

This exercise establishes the smallest trustworthy profiling workflow. You will profile one CUDA forward pass, capture both CPU and CUDA activities, and explain the relationship between a host-side operator event and the device kernels it launches. The output must identify CPU time, CUDA time, call count, and synchronization boundaries without claiming that host duration equals kernel duration.

The minimal workflow must also establish what the profiler cannot infer from a single pass. Kernel duration does not reveal whether the GPU was underutilized before the kernel, and call count does not prove that an operation was necessary. This first profile is a map of execution, not an optimization verdict. Preserve it as a reference against which later memory-enabled runs can be compared.

Your report should name the stream used by the work when the trace exposes it and identify any CUDA runtime calls associated with launch or synchronization. This makes the CPU–GPU relationship concrete before more complex multi-stream experiments appear later in the book.

Part 2 - System and Memory Mental Model

PyTorch dispatch begins on the CPU even when tensors live on CUDA. The CPU prepares and launches device work; CUDA streams execute kernels asynchronously. The profiler correlates activities, but they occupy different timelines. Self CPU time describes host work excluding children. CUDA time summarizes associated device execution. A small CPU duration can launch a long kernel, and a large CPU duration can represent framework overhead with little GPU work.

Part 3 - Quantitative Prediction Before Execution

Predict the high-level calls for one linear layer and ReLU. Calculate input, weight, bias, and output shapes. Predict at least one matrix-multiplication kernel and one activation kernel, while acknowledging that fusion and library implementation can change the exact kernel names. State which activity should dominate for a sufficiently large input.

Part 4 - Experimental Design and Instrumentation

Warm up five iterations. Synchronize before entering and after leaving the profile. Capture one measured pass, retain the output until profiling ends, and compare with an unprofiled result. Print one table sorted by CUDA time and one by self CPU time. Keep memory tracking disabled here so activity interpretation is isolated.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

def E02():
    device = torch.device("cuda:0")
    layer = torch.nn.Linear(4096, 4096).to(device)
    inputs = torch.randn((1024, 4096), device=device)

    for iteration in range(5):
        warm_output = torch.relu(layer(inputs))
    del warm_output
    torch.cuda.synchronize(device)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
    ) as profiler:
        output = torch.relu(layer(inputs))
```

```
        torch.cuda.synchronize(device)

    print(profiler.key_averages().table(
        sort_by="cuda_time_total",
        row_limit=20,
    ))
    print(profiler.key_averages().table(
        sort_by="self_cpu_time_total",
        row_limit=20,
    ))
    return output, profiler
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify output shape and finiteness. Identify which rows are high-level ATen operations and which are CUDA kernels or runtime calls. If CUDA time is absent, check profiler activities and the PyTorch build. If the first call dominates, increase warm-up. Remove the synchronization inside the region and observe how host timing becomes misleading, then restore the correct boundary.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony separates intention from completion. The CPU can request work and continue before the GPU finishes, so source-code order is not a complete timing model. Profiling teaches the engineer to follow execution across agents rather than assuming that a Python line contains the whole event. Correct attribution begins by respecting multiple timelines.

19.3.4 Exercise 03

Exercise Title: Enable profile_memory=True and Rank PyTorch Operators by Self CUDA Memory Usage

Part 1 - Exercise Contract and Why It Matters

This exercise activates operator-level memory attribution and builds a ranked hotspot report. You will sort by self CUDA memory, preserve positive and negative entries, and explain why the leader is the operation directly associated with allocation rather than necessarily the semantic layer that requested it. The result must be compared with a hand-calculated output payload.

The ranking must include allocation frequency as well as total bytes. An operator allocating 4 MiB one hundred times creates more allocator traffic than an operator allocating 128 MiB once, even if the latter has the larger single event. Both patterns can matter: one threatens peak capacity and the other may increase overhead and fragmentation pressure. Key averages should therefore be read together with raw events.

Keep all three result tensors alive until the synchronized measurement boundary so the exercise has a known lifetime model. A second trial may delete each result immediately to show how the same operator traffic can produce a different global peak.

Part 2 - System and Memory Mental Model

Self CUDA memory excludes memory attributed to child operations. A composite operation may report little self memory while an internal `aten::empty` or matrix operation owns the allocation event. Negative self memory can represent storage released during an event. Allocation traffic is not peak residency, and repeated calls may be aggregated in `key_averages()`.

Part 3 - Quantitative Prediction Before Execution

Use three operators with outputs of deliberately different sizes: a large elementwise square, a smaller matrix multiplication, and a reduction. Calculate each output payload and predict the self-memory order. Predict which saved activation remains alive until backward and how that changes global peak.

Part 4 - Experimental Design and Instrumentation

Warm up once, reset peak counters, and profile exactly one pass with memory tracking enabled. Record raw events and key averages. Sort by `self_cuda_memory_usage`, not CUDA time. Preserve the profiler configuration in the report.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

def E03():
    device = torch.device("cuda:0")
    left = torch.randn((4096, 2048), device=device)
    right = torch.randn((2048, 1024), device=device)

    torch.cuda.synchronize(device)
    torch.cuda.reset_peak_memory_stats(device)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        squared = left.square()
        product = left @ right
        reduced = squared.mean(dim=1)
        torch.cuda.synchronize(device)

    table = profiler.key_averages().table(
        sort_by="self_cuda_memory_usage",
        row_limit=30,
    )
    print(table)
    return squared, product, reduced, profiler
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare expected output bytes with the appropriate profiler rows. If an allocation appears under `aten::empty`, follow the parent relationship instead of assigning semantic purpose from the low-level name alone. Check call counts before interpreting aggregated memory. Compare the largest self allocation with global peak and explain why equality is not required.

Part 7 - Engineering Interpretation and Philosophy

Ranking creates attention, but attention is not explanation. The first row is only the largest under a selected metric and aggregation rule. A responsible engineer follows the row back to shape, lifetime, and purpose before changing code. Metrics guide inquiry; they do not decide which computation deserves to exist.

19.3.5 Exercise 04

Exercise Title: Compare Self Memory Usage Against Total Operator Memory Usage and Explain the Effect of Child Operations

Part 1 - Exercise Contract and Why It Matters

Composite PyTorch operations delegate work. This exercise profiles a named region containing several child operations and compares self and inclusive memory rankings. You must show one region with near-zero self allocation but large total memory, then locate the children that created the storage. This prevents optimizing a wrapper merely because its inclusive value is high.

Nested accounting also affects team communication. A model designer may ask which block consumes memory, while a framework engineer asks which primitive materializes it. The inclusive region answers the first question and the self row helps answer the second. The report must present both levels side by side so responsibility is not shifted incorrectly between architecture and implementation.

Include one deliberately nested subregion inside the composite feature transform. Confirm that the outer total includes it and explain why summing both totals double-counts the same descendant allocation.

Part 2 - System and Memory Mental Model

Call trees define inclusive accounting. A parent region owns an interval and its descendants, while self metrics remove descendants. If two nested parents are both summed, the same child allocation is counted more than once. Total memory is useful for comparing semantic regions; self memory is useful for finding direct allocator responsibility. Both depend on correct nesting.

Part 3 - Quantitative Prediction Before Execution

Construct a region containing a linear operation, GELU, a clone, and a reduction. Calculate each output. Predict that the custom region has little self memory because `record_function()` allocates no large tensor, but its total includes all child allocations. Predict which child leads the self ranking.

Part 4 - Experimental Design and Instrumentation

Profile one warmed call with memory tracking and custom regions. Print tables sorted by self and total CUDA memory. Inspect the event tree rather than only key averages, because aggregation can combine calls from different parents. Keep outputs live until the region ends.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile, record_function

def composite_region(layer, inputs):
    with record_function("composite_feature_transform"):
        hidden = layer(inputs)
        activated = torch.nn.functional.gelu(hidden)
        copied = activated.clone()
        summary = copied.mean(dim=1)
    return copied, summary

def E04():
    device = torch.device("cuda:0")
    layer = torch.nn.Linear(2048, 4096).to(device)
    inputs = torch.randn((512, 2048), device=device)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        copied, summary = composite_region(layer, inputs)
        torch.cuda.synchronize(device)

    by_self = profiler.key_averages().table(
        sort_by="self_cuda_memory_usage",
        row_limit=25,
    )
    by_total = profiler.key_averages().table(
        sort_by="cuda_memory_usage",
        row_limit=25,
    )
    print(by_self)
    print(by_total)
    return copied, summary, profiler
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify the named region appears and compare its self and total values. Trace total memory to children and document any deallocation events. If the region does not show inclusive memory as expected, inspect profiler version behavior and raw event nesting. Never create a total by summing already-inclusive parent rows.

Part 7 - Engineering Interpretation and Philosophy

Responsibility depends on scale. A high-level feature block is responsible for the memory demanded by its design, while a low-level allocation operator is responsible for obtaining the bytes. Self and total metrics express these two views. Good optimization connects them: architecture explains why storage is needed; implementation explains where it materializes.

19.3.6 Exercise 05

Exercise Title: Record Tensor Shapes with record_shapes=True and Correlate Input Dimensions with Operator Memory Growth

Part 1 - Exercise Contract and Why It Matters

An operator name without shape is an incomplete memory explanation. This exercise records input shapes, repeats the same computation across several batch and sequence dimensions, and derives how the profiler's memory values scale. The report must connect each growing axis to a tensor formula and distinguish parameter memory, which remains fixed, from activation memory, which changes with input dimensions.

Shape recording can increase profiler overhead and retain additional metadata. It should therefore be activated for diagnosis rather than assumed free. The exercise must measure enough configurations to establish a scaling law, not merely observe that a larger input used more memory.

The exercise must keep parameter shapes fixed across the sweep. Otherwise a larger input configuration could accidentally create a different model and mix persistent growth with activation growth. Report model parameter bytes once, then express each profiled peak as persistent baseline plus input-dependent delta.

Shape metadata may list several inputs, including weights, bias, and optional arguments. Label their semantic roles instead of copying a raw list. The student should be able to point to the axis whose change caused the measured growth and prove the expected ratio from the operator's output law.

Part 2 - System and Memory Mental Model

For a projection from D_{in} to D_{out}, an output with batch B and sequence length T contains

$$BTD_{\text{out}}$$

elements. Self-attention score storage introduces a different dependence, often proportional to BT^2H. Shape metadata exposes the input contract of the recorded operator, but the output shape may still need to be derived from operator semantics.

Part 3 - Quantitative Prediction Before Execution

Predict output bytes for batches $16, 32, 64$ and sequence lengths $64, 128, 256$ using a fixed feature width. Calculate expected ratios when only one axis doubles. State which operations should scale linearly and which could scale quadratically. Preserve predictions before profiling.

Part 4 - Experimental Design and Instrumentation

Profile one configuration per fresh active interval. Use the same model and dtype, warm each shape, and record shapes and memory. Aggregate by input shape only when the profiler interface supports it; otherwise inspect raw events. Record global peaks so operator growth is connected to residency.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

def profile_shape(layer, batch, sequence, width, device):
    inputs = torch.randn(
        (batch, sequence, width),
        dtype=torch.float32,
        device=device,
    )

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        output = layer(inputs)
        loss = output.square().mean()
        loss.backward()
        torch.cuda.synchronize(device)

    peak = torch.cuda.max_memory_allocated(device)
    return profiler, peak

def E05():
    device = torch.device("cuda:0")
    layer = torch.nn.Linear(1024, 2048).to(device)
    configurations = [
        (16, 64),
        (32, 64),
        (32, 128),
        (32, 256),
        (64, 256),
    ]

    results = []
    for batch, sequence in configurations:
        layer.zero_grad(set_to_none=True)
        torch.cuda.reset_peak_memory_stats(device)
        profiler, peak = profile_shape(
            layer, batch, sequence, 1024, device
        )
        results.append((batch, sequence, peak, profiler))
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare measured operator memory ratios with theoretical output ratios. If events with the same name collapse together, group by input shape or keep separate profiles. Check that old outputs and gradients are released before the next configuration. If a shape-doubling produces

more than linear growth, locate temporaries or broadcast expansion before concluding that the operator itself has quadratic complexity.

Part 7 - Engineering Interpretation and Philosophy

Shapes are where abstract algorithms become physical workloads. An axis named "sequence" carries a different scaling risk from an axis named "class," even when both are integers in a tuple. Profiling with shapes reconnects runtime cost to semantic structure and teaches that every dimension is both a modeling choice and a resource multiplier.

19.3.7 Exercise 06

Exercise Title: Add record_function() Regions to Separate Data Transfer, Forward, Loss, Backward, and Optimizer Memory Costs

Part 1 - Exercise Contract and Why It Matters

Raw operator lists are difficult to interpret when a training step contains hundreds of calls. This exercise adds semantic regions for data transfer, forward, loss, backward, optimizer update, and cleanup. The regions must nest correctly, preserve exceptions, and allow the reader to compare inclusive phase costs without mistaking the custom labels for direct allocation operators.

The regions must also reveal state that crosses their boundaries. Inputs created during transfer remain live through forward and backward; saved activations created during forward survive into backward; gradients created during backward survive until clearing or update. Inclusive phase memory is therefore not owned exclusively by the phase label. The label records where events occur, while the lifetime ledger records what remains afterward.

Run one experiment with optimizer state already initialized and another on the first update. This isolates steady-state optimizer traffic from lazy creation of moment tensors.

Part 2 - System and Memory Mental Model

`record_function()` attaches a named range to the profiler event tree. It does not move tensors or automatically isolate CUDA streams. Its total metrics include child work inside the range, while self memory is normally small. A region boundary defined only on the CPU may end before asynchronous device work completes, but correlation still associates launched kernels. Explicit synchronization is needed when the range must also define a measured wall-clock or state boundary.

Part 3 - Quantitative Prediction Before Execution

Create a phase ledger predicting which new objects become live: GPU inputs during transfer, saved activations during forward, a scalar loss, gradients during backward, and optimizer state during the first update. Predict which objects remain after each phase. This lifetime table is the reference for interpreting inclusive memory.

Part 4 - Experimental Design and Instrumentation

Use pinned CPU inputs and an explicit device transfer. Warm optimizer state before measurement if the goal is steady state; profile the first step separately if lazy initialization is the subject. Add nested regions but do not wrap the entire step in one label only. Validate that every phase appears once.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile, record_function

def profiled_step(model, optimizer, cpu_inputs, cpu_targets, device):
    with record_function("01_data_transfer"):
        inputs = cpu_inputs.to(device, non_blocking=True)
        targets = cpu_targets.to(device, non_blocking=True)

    with record_function("02_forward"):
        outputs = model(inputs)

    with record_function("03_loss"):
        loss = torch.nn.functional.cross_entropy(outputs, targets)

    optimizer.zero_grad(set_to_none=True)
    with record_function("04_backward"):
        loss.backward()

    with record_function("05_optimizer"):
        optimizer.step()

    return loss.detach()

def E06(model, optimizer, cpu_inputs, cpu_targets):
    device = torch.device("cuda:0")
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]

    with profile(
        activities=activities,
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        final_loss = profiled_step(
            model,
            optimizer,
            cpu_inputs,
            cpu_targets,
            device,
        )
        torch.cuda.synchronize(device)

    return final_loss, profiler
```

Part 6 - Measurement, Validation, and Failure Analysis

Inspect region order and child calls. Compare the first and later optimizer steps to reveal lazy state. If transfer memory appears in forward, verify asynchronous timing and tensor lifetimes rather than moving labels until the table looks expected. Confirm the detached returned loss

does not retain the training graph. Use DMM00 stage counters to validate inclusive phase interpretation.

Part 7 - Engineering Interpretation and Philosophy

Semantic ranges translate machine activity back into the stages humans use to reason about learning. They are maps, not territories: a label does not create isolation and cannot override asynchronous execution. Their value lies in making a complex event tree navigable while preserving access to the operators that provide causal detail.

19.3.8 Exercise 07

Exercise Title: Profile Forward and Backward Separately and Identify Which Operators Create the Largest Temporary Allocations

Part 1 - Exercise Contract and Why It Matters

Forward and backward perform different computations and create different temporary storage. This exercise profiles them in separate active intervals so their operator tables cannot be merged accidentally. You will identify the largest positive self allocation in each phase, the largest deallocation, and the phase-local peak. The report must explain why backward can allocate gradients while simultaneously freeing saved forward tensors.

To deepen the comparison, repeat the experiment with gradient clearing set to None and with zero-filled gradient tensors. The backward computation is the same, but the entry state differs because pre-existing gradient storage may be reused. This demonstrates that an operator's observed allocation is conditional on allocator and tensor state, not a permanent property of its name.

The final table should distinguish bytes allocated during the phase, bytes freed during the phase, memory live at exit, and the phase peak. Net change alone can conceal large temporary traffic.

Part 2 - System and Memory Mental Model

Forward materializes outputs and saves selected intermediates for derivative rules. Backward traverses the graph in reverse, creates input and parameter gradients, and releases saved tensors after their final consumer. Temporary workspace may depend on the chosen CUDA library algorithm. A negative net memory event in backward does not mean no allocation occurred; allocations and releases can overlap inside the phase.

Part 3 - Quantitative Prediction Before Execution

Calculate forward activation payloads and parameter-gradient payloads. Predict which linear or activation backward operator needs a full-size gradient. Predict whether the phase-local current memory ends above or below its entry state and explain the lifetimes behind that direction.

Part 4 - Experimental Design and Instrumentation

Run forward under one profiler, retain output and loss, then run backward under a second profiler. Reset peak statistics at each boundary without freeing state. Synchronize boundaries. This changes some normal overlap but provides the clean separation required by the exercise; state that limitation.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

def E07():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(4096, 8192),
        torch.nn.GELU(),
        torch.nn.Linear(8192, 4096),
    ).to(device)
    inputs = torch.randn((256, 4096), device=device)
    targets = torch.randn((256, 4096), device=device)

    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    model.zero_grad(set_to_none=True)

    torch.cuda.reset_peak_memory_stats(device)
    with profile(
        activities=activities,
        profile_memory=True,
        record_shapes=True,
    ) as forward_profiler:
        outputs = model(inputs)
        loss = torch.nn.functional.mse_loss(outputs, targets)
        torch.cuda.synchronize(device)
    forward_peak = torch.cuda.max_memory_allocated(device)

    torch.cuda.reset_peak_memory_stats(device)
    with profile(
        activities=activities,
        profile_memory=True,
        record_shapes=True,
    ) as backward_profiler:
        loss.backward()
        torch.cuda.synchronize(device)
    backward_peak = torch.cuda.max_memory_allocated(device)

    return {
        "forward_profiler": forward_profiler,
        "backward_profiler": backward_profiler,
        "forward_peak": forward_peak,
        "backward_peak": backward_peak,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Sort both tables by self CUDA memory and inspect negative rows. Confirm all parameter gradients exist after backward. Compare phase peaks with a normal combined step to quantify

instrumentation effects. If backward events are missing, ensure the graph was created with gradients enabled and was not consumed during warm-up.

Part 7 - Engineering Interpretation and Philosophy

Backward is not simply forward played in reverse. It is a different memory program whose purpose is credit assignment. Separate profiling reveals how learning changes the material behavior of an otherwise identical model. The lesson is that mathematical duality does not imply identical resource lifetimes.

19.3.9 Exercise 08

Exercise Title: Use key_averages() to Build an Operator-Level Memory Report and Verify the Results Against DMM00 CUDA Memory Counters

Part 1 - Exercise Contract and Why It Matters

`key_averages()` compresses many raw events into operator summaries. This exercise converts those summaries into a structured report containing call count, self and total CPU memory, self and total CUDA memory, CPU time, CUDA time, and known shapes. The report must then be reconciled with global allocated, reserved, and peak counters from DMM00. The goal is a repeatable analysis rather than a table copied from terminal output.

The structured report must preserve enough identity to compare runs. Include the semantic phase, input configuration, dtype, model version, and profiler options beside every operator table. Two rows with the same key but different shapes are not necessarily comparable. Add an explicit aggregation key field so later analysis knows whether calls were grouped only by operator or also by shape and stack.

The reconciliation section must explain both success and residual. Agreement between predicted output bytes and one self-allocation supports attribution; the remaining difference between live allocation and global peak belongs to overlapping objects and temporary work that must be analyzed separately.

Part 2 - System and Memory Mental Model

Aggregation reduces detail. Calls sharing a key are combined, so a large total may arise from one huge call or many small calls. Shape grouping can preserve more distinction but increases report size. Global peak cannot be reconstructed by summing key averages because event order and overlapping lifetime were discarded. Reconciliation therefore checks compatible claims: largest event traffic, phase delta, and global high-water mark.

Part 3 - Quantitative Prediction Before Execution

Define report columns and units before profiling. Predict global persistent baseline, peak increase, and the top output allocation. State three invariants: global peak is at least current allocated, allocated does not exceed reserved, and each operator's call count is positive. Do not invent an invariant equating sum of rows with peak.

Part 4 - Experimental Design and Instrumentation

Capture global counters immediately before and after a warmed profiled step. Use raw integer bytes in JSON and format MiB only for presentation. Retain the top positive allocations and top negative deallocations. Save profiler options and PyTorch version with the report.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def event_to_row(event):
    row = {}
    row["key"] = event.key
    row["count"] = event.count
    row["self_cpu_memory_usage"] = event.self_cpu_memory_usage
    row["cpu_memory_usage"] = event.cpu_memory_usage
    row["self_cuda_memory_usage"] = event.self_cuda_memory_usage
    row["cuda_memory_usage"] = event.cuda_memory_usage
    row["self_cpu_time_total"] = event.self_cpu_time_total
    row["cuda_time_total"] = event.cuda_time_total
    return row

def build_operator_report(profiler):
    rows = []
    for event in profiler.key_averages():
        rows.append(event_to_row(event))

    rows.sort(
        key=lambda row: row["self_cuda_memory_usage"],
        reverse=True,
    )
    return rows

def verify_global_counters(device):
    allocated = torch.cuda.memory_allocated(device)
    reserved = torch.cuda.memory_reserved(device)
    peak = torch.cuda.max_memory_allocated(device)
    assert allocated <= reserved
    assert allocated <= peak
    return allocated, reserved, peak

def E08(profiler):
    device = torch.device("cuda:0")
    report = build_operator_report(profiler)
    counters = verify_global_counters(device)
    return report, counters
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare raw-event count with aggregated row count and explain the information lost. Check version-specific fields before assuming every attribute exists. If call counts combine different shapes, use shape grouping or separate runs. Verify global counters at synchronized boundaries. Treat differences as a lifetime problem to investigate, not an error to erase through arbitrary normalization.

Part 7 - Engineering Interpretation and Philosophy

Aggregation is a bargain: clarity is purchased by discarding sequence and context. A useful report states what was compressed so readers know which questions it cannot answer. The engineering principle is to use the smallest summary that supports the decision while preserving a path back to raw evidence.

19.3.10 Exercise 09

Exercise Title: Deliberately Introduce an Unnecessary Tensor Copy and Locate the Exact Memory-Expensive Operator with the Profiler

Part 1 - Exercise Contract and Why It Matters

Unnecessary copies are ideal profiling targets because they consume memory without changing intended semantics. This exercise introduces a `clone()` and a forced `contiguous()` materialization, predicts their payload, locates their allocation operators, and proves which copy is avoidable. The experiment must preserve one necessary copy when layout truly requires it so that optimization does not become blind removal of all copying.

Introduce the copies in separate variants as well as one combined inefficient variant. If both are introduced simultaneously, the first may alter layout or lifetime in a way that changes the second's behavior. Single-change variants allow the report to measure each contribution and detect interaction when the combined cost differs from their simple sum.

The student must document the downstream operator's layout requirements. A layout-materialization call is unnecessary only if the consumer accepts the strided view correctly and without creating an equivalent hidden copy. Removing a visible copy while moving the same allocation into a library call is not a real optimization.

Part 2 - System and Memory Mental Model

`clone()` always creates independent storage. A transpose ordinarily creates a view with changed strides. `contiguous()` creates storage only when the input layout is not already contiguous. Downstream operators may accept strided input or materialize internally. The profiler identifies where bytes were allocated; stride inspection explains why.

Part 3 - Quantitative Prediction Before Execution

For a $(512, 4096)$ `float32` tensor, predict 8 MiB per full copy. Create a baseline with no explicit clone and an inefficient version with two copies. Predict the difference in allocation traffic and phase peak, noting that short lifetimes may prevent both copies from overlapping.

Part 4 - Experimental Design and Instrumentation

Profile baseline and inefficient functions under identical inputs. Warm both, record shapes and memory, and use custom regions. Verify output parity before comparing memory. Inspect strides and storage pointers. Keep profiler settings identical.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile, record_function

def baseline(inputs):
```

```
    return inputs * 2.0

def inefficient(inputs):
    with record_function("unnecessary_copy_region"):
        copied = inputs.clone()
        transposed = copied.transpose(0, 1)
        materialized = transposed.contiguous()
        restored = materialized.transpose(0, 1)
        output = restored * 2.0
    return output

def profile_function(function, inputs):
    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        output = function(inputs)
        torch.cuda.synchronize(inputs.device)
    return output, profiler

def E09():
    device = torch.device("cuda:0")
    inputs = torch.randn((512, 4096), device=device)
    base_output, base_profile = profile_function(baseline, inputs)
    bad_output, bad_profile = profile_function(inefficient, inputs)

    assert torch.allclose(base_output, bad_output)
    return base_profile, bad_profile
```

Part 6 - Measurement, Validation, and Failure Analysis

Locate clone, copy, empty, or contiguous-related events and match their shapes to the predicted 8 MiB payload. Compare global peaks as well as event traffic. If baseline and inefficient outputs differ, stop; memory improvement is irrelevant until semantics match. Remove one copy at a time and re-profile so causality is demonstrated.

Part 7 - Engineering Interpretation and Philosophy

Copies create independence. Sometimes that independence is required because a value must survive mutation or satisfy layout constraints. Sometimes it is only a defensive habit. Profiling helps distinguish the two, but the decision remains semantic: optimization asks whether separate storage has a purpose, not merely whether it has a cost.

19.3.11 Exercise 10

Exercise Title: Enable with_stack=True and Trace a High-Memory Operator Back to the Exact Python Source Location

Part 1 - Exercise Contract and Why It Matters

An operator name may identify a copy or allocation but not the application line that requested it. This exercise enables stack collection, locates a high-memory event, and traces it through framework frames to the exact user function and line. The report must separate the allocation operator from its caller and explain why stack capture is expensive enough to reserve for focused diagnosis.

Stack evidence should be treated as versioned diagnostic data. Refactoring can move a function to another line without changing behavior, while compilation can collapse several source operations. Store the function name, source file, operator key, shape, and measured bytes together; a bare line number will not remain meaningful.

The exercise must demonstrate escalation: begin with low-overhead key averages, enable shapes to disambiguate calls, and collect stacks only for the narrowed case. This staged process is the practical method for obtaining detail without profiling an entire training run at maximum overhead.

Part 2 - System and Memory Mental Model

Stacks connect dynamic events to the nested Python call path active when an operator was dispatched. Some CUDA kernels are launched after the originating Python frame has returned, so correlation depends on profiler metadata rather than a device stack. Framework, autograd, and module wrapper frames may appear between the event and user code. Compiled or fused execution can reduce source-level granularity.

Part 3 - Quantitative Prediction Before Execution

Use the unnecessary copy from E09 and predict its payload and source function. Write the expected call chain before profiling. Estimate the extra trace size qualitatively and define a narrow active interval containing only the suspect region.

Part 4 - Experimental Design and Instrumentation

First locate the hotspot without stacks. Then re-run only the suspect case with stack collection enabled. Export stacks grouped by the selected memory metric when supported and inspect raw events otherwise. Preserve source file and line metadata in the report without depending on one absolute workstation path.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile

def suspicious_transform(inputs):
    copied = inputs.clone()
    return copied * 3.0

def E10(output_stack_path):
    device = torch.device("cuda:0")
    inputs = torch.randn((1024, 4096), device=device)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
```

```
        record_shapes=True,
        with_stack=True,
    ) as profiler:
        output = suspicious_transform(inputs)
        torch.cuda.synchronize(device)

    profiler.export_stacks(
        output_stack_path,
        "self_cuda_memory_usage",
    )

    high_memory_events = []
    for event in profiler.events():
        if event.self_cuda_memory_usage > 0:
            high_memory_events.append(event)

    high_memory_events.sort(
        key=lambda event: event.self_cuda_memory_usage,
        reverse=True,
    )
    return output, high_memory_events
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that the stack reaches `suspicious_transform` and the clone line. If no stacks appear, check profiler build support, execution mode, and whether the inspected event is the correlated CPU operator rather than a device kernel. Measure trace size and runtime relative to the same profile without stacks. Do not leave stack collection enabled in every normal step.

Part 7 - Engineering Interpretation and Philosophy

Attribution becomes actionable when it reaches the level where a human can change a decision. A kernel name describes execution; a source line reveals intent. Stack tracing bridges them, but it also reminds us that software causes are layered. The exact allocation site and the design choice that made the allocation necessary may still be different locations.

19.3.12 Exercise 11

Exercise Title: Remove the Hidden Allocation Found by Profiling and Prove the Memory Reduction Without Changing Numerical Outputs

Part 1 - Exercise Contract and Why It Matters

Finding a hotspot is diagnosis; proving a safe repair is engineering. This exercise removes the unnecessary copy traced in E10, compares operator events and global peaks, and validates outputs and gradients. The optimized version must not merely produce similar loss once; it must preserve shape, dtype, device, values within tolerance, and parameter gradients under identical inputs.

The proof must include a lifetime comparison, not only disappearance of the clone row. Record global current memory immediately after forward and after cleanup. A compiler or downstream operator could replace the removed copy with another allocation; only global

counters and operator re-profiling together show whether residency improved.

Add a repeated-run test to detect alias-dependent mutation that may not appear on the first call. Feed the same input object twice, verify it remains unchanged, and compare both outputs. This protects against optimizations that silently introduce stateful behavior.

Part 2 - System and Memory Mental Model

Removing a copy can change aliasing. If downstream code mutates the tensor in-place, the original input may now be modified. A numerically equal forward output in one test does not prove equivalent storage semantics. The repair must inspect whether independent storage was required for mutation, lifetime, or layout. Only a semantically unnecessary copy may be removed safely.

Part 3 - Quantitative Prediction Before Execution

Predict the eliminated payload from shape and dtype. Estimate the best possible peak reduction by checking whether the copy overlaps with other large tensors. Predict zero change in output and gradient formulas. Define absolute and relative tolerances before execution.

Part 4 - Experimental Design and Instrumentation

Clone model parameters so baseline and optimized runs start identically. Use the same input tensor and seed. Profile both with identical options, reset global peaks, and run multiple repetitions. Test input immutability and storage aliasing explicitly. Compare median runtime only after correctness passes.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import torch

class Baseline(torch.nn.Module):
    def __init__(self, layer):
        super().__init__()
        self.layer = layer

    def forward(self, inputs):
        copied = inputs.clone()
        return self.layer(copied)

class Optimized(torch.nn.Module):
    def __init__(self, layer):
        super().__init__()
        self.layer = layer

    def forward(self, inputs):
        return self.layer(inputs)

def collect_gradients(model):
    gradients = []
    for parameter in model.parameters():
```

```
        gradients.append(parameter.grad.detach().clone())
    return gradients

def E11():
    device = torch.device("cuda:0")
    base_layer = torch.nn.Linear(4096, 2048).to(device)
    model_a = Baseline(copy.deepcopy(base_layer)).to(device)
    model_b = Optimized(copy.deepcopy(base_layer)).to(device)
    inputs = torch.randn((512, 4096), device=device)

    output_a = model_a(inputs)
    loss_a = output_a.square().mean()
    loss_a.backward()
    gradients_a = collect_gradients(model_a)

    output_b = model_b(inputs)
    loss_b = output_b.square().mean()
    loss_b.backward()
    gradients_b = collect_gradients(model_b)

    assert torch.allclose(output_a, output_b, atol=1e-6, rtol=1e-5)
    for index in range(len(gradients_a)):
        assert torch.allclose(
            gradients_a[index],
            gradients_b[index],
            atol=1e-6,
            rtol=1e-5,
        )
    return model_a, model_b
```

Part 6 - Measurement, Validation, and Failure Analysis

Re-profile both versions and confirm the clone allocation disappears. Measure global peak reduction and explain if it is smaller than the copy payload due to non-overlapping lifetimes or allocator reuse. Add an in-place downstream mutation test; if behavior changes, the copy was protecting semantics and must be replaced with a more careful design rather than deleted.

Part 7 - Engineering Interpretation and Philosophy

Optimization is a proof obligation. Lower memory is only a benefit if the program continues to mean the same thing. Copies often encode hidden contracts about independence, so removing them requires understanding rather than mechanical editing. Profiler evidence identifies cost; tests defend meaning.

19.3.13 Exercise 12

Exercise Title: Compare Profiler Results Across float64, float32, bfloat16, and float16 and Explain Which Operators Benefit Most

Part 1 - Exercise Contract and Why It Matters

Reduced precision changes tensor payload, arithmetic throughput, kernel choice, temporary workspaces, and numerical behavior. This exercise profiles the same model under four dtypes and determines which operators show near-proportional memory reduction, which retain higher-precision state, and which are unsupported or unstable. The report must never interpret a failed or silently promoted operation as a valid low-precision saving.

The comparison must distinguish explicit uniform dtype from automatic mixed precision. Uniform conversion is useful for understanding payload laws, while autocast represents a realistic policy in which selected operations remain or accumulate in higher precision. Profile both modes if hardware support allows, and do not combine their results into one precision category.

Record whether Tensor Core-friendly dimensions are used. Precision can change kernel selection and performance only when the hardware and shapes support the relevant paths. Memory ratios are more portable than speed ratios, but even memory can deviate through workspaces and promotion.

Part 2 - System and Memory Mental Model

Dense output payload scales with element size, but complete operator memory can include accumulation buffers and library workspaces in another dtype. `float16` and `bfloat16` both use two bytes, yet their exponent and mantissa trade-offs differ. Autocast selects dtypes per operation rather than converting the entire program uniformly. The actual output dtype must be observed.

Part 3 - Quantitative Prediction Before Execution

Calculate payload ratios $8 : 4 : 2 : 2$ bytes for `float64`, `float32`, `bfloat16`, and `float16`. Predict which full-sized activations should follow those ratios. Define numerical test inputs containing ordinary, very small, and large values. Predict where overflow, underflow, or rounding may appear.

Part 4 - Experimental Design and Instrumentation

Use separate model copies and fresh profiles for each dtype. Warm every supported case, record actual dtypes, and use identical shapes. Compare memory rows, global peaks, outputs converted to `float64`, and profiler overhead. Record unsupported cases honestly rather than changing the operator set.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import torch
from torch.profiler import ProfilerActivity, profile

def run_dtype(reference_model, reference_inputs, dtype, device):
    model = copy.deepcopy(reference_model).to(
        device=device,
        dtype=dtype,
    )
    inputs = reference_inputs.to(device=device, dtype=dtype)
    model.zero_grad(set_to_none=True)

    torch.cuda.reset_peak_memory_stats(device)
```

```
    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        output = model(inputs)
        loss = output.float().square().mean()
        loss.backward()
        torch.cuda.synchronize(device)

    return {
        "dtype": str(dtype),
        "output": output.detach().to(torch.float64).cpu(),
        "peak": torch.cuda.max_memory_allocated(device),
        "profiler": profiler,
    }

def E12(reference_model, reference_inputs):
    device = torch.device("cuda:0")
    dtypes = [
        torch.float64,
        torch.float32,
        torch.bfloat16,
        torch.float16,
    ]
    results = []
    for dtype in dtypes:
        results.append(
            run_dtype(reference_model, reference_inputs, dtype, device)
        )
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare operator memory ratios and identify deviations from element-size ratios. Inspect actual input and output dtypes. Compare values against the `float64` reference using dtype-appropriate tolerance and finite checks. If a low-precision case creates NaNs, preserve the failure evidence and locate the first non-finite operator instead of reporting only its lower peak.

Part 7 - Engineering Interpretation and Philosophy

Precision is not merely compression. It changes what distinctions the machine can represent and which algorithms hardware chooses. A memory benefit belongs to a valid numerical computation, not to bytes saved after meaning has collapsed. The right dtype is an empirical agreement between capacity, throughput, and tolerated error.

19.3.14 Exercise 13

Exercise Title: Profile Increasing Batch Sizes and Determine Which Operator Becomes the Dominant VRAM Consumer Near the OOM Boundary

Part 1 - Exercise Contract and Why It Matters

The dominant memory operator can change as batch size grows. Persistent parameter and optimizer state remain fixed while activations and gradients scale. This exercise profiles a bounded batch sweep, tracks the top allocation hotspot at each point, and identifies where dominance changes. It must estimate the boundary safely rather than forcing the main process into uncontrolled OOM.

Near the boundary, the profiler itself consumes resources and can cause a batch to fail earlier than an unprofiled workload. Measure the unprofiled safe range first, then keep the profiled sweep inside a smaller budget. Report both limits and never describe the profiler-induced boundary as the model's production capacity.

Also track the second and third largest operators. Dominance may alternate due to allocator reuse or implementation switches, and a single top row can hide a cluster of comparable consumers that require a broader architectural change.

Part 2 - System and Memory Mental Model

For operator o, model memory as

$$M_o(B) = c_o + \alpha_o B + \epsilon_o(B).$$

An operator with large constant state may dominate small batches, while a large activation with greater slope dominates later. Algorithm switches and workspaces can create discontinuities. The top self-allocation event is not necessarily the tensor dominating lifetime at peak.

Part 3 - Quantitative Prediction Before Execution

Calculate per-sample output bytes for every major layer. Predict the slopes and the crossover batch between two candidate hotspots. Set a safety budget below driver-free capacity and predict the next batch before attempting it. Use incremental growth near the boundary.

Part 4 - Experimental Design and Instrumentation

Warm each batch, reset peaks, and profile one training step. Release outputs and gradients between cases. Store top operator, self bytes, total bytes, global peak, and runtime. Stop when the predicted next peak exceeds the configured safety budget. Run dangerous confirmation only in a child process if a dedicated GPU is available.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch
from torch.profiler import ProfilerActivity, profile

def largest_allocation(profiler):
    largest_key = None
    largest_bytes = 0
    for event in profiler.key_averages():
        value = event.self_cuda_memory_usage
        if value > largest_bytes:
            largest_bytes = value
            largest_key = event.key
```

```
    return largest_key, largest_bytes

def profile_batch(model, batch_size, device):
    inputs = torch.randn((batch_size, 4096), device=device)
    targets = torch.randint(0, 1000, (batch_size,), device=device)
    model.zero_grad(set_to_none=True)
    torch.cuda.reset_peak_memory_stats(device)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
    ) as profiler:
        outputs = model(inputs)
        loss = torch.nn.functional.cross_entropy(outputs, targets)
        loss.backward()
        torch.cuda.synchronize(device)

    top_key, top_bytes = largest_allocation(profiler)
    peak = torch.cuda.max_memory_allocated(device)
    del inputs
    del targets
    del outputs
    del loss
    model.zero_grad(set_to_none=True)
    gc.collect()
    return top_key, top_bytes, peak
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot each operator's bytes and global peak against batch. Identify crossover points and discontinuities. If one generic allocation operator appears for many semantic calls, use shapes or stacks to separate them. Ensure the sweep did not retain profiler objects with CUDA tensors; raw profiler metadata can also consume host memory and should be released after extraction.

Part 7 - Engineering Interpretation and Philosophy

Bottlenecks are conditional. The operation that matters near capacity may be irrelevant at small scale, so optimization priorities must be tied to the target workload. Scaling experiments reveal not only how much memory grows but which part of the computation acquires control over the system's limit.

19.3.15 Exercise 14

Exercise Title: Use a Profiler Schedule with Warmup and Active Steps to Measure a Multi-Iteration Training Loop Without Profiling Every Step

Part 1 - Exercise Contract and Why It Matters

Continuous detailed profiling can overwhelm long training runs. This exercise uses a schedule with wait, warm-up, active, and repeat phases so only selected iterations generate traces.

You must call `profiler.step()` exactly once per training iteration, label the schedule state, and prove that inactive steps execute normally without being included in active trace windows.

The schedule must be aligned with meaningful training boundaries. If one profiler step is called per micro-batch while the analysis expects one per optimizer update, gradient accumulation changes what an "iteration" means. Declare whether the schedule advances on micro-steps, optimizer steps, or data batches and preserve that unit in trace names.

Add an anomaly-triggered extension concept: lightweight counters can detect a memory spike, after which the next scheduled window enables more detailed profiling. The implementation may remain conceptual here, but the report must describe how delayed activation affects the chance of capturing a one-time failure.

Part 2 - System and Memory Mental Model

A profiler schedule is a state machine. Wait steps collect nothing, warm-up steps prepare instrumentation while discarding results, active steps record events, and repeat starts another cycle. Warm-up here refers to profiler collection, not necessarily model or CUDA warm-up; the workload should already be stabilized before the schedule begins. The trace handler runs when an active window completes.

Part 3 - Quantitative Prediction Before Execution

For a schedule wait = 2, warmup = 1, active = 3, repeat = 2, calculate the total scheduled steps and list which iteration indices are active. Predict the number of trace callbacks and estimate metadata growth relative to profiling every iteration.

Part 4 - Experimental Design and Instrumentation

Run ordinary model warm-up first. Use a fixed number of iterations matching the schedule. Add iteration labels with `record_function()`, call `step()` after the complete iteration, and use a trace callback that stores only required summaries. Verify optimizer semantics are identical with and without profiling.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile, record_function, schedule

def E14(model, optimizer, batches, trace_handler):
    profiler_schedule = schedule(
        wait=2,
        warmup=1,
        active=3,
        repeat=2,
    )

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        schedule=profiler_schedule,
        on_trace_ready=trace_handler,
        profile_memory=True,
```

```
        record_shapes=True,
    ) as profiler:
        for iteration in range(len(batches)):
            inputs, targets = batches[iteration]
            label = f"iteration_{iteration:03d}"

            with record_function(label):
                optimizer.zero_grad(set_to_none=True)
                outputs = model(inputs)
                loss = torch.nn.functional.cross_entropy(
                    outputs,
                    targets,
                )
                loss.backward()
                optimizer.step()

            profiler.step()
```

Part 6 - Measurement, Validation, and Failure Analysis

Log callback count and active iteration labels. If traces are empty, check the number and placement of `step()` calls. If one iteration produces two steps, the schedule no longer maps to training semantics. Compare final model parameters with a controlled unprofiled run and measure host-memory growth from retained trace objects.

Part 7 - Engineering Interpretation and Philosophy

Observability is a sampling problem. Recording everything can make the observer too expensive, while recording too little can miss rare failures. Scheduling turns profiling into a deliberate allocation of attention. The design question becomes which intervals are representative and which signals should trigger a deeper capture.

19.3.16 Exercise 15

Exercise Title: Quantify Profiler Overhead from Memory Tracking, Shape Recording, and Stack Collection Under Identical CUDA Workloads

Part 1 - Exercise Contract and Why It Matters

Profiler evidence has a cost. Memory event tracking, shape capture, and stack collection add host work, metadata, synchronization pressure, and storage. This exercise measures that cost through a factorial comparison: unprofiled baseline, activity-only profiling, memory tracking, memory plus shapes, and memory plus shapes plus stacks. The workload, warm-up, iteration count, and correctness must remain identical.

The deliverable must report wall-clock duration, CUDA-event duration where appropriate, training throughput, process host-memory growth, GPU peak, and trace size. One percentage called "profiler overhead" is insufficient because different resources can be affected differently.

Profiler overhead can also change the workload indirectly. Slower host execution may alter GPU clock behavior, queue depth, and overlap. Large trace writes can contend with data loading. The experiment should place trace serialization outside the measured training interval

when measuring capture overhead, then measure serialization separately as an operational cost.

Report both multiplicative slowdown and absolute time added per step. A 100-percent overhead on a tiny microbenchmark may be less operationally important than a 10-percent overhead on a multi-hour step, and the two metrics support different decisions.

Part 2 - System and Memory Mental Model

Instrumentation changes execution through event creation and correlation. Memory tracking records allocation events. Shape recording retains metadata and may hold references or extend some object lifetimes according to profiler behavior. Stack collection unwinds or records call paths, primarily increasing CPU overhead and trace volume. GPU kernels may remain nearly unchanged while end-to-end throughput falls because the host cannot feed them as efficiently.

Part 3 - Quantitative Prediction Before Execution

Predict the overhead ordering and specify that it is a hypothesis, not a guarantee:

$$T_{\text{baseline}} \leq T_{\text{activities}} \leq T_{\text{memory}} \leq T_{\text{shapes}} \leq T_{\text{stacks}}.$$

Estimate trace events as iterations times operators per iteration. Predict which options affect host memory more than GPU peak. Define the percentage

$$\text{overhead} = \frac{T_{\text{instrumented}} - T_{\text{baseline}}}{T_{\text{baseline}}} \times 100.$$

Part 4 - Experimental Design and Instrumentation

Use at least five independent repetitions per configuration and randomize configuration order after a common warm-up. Run enough iterations to dominate startup noise but keep traces bounded. Synchronize timing boundaries, capture median and variability, and discard generated profiler objects between trials. Monitor host memory with an appropriate process tool if available.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch
from torch.profiler import ProfilerActivity, profile

def training_step(model, optimizer, inputs, targets):
    optimizer.zero_grad(set_to_none=True)
    outputs = model(inputs)
    loss = torch.nn.functional.cross_entropy(outputs, targets)
    loss.backward()
    optimizer.step()
    return loss.detach()

def timed_profile(
    model,
```

```
    optimizer,
    inputs,
    targets,
    iterations,
    memory,
    shapes,
    stacks,
):
    device = inputs.device
    torch.cuda.synchronize(device)
    start = time.perf_counter()

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=memory,
        record_shapes=shapes,
        with_stack=stacks,
    ) as profiler:
        for iteration in range(iterations):
            training_step(model, optimizer, inputs, targets)

    torch.cuda.synchronize(device)
    duration = time.perf_counter() - start
    return duration, profiler

def E15(configurations, repetitions):
    results = {}
    for name, arguments in configurations:
        durations = []
        for repetition in range(repetitions):
            duration, profiler = timed_profile(*arguments)
            durations.append(duration)
            del profiler
        results[name] = {
            "median_seconds": statistics.median(durations),
            "all_seconds": durations,
        }
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare losses and final parameters across controlled runs. Report confidence through repeated measurements rather than a single ratio. If the most detailed configuration appears faster, inspect trial order, GPU clock state, warm-up, and data reuse. Measure whether profiler metadata remains referenced after the trial. State that overhead is workload- and version-dependent and cannot be copied to another machine as a universal constant.

Part 7 - Engineering Interpretation and Philosophy

Observation consumes the same finite resources it seeks to explain. More detail is not automatically more truth if the instrument perturbs scheduling or makes the experiment unrepresentative. The right profiler configuration is the least expensive one capable of resolving the current uncertainty. Deep visibility should be activated by a question, not by habit.

19.3.17 Exercise 16

Exercise Title: Export and Analyze a CUDA Execution Trace to Correlate Memory-Heavy PyTorch Operations with GPU Kernel Activity

Part 1 - Exercise Contract and Why It Matters

Operator tables discard temporal order. This exercise exports a Chrome trace from a narrow active window and analyzes how high-memory PyTorch operators relate to CUDA runtime calls, kernels, transfers, and synchronization on the timeline. The goal is not to produce an attractive trace image; it is to answer a precise question about when an allocation becomes live relative to device work and neighboring phases.

Trace analysis must distinguish allocation lifetime from kernel lifetime. A buffer can be allocated before a kernel begins and remain live after it ends because a later operation consumes it. Selecting a kernel rectangle and assigning the entire tensor lifetime to its duration is incorrect. Correlate allocation events, producing operator, consumer events, and deallocation where available.

Include one search for hidden synchronization, such as a scalar extraction or explicit device wait. Such an event may not allocate much memory, yet it can prevent overlap and extend the time during which several buffers coexist.

Part 2 - System and Memory Mental Model

A trace contains events on multiple tracks. CPU operators enqueue CUDA work, runtime calls communicate with the driver, and kernels execute on streams. Correlation identifiers connect layers. A high-memory operator may launch a kernel whose name reflects a library implementation rather than the PyTorch operation. Memory allocation may occur on the host timeline before the kernel uses the buffer. Overlap means events can coexist across streams.

Part 3 - Quantitative Prediction Before Execution

Select one known hotspot and predict its approximate start order, allocation payload, launched kernel family, and lifetime relative to adjacent operations. Predict whether data transfer overlaps computation. Define trace questions before export so analysis does not become aimless browsing.

Part 4 - Experimental Design and Instrumentation

Warm the workload, capture only one or two active steps, add semantic ranges, enable memory and shape recording, and export to a uniquely named JSON file. Record file size and profiler options. Open the trace in a compatible viewer and preserve screenshots only as supporting artifacts; conclusions must refer to event names, timestamps, durations, streams, and correlations.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch
from torch.profiler import ProfilerActivity
from torch.profiler import profile, record_function

def E16(model, optimizer, inputs, targets, trace_path):
    output_path = Path(trace_path)
    output_path.parent.mkdir(parents=True, exist_ok=True)

    with profile(
        activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
        profile_memory=True,
        record_shapes=True,
        with_stack=False,
    ) as profiler:
        with record_function("measured_training_step"):
            optimizer.zero_grad(set_to_none=True)
            with record_function("forward"):
                outputs = model(inputs)
            with record_function("loss"):
                loss = torch.nn.functional.cross_entropy(
                    outputs,
                    targets,
                )
            with record_function("backward"):
                loss.backward()
            with record_function("optimizer"):
                optimizer.step()
        torch.cuda.synchronize(inputs.device)

    profiler.export_chrome_trace(str(output_path))
    return {
        "trace_path": str(output_path),
        "trace_bytes": output_path.stat().st_size,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Locate the semantic region, high-memory operator, associated runtime calls, and device kernels. Verify timestamp ordering and stream identifiers. If a kernel cannot be linked confidently, label the relationship as an inference. Check for synchronizations that serialize work. Ensure trace export occurs after profiling and that long schedules do not create unmanageable files.

Part 7 - Engineering Interpretation and Philosophy

Tables answer "how much" by aggregation; traces answer "when" and "alongside what." Memory pressure is fundamentally temporal, so both views are required. A trace restores sequence to the evidence but increases complexity. Its value comes from using time to test a causal story, not from inspecting every colored rectangle.

19.3.18 Exercise 17

Exercise Title: Build a Memory Regression Test That Fails When Any Critical Operator Exceeds a Defined Allocation Budget

Part 1 - Exercise Contract and Why It Matters

Memory regressions can enter during refactoring even when outputs remain correct. This exercise converts profiler evidence into an automated test that fails when named critical operators or semantic regions exceed versioned byte budgets. The test must use tolerances, fixed shapes, fixed dtype, a controlled environment, and global peak validation. It must produce an actionable failure message showing expected and observed values.

Budgets should be layered. A hard ceiling protects device capacity, a warning threshold detects drift before failure, and a normalized scaling check protects the expected relationship across batches. A change can pass the fixed small- batch ceiling while introducing a worse slope that becomes dangerous at production scale.

The test artifact must show the top observed operators even when it passes. This makes gradual changes reviewable and prevents the test from becoming a binary gate with no diagnostic value. Store only numeric summaries so the test does not retain profiler state or model tensors.

Part 2 - System and Memory Mental Model

Operator names and fusion behavior can change across PyTorch versions, so a budget tied only to one low-level name is brittle. Use semantic regions where possible and allow a small set of version-specific aliases. Absolute byte budgets detect fixed regressions; normalized bytes per sample detect scaling regressions. Global peak protects against allocations that attribution misses.

Part 3 - Quantitative Prediction Before Execution

Derive budgets from a verified baseline plus a justified tolerance:

$$L_o = M_o^{\text{baseline}}(1 + \tau) + C.$$

Choose percentage tolerance τ and absolute allowance C before introducing the regression. Define which operators are critical and why. Predict how an inserted clone should violate the budget.

Part 4 - Experimental Design and Instrumentation

Run the test in a fresh process or controlled CI worker. Warm up, profile one fixed step, extract summaries, and compare with a checked-in budget configuration. Record PyTorch and CUDA versions. Add one negative test that intentionally creates a copy and proves failure, then restore the optimized path and prove success.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def extract_self_cuda_memory(profiler):
    observed = {}
```

```
    for event in profiler.key_averages():
        observed[event.key] = event.self_cuda_memory_usage
    return observed

def check_operator_budgets(observed, budgets):
    failures = []
    for operator_name in budgets:
        limit = budgets[operator_name]
        actual = observed.get(operator_name, 0)
        if actual > limit:
            failures.append({
                "operator": operator_name,
                "limit_bytes": limit,
                "actual_bytes": actual,
                "excess_bytes": actual - limit,
            })
    return failures

def E17(profiler, peak_limit_bytes, device):
    observed = extract_self_cuda_memory(profiler)
    budgets = {
        "aten::clone": 0,
        "aten::contiguous": 0,
    }
    failures = check_operator_budgets(observed, budgets)

    peak = torch.cuda.max_memory_allocated(device)
    if peak > peak_limit_bytes:
        failures.append({
            "operator": "GLOBAL_PEAK",
            "limit_bytes": peak_limit_bytes,
            "actual_bytes": peak,
            "excess_bytes": peak - peak_limit_bytes,
        })

    if len(failures) != 0:
        raise AssertionError(f"Memory regression: {failures}")
    return observed
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify the test fails for the deliberate clone and passes after removal. Inspect whether zero budget is valid; some framework paths may legitimately clone. If operator names change, fail with an "unresolved metric" message rather than silently passing because the key disappeared. Separate environmental drift from code regressions by retaining version metadata.

Part 7 - Engineering Interpretation and Philosophy

A regression test turns past understanding into a future constraint. It says that memory behavior is part of correctness, not an optional performance detail. Yet budgets must remain

explainable and revisable; otherwise yesterday's implementation becomes a prison. The test protects an engineering intention, not a sacred number.

19.3.19 Exercise 18

Exercise Title: Build a Reusable PyTorch Memory Profiler That Automatically Reports the Top Allocation Hotspots in a Training Step

Part 1 - Exercise Contract and Why It Matters

This exercise packages the chapter's methods into a reusable diagnostic tool. The tool accepts a training-step callable, profiler configuration, device, row limit, and output directory. It produces structured JSON containing global counters, top positive and negative operator events, semantic regions, shapes, times, configuration, and environment metadata. It must not retain output tensors or profiler objects after extraction.

The reusable tool must protect users from invalid comparisons. It should reject a report if the active interval contains no CUDA events, if the selected device differs from workload tensors, or if outputs are not synchronized before final counters. Warnings should distinguish missing evidence from an observed zero; an absent operator is not automatically a zero-byte operator.

Add configurable grouping by operator, input shape, or stack. Default to operator grouping for compactness, then escalate when several semantic calls share a key. The report should record the grouping method so later regression tools interpret rows correctly.

Part 2 - System and Memory Mental Model

Reusable tooling needs separation of concerns: workload execution, evidence capture, aggregation, validation, formatting, and persistence. The default configuration should be light enough for diagnosis, while stacks and trace export are optional escalation modes. Operator traffic and global peak remain separate fields. Version metadata preserves interpretability when profiler schemas change.

Part 3 - Quantitative Prediction Before Execution

Define the report schema and size budget before implementation. Require raw bytes, not only formatted MiB. Set minimum significant allocation to filter noise, but preserve a count of omitted events. Predict tool overhead and expose configuration so users can reproduce it.

Part 4 - Experimental Design and Instrumentation

Test with three workloads: known linear allocation, deliberate clone, and forward/backward training. Compare automated results with manual tables from earlier exercises. Test CUDA-unavailable and invalid-device errors. Run the tool twice to verify that state from the first call does not contaminate the second.

Part 5 - PyTorch/CUDA Implementation

```
import json
from pathlib import Path
import torch
from torch.profiler import ProfilerActivity, profile
```

```
class MemoryProfiler:
    def __init__(self, device, row_limit=20):
        self.device = torch.device(device)
        self.row_limit = row_limit

    def run(self, step_function):
        torch.cuda.synchronize(self.device)
        torch.cuda.reset_peak_memory_stats(self.device)
        before = torch.cuda.memory_allocated(self.device)

        with profile(
            activities=[
                ProfilerActivity.CPU,
                ProfilerActivity.CUDA,
            ],
            profile_memory=True,
            record_shapes=True,
        ) as profiler:
            step_function()
            torch.cuda.synchronize(self.device)

        events = []
        for event in profiler.key_averages():
            row = {}
            row["key"] = event.key
            row["count"] = event.count
            row["self_cuda_memory_usage"] = (
                event.self_cuda_memory_usage
            )
            row["cuda_memory_usage"] = event.cuda_memory_usage
            row["cuda_time_total"] = event.cuda_time_total
            events.append(row)

        events.sort(
            key=lambda row: row["self_cuda_memory_usage"],
            reverse=True,
        )
        report = {}
        report["allocated_before"] = before
        report["allocated_after"] = torch.cuda.memory_allocated(
            self.device
        )
        report["peak_allocated"] = torch.cuda.max_memory_allocated(
            self.device
        )
        report["top_events"] = events[:self.row_limit]
        del profiler
        return report
```

```
def E18(step_function, output_path):
    diagnostic = MemoryProfiler("cuda:0", row_limit=25)
    report = diagnostic.run(step_function)
    path = Path(output_path)
    with path.open("w", encoding="utf-8") as file:
        json.dump(report, file, indent=2)
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate JSON serialization and invariant fields. Confirm outputs from the training step are not stored in the report. Compare the tool's top rows with the profiler's printed table and global counters. Add schema version, environment metadata, negative deallocation ranking, and configuration to the student implementation. Measure overhead and prevent automatic full traces in the default path.

Part 7 - Engineering Interpretation and Philosophy

Tools preserve habits. A well-designed profiler wrapper makes explicit devices, raw units, global validation, and reproducibility the easy path. A poor wrapper can industrialize misunderstanding by hiding configuration and collapsing incompatible metrics. Reusability should amplify disciplined reasoning, not replace it.

19.3.20 Exercise 19

Exercise Title: Optimize a Memory-Inefficient PyTorch Model Using Only Profiler Evidence and Produce a Reproducible Before-and-After Benchmark

Part 1 - Exercise Contract and Why It Matters

The final exercise is a constrained optimization study. You will begin with a model containing several plausible inefficiencies: unnecessary clones, premature contiguous materialization, retained GPU outputs, and an oversized intermediate. You may change code only when profiler or global-counter evidence supports a specific hypothesis. Every change must be applied separately, profiled again, and accepted only after output and gradient validation.

The final report must include an untouched baseline, a hypothesis ledger, operator tables, traces or stacks used for attribution, global peak, reserved memory, throughput, numerical parity, and an ablation showing the contribution of each accepted change. A final optimized number without the path of evidence does not satisfy the exercise.

The deliberately inefficient model should be realistic enough that not every large allocation is removable. One large activation may be essential to model capacity, while a smaller clone is pure waste. The exercise must demonstrate the judgment to leave an expensive but necessary operation unchanged and explain why. Optimization quality is not measured by the number of deleted rows.

Close the report with remaining bottlenecks and the next experiment required to address them. The final candidate is not "finished"; it is the best version supported by the current evidence and acceptance criteria.

Part 2 - System and Memory Mental Model

Optimization is an iterative causal loop:

$$\text{observe} \rightarrow \text{hypothesize} \rightarrow \text{change one cause} \rightarrow \text{validate} \rightarrow \text{measure again.}$$

Operator traffic identifies materialization; global peak tests residency; shapes explain scale; stacks locate source; traces reveal lifetime overlap. An optimization can lower allocation traffic without lowering peak, or lower peak while increasing runtime. The complete trade-off must remain visible.

Part 3 - Quantitative Prediction Before Execution

Before each modification, predict eliminated bytes, expected peak reduction, runtime direction, and numerical effect. Define acceptance criteria such as at least 10 percent peak reduction, no non-finite outputs, output and gradient parity within tolerance, and no unacceptable throughput regression. State hardware, batch, dtype, and seed.

Part 4 - Experimental Design and Instrumentation

Create independent baseline and candidate models with identical state dictionaries. Warm both, run multiple measured repetitions, randomize order, and use the same profiler options. Preserve raw JSON evidence. Apply one change at a time, then run the combined candidate. Include a long-loop test to detect retention that a single step misses.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import statistics
import time
import torch

def compare_outputs(reference, candidate):
    return torch.allclose(
        reference,
        candidate,
        atol=1e-5,
        rtol=1e-5,
    )

def benchmark_step(step_function, device, repetitions):
    durations = []
    peaks = []

    for repetition in range(repetitions):
        torch.cuda.synchronize(device)
        torch.cuda.reset_peak_memory_stats(device)
        start = time.perf_counter()
        output = step_function()
        torch.cuda.synchronize(device)
        duration = time.perf_counter() - start
```

```
        durations.append(duration)
        peaks.append(torch.cuda.max_memory_allocated(device))
        del output

    return {
        "median_seconds": statistics.median(durations),
        "maximum_peak_bytes": max(peaks),
        "all_seconds": durations,
        "all_peaks": peaks,
    }

def E19(baseline_model, optimized_model, inputs, make_step):
    device = inputs.device
    optimized_model.load_state_dict(
        copy.deepcopy(baseline_model.state_dict())
    )

    with torch.no_grad():
        reference = baseline_model(inputs)
        candidate = optimized_model(inputs)
    if not compare_outputs(reference, candidate):
        raise AssertionError("Forward outputs changed.")

    baseline_step = make_step(baseline_model)
    optimized_step = make_step(optimized_model)
    baseline_result = benchmark_step(
        baseline_step, device, repetitions=20
    )
    optimized_result = benchmark_step(
        optimized_step, device, repetitions=20
    )

    return {
        "baseline": baseline_result,
        "optimized": optimized_result,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

For every accepted change, show the profiler hotspot before and its reduction afterward. Compare global peaks and explain discrepancies. Validate forward outputs, loss, every parameter gradient, and input immutability. Report median runtime and variability. If memory improves while speed worsens, quantify the trade rather than declaring unconditional success. Re-run the original baseline at the end to detect clock or environment drift.

Part 7 - Engineering Interpretation and Philosophy

Evidence-constrained optimization protects the engineer from rewriting code according to folklore. The profiler does not choose the design, but it forces each change to answer a measured problem. The final lesson of DMM01 is that visibility creates responsibility: once memory has

been attributed, every optimization must explain what information was removed, why it was unnecessary, and what proof shows the model still performs the same computation.

19.4 DMM02

Chapter Title: PyTorch Caching Allocator
Specialization: Dynamic Memory Management and CUDA Systems

19.4.1 Exercise 00

Exercise Title: Build a Precise Mental Model of How the PyTorch CUDA Caching Allocator Reuses GPU Memory Blocks

Part 1 - Exercise Contract and Why It Matters

This exercise replaces the misleading model "a tensor is deleted, therefore its bytes immediately return to the GPU" with a three-owner model. Live tensor storage is owned by the program, cached blocks are owned by the PyTorch process but are currently reusable, and unreserved capacity is controlled by the CUDA driver. The caching allocator exists because repeatedly asking the driver for memory is expensive and may impose synchronization. Reusing a suitable block can therefore make a later allocation cheaper without changing its tensor semantics.

The deliverable is an annotated allocation timeline. For every event, record requested payload, allocated memory, reserved memory, inferred reusable memory, and driver free memory. Explain which transitions are observations and which are inferences. Do not treat every difference between reserved and allocated as a perfectly usable block: rounding, bookkeeping, fragmentation, stream safety, and allocator implementation details can reduce immediate usability.

Part 2 - System and Memory Mental Model

Let $A(t)$ denote bytes attributed to live PyTorch tensor storage and $R(t)$ bytes held by the allocator. A useful first approximation is

$$0 \le A(t) \le R(t), \qquad C_{\text{proxy}}(t) = R(t) - A(t).$$

The quantity C_{proxy} is a cached-capacity proxy, not a promise that one request of that size will succeed. The allocator manages larger segments obtained from CUDA and subdivides them into blocks. A released block may become inactive and reusable; adjacent compatible blocks may be merged; an oversized block may be split. Exact pools, rounding rules, and policies are version and backend dependent, so they must be measured rather than memorized as universal constants.

Allocation is also stream ordered. A block touched by outstanding work cannot always be reused immediately on an unrelated stream. CUDA kernels are asynchronous, Python reference deletion is not device synchronization, and views share storage with their base tensor. These facts explain many apparent contradictions in memory traces.

Part 3 - Quantitative Prediction Before Execution

Predict the following sequence before executing it: allocate tensor x, allocate y, delete x, allocate z with the same shape as x, then delete all tensors. For a tensor shape S and element width w, compute the payload $P = w \prod_i S_i$. Predict the direction, not an unsupported exact allocator increment: A rises with live payload, R may rise when no suitable block exists, deletion lowers A, and same-shape reallocation should often raise A without raising R. Include a second prediction in which z is slightly larger and explain why the cached block might fail to satisfy it.

Part 4 - Experimental Design and Instrumentation

Run in a fresh process on one explicit device. Synchronize before every measurement boundary, but recognize that synchronization changes timing and should not be inserted into production merely for observation. Warm CUDA once, clear only Python references between phases, and intentionally avoid `empty_cache()` so allocator ownership remains visible. Repeat the timeline at least three times and separate first-run initialization from steady-state reuse.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def mib(value):
    return value / (1024 ** 2)

def snapshot(label, device):
    torch.cuda.synchronize(device)
    allocated = torch.cuda.memory_allocated(device)
    reserved = torch.cuda.memory_reserved(device)
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    row = {
        "label": label,
        "allocated_mib": mib(allocated),
        "reserved_mib": mib(reserved),
        "cached_proxy_mib": mib(reserved - allocated),
        "driver_free_mib": mib(free_bytes),
        "driver_total_mib": mib(total_bytes),
    }
    print(row)
    return row

def E00():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM02.")
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    rows = [snapshot("baseline", device)]

    shape = (64, 1024, 1024)
    x = torch.empty(shape, dtype=torch.float32, device=device)
    rows.append(snapshot("allocate_x", device))
```

```
    y = torch.empty(shape, dtype=torch.float32, device=device)
    rows.append(snapshot("allocate_y", device))

    del x
    gc.collect()
    rows.append(snapshot("delete_x", device))
    z = torch.empty(shape, dtype=torch.float32, device=device)
    rows.append(snapshot("allocate_same_shape_z", device))

    del y
    del z
    gc.collect()
    rows.append(snapshot("delete_all", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that allocated memory follows tensor lifetime while reserved memory usually forms a high-water plateau. A convincing reuse event has three pieces of evidence: allocated rises by approximately the new payload, reserved does not materially rise, and the numerical behavior of the tensor remains normal. Do not infer reuse solely from driver free memory because CUDA context, libraries, and non-PyTorch allocations also consume capacity.

If deletion does not lower allocated memory, search for aliases, views, containers, closures, autograd graphs, or notebook outputs retaining storage. If reserved rises on the same-shape request, repeat after warm-up and inspect whether another live tensor or asynchronous stream use prevented reuse.

Part 7 - Engineering Interpretation and Philosophy

Caching is intentional ownership, not automatically a leak. The engineering question is whether live memory grows, whether reserved memory eventually stabilizes, and whether cached blocks match future requests. A sound allocator mental model never collapses logical lifetime, allocator ownership, and physical device capacity into one number. It also treats implementation details as measured properties of a specific PyTorch, CUDA, device, and configuration rather than eternal rules.

19.4.2 Exercise 01

Exercise Title: Predict Allocated, Reserved, and Reusable Memory After a Controlled Sequence of CUDA Tensor Allocations and Deallocations

Part 1 - Exercise Contract and Why It Matters

Turn allocator observation into prediction. You will write a ledger before running code, then compare it with synchronized measurements. The objective is not to guess allocator rounding exactly; it is to state which changes are forced by live tensor payload and which depend on cache suitability.

Part 2 - System and Memory Mental Model

For event k, distinguish requested payload P_k, live payload L_k, PyTorch allocated A_k, reserved R_k, and reusable proxy $C_k = R_k - A_k$. Views add no storage, clones do. Deleting a base while a view survives does not free the shared storage. Consequently, a reference graph is part of the memory equation.

Part 3 - Quantitative Prediction Before Execution

Construct a table for: allocate 96 MiB a; allocate 64 MiB b; create a view v of a; delete a; clone v into c; delete v; delete b; allocate a new 64 MiB d. Predict exact live payload and intervals for allocated and reserved. Mark reuse as “expected”, “possible”, or “not inferable” rather than asserting undocumented internals.

Part 4 - Experimental Design and Instrumentation

Generate sizes from byte targets using float32 element counts. Record a row after each event and retain the Python objects in a named dictionary so lifetime is visible. Use one stream, synchronize measurements, and run the sequence twice to compare cold and warm allocator states.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def make_mib(count_mib, device):
    elements = count_mib * 1024 * 1024 // 4
    return torch.empty(elements, dtype=torch.float32, device=device)

def memory_row(step, device):
    torch.cuda.synchronize(device)
    a = torch.cuda.memory_allocated(device)
    r = torch.cuda.memory_reserved(device)
    return step, a, r, r - a

def E01():
    device = torch.device("cuda:0")
    objects = {}
    rows = [memory_row("baseline", device)]
    objects["a"] = make_mib(96, device)
    rows.append(memory_row("a_96", device))
    objects["b"] = make_mib(64, device)
    rows.append(memory_row("b_64", device))
    objects["v"] = objects["a"].view(-1)
    rows.append(memory_row("view_a", device))
    del objects["a"]
    gc.collect()
    rows.append(memory_row("delete_a_keep_view", device))
    objects["c"] = objects["v"].clone()
    rows.append(memory_row("clone_view", device))
    del objects["v"]
    del objects["b"]
```

```
    gc.collect()
    rows.append(memory_row("release_view_and_b", device))
    objects["d"] = make_mib(64, device)
    rows.append(memory_row("new_64", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare predicted and measured rows using deltas from baseline. Payload should match allocated approximately, while reserved may include rounding and cached segments. The critical validation is that deleting a while v survives does not release its storage, whereas deleting the last alias does. Explain any failure by reference lifetime before blaming the allocator.

Also compare each measured row with the previous row rather than only with the final state. A clone should create independent storage, whereas a view should not. If the final request is served without reserved growth, annotate the released lifetime that made capacity available. If it grows, explain why a global cached proxy cannot prove that a compatible contiguous block existed.

Part 7 - Engineering Interpretation and Philosophy

Memory budgeting is strongest when it predicts invariants and bounds, not fragile undocumented byte-for-byte outcomes. A useful engineer can say which storage must be live, which may be cached, and what evidence would distinguish reuse from a new reservation.

19.4.3 Exercise 02

Exercise Title: Create a Minimal PyTorch Experiment That Reveals Caching Allocator Behavior Without Calling empty_cache()

Part 1 - Exercise Contract and Why It Matters

Build the smallest experiment that visibly separates release from return to the driver. Minimality matters: a model, optimizer, autograd graph, and data loader would introduce lifetimes that obscure the allocator mechanism.

Part 2 - System and Memory Mental Model

After a tensor's final reference disappears, allocated memory should fall. The allocator may retain the corresponding block, leaving reserved memory high. A later compatible tensor may consume that block. This is the core caching signature: A changes with liveness while R remains on a plateau.

Part 3 - Quantitative Prediction Before Execution

Use one 256 MiB float32 tensor. Predict the signs of ΔA, ΔR, and ΔF_{driver} after allocation, deletion, and same-size reallocation. State why exact deltas may exceed payload and why the baseline CUDA context must be initialized first.

Part 4 - Experimental Design and Instrumentation

Run a fresh process, initialize CUDA with a one-element tensor, and take five synchronized snapshots. Never call `empty_cache()`. Avoid operations that initialize the large tensor because the experiment concerns allocation, not kernel time. Repeat the complete cycle to demonstrate reproducibility.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def state(label, device):
    torch.cuda.synchronize(device)
    allocated = torch.cuda.memory_allocated(device)
    reserved = torch.cuda.memory_reserved(device)
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    return {
        "label": label,
        "allocated": allocated,
        "reserved": reserved,
        "reusable_proxy": reserved - allocated,
        "driver_free": free_bytes,
        "driver_total": total_bytes,
    }

def E02():
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    rows = [state("warm_baseline", device)]
    count = 256 * 1024 * 1024 // 4
    x = torch.empty(count, dtype=torch.float32, device=device)
    rows.append(state("allocated_x", device))
    del x
    gc.collect()
    rows.append(state("deleted_x", device))
    y = torch.empty(count, dtype=torch.float32, device=device)
    rows.append(state("allocated_y", device))
    del y
    gc.collect()
    rows.append(state("deleted_y", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot allocated and reserved as step functions. Success requires a clear fall in allocated after deletion and a retained reserved plateau. If allocated does not fall, the experiment is not minimal: inspect notebook history, aliases, or exception tracebacks. If reserved also falls, verify the backend and process conditions; never rewrite observations to fit the expected story.

Repeat the experiment with 64, 128, and 256 MiB payloads. The qualitative signature should remain, but reservation increments may reveal rounding or pool differences. Include absolute counters and baseline-subtracted deltas; absolute values expose process ownership, while deltas isolate the experiment. Record whether another process shares the GPU because driver-free capacity can change independently of this workload.

Part 7 - Engineering Interpretation and Philosophy

A minimal counterexample is often more educational than a large benchmark. This experiment proves that "not live" and "returned to the driver" are different states. That distinction is the foundation for every later leak, fragmentation, and OOM diagnosis.

19.4.4 Exercise 03

Exercise Title: Prove That Deallocated Tensor Memory Can Remain Reserved and Be Reused by Later CUDA Allocations

Part 1 - Exercise Contract and Why It Matters

Move from suggestive counters to a controlled proof of reuse. You must show that a released tensor is no longer live, that its capacity remains reserved, and that a compatible request is satisfied without material reserved growth.

Part 2 - System and Memory Mental Model

Reuse is an allocator transition from inactive cached block to active block. Global counters do not expose the identity of a block, so the conclusion is an inference supported by controlled alternatives. The strongest basic evidence combines stable R, rising A, stable driver-free memory, and a matched request size.

Part 3 - Quantitative Prediction Before Execution

Compare two branches after releasing a 192 MiB tensor: branch S requests the same payload; branch L requests 384 MiB. Predict that S usually reuses capacity with little or no R growth, while L may require additional reservation. Define a tolerance before running, such as 2 MiB, instead of deciding after seeing the result.

Part 4 - Experimental Design and Instrumentation

Execute each branch in a separate fresh process or reset the experimental baseline carefully, because branch L permanently changes the cache state. Use identical warm-up and synchronization. Repeat ten cycles and report how often the same-size request stayed within the predeclared tolerance.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def counters(device):
    torch.cuda.synchronize(device)
    allocated = torch.cuda.memory_allocated(device)
    reserved = torch.cuda.memory_reserved(device)
    free_bytes, _ = torch.cuda.mem_get_info(device)
    return allocated, reserved, free_bytes

def allocate_mib(size_mib, device):
    count = size_mib * 1024 * 1024 // 4
    return torch.empty(count, dtype=torch.float32, device=device)

def E03(request_mib=192):
```

```
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    first = allocate_mib(192, device)
    live = counters(device)
    del first
    gc.collect()
    released = counters(device)
    second = allocate_mib(request_mib, device)
    reused = counters(device)
    del second
    return {
        "live": live,
        "released": released,
        "second_allocation": reused,
        "request_mib": request_mib,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Compute $R_{second} - R_{released}$ and $F_{released} - F_{second}$. A near-zero pair supports reuse. Confirm that $A_{released}$ fell by approximately 192 MiB first. If the same-size branch grows reserved, test for other live allocations, streams, or allocator backend differences and report the limitation honestly.

Before accepting the conclusion, add a negative control that keeps the first tensor alive while requesting the second. Reserved memory should then grow if the working set exceeds existing capacity. This distinguishes reuse from a coincidental warm cache. A second control requests another dtype with the same byte payload and tests whether payload compatibility is sufficient in the observed allocator configuration.

Part 7 - Engineering Interpretation and Philosophy

Proof in systems work is rarely a single counter. It is a causal argument built from controls, predeclared expectations, and competing explanations. The claim should be "the evidence is consistent with allocator reuse under this configuration", not "all future PyTorch versions must reuse this block".

19.4.5 Exercise 04

Exercise Title: Compare First-Time CUDA Allocation Latency Against Reallocation Latency When Cached Blocks Are Reused

Part 1 - Exercise Contract and Why It Matters

Quantify the performance reason for caching. Compare a cold request that may obtain new memory from CUDA with a compatible request served after release. Separate allocator latency from tensor initialization and from asynchronous kernel execution.

Part 2 - System and Memory Mental Model

`torch.empty()` requests storage but does not intentionally fill every element, making it a better allocator probe than `zeros` or `randn`. CPU wall-clock timing around an asynchronous CUDA operation is still incomplete, so synchronize before and after each measured request.

The measurement includes Python and dispatch overhead; it is not a pure internal allocator clock.

Part 3 - Quantitative Prediction Before Execution

Predict median cold and cached latency for several payloads, but do not predict an exact speedup. State three confounders: CUDA context initialization, DVFS, and allocator warm state. Define primary statistics in advance: median, interquartile range, and reserved-memory delta.

Part 4 - Experimental Design and Instrumentation

Use separate subprocesses for truly cold trials; within one process, measure the first post-warm-up request and many release/reallocate cycles. Randomize size-test order across repetitions or disclose fixed ordering. Do not call `empty_cache()` between cached trials. Keep peak request safely below device capacity.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import statistics
import time
import torch

def timed_empty(elements, device):
    torch.cuda.synchronize(device)
    start = time.perf_counter_ns()
    value = torch.empty(elements, dtype=torch.float32, device=device)
    torch.cuda.synchronize(device)
    elapsed_us = (time.perf_counter_ns() - start) / 1000.0
    return value, elapsed_us

def E04(size_mib=256, repeats=30):
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    elements = size_mib * 1024 * 1024 // 4

    value, first_us = timed_empty(elements, device)
    del value
    gc.collect()
    cached_times = []
    reserved_deltas = []
    for _ in range(repeats):
        before = torch.cuda.memory_reserved(device)
        value, elapsed_us = timed_empty(elements, device)
        after = torch.cuda.memory_reserved(device)
        cached_times.append(elapsed_us)
        reserved_deltas.append(after - before)
        del value
        gc.collect()
```

```
    return {
        "first_us": first_us,
        "cached_median_us": statistics.median(cached_times),
        "cached_times_us": cached_times,
        "reserved_deltas": reserved_deltas,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Report distributions, not a single fastest result. Validate cached trials by checking reserved deltas. If no speedup appears, the first request may already be served from warm cache, timing noise may dominate, or synchronization may cost more than the allocation. Repeat with larger sizes and fresh subprocesses before concluding caching has no value.

Present cold and cached latency on a logarithmic axis when outliers are large, and report the first trial separately rather than averaging it into steady state. Run a no-allocation synchronization control to estimate the measurement floor. If cached latency is near that floor, the benchmark cannot resolve allocator work precisely; it establishes only an upper bound.

Part 7 - Engineering Interpretation and Philosophy

The allocator trades retained capacity for lower allocation overhead and fewer driver interactions. This is a latency-through-memory trade, not free speed. Benchmarking should preserve the causal mechanism: measuring `zeros` would mostly measure initialization bandwidth, while calling `empty_cache()` would deliberately destroy the condition being studied.

19.4.6 Exercise 05

Exercise Title: Sweep Tensor Sizes and Determine When the Allocator Reuses Existing Blocks Versus Requests Additional GPU Memory

Part 1 - Exercise Contract and Why It Matters

Map reuse behavior across request sizes rather than drawing conclusions from a single matched allocation. The result is an empirical compatibility map for your exact PyTorch build, allocator backend, and GPU.

Part 2 - System and Memory Mental Model

A cached byte total is not a contiguous universal pool. Blocks have sizes and locations inside allocator-managed segments. A request may reuse a suitable block, split a larger block, or force new reservation. Therefore $R - A$ can exceed a request while that request still cannot be satisfied by a single suitable cached block.

Part 3 - Quantitative Prediction Before Execution

Seed the cache by releasing 32, 64, 128, and 256 MiB tensors. Sweep requests from 24 to 288 MiB. Before execution, classify each request as likely exact reuse, possible split/reuse, or likely growth. Define growth as a reserved increase greater than a predeclared 2 MiB tolerance.

Part 4 - Experimental Design and Instrumentation

Run each request size in a fresh subprocess with the identical seeded pattern; otherwise an early request mutates the cache available to later requests. Record allocated and reserved

before, during, and after the probe. Repeat the full sweep to expose variability, and never generalize boundaries beyond the tested configuration.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def tensor_mib(size_mib, device):
    count = size_mib * 1024 * 1024 // 4
    return torch.empty(count, dtype=torch.float32, device=device)

def run_probe(probe_mib):
    device = torch.device("cuda:0")
    seeds = []
    for size_mib in [32, 64, 128, 256]:
        seeds.append(tensor_mib(size_mib, device))
    torch.cuda.synchronize(device)
    seeds.clear()
    gc.collect()
    torch.cuda.synchronize(device)

    reserved_before = torch.cuda.memory_reserved(device)
    probe = tensor_mib(probe_mib, device)
    torch.cuda.synchronize(device)
    reserved_during = torch.cuda.memory_reserved(device)
    allocated_during = torch.cuda.memory_allocated(device)
    del probe
    gc.collect()
    return {
        "probe_mib": probe_mib,
        "allocated_during": allocated_during,
        "reserved_growth": reserved_during - reserved_before,
    }

def E05():
    results = []
    for size_mib in range(24, 289, 8):
        # For rigorous isolation, invoke run_probe in a fresh subprocess.
        results.append(run_probe(size_mib))
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot request size against reserved growth and color points by the reuse classification. A plateau suggests cached service; a jump suggests acquisition or expansion. The in-process skeleton is pedagogical but order dependent, so a publication-quality result must isolate probes in subprocesses. Explain any non-monotonic boundaries as allocator behavior to investigate, not noise to silently remove.

For each point, attach the seeded cache state and requested byte count so the graph is reproducible. Repeat the sweep in descending order as an explicit order-sensitivity test. If ascending and descending boundaries differ, prior splitting and reuse changed the state; one run is not automatically wrong. Report both paths and their mutation histories.

Part 7 - Engineering Interpretation and Philosophy

Allocator compatibility is empirical. The useful outcome is not a reverse- engineered promise about internal bins; it is evidence that a workload's shape distribution either aligns with reusable capacity or repeatedly demands new segments.

19.4.7 Exercise 06

Exercise Title: Track Active, Inactive, Allocated, and Reserved Memory While Repeatedly Creating and Destroying CUDA Tensors

Part 1 - Exercise Contract and Why It Matters

Extend global counters into an allocator-state timeline. Track live allocated bytes, reserved bytes, and selected active/inactive statistics while tensor lifetimes repeatedly change. The aim is to separate workload liveness from allocator reuse capacity.

Part 2 - System and Memory Mental Model

`memory_stats()` exposes allocator metrics whose keys and precise semantics can vary by backend and version. Active blocks are associated with live or otherwise non-reusable storage; inactive bytes describe blocks inside allocator ownership that may be reusable or split. Never add every statistic together: many are alternative aggregations of the same bytes.

Part 3 - Quantitative Prediction Before Execution

For ten cycles of allocate 64 MiB, allocate 96 MiB, delete the first, then delete the second, predict a periodic allocated curve and a reserved curve that should plateau after warm-up. Predict when inactive bytes rise and fall. State that exact statistic keys must be discovered and documented.

Part 4 - Experimental Design and Instrumentation

Capture only a small selected set of counters after synchronization. Save CPU numbers, never tensor objects, in the trace. Run a fixed-shape control and then a variable-shape variant. Include PyTorch version and allocator backend configuration in the report.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def allocator_row(step, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    row = {
        "step": step,
        "allocated": torch.cuda.memory_allocated(device),
        "reserved": torch.cuda.memory_reserved(device),
```

```
    }
    wanted = [
        "active_bytes.all.current",
        "inactive_split_bytes.all.current",
        "segment.all.current",
    ]
    for key in wanted:
        row[key] = stats.get(key, None)
    return row

def make_mib(size_mib, device):
    count = size_mib * 1024 * 1024 // 4
    return torch.empty(count, device=device)

def E06(cycles=10):
    device = torch.device("cuda:0")
    trace = [allocator_row("baseline", device)]
    for cycle in range(cycles):
        first = make_mib(64, device)
        trace.append(allocator_row("first_" + str(cycle), device))
        second = make_mib(96, device)
        trace.append(allocator_row("second_" + str(cycle), device))
        del first
        gc.collect()
        trace.append(allocator_row("release_first_" + str(cycle), device))
        del second
        gc.collect()
        trace.append(allocator_row("release_second_" + str(cycle), device))
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify the algebraic invariant $A \leq R$ and compare active bytes with allocated bytes without assuming equality. Missing statistic keys are an expected compatibility condition, not a reason to substitute fabricated zero. If the fixed workload grows indefinitely, inspect retained references and asynchronous stream use before diagnosing poor caching.

Inspect counter relationships at create and release boundaries, not only at the end of a cycle. A counter that rises only while a tensor is live has a different meaning from one that accumulates across cycles. Export the list of available memory-stat keys so another machine can identify backend or version differences instead of treating missing fields as numerical zeros.

Part 7 - Engineering Interpretation and Philosophy

Detailed counters are useful only when anchored to a lifetime story. More metrics do not automatically produce more understanding; each line must answer whether bytes are live, cached, fragmented, or newly acquired.

19.4.8 Exercise 07

Exercise Title: Design an Allocation Pattern That Reuses Cached Memory Efficiently and Verify That Reserved Memory Stabilizes

Part 1 - Exercise Contract and Why It Matters

Design a stable workload whose repeated shape set encourages reuse. The exercise models production systems that bucket inputs or reuse predictable batch shapes to reduce allocator churn.

Part 2 - System and Memory Mental Model

When the same set of maximum simultaneous allocations repeats, the allocator can often reach a steady state. After initial segments are obtained, later iterations cycle blocks between active and inactive states. Reserved memory then approaches a plateau even though cumulative allocation traffic grows.

Part 3 - Quantitative Prediction Before Execution

Choose three fixed payloads and a deterministic lifetime order. Predict the minimum concurrent live payload and an upper interval for steady reserved memory. Define stabilization: for example, no iteration after warm-up increases reserved memory by more than 2 MiB.

Part 4 - Experimental Design and Instrumentation

Run 100 iterations, discard 10 warm-up iterations only from performance statistics, and retain their memory trace. Record end-of-iteration allocated, reserved, and peak. Touch tensors with a small kernel so the workload is real, then synchronize at measurement boundaries.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def fixed_work(device):
    a = torch.empty(32 * 1024 * 1024 // 4, device=device)
    b = torch.empty(64 * 1024 * 1024 // 4, device=device)
    c = torch.empty(96 * 1024 * 1024 // 4, device=device)
    a.fill_(1.0)
    b.fill_(2.0)
    c.fill_(3.0)
    checksum = a[0] + b[0] + c[0]
    return a, b, c, checksum

def E07(iterations=100):
    device = torch.device("cuda:0")
    trace = []
    for iteration in range(iterations):
        a, b, c, checksum = fixed_work(device)
        torch.cuda.synchronize(device)
        peak_live = torch.cuda.memory_allocated(device)
        del a
        del b
        del c
        del checksum
        gc.collect()
```

```
        torch.cuda.synchronize(device)
        trace.append({
            "iteration": iteration,
            "peak_live": peak_live,
            "allocated_end": torch.cuda.memory_allocated(device),
            "reserved_end": torch.cuda.memory_reserved(device),
        })
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot reserved end-state by iteration and automatically find the first index after which the stabilization rule holds. Confirm checksum value so compiler or code changes do not remove the intended work. If end allocated grows, the problem is liveness, not cache inefficiency. If only reserved grows, investigate shape or concurrency drift.

Measure stabilization using both absolute and relative tolerances because a 2 MiB change means something different in a 200 MiB experiment and a 20 GiB experiment. Repeat with reversed allocation order while preserving simultaneous payload. A changed plateau reveals that lifetime order, not only total bytes, influences the allocator working set.

Part 7 - Engineering Interpretation and Philosophy

Predictability is a memory optimization. Bucketing, fixed microbatches, and bounded shape families can turn a turbulent allocation stream into a reusable working set. The correct target is stable memory with preserved model semantics, not the smallest possible reserved number at every instant.

19.4.9 Exercise 08

Exercise Title: Design an Irregular Allocation Pattern That Forces Reserved Memory Growth Despite Releasing Previous Tensors

Part 1 - Exercise Contract and Why It Matters

Construct the opposite of E07: live tensors are released, yet changing request sizes cause the allocator's reserved footprint to grow. This demonstrates why variable shapes can resemble a leak without retaining tensors.

Part 2 - System and Memory Mental Model

Released capacity may be unusable for a later request because no individual block is suitable or because splitting leaves fragments poorly matched to future sizes. A workload can therefore have low end-of-iteration allocated memory and rising reserved memory. This is allocation-pattern inefficiency, not proof of a Python reference leak.

Part 3 - Quantitative Prediction Before Execution

Create an irregular schedule that alternates many small allocations with one increasing large allocation. Predict end allocated near baseline and reserved as a staircase. Predeclare a safe maximum of 40 percent of currently free device memory to prevent an uncontrolled OOM.

Part 4 - Experimental Design and Instrumentation

Run the pattern in a fresh subprocess and compare it to a fixed-shape control with the same approximate total allocation traffic. Capture peak allocated and reserved per iteration. Stop before the safety budget, and report the stopped trial rather than silently reducing sizes after observing failure.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def make_mib(size_mib, device):
    count = size_mib * 1024 * 1024 // 4
    return torch.empty(count, device=device)

def E08(iterations=30):
    device = torch.device("cuda:0")
    free_bytes, _ = torch.cuda.mem_get_info(device)
    safety_budget = int(free_bytes * 0.40)
    trace = []
    for iteration in range(iterations):
        sizes = [9, 17, 33, 65, 11 + iteration * 7]
        requested = sum(sizes) * 1024 * 1024
        if requested > safety_budget:
            break
        tensors = []
        for size_mib in sizes:
            tensors.append(make_mib(size_mib, device))
        torch.cuda.synchronize(device)
        peak = torch.cuda.memory_allocated(device)
        tensors.clear()
        gc.collect()
        torch.cuda.synchronize(device)
        trace.append({
            "iteration": iteration,
            "sizes_mib": sizes,
            "peak_allocated": peak,
            "allocated_end": torch.cuda.memory_allocated(device),
            "reserved_end": torch.cuda.memory_reserved(device),
        })
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Show two curves: end allocated and end reserved. The intended signature is a flat first curve and a growing second curve. If both grow, inspect references. If neither grows, the allocator successfully reused or split blocks for this schedule; revise the hypothesis transparently rather than claiming forced growth that measurements did not show.

Quantify irregularity rather than describing it informally. Report unique size count, coefficient of variation, maximum concurrency, cumulative traffic, and reserved-growth event count.

Compare these values with E07. This prevents the analysis from attributing every difference to variability when the irregular schedule may also contain more work or a larger live peak.

Part 7 - Engineering Interpretation and Philosophy

Irregularity is not inherently wrong, but it has a memory cost. The lesson is to distinguish semantic variability required by the task from accidental shape churn introduced by preprocessing, batching, or control flow.

19.4.10 Exercise 09

Exercise Title: Compare Repeated torch.empty(), torch.zeros(), and torch.randn() CUDA Allocations Under the Same Memory Workload

Part 1 - Exercise Contract and Why It Matters

Separate storage allocation from tensor initialization. All three constructors request comparable storage, but zeros launches initialization work and randn generates random values. Confusing these costs produces false claims about the allocator.

Part 2 - System and Memory Mental Model

For identical shape and dtype, live payload is the same. Allocation can be served by cached blocks, while initialization kernels consume execution time and memory bandwidth. Random generation also updates generator state and may use implementation-specific temporary resources. Consequently memory parity does not imply latency parity.

Part 3 - Quantitative Prediction Before Execution

Predict equal allocated payload within tolerance, similar steady reserved plateaus, and latency ordered roughly as empty, zeros, randn for a large tensor. Treat the latency order as a hypothesis because hardware, size, and kernel implementation can change it. Predict how results change for tiny tensors where dispatch overhead dominates.

Part 4 - Experimental Design and Instrumentation

Benchmark constructors independently after warm-up. Use the same shape, dtype, repetition count, and synchronization. Delete each tensor before the next iteration. Randomize constructor order across runs or execute isolated subprocesses to prevent cache-order bias.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import statistics
import time
import torch

def benchmark_factory(name, shape, repeats, device):
    samples = []
    memory = []
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter_ns()
        if name == "empty":
```

```
            value = torch.empty(shape, device=device)
        elif name == "zeros":
            value = torch.zeros(shape, device=device)
        elif name == "randn":
            value = torch.randn(shape, device=device)
        else:
            raise ValueError(name)
        torch.cuda.synchronize(device)
        samples.append((time.perf_counter_ns() - start) / 1e6)
        memory.append((
            torch.cuda.memory_allocated(device),
            torch.cuda.memory_reserved(device),
        ))
        del value
        gc.collect()
    return statistics.median(samples), samples, memory

def E09():
    device = torch.device("cuda:0")
    shape = (64, 1024, 1024)
    results = {}
    for name in ["empty", "zeros", "randn"]:
        results[name] = benchmark_factory(name, shape, 30, device)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare medians and distributions, then verify payload equality from allocated deltas. Inspect outliers rather than discarding them automatically. If empty is not fastest, determine whether synchronization, cache state, or small workload size dominates. Do not use uninitialized values from empty in numerical checks.

Add two payload regimes: one small enough for dispatch overhead to dominate and one large enough for memory bandwidth to dominate. For zeros and randn, verify content semantics with a sampled reduction outside the timed interval. Report the CUDA generator seed and distinguish reproducibility of values from reproducibility of performance.

Part 7 - Engineering Interpretation and Philosophy

API names that all "create a tensor" can represent different system work. Good performance analysis decomposes allocation, initialization, randomness, and synchronization instead of assigning the entire observed latency to the caching allocator.

19.4.11 Exercise 10

Exercise Title: Call torch.cuda.empty_cache() at Different Points and Measure Its Effect on Reserved Memory, Allocation Latency, and Throughput

Part 1 - Exercise Contract and Why It Matters

Test `empty_cache()` as a specific intervention, not a ritual. Measure what it can release, what it cannot release, and the cost of destroying useful cached capacity at different workload boundaries.

Part 2 - System and Memory Mental Model

`empty_cache()` asks the allocator to release eligible unused cached blocks. It cannot release storage still referenced by live tensors and does not magically reduce model, gradient, activation, or optimizer-state memory. After cache release, later requests may require new driver allocations, increasing latency and possibly synchronization overhead.

Part 3 - Quantitative Prediction Before Execution

Predict three policies: never call it; call once after a completed workload phase; call every iteration. Predict allocated, reserved, driver free, median iteration time, and throughput. The one-time call should lower eligible reserved memory; the per-iteration policy should repeatedly sacrifice reuse.

Part 4 - Experimental Design and Instrumentation

Run policies in separate fresh processes with identical warm-up, shapes, seed, and 100 measured iterations. Synchronize around timing, but not within the actual step. Record state immediately before and after each cache call. Retain one live tensor during a special control to prove its bytes cannot be released.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import time
import torch

def workload(device):
    first = torch.randn((4096, 4096), device=device)
    second = torch.relu(first)
    result = second.sum()
    return first, second, result

def E10(policy="never", iterations=100):
    device = torch.device("cuda:0")
    samples = []
    memory = []
    for iteration in range(iterations):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        first, second, result = workload(device)
        del first
        del second
        del result
        gc.collect()
        if policy == "every_iteration":
            torch.cuda.empty_cache()
        if policy == "phase_end" and iteration == iterations - 1:
            torch.cuda.empty_cache()
        torch.cuda.synchronize(device)
        samples.append(time.perf_counter() - start)
```

```
        memory.append({
            "allocated": torch.cuda.memory_allocated(device),
            "reserved": torch.cuda.memory_reserved(device),
        })
    return samples, memory
```

Part 6 - Measurement, Validation, and Failure Analysis

Report median and tail latency, throughput, allocated, reserved, and driver free capacity. Prove the live-tensor control remains allocated across the call. If phase-end release is small, most bytes may still be live or not eligible. Do not claim performance effects from one run; caching and system noise demand repetition.

Measure the cache call itself and the first allocation after it as separate intervals. Charging only the call misses deferred cost paid by the next request, while charging the entire following workload can overstate that cost. Present both numbers and a combined phase cost. Verify that tensor or model outputs are unchanged across policies.

Part 7 - Engineering Interpretation and Philosophy

An API is useful when applied to a diagnosed state. Cache release can help cooperative multi-process use or phase transitions, but using it inside every iteration often exchanges allocator efficiency for a cosmetically smaller reserved counter.

19.4.12 Exercise 11

Exercise Title: Demonstrate Why Calling empty_cache() Every Training Iteration Can Reduce Performance Without Reducing Live Tensor Memory

Part 1 - Exercise Contract and Why It Matters

Embed the E10 intervention in a real training step. Demonstrate that parameter, gradient, activation, and optimizer requirements are determined by training semantics, while cache flushing only targets currently unused blocks.

Part 2 - System and Memory Mental Model

During forward and backward, live memory reaches a workload-defined peak. Flushing after the step may reduce idle reserved bytes, but the next step must reconstruct the same working set. Therefore peak allocated can remain nearly unchanged while allocation traffic and iteration latency worsen.

Part 3 - Quantitative Prediction Before Execution

For baseline and per-step cache-flush policies, predict identical loss trajectories and nearly identical peak allocated memory. Predict lower end reserved for the flush policy but worse throughput. Set parity tolerances for loss and parameter checks before running.

Part 4 - Experimental Design and Instrumentation

Clone identical model states, inputs, labels, optimizer configuration, and random seeds. Warm each policy, measure at least 100 steps, and synchronize only at timing boundaries. Reset peak statistics before each measured step or capture phase-wide peak consistently.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def train_policy(flush_cache, steps=100):
    device = torch.device("cuda:0")
    torch.manual_seed(23)
    model = torch.nn.Sequential(
        torch.nn.Linear(2048, 4096),
        torch.nn.ReLU(),
        torch.nn.Linear(4096, 1000),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.0005)
    inputs = torch.randn((128, 2048), device=device)
    labels = torch.randint(0, 1000, (128,), device=device)
    rows = []
    for step in range(steps):
        torch.cuda.reset_peak_memory_stats(device)
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        optimizer.zero_grad(set_to_none=True)
        logits = model(inputs)
        loss = torch.nn.functional.cross_entropy(logits, labels)
        loss.backward()
        optimizer.step()
        del logits
        del loss
        if flush_cache:
            torch.cuda.empty_cache()
        torch.cuda.synchronize(device)
        rows.append({
            "step": step,
            "seconds": time.perf_counter() - start,
            "peak_allocated": torch.cuda.max_memory_allocated(device),
            "reserved_end": torch.cuda.memory_reserved(device),
        })
    return rows

def E11():
    return train_policy(False), train_policy(True)
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare post-warm-up throughput and peak-allocated distributions. Verify model outputs or loss history under deterministic settings; timing without semantic parity is invalid. If flushing appears faster, repeat randomized trial order and inspect whether thermal state or prior cache history biased the baseline.

Compare peak allocated before and after the flush rather than taking only an end-of-step sample. A flush can make the idle state smaller while the training peak remains identical.

Include optimizer initialization in warm-up because AdamW state is created lazily; otherwise the first measured step mixes state growth with allocator-policy cost.

Part 7 - Engineering Interpretation and Philosophy

Optimization targets the workload's critical path, not a visually pleasing counter. Lower reserved memory at idle is not an improvement when the same live peak returns every step and throughput falls.

19.4.13 Exercise 12

Exercise Title: Reproduce a Workload Where Changing Tensor Shapes Causes the Caching Allocator to Continuously Acquire New Memory Blocks

Part 1 - Exercise Contract and Why It Matters

Create a bounded variable-shape workload that exhibits repeated reservation growth. The experiment connects data-shape variability to allocator behavior without relying on a model memory leak.

Part 2 - System and Memory Mental Model

Changing shapes changes requested byte sizes and temporary-operation shapes. Previously cached blocks may be too small, badly partitioned, or otherwise unsuitable. Live memory can return to baseline after every iteration while reserved memory acquires new high-water levels.

Part 3 - Quantitative Prediction Before Execution

Generate a deterministic sequence of increasing and alternating dimensions. Compute payload for input, matrix output, and activation. Predict which iterations create a new live peak and which might grow reserved despite a lower live peak. Set a safe cap from driver-free capacity.

Part 4 - Experimental Design and Instrumentation

Use one fixed weight matrix and variable batch/sequence dimensions so the model is constant. Delete outputs and synchronize before each end-state sample. Run a fixed-shape control with the same number of operations. Stop at 35 percent of initial free memory.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def E12():
    device = torch.device("cuda:0")
    feature = 1024
    weight = torch.randn((feature, feature), device=device)
    free_bytes, _ = torch.cuda.mem_get_info(device)
    budget = int(free_bytes * 0.35)
    shapes = []
    for index in range(1, 41):
        batch = 8 + (index % 7) * 5
        length = 64 + index * 13
```

```
        shapes.append((batch, length, feature))

    trace = []
    for batch, length, width in shapes:
        estimated = batch * length * width * 4 * 3
        if estimated > budget:
            break
        inputs = torch.randn((batch, length, width), device=device)
        output = torch.matmul(inputs, weight)
        activated = torch.relu(output)
        torch.cuda.synchronize(device)
        peak_live = torch.cuda.memory_allocated(device)
        del inputs
        del output
        del activated
        gc.collect()
        torch.cuda.synchronize(device)
        trace.append({
            "shape": (batch, length, width),
            "peak_live": peak_live,
            "allocated_end": torch.cuda.memory_allocated(device),
            "reserved_end": torch.cuda.memory_reserved(device),
        })
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot reserved growth against requested payload and mark iterations that raised the previous live peak. Continuous acquisition is supported only if reserved has multiple positive jumps while end allocated remains stable. If autograd is enabled accidentally, graph retention changes the experiment; use no-grad or inputs without gradients as shown.

Decompose each reserved jump into two hypotheses: a genuinely larger live working set or inability to fit the new shape into existing cached blocks. A jump without a new allocated peak supports the second hypothesis. If both peaks rise together, additional reservation may simply be required by the larger workload and should not be labeled fragmentation.

Part 7 - Engineering Interpretation and Philosophy

Variable shapes are a systems property of the data pipeline, not merely tensor metadata. Bucketing and padding trade extra arithmetic for a more predictable allocation working set. The right choice requires joint measurement of memory, throughput, and task quality.

19.4.14 Exercise 13

Exercise Title: Compare Fixed-Shape and Variable-Shape Training Workloads and Quantify Their Impact on Reserved CUDA Memory

Part 1 - Exercise Contract and Why It Matters

Transform E12 into a fair training comparison. Quantify whether shape variability increases reservation growth, peak memory, or latency when model, sample count, optimizer, and numerical objective are controlled.

Part 2 - System and Memory Mental Model

Fixed shapes tend to repeat the same activation and workspace requirements. Variable shapes produce a distribution of requests. Padding to a bucket may increase per-step live payload but improve cache reuse and batching efficiency. Thus lower arithmetic volume does not guarantee lower reserved memory.

Part 3 - Quantitative Prediction Before Execution

Define fixed and variable schedules with the same total tokens. Predict total payload traffic, expected maximum live payload, reserved growth events, and tokens per second. Predeclare metrics: final reserved, maximum reserved, reserved slope after warm-up, and peak allocated.

Part 4 - Experimental Design and Instrumentation

Run schedules in separate fresh processes from identical model weights and seeds. Use the same optimizer and number of tokens, not merely the same number of steps. Synchronize for timing and store scalar loss only after detaching it to CPU. Do not call cache release during either policy.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def run_schedule(schedule):
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(512, 1024),
        torch.nn.GELU(),
        torch.nn.Linear(1024, 512),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.0003)
    rows = []
    for step, shape in enumerate(schedule):
        batch, length = shape
        inputs = torch.randn((batch, length, 512), device=device)
        targets = torch.randn((batch, length, 512), device=device)
        torch.cuda.reset_peak_memory_stats(device)
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        optimizer.zero_grad(set_to_none=True)
        predictions = model(inputs)
        loss = torch.nn.functional.mse_loss(predictions, targets)
        loss.backward()
        optimizer.step()
        torch.cuda.synchronize(device)
        rows.append({
            "step": step,
            "tokens": batch * length,
            "seconds": time.perf_counter() - start,
```

```
            "peak_allocated": torch.cuda.max_memory_allocated(device),
            "reserved": torch.cuda.memory_reserved(device),
            "loss": float(loss.detach().cpu()),
        })
        del inputs, targets, predictions, loss
    return rows

def E13():
    # Both schedules contain exactly 220,160 tokens.
    fixed = [(16, 344)] * 40
    variable = [(8, 128), (32, 384), (16, 256), (24, 192)] * 10
    return run_schedule(fixed), run_schedule(variable)
```

Part 6 - Measurement, Validation, and Failure Analysis

Normalize throughput by tokens and verify the equal schedule token totals. Compare reserved slopes after warm-up with confidence intervals across process repetitions. If variable shapes win, explain whether smaller average work outweighed allocator churn rather than rejecting the measurement.

Check numerical comparability by evaluating both trained models on one fixed validation batch. Equal token count does not guarantee identical gradient statistics because batching and shape composition differ. Report quality beside systems metrics, and state whether padding changes the loss mask. Training on padding tokens is not a valid memory optimization.

Part 7 - Engineering Interpretation and Philosophy

Shape policy is an end-to-end design choice. Fixed buckets can waste padded compute but stabilize memory; exact shapes can save compute but diversify allocations. Engineering requires measuring both sides under equal useful work.

19.4.15 Exercise 14

Exercise Title: Build a PyTorch Allocation Trace That Records Tensor Size, Lifetime, Allocated Memory, and Reserved Memory for Every Step

Part 1 - Exercise Contract and Why It Matters

Build an explicit semantic trace connecting tensor birth and death to global allocator counters. This trace is intentionally application-level: it teaches you to account for lifetimes before moving to lower-level allocator snapshots.

Part 2 - System and Memory Mental Model

Each trace event has an operation, logical tensor identifier, payload, lifetime state, allocated, and reserved. Payload is computed from shape, element size, and count. The trace must store metadata only; storing the tensor inside the trace would extend its lifetime and invalidate the measurement.

Part 3 - Quantitative Prediction Before Execution

Draw a Gantt-style lifetime plan for three overlapping tensors. Calculate live payload after each create/delete event and predict where allocated peaks. Add a view event and predict zero

new payload. Define a residual $E = A - A_{baseline} - L_{payload}$ to expose allocator rounding or untracked live storage.

Part 4 - Experimental Design and Instrumentation

Centralize creation and deletion in named functions. Synchronize before global counter capture and add a monotonically increasing event index. Record dtype, shape, payload, and alive identifiers as immutable CPU metadata. Validate the trace on a small deterministic sequence before using it with models.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

class AllocationTrace:
    def __init__(self, device):
        self.device = device
        self.objects = {}
        self.rows = []

    def record(self, action, name, payload=0):
        torch.cuda.synchronize(self.device)
        self.rows.append({
            "event": len(self.rows),
            "action": action,
            "name": name,
            "payload": payload,
            "alive": tuple(sorted(self.objects.keys())),
            "allocated": torch.cuda.memory_allocated(self.device),
            "reserved": torch.cuda.memory_reserved(self.device),
        })

    def create(self, name, shape):
        value = torch.empty(shape, device=self.device)
        self.objects[name] = value
        payload = value.numel() * value.element_size()
        self.record("create", name, payload)

    def view(self, source, name):
        self.objects[name] = self.objects[source].view(-1)
        self.record("view", name, 0)

    def delete(self, name):
        del self.objects[name]
        gc.collect()
        self.record("delete", name, 0)

def E14():
    trace = AllocationTrace(torch.device("cuda:0"))
```

```
    trace.record("baseline", "none")
    trace.create("a", (32, 1024, 1024))
    trace.create("b", (16, 1024, 1024))
    trace.view("a", "a_view")
    trace.delete("a")
    trace.create("c", (24, 1024, 1024))
    trace.delete("a_view")
    trace.delete("b")
    trace.delete("c")
    return trace.rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Recompute live payload from the event log and compare it to allocated deltas. Assert event order, unique names, and valid deletion. Confirm the view keeps base storage alive after the base name is deleted. If trace collection changes lifetime, inspect metadata for tensor objects or closures capturing them.

Add automatic consistency checks: every create introduces a unique identifier, every delete targets a live identifier, payload is nonnegative, and allocated never exceeds reserved. Serialize only CPU-native types. Then reconstruct the lifetime diagram from the saved trace to prove the record is self-contained and does not rely on hidden tensor objects.

Part 7 - Engineering Interpretation and Philosophy

Instrumentation is part of the experiment and can create the bug it observes. A trustworthy trace records identities and numbers without retaining storage. It connects semantic objects to allocator state while preserving the workload's true lifetime graph.

19.4.16 Exercise 15

Exercise Title: Detect a False Memory-Leak Diagnosis Caused by Misinterpreting Cached Reserved Memory as Live Tensor Memory

Part 1 - Exercise Contract and Why It Matters

Diagnose a deliberately misleading trace in which reserved memory stays high after tensors are deleted. Decide whether it is a live-reference leak, a stable cache, or an allocator-pattern problem. A wrong diagnosis can lead to harmful cache flushing or unnecessary model redesign.

Part 2 - System and Memory Mental Model

A leak requires loss of control over memory that remains live or grows without intended bounds. Stable reserved memory with allocated returning to baseline is not sufficient evidence. Use three signatures: live leak means end allocated trends upward; stable cache means allocated returns and reserved plateaus; poor-fit caching means allocated returns while reserved continues to acquire capacity under changing requests.

Part 3 - Quantitative Prediction Before Execution

Predict traces for a correct loop, a loop appending CUDA losses to a Python list, and a variable-shape loop. Specify diagnostic thresholds: allocated slope, reserved slope after warm-up, and number of live Python tensor references. Avoid classifying from a single endpoint.

Part 4 - Experimental Design and Instrumentation

Run each scenario in a fresh process for equal iterations. Detach scalars to CPU in the correct version. Synchronize at end-of-iteration measurement and fit slopes only after warm-up. Use `empty_cache()` once as a diagnostic probe after all live references are controlled, not as the primary test.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def run_case(retain_losses, variable_shapes, steps=80):
    device = torch.device("cuda:0")
    retained = []
    rows = []
    for step in range(steps):
        width = 1024
        batch = 64
        if variable_shapes:
            batch = 32 + (step % 11) * 7
        value = torch.randn(
            (batch, width, width // 8),
            device=device,
            requires_grad=True,
        )
        loss = value.square().mean()
        if retain_losses:
            retained.append(loss)
        else:
            retained.append(float(loss.detach().cpu()))
            if len(retained) > 4:
                retained.pop(0)
        del value
        del loss
        gc.collect()
        torch.cuda.synchronize(device)
        rows.append({
            "step": step,
            "allocated": torch.cuda.memory_allocated(device),
            "reserved": torch.cuda.memory_reserved(device),
        })
    return rows

def E15():
    stable = run_case(False, False)
    true_leak = run_case(True, False)
    variable_cache = run_case(False, True)
    return stable, true_leak, variable_cache
```

Part 6 - Measurement, Validation, and Failure Analysis

Label traces without seeing scenario names, then reveal them. The retained-loss case should increase allocated because each scalar retains its autograd graph; the stable case should plateau. Confirm that the input requires gradients and that the retained losses have a non-null gradient function, so the intended true-leak control actually retains a graph. This validation is essential: an unverified synthetic bug proves nothing.

Use a robust slope estimate and inspect the raw curve because allocator growth is stepwise rather than perfectly linear. After classification, fix only the true-leak case by storing detached CPU scalars, then rerun from a fresh process. A diagnosis is complete only when the predicted signature disappears without changing the intended numerical computation.

Part 7 - Engineering Interpretation and Philosophy

Leak diagnosis is classification under uncertainty. The cure depends on the class: remove references for a live leak, stabilize shapes for poor cache fit, or do nothing when a healthy cache is serving the workload efficiently.

19.4.17 Exercise 16

Exercise Title: Stress-Test the Caching Allocator with Thousands of Mixed-Size CUDA Allocations and Identify When Memory Reuse Efficiency Degrades

Part 1 - Exercise Contract and Why It Matters

Stress the allocator with thousands of bounded mixed-size requests while preserving experimental safety. Identify the workload region where reserved growth or latency indicates degrading reuse efficiency.

Part 2 - System and Memory Mental Model

Allocator stress depends on both size distribution and lifetime overlap. Total requested traffic can be enormous while peak live memory stays moderate. Efficiency degradation appears when new reservations grow relative to repeated traffic, inactive fragmentation proxies rise, or allocation latency develops a tail.

Part 3 - Quantitative Prediction Before Execution

Choose a reproducible size distribution from 1 to 64 MiB and random lifetimes of 1 to 20 events. Estimate maximum simultaneous payload by simulating the schedule on CPU first. Reject schedules exceeding 35 percent of initial free VRAM. Define a reuse proxy:

$$\eta = 1 - \frac{\max(0, R_{end} - R_{start})}{\sum_k P_k},$$

and state that it measures reservation-growth efficiency, not exact block reuse.

Part 4 - Experimental Design and Instrumentation

Pre-generate the complete event schedule with a fixed CPU seed. Keep a bounded dictionary of live tensors and delete them at scheduled expiry. Sample every 25 events to reduce synchronization distortion. Run in a disposable subprocess so an OOM cannot contaminate later chapter experiments.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import random
import time
import torch

def E16(events=3000, seed=41):
    device = torch.device("cuda:0")
    generator = random.Random(seed)
    schedule = []
    for event in range(events):
        size_mib = generator.randint(1, 64)
        lifetime = generator.randint(1, 20)
        schedule.append((event, size_mib, lifetime))

    live = {}
    trace = []
    free_bytes, _ = torch.cuda.mem_get_info(device)
    budget = int(free_bytes * 0.35)
    for event, size_mib, lifetime in schedule:
        expired = []
        for name, item in live.items():
            _, death = item
            if death <= event:
                expired.append(name)
        for name in expired:
            del live[name]
        gc.collect()

        requested = size_mib * 1024 * 1024
        current_live = torch.cuda.memory_allocated(device)
        if current_live + requested > budget:
            continue
        count = requested // 4
        start = time.perf_counter_ns()
        tensor = torch.empty(count, device=device)
        live[str(event)] = (tensor, event + lifetime)
        if event % 25 == 0:
            torch.cuda.synchronize(device)
            trace.append({
                "event": event,
                "latency_us": (time.perf_counter_ns() - start) / 1000,
                "allocated": torch.cuda.memory_allocated(device),
                "reserved": torch.cuda.memory_reserved(device),
                "live_count": len(live),
            })
    return trace
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate the CPU schedule's predicted peak against observed allocated memory. Plot reserved, allocated, cached proxy, and latency quantiles over event index. The sparse timing skeleton measures synchronization at samples, so a rigorous latency benchmark should isolate every timed allocation; disclose this tradeoff. Never interpret skipped budget events as successful allocations.

Run three controlled distributions: narrow repeated sizes, uniform mixed sizes, and a heavy tail with occasional large requests. Hold event count and expected traffic approximately constant. Report skipped events and achieved traffic, because the safety controller changes the executed distribution. Separate allocator degradation from workload admission effects.

Part 7 - Engineering Interpretation and Philosophy

Stress tests should reveal boundaries, not recklessly cross them. A useful result identifies which distribution and lifetime properties degrade reuse and turns them into production controls such as bucketing or admission limits.

19.4.18 Exercise 17

Exercise Title: Benchmark Memory Reuse Efficiency, Allocation Latency, and Peak VRAM Across Stable, Bursty, and Highly Variable Workloads

Part 1 - Exercise Contract and Why It Matters

Build a controlled benchmark comparing three workload families. The deliverable must distinguish memory footprint, allocation latency, and useful throughput; no single score can describe allocator quality.

Part 2 - System and Memory Mental Model

Stable workloads repeat sizes and concurrency. Bursty workloads periodically raise their live high-water mark. Highly variable workloads diversify size and lifetime. These axes affect peak allocated, peak reserved, reservation growth, cache proxy, and latency differently.

Part 3 - Quantitative Prediction Before Execution

Equalize total requested bytes and event count across families. Predict stable to plateau earliest, bursty to reserve for its largest burst, and variable to show the most growth or fragmentation. Define throughput as processed requested MiB per second and report it beside latency percentiles.

Part 4 - Experimental Design and Instrumentation

Generate schedules before GPU execution, validate their equality, and run each in a fresh subprocess. Use multiple seeds for variable workloads. Randomize family order, warm CUDA equally, reset peaks, and collect environment metadata.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import statistics
import time
import torch

def execute_schedule(name, sizes_mib):
```

```
    device = torch.device("cuda:0")
    timings = []
    torch.cuda.reset_peak_memory_stats(device)
    reserved_start = torch.cuda.memory_reserved(device)
    for size_mib in sizes_mib:
        count = size_mib * 1024 * 1024 // 4
        torch.cuda.synchronize(device)
        start = time.perf_counter_ns()
        value = torch.empty(count, device=device)
        torch.cuda.synchronize(device)
        timings.append((time.perf_counter_ns() - start) / 1000)
        del value
        gc.collect()
    return {
        "name": name,
        "events": len(sizes_mib),
        "traffic_mib": sum(sizes_mib),
        "median_us": statistics.median(timings),
        "max_us": max(timings),
        "peak_allocated": torch.cuda.max_memory_allocated(device),
        "peak_reserved": torch.cuda.max_memory_reserved(device),
        "reserved_growth": (
            torch.cuda.memory_reserved(device) - reserved_start
        ),
    }

def E17():
    # Every family has 400 events and 19,200 MiB of request traffic.
    stable = [48] * 400
    bursty = ([16] * 8 + [176, 176]) * 40
    variable = [7, 91, 23, 115, 41, 67, 11, 29] * 50
    return (
        execute_schedule("stable", stable),
        execute_schedule("bursty", bursty),
        execute_schedule("variable", variable),
    )
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that the schedules have identical traffic and event counts before every run. Report medians, p95/p99, peaks, and growth across repeated subprocesses. A workload can win latency while losing peak VRAM; preserve this tradeoff rather than collapsing it into an arbitrary average score.

Add confidence intervals across fresh-process repetitions and publish the schedule generator. Peak metrics require reset and synchronization at identical boundaries. Include p50, p95, p99, and worst latency because bursty driver acquisitions may disappear in the median. State which percentile and memory ceiling the final decision optimizes.

Part 7 - Engineering Interpretation and Philosophy

Benchmarks are models of deployment. A representative distribution and lifetime pattern matter more than a perfect microbenchmark. State which production question each workload family represents and what it omits.

19.4.19 Exercise 18

Exercise Title: Build a Reusable Allocator Experiment Harness That Visualizes Live Memory, Cached Memory, Reuse Rate, and Allocation Growth

Part 1 - Exercise Contract and Why It Matters

Package the chapter's instrumentation into a reusable harness. It must execute a workload, collect scalar memory events, calculate explicitly named proxy metrics, validate invariants, and produce plots without retaining CUDA tensors.

Part 2 - System and Memory Mental Model

Live memory is measured by allocated bytes. Cached proxy is $R - A$. Allocation growth is the positive change in reserved bytes. Exact reuse is not observable from these globals, so define "reuse rate" as a proxy based on requested traffic not accompanied by reservation growth. Label it clearly to prevent a visualization from overstating evidence.

Part 3 - Quantitative Prediction Before Execution

Specify harness inputs, outputs, and invariants before implementation. Inputs include device, schedule, safety fraction, synchronization policy, and seed. Outputs include event rows, environment metadata, summary statistics, and four plots. Predict results for fixed and variable schedules to unit-test the harness.

Part 4 - Experimental Design and Instrumentation

Separate schedule generation, execution, metric calculation, and rendering. The executor returns only CPU dictionaries. Write plot functions that consume saved rows so visualization never reruns GPU work. Include baselines and use MiB consistently.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

class AllocatorHarness:
    def __init__(self, device, safety_fraction=0.35):
        self.device = torch.device(device)
        free_bytes, _ = torch.cuda.mem_get_info(self.device)
        self.budget = int(free_bytes * safety_fraction)

    def run(self, sizes_mib):
        rows = []
        previous_reserved = torch.cuda.memory_reserved(self.device)
        total_requested = 0
        total_growth = 0
        for event, size_mib in enumerate(sizes_mib):
            request = size_mib * 1024 * 1024
```

```
            if request > self.budget:
                raise ValueError("Request exceeds the safety budget.")
            value = torch.empty(request // 4, device=self.device)
            torch.cuda.synchronize(self.device)
            allocated = torch.cuda.memory_allocated(self.device)
            reserved = torch.cuda.memory_reserved(self.device)
            growth = max(0, reserved - previous_reserved)
            total_requested += request
            total_growth += growth
            rows.append({
                "event": event,
                "request": request,
                "allocated": allocated,
                "reserved": reserved,
                "cached_proxy": reserved - allocated,
                "reserved_growth": growth,
                "reuse_proxy": 1.0 - total_growth / total_requested,
            })
            previous_reserved = reserved
            del value
            gc.collect()
        return rows

def E18():
    harness = AllocatorHarness("cuda:0")
    fixed_rows = harness.run([32, 64, 32, 64] * 25)
    return fixed_rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert nonnegative allocated, reserved, cached proxy, and growth, plus $A \leq R$. Explain that the reuse proxy can become misleading when baseline cache already contains blocks or when released blocks serve future requests; report baseline and treat the metric comparatively. Test empty, one-event, oversized, and repeated schedules.

Place allocated and reserved on one axis, cached proxy on a derived panel, positive reservation growth as event bars, and reuse proxy with its definition in the legend. Include request size and event index in the supporting table. Never smooth stepwise counters into an apparently continuous physical process without labeling the smoothing as cosmetic.

Part 7 - Engineering Interpretation and Philosophy

Reusable tooling is valuable only when its names preserve epistemic limits. Calling a proxy "exact reuse" would convert a convenient formula into false certainty. Good harnesses automate evidence collection while keeping the meaning of every metric auditable.

19.4.20 Exercise 19

Exercise Title: Build and Defend a Memory Allocation Policy for a Variable-Shape PyTorch Workload Using Measured Caching Allocator Behavior

Part 1 - Exercise Contract and Why It Matters

Synthesize the chapter into a defendable allocation policy for a variable- shape service or training pipeline. The policy must connect measured evidence to operational rules, failure handling, and performance objectives.

Part 2 - System and Memory Mental Model

A policy controls shape bucketing, maximum request size, concurrency, cache release boundaries, admission, and observability. It cannot change required live tensor bytes, but it can shape request distribution and lifetime overlap. Reserved headroom must coexist with CUDA context, libraries, and other processes; using every reported free byte is unsafe.

Part 3 - Quantitative Prediction Before Execution

Define a service-level budget: maximum allocated peak, reserved ceiling, minimum throughput, p95 latency, and OOM-free safety margin. Compare at least three candidate policies: exact shapes, coarse buckets, and fixed maximum padding. Predict compute waste, cache reuse, and latency for each before benchmarking.

Part 4 - Experimental Design and Instrumentation

Replay the same recorded shape distribution through every policy in fresh processes. Include normal, burst, and worst-allowed traffic. Measure requested payload, padded payload, allocated/reserved peaks, reservation growth, latency, and throughput. Reserve a holdout trace so the policy is not optimized only for the development distribution.

Part 5 - PyTorch/CUDA Implementation

```
import bisect

class AllocationPolicy:
    def __init__(self, buckets, maximum_tokens, safety_margin_mib):
        self.buckets = sorted(buckets)
        self.maximum_tokens = maximum_tokens
        self.safety_margin_mib = safety_margin_mib

    def choose_bucket(self, tokens):
        if tokens <= 0:
            raise ValueError("tokens must be positive")
        if tokens > self.maximum_tokens:
            return {"decision": "reject", "reason": "token_limit"}
        index = bisect.bisect_left(self.buckets, tokens)
        if index == len(self.buckets):
            return {"decision": "reject", "reason": "no_bucket"}
        return {
            "decision": "admit",
            "requested_tokens": tokens,
            "bucket_tokens": self.buckets[index],
            "padding_tokens": self.buckets[index] - tokens,
        }
```

```
def E19(shape_trace):
    policy = AllocationPolicy(
        buckets=[128, 256, 512, 1024, 2048],
        maximum_tokens=2048,
        safety_margin_mib=768,
    )
    decisions = []
    for tokens in shape_trace:
        decisions.append(policy.choose_bucket(tokens))
    # Feed admitted bucket sizes into the E18 harness, then attach
    # measured memory and latency evidence to every policy decision.
    return decisions
```

Part 6 - Measurement, Validation, and Failure Analysis

Defend every threshold with a measured curve and safety margin. Validate policy behavior at bucket edges, impossible requests, bursts, and distribution shift. Specify automatic responses: reduce concurrency, split work, reject safely, or move to a larger resource class. Cache flushing should appear only at measured phase boundaries where its cost is justified. Include rollback criteria if the new policy worsens latency or correctness.

Require a decision table containing observed condition, measured evidence, selected action, expected benefit, possible harm, and rollback signal. Test on the holdout distribution and inject oversized and burst requests deliberately. A policy that works on average but has no controlled tail response is not ready for production.

Part 7 - Engineering Interpretation and Philosophy

The final policy is not "make reserved memory small." It is a contract that balances useful work, predictable capacity, latency, and failure containment. Evidence from one GPU and software version establishes a baseline, not a universal law; the policy must be revalidated after upgrades, model changes, or traffic shifts. The deepest lesson of allocator engineering is to control distributions and lifetimes while preserving semantic correctness, then let measurements decide which tradeoffs are acceptable.

19.5 DMM03

Chapter Title: PyTorch CUDA Memory Statistics
Specialization: Dynamic Memory Management and CUDA Systems

19.5.1 Exercise 00

Exercise Title: Build a Precise Mental Model of What torch.cuda.memory_stats() Reveals About the CUDA Caching Allocator

Part 1 - Exercise Contract and Why It Matters

This exercise turns `torch.cuda.memory_stats()` from a large dictionary of intimidating names into a structured account of allocator history and state. The API exposes counters for allocation requests, allocator-managed segments, active blocks, inactive split blocks, byte totals, retries, and OOM events. It is more detailed than `memory_allocated()` and

`memory_reserved()`, but it remains an allocator summary rather than a complete map of every physical GPU byte.

Your deliverable is a counter taxonomy and a synchronized event timeline. For every selected key, identify three dimensions: the resource being counted, the pool scope, and the statistic form. Explain whether the value describes a current state, a historical peak, cumulative acquisition, or cumulative release. Never compare counters with different units as though they were the same quantity.

Part 2 - System and Memory Mental Model

Many keys follow a conceptual pattern `metric.pool.statistic`. A metric may count events or bytes; the pool may be `all`, `small_pool`, or `large_pool`; and the statistic may be `current`, `peak`, `allocated`, or `freed`. In simplified form,

$$X_{current} = X_{allocated} - X_{freed},$$

when the selected counter family obeys cumulative acquisition/release accounting. Verify this identity empirically rather than imposing it on every unfamiliar key. An allocation count describes allocator events, while allocated bytes describe capacity. One 256 MiB allocation and 256 one-MiB allocations can therefore have similar bytes but radically different event counts.

Segments are larger regions obtained by the allocator from CUDA. Blocks live inside segments. Active bytes generally correspond to blocks not currently available for reuse, allocated bytes track tensor storage recognized as live, and inactive split bytes expose capacity stranded in split blocks. Exact relationships are backend and version dependent. The native and asynchronous allocator backends may expose different meaningful fields, so absence of a key must remain `None`, not be rewritten as zero.

Part 3 - Quantitative Prediction Before Execution

Before running, predict counter directions for: warm CUDA; allocate a 64 MiB tensor; create a view; clone the view; delete the original while the view survives; delete the last alias; then delete the clone. Predict which events change allocation counts, byte counts, active state, and reserved segments. Create a units column containing “events”, “bytes”, or “occurrences”. Also predict which cumulative counters never decrease during a process.

Part 4 - Experimental Design and Instrumentation

Use one fresh process, one explicit CUDA device, fixed shapes, and synchronized measurement boundaries. Capture the full dictionary once for discovery, then log a deliberately small selected subset during the experiment. Record PyTorch version, device name, and allocator configuration. Avoid resetting statistics until the timeline is finished because resets change historical peaks and would destroy the story being analyzed.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

SELECTED_KEYS = [
    "allocation.all.current",
```

```
    "allocation.all.peak",
    "allocated_bytes.all.current",
    "allocated_bytes.all.peak",
    "reserved_bytes.all.current",
    "reserved_bytes.all.peak",
    "active_bytes.all.current",
    "inactive_split_bytes.all.current",
    "segment.all.current",
    "num_alloc_retries",
    "num_ooms",
]

def stats_row(label, device):
    torch.cuda.synchronize(device)
    raw = torch.cuda.memory_stats(device)
    row = {"label": label}
    for key in SELECTED_KEYS:
        row[key] = raw.get(key, None)
    return row

def E00():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM03.")
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    rows = [stats_row("baseline", device)]

    x = torch.empty((16, 1024, 1024), device=device)
    rows.append(stats_row("allocate_x", device))
    view = x.view(-1)
    rows.append(stats_row("create_view", device))
    clone = view.clone()
    rows.append(stats_row("clone_view", device))
    del x
    gc.collect()
    rows.append(stats_row("delete_x_keep_view", device))
    del view
    gc.collect()
    rows.append(stats_row("delete_last_alias", device))
    del clone
    gc.collect()
    rows.append(stats_row("delete_clone", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that a view does not request independent storage and that deleting a base name does not release storage while an alias survives. Compare `allocated_bytes.all.current` with `memory_allocated()` and reserved bytes with `memory_reserved()` at the same synchronized

boundary. Small differences require investigation; comparisons captured at different times are invalid.

For every missing key, report backend/version incompatibility explicitly. If a cumulative counter decreases unexpectedly, verify that a reset API was not called. If allocated bytes remain high after all intended references are deleted, inspect autograd graphs, containers, notebook output, and exception tracebacks before claiming allocator failure.

Part 7 - Engineering Interpretation and Philosophy

The dictionary is a language for hypotheses, not a diagnosis generator. A reliable interpretation moves from semantic lifetime, to allocator state, to counter evidence. It never labels reserved bytes a leak, inactive split bytes proof of fragmentation by themselves, or retries proof of failure without a controlled workload history. The purpose of detailed statistics is to make a causal argument more defensible, not merely more numerical.

19.5.2 Exercise 01

Exercise Title: Print the Complete memory_stats() Dictionary and Classify Counters into Allocation, Segment, Active, Inactive, and Retry Categories

Part 1 - Exercise Contract and Why It Matters

Discover the actual dictionary supplied by your installed PyTorch rather than copying a static list from another version. Classify every key by category, pool, statistic form, and unit, preserving unknown keys for later research.

Part 2 - System and Memory Mental Model

Key names encode a hierarchy, but not every counter uses every component. Allocation and segment counters may describe events; byte families describe capacity; retry and OOM counters are scalar occurrences. A robust classifier must tolerate keys with one, two, or three dotted fields and must never discard an unfamiliar field merely because it violates the expected template.

Part 3 - Quantitative Prediction Before Execution

Predict the major categories and count how many keys you expect in each. Define classification rules in writing first. Mark units from the metric name rather than numeric magnitude, because a value of 4096 could mean events or bytes.

Part 4 - Experimental Design and Instrumentation

Initialize CUDA, capture one full dictionary, sort keys for deterministic output, and write a CPU-native table. Run again after a meaningful allocation to distinguish keys that exist but remain zero from keys that do not exist.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def classify_key(key):
    prefix = key.split(".")[0]
    if prefix.startswith("allocation") or prefix.startswith("allocated"):
```

```
        category = "allocation"
    elif prefix.startswith("segment") or prefix.startswith("reserved"):
        category = "segment_or_reserved"
    elif prefix.startswith("active"):
        category = "active"
    elif prefix.startswith("inactive"):
        category = "inactive"
    elif "retry" in key or "oom" in key:
        category = "retry_or_oom"
    else:
        category = "unclassified"
    unit = "bytes" if "bytes" in prefix else "events_or_occurrences"
    return category, unit

def E01():
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    raw = torch.cuda.memory_stats(device)
    rows = []
    for key in sorted(raw.keys()):
        category, unit = classify_key(key)
        rows.append({
            "key": key,
            "value": int(raw[key]),
            "category": category,
            "unit": unit,
        })
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Manually audit every unclassified key and refine rules without hiding it. Verify that sorting produces identical order across runs. Save PyTorch version beside the table. The classifier's unit inference is intentionally conservative; review documentation for ambiguous metrics before using them in arithmetic.

Part 7 - Engineering Interpretation and Philosophy

Schema discovery is part of systems engineering. Code that assumes a permanent dictionary silently breaks when backends evolve. A trustworthy tool preserves unknown evidence and makes its classification logic inspectable.

19.5.3 Exercise 02

Exercise Title: Extract Current, Peak, Allocated, and Freed Byte Counters from memory_stats() and Verify Them with Controlled Tensor Allocations

Part 1 - Exercise Contract and Why It Matters

Learn the difference between current state, historical peak, cumulative bytes allocated, and cumulative bytes freed. These four forms answer different questions and must not be substituted for one another.

Part 2 - System and Memory Mental Model

Current bytes describe the measurement boundary. Peak is the maximum since initialization or the last relevant reset. Allocated and freed forms are cumulative traffic. A workload can allocate and free one GiB one hundred times, producing enormous cumulative traffic while current and peak remain bounded.

Part 3 - Quantitative Prediction Before Execution

Predict counters across three 64 MiB allocate/delete cycles. Current should oscillate, peak should rise once and remain, and cumulative acquisition/release should advance every cycle. Test the approximate identity current equals cumulative allocated minus cumulative freed for the same family.

Part 4 - Experimental Design and Instrumentation

Warm CUDA, reset peak statistics once, and record after every allocation and deletion. Use deltas from baseline because context initialization precedes the experiment. Synchronize each boundary and avoid `empty_cache()`.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

KEYS = [
    "allocated_bytes.all.current",
    "allocated_bytes.all.peak",
    "allocated_bytes.all.allocated",
    "allocated_bytes.all.freed",
]

def read_bytes(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    row = {"label": label}
    for key in KEYS:
        row[key] = stats.get(key, None)
    return row

def E02():
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    torch.cuda.reset_peak_memory_stats(device)
    rows = [read_bytes("baseline", device)]
    count = 64 * 1024 * 1024 // 4
    for cycle in range(3):
        value = torch.empty(count, device=device)
        rows.append(read_bytes("allocate_" + str(cycle), device))
        del value
        gc.collect()
```

```
        rows.append(read_bytes("delete_" + str(cycle), device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Subtract baseline cumulative values before comparing traffic. Check the identity only when all four keys exist and document allocator rounding. Peak must never fall during the timeline. If it does, search for an unintended reset or process boundary rather than assuming a physical memory release changed history.

Part 7 - Engineering Interpretation and Philosophy

Residency and traffic are different performance dimensions. Current and peak budget capacity; cumulative counters expose churn. Optimization can reduce one without reducing the other, so reports should retain both.

19.5.4 Exercise 03

Exercise Title: Track allocation.all.current Across Repeated Tensor Creation and Deletion and Explain Every Counter Transition

Part 1 - Exercise Contract and Why It Matters

Interpret allocation count rather than byte capacity. Track how many allocator allocations are current while tensors, views, clones, and sliced copies appear and disappear.

Part 2 - System and Memory Mental Model

One tensor does not always imply one allocation, and one allocation can back multiple views. Operations may create temporary storage, and allocator rounding is independent of logical tensor count. The counter is evidence about allocator events, not a Python object census.

Part 3 - Quantitative Prediction Before Execution

Predict transitions for a base tensor, two views, one clone, and one advanced- indexed copy. Views should share storage; clone and indexed copy should allocate. Predict what happens when names are deleted in different orders.

Part 4 - Experimental Design and Instrumentation

Use a small tensor but synchronize boundaries. Record current allocation count, allocated bytes, and a manually maintained logical-object count. The mismatch between these columns is the phenomenon to explain, not an error to erase.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def row(label, device, logical_objects):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    return {
```

```
        "label": label,
        "logical_objects": logical_objects,
        "allocation_current": stats.get("allocation.all.current"),
        "allocated_bytes": stats.get("allocated_bytes.all.current"),
    }

def E03():
    device = torch.device("cuda:0")
    rows = []
    base = torch.arange(1024 * 1024, device=device)
    rows.append(row("base", device, 1))
    first_view = base.view(1024, 1024)
    second_view = base[100:200]
    rows.append(row("two_views", device, 3))
    clone = first_view.clone()
    rows.append(row("clone", device, 4))
    indices = torch.tensor([1, 3, 5, 7], device=device)
    indexed = base[indices]
    rows.append(row("indexed_copy", device, 6))
    del base, first_view, second_view, clone, indices, indexed
    gc.collect()
    rows.append(row("delete_all", device, 0))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Explain every delta using storage creation and aliasing. The index tensor is itself a CUDA allocation and must be counted. If temporary allocations vanish before synchronization, the current counter may miss them; use cumulative and peak forms to reveal transient traffic. Repeat deletion one object at a time to locate the final alias holding storage.

Part 7 - Engineering Interpretation and Philosophy

Logical objects, storage objects, and allocator blocks occupy different layers. Correct memory reasoning keeps these layers distinct instead of expecting a one-to-one mapping that PyTorch never promised.

19.5.5 Exercise 04

Exercise Title: Compare allocated_bytes, reserved_bytes, and active_bytes and Prove Why They Represent Different Memory States

Part 1 - Exercise Contract and Why It Matters

Build a controlled proof that allocated, reserved, and active bytes are related but not interchangeable. The experiment must connect each counter to storage lifetime and allocator ownership.

Part 2 - System and Memory Mental Model

Allocated bytes approximate live tensor storage. Reserved bytes represent segments controlled by the allocator. Active bytes represent blocks not currently available for ordinary reuse

and can differ from allocated bytes due to allocator state. A useful expectation is allocated no greater than active, and active no greater than reserved, but verify backend-specific behavior before turning this expectation into a hard universal assertion.

Part 3 - Quantitative Prediction Before Execution

Allocate two unequal tensors, delete one, reallocate a compatible tensor, then delete all. Predict which counter follows live payload, which remains near its high-water mark, and which exposes block activity. Include cached proxy and inactive split bytes as supporting evidence.

Part 4 - Experimental Design and Instrumentation

Capture identical keys at synchronized boundaries and compare with payload computed from `numel()` and `element_size()`. Run both fixed and slightly mismatched replacement sizes. Keep missing keys visible.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def memory_states(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    return {
        "label": label,
        "allocated": stats.get("allocated_bytes.all.current"),
        "active": stats.get("active_bytes.all.current"),
        "reserved": stats.get("reserved_bytes.all.current"),
        "inactive_split": stats.get(
            "inactive_split_bytes.all.current"
        ),
    }

def make_mib(size_mib, device):
    count = size_mib * 1024 * 1024 // 4
    return torch.empty(count, device=device)

def E04():
    device = torch.device("cuda:0")
    rows = [memory_states("baseline", device)]
    first = make_mib(96, device)
    second = make_mib(160, device)
    rows.append(memory_states("two_live", device))
    del first
    gc.collect()
    rows.append(memory_states("release_first", device))
    replacement = make_mib(96, device)
    rows.append(memory_states("replacement", device))
    del second, replacement
    gc.collect()
```

```
    rows.append(memory_states("release_all", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compute pairwise gaps and explain them by state, never by name alone. Confirm allocated against `memory_allocated()` and reserved against `memory_reserved()`. If active is unavailable or identical throughout, record backend limits. A one-run equality does not prove semantic equivalence; the counters must diverge under a designed lifetime transition.

Part 7 - Engineering Interpretation and Philosophy

Memory counters answer ownership questions. Allocated asks what tensor storage is live, reserved asks what capacity PyTorch controls, and active asks what blocks are unavailable for reuse. Diagnosis begins by asking the correct ownership question before choosing a number.

19.5.6 Exercise 05

Exercise Title: Measure Small-Pool and Large-Pool Allocations Separately and Discover Which Tensor Sizes Trigger Each Allocator Path

Part 1 - Exercise Contract and Why It Matters

Empirically map requests to allocator pool statistics. The goal is not to memorize a size threshold from one release; it is to build a reproducible sweep that reveals the behavior of your exact backend and configuration.

Part 2 - System and Memory Mental Model

The native caching allocator reports small- and large-pool families for many counters. Pools reduce interference between request scales, but requested payload, rounded block size, and segment policy are distinct. Alternative backends may not report these counters meaningfully, so capability detection is part of the experiment.

Part 3 - Quantitative Prediction Before Execution

Sweep logarithmic sizes from KiB to tens of MiB. Predict a region dominated by small-pool deltas and another by large-pool deltas. Define the transition as an observed change in selected counter deltas, not as the first size that merely sounds large.

Part 4 - Experimental Design and Instrumentation

Run each size in a fresh subprocess or restore an identical baseline because prior allocations mutate cumulative statistics and cache state. Measure allocation count and bytes for both pools immediately before and during a live request. Repeat around the apparent boundary with finer increments.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

POOL_KEYS = [
    "allocation.small_pool.allocated",
```

```
    "allocation.large_pool.allocated",
    "allocated_bytes.small_pool.allocated",
    "allocated_bytes.large_pool.allocated",
]

def probe_size(size_bytes, device):
    torch.cuda.synchronize(device)
    before = torch.cuda.memory_stats(device)
    count = (size_bytes + 3) // 4
    value = torch.empty(count, dtype=torch.float32, device=device)
    torch.cuda.synchronize(device)
    after = torch.cuda.memory_stats(device)
    del value
    gc.collect()
    result = {"requested_bytes": size_bytes}
    for key in POOL_KEYS:
        if key in before and key in after:
            result[key] = int(after[key] - before[key])
        else:
            result[key] = None
    return result

def E05():
    device = torch.device("cuda:0")
    sizes = [
        4 * 1024,
        64 * 1024,
        256 * 1024,
        512 * 1024,
        768 * 1024,
        1024 * 1024,
        2 * 1024 * 1024,
        8 * 1024 * 1024,
        32 * 1024 * 1024,
    ]
    rows = []
    for size_bytes in sizes:
        rows.append(probe_size(size_bytes, device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot payload against both pool deltas and refine around the change. The in-process skeleton is order dependent; the final boundary report must use fresh-process probes. If both pool families are absent or unchanged, document the allocator backend rather than manufacturing a threshold. Compare requested bytes with allocator-accounted bytes to expose rounding.

Part 7 - Engineering Interpretation and Philosophy

Pool thresholds are implementation facts, not mathematical constants. The durable skill is designing a capability-aware measurement that remains honest when PyTorch changes its allocator.

19.5.7 Exercise 06

Exercise Title: Track Segment Creation and Release While Growing a CUDA Workload from Small Tensors to Multi-Gigabyte Allocations

Part 1 - Exercise Contract and Why It Matters

Observe how allocator segments evolve as the live working set grows from small requests to GiB-scale storage. The experiment must remain safe on an 8 GiB GPU and stop before external memory pressure becomes dangerous.

Part 2 - System and Memory Mental Model

Segments are regions obtained from CUDA and managed internally as blocks. Segment count and reserved bytes can rise in steps rather than exactly matching payload. Deleting tensors frees blocks; segments may remain cached until they become eligible for release or `empty_cache()` is called.

Part 3 - Quantitative Prediction Before Execution

Predict segment and reserved growth for cumulative live payloads of 16, 64, 256, 512, 1024, and 2048 MiB. Compute safety against current free memory and limit total experimental live payload to at most 35 percent of it. Predict the post-deletion state both before and after a deliberate cache release.

Part 4 - Experimental Design and Instrumentation

Use `torch.empty()` to focus on storage. Synchronize each step, record segment current/allocated/freed plus reserved bytes, and retain tensors in an explicit list. Run in a disposable process. Never catch an OOM and continue as though the allocator state were a clean baseline.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def segment_row(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    keys = [
        "segment.all.current",
        "segment.all.allocated",
        "segment.all.freed",
        "reserved_bytes.all.current",
        "allocated_bytes.all.current",
    ]
    row = {"label": label}
    for key in keys:
```

```
        row[key] = stats.get(key, None)
    return row

def E06():
    device = torch.device("cuda:0")
    free_bytes, _ = torch.cuda.mem_get_info(device)
    budget = int(free_bytes * 0.35)
    sizes_mib = [16, 64, 256, 512, 1024, 2048]
    live = []
    rows = [segment_row("baseline", device)]
    cumulative = 0
    for size_mib in sizes_mib:
        request = size_mib * 1024 * 1024
        if cumulative + request > budget:
            break
        value = torch.empty(request // 4, device=device)
        live.append(value)
        cumulative += request
        rows.append(segment_row("add_" + str(size_mib), device))
    live.clear()
    gc.collect()
    rows.append(segment_row("delete_all", device))
    torch.cuda.empty_cache()
    rows.append(segment_row("release_cache", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Graph live payload, allocated, reserved, and segment count together. Confirm that skipped GiB requests are reported. After deletion, allocated should fall; after cache release, eligible segments may be returned. If segments do not fall, check live references and backend semantics. Do not infer segment size by dividing reserved by count when segments are heterogeneous.

Part 7 - Engineering Interpretation and Philosophy

Capacity grows through allocator units, not perfectly continuous payload bytes. Safe experiments respect the device as a shared finite system and produce useful evidence without proving courage through avoidable OOMs.

19.5.8 Exercise 07

Exercise Title: Measure Active and Inactive Split Blocks and Relate Them to Real Memory Reuse Behavior

Part 1 - Exercise Contract and Why It Matters

Connect split-block statistics to an actual reuse sequence. You will create a large request, release it, serve smaller requests, and observe how active and inactive split bytes change.

Part 2 - System and Memory Mental Model

When a larger block is split to satisfy a smaller request, one portion can become active while a remainder becomes inactive. Inactive split bytes indicate capacity inside split segments that is not currently active. They are a fragmentation signal, but not proof that the bytes are permanently unusable.

Part 3 - Quantitative Prediction Before Execution

Seed and release a 256 MiB allocation, then request 96 and 80 MiB concurrently. Predict active growth, possible inactive remainder, and stable reserved bytes. After releasing both, predict whether inactive split capacity can coalesce or remain represented depending on allocator state.

Part 4 - Experimental Design and Instrumentation

Record active blocks/bytes, inactive split blocks/bytes, allocated bytes, and reserved bytes. Use a same-size reallocation control and an unequal-size split candidate. Execute branches in fresh processes because each mutates the cache.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def split_row(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    keys = [
        "active.all.current",
        "active_bytes.all.current",
        "inactive_split.all.current",
        "inactive_split_bytes.all.current",
        "allocated_bytes.all.current",
        "reserved_bytes.all.current",
    ]
    row = {"label": label}
    for key in keys:
        row[key] = stats.get(key, None)
    return row

def make_mib(size_mib, device):
    return torch.empty(size_mib * 1024 * 1024 // 4, device=device)

def E07():
    device = torch.device("cuda:0")
    rows = [split_row("baseline", device)]
    seed = make_mib(256, device)
    rows.append(split_row("seed_live", device))
    del seed
    gc.collect()
    rows.append(split_row("seed_released", device))
    first = make_mib(96, device)
```

```
    second = make_mib(80, device)
    rows.append(split_row("two_smaller_live", device))
    del first, second
    gc.collect()
    rows.append(split_row("release_smaller", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not declare a split solely because requested sizes sum below the seed. The allocator may choose another segment or block. Require a matching rise in inactive split statistics and stable reserved capacity. If counters remain zero, report that the designed pattern did not trigger the intended state and adjust sizes systematically.

Part 7 - Engineering Interpretation and Philosophy

Fragmentation evidence is strongest when a counter transition is tied to a controlled lifetime event. Names such as "inactive split" suggest a mechanism, but experiments must establish that the mechanism occurred in this workload.

19.5.9 Exercise 08

Exercise Title: Design Variable-Shape Allocations That Increase inactive_split_bytes and Quantify the Resulting Memory Waste

Part 1 - Exercise Contract and Why It Matters

Create a variable-shape schedule intended to grow inactive split bytes, then quantify the gap between live payload and allocator-reserved capacity. The exercise must allow the hypothesis to fail honestly.

Part 2 - System and Memory Mental Model

Alternating request sizes can split cached blocks into remainders that poorly match future requests. Define observed waste carefully: inactive split bytes are a direct allocator statistic when available, while reserved minus active is a broader slack measure containing more than fragmentation.

Part 3 - Quantitative Prediction Before Execution

Design a deterministic sequence around several close but unequal MiB sizes. Predict inactive split growth and define $W_{split} = I_{split}/R$ when $R > 0$. Also track useful live payload so a larger ratio is not merely caused by measuring at an idle boundary.

Part 4 - Experimental Design and Instrumentation

Use overlapping lifetimes, because allocating and immediately deleting one tensor may permit easy coalescing. Compare at identical peak-live and idle boundaries. Keep total live payload below 35 percent of free VRAM and repeat in fresh processes.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def E08(iterations=40):
    device = torch.device("cuda:0")
    patterns = [73, 119, 191, 83, 137, 211]
    live = []
    rows = []
    for iteration in range(iterations):
        size_mib = patterns[iteration % len(patterns)]
        value = torch.empty(size_mib * 1024 * 1024 // 4, device=device)
        live.append(value)
        if len(live) > 3:
            del live[0]
            gc.collect()
        torch.cuda.synchronize(device)
        stats = torch.cuda.memory_stats(device)
        reserved = stats.get("reserved_bytes.all.current", None)
        inactive = stats.get("inactive_split_bytes.all.current", None)
        ratio = None
        if reserved is not None and reserved > 0 and inactive is not None:
            ratio = inactive / reserved
        rows.append({
            "iteration": iteration,
            "size_mib": size_mib,
            "allocated": stats.get("allocated_bytes.all.current"),
            "reserved": reserved,
            "inactive_split": inactive,
            "split_waste_ratio": ratio,
        })
    live.clear()
    gc.collect()
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot absolute inactive split bytes and the ratio beside allocated/reserved curves. A ratio measured only after deletion can exaggerate application impact; report peak-live boundaries too. If inactive split stays zero, inspect backend support and revise the schedule rather than replacing observed values with the broader reserved-minus-allocated gap.

Part 7 - Engineering Interpretation and Philosophy

"Waste" is meaningful only relative to a workload objective. Cached slack may serve the next request efficiently, while inactive split capacity may obstruct a large contiguous request. Metrics must be interpreted through future demand.

19.5.10 Exercise 09

Exercise Title: Compare a Stable-Shape Workload Against a Variable-Shape Workload Using Identical Compute but Different Allocator Statistics

Part 1 - Exercise Contract and Why It Matters

Compare shape policies while controlling useful computation. Demonstrate that equal arithmetic intent can generate different allocator states because tensor sizes and lifetime patterns differ.

Part 2 - System and Memory Mental Model

Stable shapes repeat a small set of blocks and often reach steady state. Variable shapes diversify allocation requests. Equal total elements alone may not equalize kernel efficiency, so report both requested compute and measured runtime rather than claiming perfect hardware equivalence.

Part 3 - Quantitative Prediction Before Execution

Construct stable and variable schedules with equal total elements per four-step cycle. Predict similar cumulative payload traffic but more reserved growth, segments, or inactive split bytes for variable shapes. Predeclare comparison metrics and tolerances.

Part 4 - Experimental Design and Instrumentation

Run policies in separate fresh processes with one fixed weight matrix and no autograd. Record stats after every step and synchronize timing. Verify equal total input elements and checksum semantics. Do not call cache release.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def run_shapes(shapes):
    device = torch.device("cuda:0")
    rows = []
    for step, shape in enumerate(shapes):
        value = torch.randn(shape, device=device)
        output = torch.relu(value)
        checksum = output.sum()
        torch.cuda.synchronize(device)
        stats = torch.cuda.memory_stats(device)
        rows.append({
            "step": step,
            "elements": value.numel(),
            "allocated": stats.get("allocated_bytes.all.current"),
            "reserved": stats.get("reserved_bytes.all.current"),
            "segments": stats.get("segment.all.current"),
            "inactive_split": stats.get(
                "inactive_split_bytes.all.current"
            ),
            "checksum": float(checksum.cpu()),
        })
        del value, output, checksum
        gc.collect()
```

```
    return rows

def E09():
    stable = [(32, 1024, 256)] * 40
    variable_cycle = [
        (16, 1024, 256),
        (48, 1024, 256),
        (24, 1024, 256),
        (40, 1024, 256),
    ]
    variable = variable_cycle * 10
    return run_shapes(stable), run_shapes(variable)
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify both schedules process identical total elements. Compare end allocated, peak reserved, reserved-growth events, segment activity, and inactive splits. The random checksum values need not match; their purpose is to force compute. Use a deterministic input construction if numerical parity is part of the claim. Repeat process-level trials and report variation.

Part 7 - Engineering Interpretation and Philosophy

Fair allocator experiments control semantic work while acknowledging that shape itself affects kernels. The conclusion should describe the full systems trade, not pretend memory can be isolated from computation perfectly.

19.5.11 Exercise 10

Exercise Title: Trigger Allocator Memory Retries Under High VRAM Pressure and Identify the Conditions That Increase num_alloc_retries

Part 1 - Exercise Contract and Why It Matters

Investigate allocator retries as a pressure signal without assuming every high-memory workload will trigger one. The experiment is successful if it either produces a controlled retry or establishes the tested boundary and explains why no retry occurred.

Part 2 - System and Memory Mental Model

An allocation retry indicates that the allocator had to recover and attempt an allocation again, commonly by releasing eligible cached capacity. It is a cumulative occurrence counter, not a byte count and not automatically an OOM. A retry can precede successful allocation; zero retries does not prove abundant memory if the next request fails directly or the backend reports differently.

Part 3 - Quantitative Prediction Before Execution

Read current free capacity, reserve a bounded working set, release several irregular blocks, and request a large block. Predict conditions under which the cache contains enough total slack but no suitable block, potentially provoking recovery. Set a strict upper target below driver free memory and run in a disposable subprocess.

Part 4 - Experimental Design and Instrumentation

Record retries, OOMs, allocated, reserved, active, and inactive split bytes before pressure, after cache seeding, before the probe, and after it. Increase pressure in small steps across separate processes. Stop immediately after the first retry or OOM; do not continue from an ambiguous allocator state.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def pressure_row(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    return {
        "label": label,
        "retries": stats.get("num_alloc_retries"),
        "ooms": stats.get("num_ooms"),
        "allocated": stats.get("allocated_bytes.all.current"),
        "reserved": stats.get("reserved_bytes.all.current"),
        "active": stats.get("active_bytes.all.current"),
        "inactive_split": stats.get(
            "inactive_split_bytes.all.current"
        ),
    }

def E10(pressure_fraction=0.55):
    device = torch.device("cuda:0")
    free_bytes, _ = torch.cuda.mem_get_info(device)
    if pressure_fraction <= 0.0 or pressure_fraction >= 0.70:
        raise ValueError("Use a pressure fraction below 0.70.")
    budget = int(free_bytes * pressure_fraction)
    rows = [pressure_row("baseline", device)]
    blocks = []
    block_bytes = 64 * 1024 * 1024
    while (len(blocks) + 1) * block_bytes < budget:
        blocks.append(torch.empty(block_bytes // 4, device=device))
    rows.append(pressure_row("working_set", device))
    index = len(blocks) - 1
    while index >= 0:
        if index % 2 == 0:
            del blocks[index]
        index -= 1
    gc.collect()
    rows.append(pressure_row("irregular_slack", device))
    probe_bytes = min(int(free_bytes * 0.15), 512 * 1024 * 1024)
    probe = torch.empty(probe_bytes // 4, device=device)
    rows.append(pressure_row("probe_success", device))
    del probe
    blocks.clear()
```

```
    gc.collect()
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compute retry deltas rather than reading only absolute history. If no retry appears, report maximum pressure, slack pattern, and successful probe size. Increase pressure only in fresh subprocesses. If an OOM occurs first, the experiment found a failure boundary but did not prove retry behavior. Never raise the safety fraction automatically after failure.

Part 7 - Engineering Interpretation and Philosophy

Retries are leading indicators of allocator stress, not moral failures. A defensible operational threshold comes from correlation with latency and OOM risk under representative traffic, not from demanding that the counter always remain mathematically zero.

19.5.12 Exercise 11

Exercise Title: Trigger a Controlled CUDA OOM and Inspect num_ooms, Reserved Bytes, Active Bytes, and Inactive Blocks Immediately After Failure

Part 1 - Exercise Contract and Why It Matters

Produce one deliberate, isolated OOM to learn what evidence remains after failure. This is a diagnostic laboratory exercise, not code to embed in a training process. It must run in a disposable subprocess on an otherwise idle GPU.

Part 2 - System and Memory Mental Model

An OOM is a failed request, not necessarily exhaustion of every reported byte. Live allocations, reserved segments, fragmentation, external processes, and request contiguity all affect the outcome. `num_ooms` records allocator events, while the exception message provides request context. Catching the exception does not guarantee every later CUDA operation is a scientifically clean continuation.

Part 3 - Quantitative Prediction Before Execution

Measure driver-free bytes and request slightly more than that in one tensor. Predict an OOM delta of at least one where supported, unchanged intended live working set, and possible retry activity. Predeclare that only statistics and the error text will be collected after failure; no training continues.

Part 4 - Experimental Design and Instrumentation

Run the script alone in a child process. Capture stats immediately before and inside the exception handler. Keep no valuable GPU state in the process. After recording, terminate normally and start a fresh process for all later tests.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def selected(device):
    stats = torch.cuda.memory_stats(device)
```

```
    keys = [
        "num_ooms",
        "num_alloc_retries",
        "allocated_bytes.all.current",
        "reserved_bytes.all.current",
        "active_bytes.all.current",
        "inactive_split_bytes.all.current",
    ]
    row = {}
    for key in keys:
        row[key] = stats.get(key, None)
    return row

def E11():
    device = torch.device("cuda:0")
    torch.empty(1, device=device)
    torch.cuda.synchronize(device)
    before = selected(device)
    free_bytes, _ = torch.cuda.mem_get_info(device)
    request_bytes = free_bytes + 256 * 1024 * 1024
    error_text = None
    after = None
    try:
        impossible = torch.empty(request_bytes // 4, device=device)
        del impossible
    except torch.OutOfMemoryError as error:
        error_text = str(error)
        after = selected(device)
    if error_text is None:
        raise RuntimeError("The controlled OOM did not occur.")
    return {
        "requested_bytes": request_bytes,
        "before": before,
        "after": after,
        "error": error_text,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify the OOM delta and compare active/reserved/inactive states. The requested size intentionally exceeds free capacity, so this test diagnoses basic failure accounting more than fragmentation. Keep the exception text but redact unrelated paths if sharing the report. If the exception type differs by version, document it and broaden the handler only enough to capture CUDA OOM, not every runtime error.

Part 7 - Engineering Interpretation and Philosophy

Failure experiments deserve stricter isolation than success benchmarks. Their value comes from learning observable signals and recovery boundaries without turning a damaged process state into misleading subsequent measurements.

19.5.13 Exercise 12

Exercise Title: Reset Peak CUDA Memory Statistics Between Experiments and Build Reproducible Memory Benchmarks

Part 1 - Exercise Contract and Why It Matters

Build a benchmark protocol in which each trial has an intentional peak-history boundary. Without correct resets, later trials inherit earlier high-water marks and cannot be compared.

Part 2 - System and Memory Mental Model

Peak statistics are historical state inside the process. Resetting peaks does not free memory, delete tensors, or reset cumulative allocation traffic. It changes the reference point for maximum values. A clean benchmark therefore needs stable live baseline memory before the reset and identical synchronization boundaries.

Part 3 - Quantitative Prediction Before Execution

Predict peaks for 64, 128, and 192 MiB trials executed in ascending and descending order. Without reset, every later reported peak is at least the largest previous one. With reset at a clean baseline, peaks should track each trial independently.

Part 4 - Experimental Design and Instrumentation

Warm CUDA, delete prior trial tensors, synchronize, assert baseline allocated within tolerance, reset peak memory stats, run one trial, synchronize, and read peak. Repeat orders and compare. Record current memory beside peak to prove the reset itself did not release storage.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def run_trial(size_mib, device):
    gc.collect()
    torch.cuda.synchronize(device)
    baseline = torch.cuda.memory_allocated(device)
    torch.cuda.reset_peak_memory_stats(device)
    value = torch.empty(size_mib * 1024 * 1024 // 4, device=device)
    torch.cuda.synchronize(device)
    current = torch.cuda.memory_allocated(device)
    peak = torch.cuda.max_memory_allocated(device)
    del value
    gc.collect()
    torch.cuda.synchronize(device)
    return {
        "size_mib": size_mib,
        "baseline": baseline,
        "current": current,
        "peak": peak,
        "end": torch.cuda.memory_allocated(device),
    }
```

```
def E12():
    device = torch.device("cuda:0")
    ascending = []
    for size_mib in [64, 128, 192]:
        ascending.append(run_trial(size_mib, device))
    descending = []
    for size_mib in [192, 128, 64]:
        descending.append(run_trial(size_mib, device))
    return ascending, descending
```

Part 6 - Measurement, Validation, and Failure Analysis

Subtract each trial baseline from peak and compare with payload. Assert that end allocated returns to baseline before the next reset. If not, repair lifetime control. Reserved cache may differ by order while allocated peak deltas remain comparable; report both because reproducible semantics do not require identical cache history.

Part 7 - Engineering Interpretation and Philosophy

Reproducibility requires defining which state is reset and which state is allowed to persist. A peak reset is statistical bookkeeping, not process purification. Honest benchmarks state both facts.

19.5.14 Exercise 13

Exercise Title: Build a Memory Efficiency Metric from Active, Allocated, Reserved, and Inactive Bytes and Validate It on Multiple Workloads

Part 1 - Exercise Contract and Why It Matters

Design a small metric family rather than one magical score. Separate payload utilization, active-block utilization, and split-fragment pressure so a poor result can be interpreted causally.

Part 2 - System and Memory Mental Model

For positive reserved bytes define

$$U_A = A/R, \qquad U_{active} = H/R, \qquad F_{split} = I/R,$$

where A is allocated, H active, R reserved, and I inactive split bytes. These ratios describe a measurement boundary. Low utilization at idle is expected; comparisons must use equivalent workload phases.

Part 3 - Quantitative Prediction Before Execution

Predict ratios for a live fixed-shape peak, an idle cached state, and a variable-shape peak. Define valid ranges and missing-key behavior. Do not combine ratios into a weighted score until weights are justified by deployment goals.

Part 4 - Experimental Design and Instrumentation

Capture each workload at identical semantic boundaries and preserve raw bytes beside ratios. Run repeated fixed, bursty, and variable schedules in fresh processes. Include OOM/retry counts so apparent efficiency is not rewarded when the workload fails.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def efficiency_row(label, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    allocated = stats.get("allocated_bytes.all.current")
    active = stats.get("active_bytes.all.current")
    reserved = stats.get("reserved_bytes.all.current")
    inactive = stats.get("inactive_split_bytes.all.current")
    row = {
        "label": label,
        "allocated": allocated,
        "active": active,
        "reserved": reserved,
        "inactive_split": inactive,
    }
    if reserved is None or reserved == 0:
        row["allocated_utilization"] = None
        row["active_utilization"] = None
        row["split_pressure"] = None
    else:
        row["allocated_utilization"] = allocated / reserved
        row["active_utilization"] = active / reserved
        row["split_pressure"] = inactive / reserved
    return row

def E13():
    device = torch.device("cuda:0")
    baseline = efficiency_row("baseline", device)
    value = torch.empty((64, 1024, 1024), device=device)
    live = efficiency_row("live_peak", device)
    del value
    idle = efficiency_row("idle_cache", device)
    return baseline, live, idle
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert ratios lie between zero and one only when backend semantics support the expected ordering. A low idle U_A is not inefficiency by itself; the cache may accelerate the next iteration. Validate metrics against known stable and variable controls and report raw counters whenever a ratio changes.

Part 7 - Engineering Interpretation and Philosophy

Metrics compress evidence and therefore discard context. A responsible metric design keeps the raw quantities, phase label, and failure counters close enough that the compression can be challenged.

19.5.15 Exercise 14

Exercise Title: Detect Allocator Fragmentation Using Only memory_stats() Counters Before Inspecting Any Memory Snapshot

Part 1 - Exercise Contract and Why It Matters

Build a first-pass fragmentation detector using summary counters only. Its output must be a suspicion level with evidence, never a definitive block-layout claim that requires a memory snapshot.

Part 2 - System and Memory Mental Model

Fragmentation suspicion rises when inactive split bytes are large relative to reserved memory, reserved greatly exceeds active/allocated memory at a live boundary, retries increase, or a large request fails despite substantial aggregate slack. None is individually conclusive. Cached idle memory and intentional workspace can produce similar gaps.

Part 3 - Quantitative Prediction Before Execution

Define transparent rules: split-pressure warning, reserved-slack warning, retry escalation, and OOM escalation. Choose thresholds from controlled stable and variable workloads, not arbitrary universal constants. Predict detector output for each control before implementation.

Part 4 - Experimental Design and Instrumentation

Feed synchronized rows from E07–E10 into the detector. Require at least two independent signals for high suspicion unless an OOM follows a large-slack state. Preserve missing keys and return reasons with every classification.

Part 5 - PyTorch/CUDA Implementation

```
def fragmentation_signals(row, split_limit=0.20, slack_limit=0.40):
    reserved = row.get("reserved")
    allocated = row.get("allocated")
    inactive = row.get("inactive_split")
    reasons = []
    if reserved is None or reserved <= 0:
        return {"level": "unknown", "reasons": ["missing_reserved"]}
    if inactive is not None and inactive / reserved >= split_limit:
        reasons.append("high_inactive_split_ratio")
    if allocated is not None:
        slack = (reserved - allocated) / reserved
        if slack >= slack_limit:
            reasons.append("large_reserved_slack")
    if row.get("retry_delta", 0) > 0:
        reasons.append("allocation_retry")
    if row.get("oom_delta", 0) > 0:
        reasons.append("oom_event")
    if "oom_event" in reasons and len(reasons) >= 2:
        level = "high"
    elif len(reasons) >= 2:
        level = "moderate"
```

```
    elif len(reasons) == 1:
        level = "watch"
    else:
        level = "low"
    return {"level": level, "reasons": reasons}

def E14(rows):
    results = []
    for row in rows:
        results.append(fragmentation_signals(row))
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Measure false positives on idle-cache and burst controls and false negatives on the variable split-heavy control. Thresholds tuned on one trace require holdout validation. The detector should recommend snapshot inspection for moderate/high suspicion; it must not claim block addresses or contiguity from summary counters.

Part 7 - Engineering Interpretation and Philosophy

Good anomaly detection narrows investigation. It does not replace stronger evidence. Returning reasons and uncertainty makes the detector useful to an engineer instead of turning thresholds into an oracle.

19.5.16 Exercise 15

Exercise Title: Record memory_stats() at Forward, Loss, Backward, Optimizer, and Zero-Grad Boundaries and Explain the Training Memory Lifecycle

Part 1 - Exercise Contract and Why It Matters

Instrument a complete training iteration at semantic boundaries. The objective is to connect counter transitions to parameters, activations, loss, gradients, optimizer state, and gradient clearing rather than presenting one unexplained peak.

Part 2 - System and Memory Mental Model

Model parameters and inputs exist before forward. Forward creates outputs and saved activations. Loss adds output-dependent state. Backward consumes saved state while creating gradients and temporary workspaces. The first optimizer step may lazily allocate optimizer state. With `zero_grad(set_to_none=True)`, gradient storage can be released for reuse; setting gradients to zero may retain buffers.

Part 3 - Quantitative Prediction Before Execution

Compute parameter payload and predict the direction of allocated, active, reserved, allocation count, and peaks at every boundary. Distinguish the first iteration from steady state because optimizer state and library initialization are lazy. Predict two zero-grad strategies separately.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds and one fixed batch. Capture synchronized rows before forward, after forward, after loss, after backward, after optimizer step, and after zero-grad. Warm only CUDA and model kernels for one report; retain the cold first optimizer step in a separate report so its state allocation is visible.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def stage_row(stage, device):
    torch.cuda.synchronize(device)
    stats = torch.cuda.memory_stats(device)
    keys = [
        "allocation.all.current",
        "allocated_bytes.all.current",
        "allocated_bytes.all.peak",
        "active_bytes.all.current",
        "reserved_bytes.all.current",
        "inactive_split_bytes.all.current",
    ]
    row = {"stage": stage}
    for key in keys:
        row[key] = stats.get(key, None)
    return row

def E15():
    device = torch.device("cuda:0")
    torch.manual_seed(71)
    model = torch.nn.Sequential(
        torch.nn.Linear(2048, 4096),
        torch.nn.GELU(),
        torch.nn.Linear(4096, 1000),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.0003)
    inputs = torch.randn((128, 2048), device=device)
    targets = torch.randint(0, 1000, (128,), device=device)
    torch.cuda.reset_peak_memory_stats(device)
    rows = [stage_row("before_forward", device)]
    logits = model(inputs)
    rows.append(stage_row("after_forward", device))
    loss = torch.nn.functional.cross_entropy(logits, targets)
    rows.append(stage_row("after_loss", device))
    loss.backward()
    rows.append(stage_row("after_backward", device))
    optimizer.step()
    rows.append(stage_row("after_optimizer", device))
    optimizer.zero_grad(set_to_none=True)
    rows.append(stage_row("after_zero_grad", device))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Annotate every positive and negative delta with expected tensor lifetime. Inspect peak separately because temporaries may appear and disappear between boundaries. Repeat the second iteration to isolate one-time optimizer state. If zero-grad does not reduce allocated bytes, verify strategy, gradient references, and whether another object retains the graph. Confirm loss is finite so a memory trace is not documenting a numerically failed step.

Part 7 - Engineering Interpretation and Philosophy

Training memory is a lifecycle, not a static model size. Stage boundaries turn an OOM into a precise question: which semantic object became live, which workspace peaked, and which intended lifetime failed to end?

19.5.17 Exercise 16

Exercise Title: Compare SGD and AdamW Training Memory Behavior Through Allocator Statistics and Identify Optimizer-State Allocation Patterns

Part 1 - Exercise Contract and Why It Matters

Compare optimizer memory under identical model, data, precision, and step boundaries. Reveal when state is allocated and quantify steady-state cost rather than relying only on theoretical parameter multiples.

Part 2 - System and Memory Mental Model

Plain SGD without momentum may maintain little persistent per-parameter state. Momentum adds a buffer. AdamW typically maintains first- and second-moment states and a step value. Implementation choices, foreach/fused paths, precision, and temporary workspaces affect observed allocation beyond the conceptual state tensors.

Part 3 - Quantitative Prediction Before Execution

Calculate model parameter bytes and predict persistent optimizer-state payload for SGD, SGD with momentum, and AdamW. Predict the first step to allocate state lazily and later steps to reuse it. Define observed state cost as steady allocated memory after optimizer initialization minus an identical model/input baseline.

Part 4 - Experimental Design and Instrumentation

Run optimizers in separate fresh processes from the same saved initial model state. Use identical gradients by fixing inputs and seeds. Capture before backward, after backward, after first step, after zero-grad, and after second step. Record optimizer configuration including foreach/fused defaults.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def run_optimizer(kind):
    device = torch.device("cuda:0")
    torch.manual_seed(83)
    model = torch.nn.Linear(4096, 4096).to(device)
```

```
    if kind == "sgd":
        optimizer = torch.optim.SGD(model.parameters(), lr=0.01)
    elif kind == "momentum":
        optimizer = torch.optim.SGD(
            model.parameters(), lr=0.01, momentum=0.9
        )
    elif kind == "adamw":
        optimizer = torch.optim.AdamW(model.parameters(), lr=0.001)
    else:
        raise ValueError(kind)
    inputs = torch.randn((64, 4096), device=device)
    targets = torch.randn((64, 4096), device=device)
    rows = []
    for step in range(2):
        optimizer.zero_grad(set_to_none=True)
        output = model(inputs)
        loss = torch.nn.functional.mse_loss(output, targets)
        loss.backward()
        optimizer.step()
        optimizer.zero_grad(set_to_none=True)
        torch.cuda.synchronize(device)
        stats = torch.cuda.memory_stats(device)
        rows.append({
            "kind": kind,
            "step": step,
            "allocated": stats.get("allocated_bytes.all.current"),
            "reserved": stats.get("reserved_bytes.all.current"),
            "allocation_count": stats.get("allocation.all.current"),
            "peak": stats.get("allocated_bytes.all.peak"),
        })
        del output, loss
    return rows

def E16():
    sgd_rows = run_optimizer("sgd")
    momentum_rows = run_optimizer("momentum")
    adamw_rows = run_optimizer("adamw")
    return sgd_rows, momentum_rows, adamw_rows
```

Part 6 - Measurement, Validation, and Failure Analysis

The single-process skeleton contaminates later baselines with prior cache state; the final benchmark must run each optimizer in a fresh process. Enumerate optimizer state tensors and compute their bytes as a semantic cross-check. Confirm parameter initialization and loss are identical before comparing. Separate persistent post-zero-grad allocation from transient peak.

Part 7 - Engineering Interpretation and Philosophy

Optimizer choice is a memory architecture decision as well as a convergence decision. Theoretical state size predicts direction; allocator statistics show when and how that cost materializes

on the actual system.

19.5.18 Exercise 17

Exercise Title: Build a Time-Series Logger That Captures Selected CUDA Allocator Statistics Across Hundreds of Training Iterations

Part 1 - Exercise Contract and Why It Matters

Build a low-retention logger that records selected allocator statistics across hundreds of iterations without keeping CUDA tensors or autograd graphs. Long traces reveal drift, periodic bursts, lazy initialization, and steady-state plateaus invisible in one snapshot.

Part 2 - System and Memory Mental Model

Logging frequency trades temporal resolution against synchronization overhead. Every synchronization changes execution timing. The logger should store only CPU-native scalars and phase labels, sample frequently during warm-up, then less frequently during steady state. Cumulative counters need deltas; current counters can be plotted directly.

Part 3 - Quantitative Prediction Before Execution

Predict first-step optimizer growth, early cache stabilization, and stable end-of-step allocated memory. Define slope and jump metrics before training. Estimate row count and storage so logging itself stays bounded.

Part 4 - Experimental Design and Instrumentation

Create an explicit key allowlist. Convert each value to Python `int` and loss to detached CPU `float`. Never append output, loss tensor, or raw stats objects containing unexpected GPU references. Record environment and sampling policy once.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

class MemoryStatsLogger:
    def __init__(self, device, every=10):
        self.device = device
        self.every = every
        self.rows = []
        self.keys = [
            "allocated_bytes.all.current",
            "allocated_bytes.all.peak",
            "reserved_bytes.all.current",
            "active_bytes.all.current",
            "inactive_split_bytes.all.current",
            "num_alloc_retries",
            "num_ooms",
        ]

    def capture(self, step, loss_value):
```

```
        if step >= 10 and step % self.every != 0:
            return
        torch.cuda.synchronize(self.device)
        stats = torch.cuda.memory_stats(self.device)
        row = {
            "step": step,
            "time": time.time(),
            "loss": float(loss_value),
        }
        for key in self.keys:
            value = stats.get(key, None)
            row[key] = None if value is None else int(value)
        self.rows.append(row)

def E17(model, optimizer, batches, device):
    logger = MemoryStatsLogger(device, every=10)
    for step, batch in enumerate(batches):
        inputs, targets = batch
        inputs = inputs.to(device, non_blocking=True)
        targets = targets.to(device, non_blocking=True)
        optimizer.zero_grad(set_to_none=True)
        output = model(inputs)
        loss = torch.nn.functional.cross_entropy(output, targets)
        loss.backward()
        optimizer.step()
        logger.capture(step, loss.detach().cpu().item())
        del inputs, targets, output, loss
    return logger.rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify row count against sampling policy and assert no tensor objects occur in rows. Benchmark with logging disabled and enabled to quantify overhead. Plot current counters, cumulative deltas, and loss on separate axes. A rising allocated slope needs semantic reference investigation; a reserved staircase with flat allocated suggests changing allocation demand instead.

Part 7 - Engineering Interpretation and Philosophy

Observability must not rewrite the system it observes. Selective scalar logging provides longitudinal evidence while keeping overhead and lifetime interference measurable and bounded.

19.5.19 Exercise 18

Exercise Title: Implement Automatic Memory-Anomaly Detection for Sudden Reserved-Memory Growth, Fragmentation, Retries, and OOM Events

Part 1 - Exercise Contract and Why It Matters

Convert the E17 time series into an explainable detector for four anomaly families: reserved jumps, split pressure, retry increments, and OOM increments. Every alert must include evidence and severity.

Part 2 - System and Memory Mental Model

Current counters require level or jump rules; cumulative counters require positive deltas. Baselines change during warm-up, so static thresholds generate false alerts. Use a warm-up window and robust distributions such as median and median absolute deviation, while retaining hard alerts for retry/OOM deltas.

Part 3 - Quantitative Prediction Before Execution

Inject synthetic rows containing one reserved jump, one inactive-split rise, one retry, and one OOM. Predict exact alerts before writing the detector. Define warning versus critical severity and cooldown behavior so one persistent state does not emit hundreds of identical events.

Part 4 - Experimental Design and Instrumentation

Separate detector training/baseline rows from evaluation rows. Preserve raw row indices and previous values. Test missing counters, zero reserved memory, counter reset, and process restart. Never treat a negative cumulative delta as normal workload behavior; classify it as reset/restart metadata.

Part 5 - PyTorch/CUDA Implementation

```
def detect_anomalies(rows, reserved_jump_bytes, split_ratio_limit=0.20):
    alerts = []
    previous = None
    for row in rows:
        if previous is None:
            previous = row
            continue
        reserved = row.get("reserved_bytes.all.current")
        old_reserved = previous.get("reserved_bytes.all.current")
        inactive = row.get("inactive_split_bytes.all.current")
        retry = row.get("num_alloc_retries")
        old_retry = previous.get("num_alloc_retries")
        ooms = row.get("num_ooms")
        old_ooms = previous.get("num_ooms")

        if reserved is not None and old_reserved is not None:
            if reserved - old_reserved >= reserved_jump_bytes:
                alerts.append((row["step"], "warning", "reserved_jump"))
        if reserved is not None and reserved > 0 and inactive is not None:
            if inactive / reserved >= split_ratio_limit:
                alerts.append((row["step"], "warning", "split_pressure"))
        if retry is not None and old_retry is not None and retry > old_retry:
            alerts.append((row["step"], "warning", "allocation_retry"))
        if ooms is not None and old_ooms is not None and ooms > old_ooms:
            alerts.append((row["step"], "critical", "oom"))
        previous = row
    return alerts

def E18(rows):
    return detect_anomalies(rows, reserved_jump_bytes=128 * 1024 * 1024)
```

Part 6 - Measurement, Validation, and Failure Analysis

Measure precision and recall on labeled synthetic and controlled real traces. Tune thresholds on development traces and validate on holdout workloads. A split-pressure alert at idle may be harmless; correlate it with live phase, retries, latency, or failed requests. Add deduplication only after confirming it does not hide new OOM increments.

Part 7 - Engineering Interpretation and Philosophy

Automation should accelerate human diagnosis, not conceal uncertainty. An alert is a structured question with evidence. The response can then escalate from counters to snapshots, profiler traces, or workload inspection.

19.5.20 Exercise 19

Exercise Title: Diagnose an Unknown Memory-Inefficient PyTorch Workload Using Only memory_stats() Evidence and Produce a Defensible Root-Cause Analysis

Part 1 - Exercise Contract and Why It Matters

Perform a blind diagnosis. Receive only a timestamped `memory_stats()` trace and phase labels, classify the most likely root-cause family, identify competing explanations, and propose the next discriminating experiment. Do not inspect source code or memory snapshots during the initial analysis.

Part 2 - System and Memory Mental Model

Candidate families include retained live tensors, stable healthy cache, variable-shape cache growth, split fragmentation, optimizer lazy state, transient workspace peaks, and external memory pressure. Counter signatures overlap. Rising allocated current supports retained liveness; flat allocated with rising reserved supports allocation-shape change; inactive split and retries strengthen fragmentation suspicion; a one-time step-one jump suggests lazy initialization.

Part 3 - Quantitative Prediction Before Execution

Build a signature matrix mapping every candidate to expected slopes, jumps, retry/OOM deltas, split pressure, and phase timing. Assign confidence only after listing evidence for and against each candidate. Predeclare what observation would falsify the leading hypothesis.

Part 4 - Experimental Design and Instrumentation

Analyze raw counters, first differences, rolling slopes, and phase-aligned averages. Separate warm-up from steady state. Compare current versus cumulative counters and detect resets. Keep the dataset blind until the report is frozen; then reveal workload identity and measure diagnostic accuracy.

Part 5 - PyTorch/CUDA Implementation

```
def summarize_trace(rows):
    if len(rows) < 2:
        raise ValueError("At least two rows are required.")
    first = rows[0]
    last = rows[-1]
    keys = [
```

```
        "allocated_bytes.all.current",
        "reserved_bytes.all.current",
        "active_bytes.all.current",
        "inactive_split_bytes.all.current",
        "num_alloc_retries",
        "num_ooms",
    ]
    deltas = {}
    for key in keys:
        start = first.get(key)
        end = last.get(key)
        if start is None or end is None:
            deltas[key] = None
        else:
            deltas[key] = end - start
    return deltas

def initial_hypotheses(deltas):
    hypotheses = []
    allocated = deltas.get("allocated_bytes.all.current")
    reserved = deltas.get("reserved_bytes.all.current")
    inactive = deltas.get("inactive_split_bytes.all.current")
    if allocated is not None and allocated > 0:
        hypotheses.append("retained_live_storage")
    if reserved is not None and reserved > 0:
        if allocated is not None and allocated <= 0:
            hypotheses.append("cache_or_shape_growth")
    if inactive is not None and inactive > 0:
        hypotheses.append("split_fragmentation_suspected")
    return hypotheses

def E19(rows):
    deltas = summarize_trace(rows)
    return {
        "deltas": deltas,
        "initial_hypotheses": initial_hypotheses(deltas),
        "required_next_step": "phase_aligned_and_slope_analysis",
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Endpoint deltas are only triage; the final report must analyze the full curve. Test the method on hidden traces produced by known bugs and controls. Report confusion cases. A defensible conclusion includes confidence, alternatives, falsification test, and expected counter change after the proposed fix. After source reveal, apply the fix and reproduce the predicted counter response.

Part 7 - Engineering Interpretation and Philosophy

Root-cause analysis is an argument under incomplete evidence. Expertise is not pretending certainty; it is narrowing hypotheses, stating what would prove you wrong, and selecting the cheapest next measurement that separates competing causes. `memory_stats()` is powerful precisely when its limits remain visible.

19.6 DMM04

Chapter Title: PyTorch CUDA Memory Snapshots
Specialization: Dynamic Memory Management and CUDA Systems

19.6.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Segments, Blocks, Allocation Events, and Memory History in PyTorch CUDA Snapshots

Part 1 - Exercise Contract and Why It Matters

This exercise moves from aggregate counters to allocator topology and history. A memory snapshot can describe allocator-managed segments, the blocks inside them, block states, requested sizes, addresses, streams, source frames, and— when history recording is enabled— a sequence of allocator events. The purpose is not to memorize one serialized schema. The purpose is to reconstruct a defensible story of where capacity came from, how it was divided, which blocks remain active, and why aggregate free space may not satisfy one large request.

Your deliverable is a four-layer model. Layer one is CUDA driver capacity. Layer two is PyTorch segments reserved from that capacity. Layer three is the block layout inside each segment. Layer four is the time-ordered event history. For every claim, identify whether it came from current topology, recorded history, a source stack, or an inference. Snapshot formats and private history APIs can change between PyTorch versions, so the parser must preserve unknown fields and fail visibly when required fields are absent.

Part 2 - System and Memory Mental Model

Model segment s as an address interval $[a_s, a_s + T_s)$ with total size T_s. Its ordered blocks b_i should cover the allocator-described layout. Each block has an address, size, and state such as `active_allocated`, `active_awaiting_free`, or `inactive`. A simplified accounting identity is

$$T_s = \sum_i |b_i|,$$

subject to the exact schema. Requested size can be smaller than block size due to rounding and alignment. Allocated space is active tensor storage; awaiting- free space has been logically released but is not yet reusable because device work has not completed; inactive space is allocator-owned free capacity.

Topology answers "what exists now." History answers "how did it get here." Events can include allocation, segment allocation/free, requested/free-completed transitions, OOM, and snapshot markers depending on version and recording configuration. The public snapshot API commonly returns segment information. The private full-snapshot representation used for dumping can also contain device traces when history is enabled. Treat these interfaces separately and check capabilities at runtime.

Part 3 - Quantitative Prediction Before Execution

Before capturing anything, draw one 256 MiB segment split into a 96 MiB active block, an 80 MiB active block, and an 80 MiB inactive remainder. Calculate active ratio, inactive ratio, internal rounding waste, and largest contiguous inactive block. Explain why 80 MiB of total inactive capacity does not imply that a 96 MiB request can succeed. Then predict how allocation and release events transform the diagram over time.

Part 4 - Experimental Design and Instrumentation

Use a fresh process, explicit CUDA device, fixed seed, fixed streams, and synchronized snapshot boundaries. Capture a baseline, a live-allocation state, and a released-cache state. Record PyTorch/CUDA versions and allocator backend. Keep raw snapshots immutable; build derived tables separately. Never store live tensors inside analyzer results because instrumentation would extend lifetimes.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def summarize_segments(segments):
    summary = []
    for segment_index, segment in enumerate(segments):
        block_rows = []
        for block_index, block in enumerate(segment.get("blocks", [])):
            block_rows.append({
                "block_index": block_index,
                "address": block.get("address"),
                "size": block.get("size"),
                "requested_size": block.get("requested_size"),
                "state": block.get("state"),
            })
        summary.append({
            "segment_index": segment_index,
            "device": segment.get("device"),
            "address": segment.get("address"),
            "total_size": segment.get("total_size"),
            "allocated_size": segment.get("allocated_size"),
            "active_size": segment.get("active_size"),
            "stream": segment.get("stream"),
            "segment_type": segment.get("segment_type"),
            "blocks": block_rows,
        })
    return summary

def E00():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM04.")
    device = torch.device("cuda:0")
```

```
    torch.empty(1, device=device)
    torch.cuda.synchronize(device)
    baseline = torch.cuda.memory_snapshot()
    first = torch.empty((24, 1024, 1024), device=device)
    second = torch.empty((16, 1024, 1024), device=device)
    torch.cuda.synchronize(device)
    live = torch.cuda.memory_snapshot()
    del first, second
    gc.collect()
    torch.cuda.synchronize(device)
    released = torch.cuda.memory_snapshot()
    return {
        "baseline": summarize_segments(baseline),
        "live": summarize_segments(live),
        "released": summarize_segments(released),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that block sizes sum to segment total size when the schema promises full coverage. Check address ordering and non-overlap. Sum active, inactive, and awaiting-free states independently; compare derived segment totals with fields stored by PyTorch without silently forcing equality. Differences can reveal schema semantics, rounding, or parser errors.

If a field is missing, preserve `None` and record version/backend. If addresses differ across clean-process repetitions, do not use raw address as a cross-process identity. If the released snapshot retains segments, recognize healthy cache ownership rather than declaring a leak. A snapshot cannot account for memory allocated outside the PyTorch allocator.

Part 7 - Engineering Interpretation and Philosophy

A snapshot is a structured piece of evidence, not a picture that interprets itself. Topology explains contiguity and ownership; history explains causality; stacks connect events to source; device-level counters reveal what lies outside PyTorch. Deep diagnosis comes from joining these views while respecting the question each can answer.

19.6.2 Exercise 01

Exercise Title: Capture Your First CUDA Allocator Snapshot with torch.cuda.memory_snapshot() and Inspect Its Raw Structure

Part 1 - Exercise Contract and Why It Matters

Capture and inspect the public snapshot without assuming its shape in advance. Enumerate segment and block keys, value types, and state values. The output is a schema inventory for your installed PyTorch.

Part 2 - System and Memory Mental Model

The public API usually returns a list of segment dictionaries. Each segment contains metadata and a block list. Blocks represent an address layout, not a Python tensor list. Multiple

tensors can share storage; views may create no new block; temporary blocks may disappear before capture.

Part 3 - Quantitative Prediction Before Execution

Predict the minimum fields required to calculate total segment size, active space, inactive space, and largest block. Predict state labels but mark them as hypotheses until observed. Calculate expected payload of two known tensors.

Part 4 - Experimental Design and Instrumentation

Warm CUDA, allocate two tensors, synchronize, and capture exactly once. Print only bounded samples of nested data to avoid an unreadable console. Build a recursive type/schema walker that never stores tensor objects.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def describe(value, path, rows, depth=0):
    rows.append({
        "path": path,
        "type": type(value).__name__,
        "depth": depth,
    })
    if isinstance(value, dict):
        for key in sorted(value.keys()):
            describe(value[key], path + "." + str(key), rows, depth + 1)
    elif isinstance(value, list) and len(value) > 0:
        describe(value[0], path + "[0]", rows, depth + 1)

def E01():
    device = torch.device("cuda:0")
    first = torch.empty((8, 1024, 1024), device=device)
    second = torch.empty((4, 1024, 1024), device=device)
    torch.cuda.synchronize(device)
    snapshot = torch.cuda.memory_snapshot()
    schema_rows = []
    describe(snapshot, "snapshot", schema_rows)
    states = set()
    for segment in snapshot:
        for block in segment.get("blocks", []):
            states.add(block.get("state"))
    return schema_rows, sorted(str(state) for state in states)
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare observed keys against the analyzer requirements, not against an unversioned internet example. Verify known payload appears within active block accounting. A one-snapshot schema walker samples the first list element, so audit later elements for optional keys before claiming completeness.

Part 7 - Engineering Interpretation and Philosophy

Schema inspection precedes parser construction. Preserving the raw structure and optional fields prevents a convenient script from becoming a source of false certainty.

19.6.3 Exercise 02

Exercise Title: Enable Allocation History with torch.cuda.memory._record_memory_history() and Explain What Additional Information Becomes Available

Part 1 - Exercise Contract and Why It Matters

Enable allocator history and compare history-disabled and history-enabled snapshots. Determine which frames and device-trace events become available and measure the additional diagnostic value.

Part 2 - System and Memory Mental Model

Topology records the current allocator layout. History records transitions and can attach Python/native stack context. Recording is not free: it consumes host memory, adds bookkeeping, and retains only a bounded number of entries when configured. The leading underscore marks a private/version-sensitive API, so code must detect availability and record the exact PyTorch version.

Part 3 - Quantitative Prediction Before Execution

Predict events for segment acquisition, tensor allocation, requested free, and completed free. Predict that source frames may appear for active blocks and trace actions. Define what history would prove that topology alone cannot: the source and timing of a block's creation or release.

Part 4 - Experimental Design and Instrumentation

Run in a fresh process, enable history before the target workload, use one short deterministic sequence, capture the private full snapshot, then disable recording in a `finally` block. Keep entry count bounded.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def E02():
    device = torch.device("cuda:0")
    recorder = getattr(torch.cuda.memory, "_record_memory_history", None)
    snapshot_function = getattr(torch.cuda.memory, "_snapshot", None)
    if recorder is None or snapshot_function is None:
        raise RuntimeError("This PyTorch build lacks memory-history APIs.")
    try:
        recorder(
            enabled="all",
            context="all",
            stacks="all",
```

```
            max_entries=10000,
            device=device,
        )
        first = torch.empty((16, 1024, 1024), device=device)
        second = first.clone()
        del first
        gc.collect()
        torch.cuda.synchronize(device)
        full_snapshot = snapshot_function()
        del second
        return full_snapshot
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Inspect top-level keys, device traces, event actions, frames, and segment blocks. If keyword arguments are rejected, inspect the installed signature and adapt explicitly; do not catch every exception and silently run without history. Verify entry bound and note whether native stacks require additional build support.

Part 7 - Engineering Interpretation and Philosophy

History converts "this block exists" into "this event created it here." The extra causal power carries overhead and version risk, so history should be enabled around focused investigations rather than left unbounded by habit.

19.6.4 Exercise 03

Exercise Title: Dump a CUDA Memory Snapshot to Disk with _dump_snapshot() and Reproduce the Same Workload from a Clean Process

Part 1 - Exercise Contract and Why It Matters

Create a portable snapshot artifact and reproduce its workload in a clean process. Reproducibility is defined by comparable topology and event patterns, not identical addresses or byte-for-byte pickle equality.

Part 2 - System and Memory Mental Model

`_dump_snapshot()` serializes the full private snapshot representation used by PyTorch memory tooling. It may contain segments, traces, and frames. Addresses can change across processes because allocation placement is not a stable identity. Dump files can contain source paths and should be handled as diagnostic data, not blindly published.

Part 3 - Quantitative Prediction Before Execution

Predict invariant fields across two clean runs: requested shapes, active byte totals at the capture boundary, event categories, and approximate segment layout. Predict non-invariants: raw addresses, timestamps, and initialization noise. Define comparison tolerances before running.

Part 4 - Experimental Design and Instrumentation

Use a script launched twice as separate processes with identical environment, seed, device, and workload. Enable bounded history, synchronize capture, dump to unique filenames, disable recording, and record file size plus cryptographic hash only for integrity, not semantic equality.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

def E03(output_path):
    device = torch.device("cuda:0")
    output = Path(output_path)
    if output.exists():
        raise FileExistsError(str(output))
    torch.manual_seed(101)
    recorder = torch.cuda.memory._record_memory_history
    try:
        recorder(max_entries=20000)
        first = torch.randn((32, 1024, 512), device=device)
        second = torch.relu(first)
        result = second @ torch.randn((512, 256), device=device)
        torch.cuda.synchronize(device)
        torch.cuda.memory._dump_snapshot(str(output))
        checksum = float(result.sum().cpu())
        return {"path": str(output), "checksum": checksum}
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Load both artifacts only with trusted tooling because pickle-like formats can execute unsafe content when deserialized. Compare semantic summaries after normalizing addresses. Verify checksums and environment metadata. If topology differs, distinguish acceptable allocator nondeterminism from a workload or configuration mismatch.

Part 7 - Engineering Interpretation and Philosophy

Reproducibility means preserving the causal experiment and interpreting stable features correctly. Demanding identical addresses would mistake an incidental runtime detail for scientific identity.

19.6.5 Exercise 04

Exercise Title: Parse Snapshot Segments Programmatically and Compute Total Reserved, Active, and Free Space Without Using memory_stats()

Part 1 - Exercise Contract and Why It Matters

Build allocator accounting directly from segment/block topology. This provides an independent cross-check for aggregate counters and forces precise handling of block states.

Part 2 - System and Memory Mental Model

Reserved topology is the sum of segment total sizes. Active space can be derived from active block states or compared with segment active fields. Allocator-free space is the sum of inactive blocks. It is not CUDA-driver free memory and may not be one contiguous region.

Part 3 - Quantitative Prediction Before Execution

For each segment, predict totals for reserved, active-allocated, active-awaiting-free, inactive, requested payload, rounding gap, and largest inactive block. Define consistency equations and error tolerances.

Part 4 - Experimental Design and Instrumentation

Parse a synchronized snapshot, preserve unknown states in a separate bucket, and validate block coverage. Use Python integers. Never call `memory_stats()` inside the primary derivation; perform external cross-validation only after results are frozen.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def parse_snapshot(segments):
    totals = {
        "reserved": 0,
        "active_allocated": 0,
        "active_awaiting_free": 0,
        "inactive": 0,
        "requested": 0,
        "unknown": 0,
        "largest_inactive_block": 0,
    }
    for segment in segments:
        totals["reserved"] += int(segment.get("total_size", 0))
        block_sum = 0
        for block in segment.get("blocks", []):
            size = int(block.get("size", 0))
            requested = int(block.get("requested_size", 0))
            state = block.get("state")
            block_sum += size
            totals["requested"] += requested
            if state == "active_allocated":
                totals["active_allocated"] += size
            elif state == "active_awaiting_free":
                totals["active_awaiting_free"] += size
            elif state == "inactive":
                totals["inactive"] += size
                if size > totals["largest_inactive_block"]:
                    totals["largest_inactive_block"] = size
            else:
                totals["unknown"] += size
```

```
        if block_sum != int(segment.get("total_size", 0)):
            raise ValueError("Block coverage does not match segment size.")
    return totals

def E04():
    device = torch.device("cuda:0")
    value = torch.empty((32, 1024, 1024), device=device)
    torch.cuda.synchronize(device)
    return parse_snapshot(torch.cuda.memory_snapshot())
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that categorized block bytes plus unknown bytes equal reserved bytes. Report allocator-free space and largest free block together. A parser that sees an unknown state must not classify it as inactive. After freezing results, compare reserved/active values with DMM03 counters and explain semantic gaps.

Part 7 - Engineering Interpretation and Philosophy

Independent derivation exposes hidden assumptions in convenience counters. Topology also reveals why total free bytes and allocatable contiguous bytes are different questions.

19.6.6 Exercise 05

Exercise Title: Reconstruct How One CUDA Segment Is Split into Multiple Allocation Blocks and Identify Reusable Free Regions

Part 1 - Exercise Contract and Why It Matters

Select one segment and reconstruct its ordered address map. Identify active, awaiting-free, inactive, and unknown regions, then determine which individual inactive regions can satisfy candidate requests.

Part 2 - System and Memory Mental Model

Free space is geometric. Two inactive 64 MiB blocks separated by an active block provide 128 MiB total slack but not one 128 MiB contiguous block. Allocator splitting, merging, alignment, and stream state determine whether a region is reusable. The snapshot exposes present topology but not a universal guarantee about the next allocation decision.

Part 3 - Quantitative Prediction Before Execution

For one selected segment, compute block start/end addresses, coverage, state totals, largest inactive region, and external fragmentation proxy $1 - L/F$, where F is total inactive space and L its largest block. Define the ratio as zero when $F = 0$.

Part 4 - Experimental Design and Instrumentation

Create overlapping unequal allocations, release alternating objects, and capture after synchronization. Select the segment containing the most blocks, not simply the first segment. Preserve raw order and separately sort by address to verify the source structure.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def reconstruct_segment(segment):
    blocks = sorted(
        segment.get("blocks", []),
        key=lambda block: int(block.get("address", 0)),
    )
    rows = []
    total_inactive = 0
    largest_inactive = 0
    for block in blocks:
        address = int(block.get("address", 0))
        size = int(block.get("size", 0))
        state = block.get("state")
        rows.append({
            "start": address,
            "end": address + size,
            "size": size,
            "state": state,
        })
        if state == "inactive":
            total_inactive += size
            largest_inactive = max(largest_inactive, size)
    fragmentation = 0.0
    if total_inactive > 0:
        fragmentation = 1.0 - largest_inactive / total_inactive
    return rows, total_inactive, largest_inactive, fragmentation

def E05():
    segments = torch.cuda.memory_snapshot()
    if len(segments) == 0:
        raise RuntimeError("No allocator segments are present.")
    selected = max(segments, key=lambda item: len(item.get("blocks", [])))
    return reconstruct_segment(selected)
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert consecutive address ranges do not overlap and remain inside the segment. Test candidate sizes against largest inactive block, not total inactive bytes. Do not label every inactive block immediately reusable across streams. If the selected segment has one block, redesign the workload; topology cannot be studied when splitting did not occur.

Part 7 - Engineering Interpretation and Philosophy

Memory availability is shape and location, not only quantity. Segment maps transform an abstract “free MiB” number into the exact spatial constraint that determines whether a large request can fit.

19.6.7 Exercise 06

Exercise Title: Trace a CUDA Allocation Back to the Python Source Line That Created the Tensor Using Recorded Stack Frames

Part 1 - Exercise Contract and Why It Matters

Connect one active block to the Python call site that created it. The result must distinguish user frames from PyTorch internals and preserve the full stack for auditability.

Part 2 - System and Memory Mental Model

History recording can attach frames to allocation events or active blocks. Frames may contain filename, line number, and function name. The top frame is not always the most useful user frame; wrappers, module calls, and dispatcher layers can intervene. Stack availability depends on recording configuration and build support.

Part 3 - Quantitative Prediction Before Execution

Create allocation through a named helper and predict that its file and line appear in a recorded stack. Define a user-frame selector that excludes known library prefixes but returns the full stack when no user frame is found.

Part 4 - Experimental Design and Instrumentation

Enable context/stacks before calling the helper. Tag the allocation by its unique requested size, capture while it remains live, and locate candidate blocks. Use requested size as a filter, not a globally unique identity.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def allocation_site(device):
    return torch.empty((13, 1024, 1024), device=device)

def candidate_frames(snapshot, requested_bytes):
    candidates = []
    for segment in snapshot.get("segments", []):
        for block in segment.get("blocks", []):
            if block.get("state") != "active_allocated":
                continue
            if int(block.get("requested_size", -1)) != requested_bytes:
                continue
            candidates.append({
                "address": block.get("address"),
                "frames": block.get("frames", []),
            })
    return candidates

def E06():
    device = torch.device("cuda:0")
    recorder = torch.cuda.memory._record_memory_history
```

```
    try:
        recorder(context="all", stacks="all", max_entries=10000)
        value = allocation_site(device)
        torch.cuda.synchronize(device)
        snapshot = torch.cuda.memory._snapshot()
        requested = value.numel() * value.element_size()
        return candidate_frames(snapshot, requested)
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify at least one candidate includes the helper filename and line. If several blocks share requested size, use event order or a second distinguishing allocation. Missing frames require checking recorder options and build support; do not invent a call site from current Python variables.

Part 7 - Engineering Interpretation and Philosophy

Source attribution turns allocator evidence into an actionable repair location. It is strongest when the raw stack remains available and the frame-selection heuristic can be challenged.

19.6.8 Exercise 07

Exercise Title: Follow One Tensor Through Allocation, free_requested, and free_completed Events and Explain Why Those Events Can Occur at Different Times

Part 1 - Exercise Contract and Why It Matters

Trace one allocation through logical release and physical reuse eligibility. Explain why Python deletion can request a free before CUDA completes work that uses the storage.

Part 2 - System and Memory Mental Model

CUDA execution is asynchronous. When the final Python reference disappears, the allocator may record `free_requested`; the block can remain `active_awaiting_free` until stream work finishes. A later `free_completed` event marks completion. Immediate synchronization can collapse the interval and hide the phenomenon.

Part 3 - Quantitative Prediction Before Execution

Launch a long operation using a tensor, delete its Python reference without host synchronization, and capture history. Predict allocation, free request, then completion after explicit synchronization. Identify the allocation by address/request size and sequence order.

Part 4 - Experimental Design and Instrumentation

Use a dedicated CUDA stream and events rather than an uncontrolled sleep. Record history before allocation, capture once before stream synchronization and again after. Do not access the deleted tensor. Repeat with default-stream synchronization as a control.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def E07():
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    recorder = torch.cuda.memory._record_memory_history
    try:
        recorder(context="all", max_entries=20000)
        with torch.cuda.stream(stream):
            value = torch.randn((4096, 4096), device=device)
            result = value @ value
        del value
        gc.collect()
        before_completion = torch.cuda.memory._snapshot()
        stream.synchronize()
        after_completion = torch.cuda.memory._snapshot()
        del result
        return before_completion, after_completion
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Search device traces for event actions and correlate addresses. If no awaiting- free interval appears, the operation may have completed too quickly or allocator stream semantics may differ. Increase controlled work, not arbitrary host delay. Ensure snapshot capture itself does not synchronize in a way that erases the window; document observed behavior.

Part 7 - Engineering Interpretation and Philosophy

Object lifetime and device safety are separate clocks. Understanding their boundary prevents false leak diagnoses and unsafe assumptions about when a deleted allocation becomes reusable.

19.6.9 Exercise 08

Exercise Title: Generate Multiple Snapshots During Forward, Backward, Optimizer Step, and Gradient Reset and Reconstruct the Training Memory Lifecycle

Part 1 - Exercise Contract and Why It Matters

Capture topology at every training boundary and reconstruct which blocks appear, persist, or disappear. This extends DMM03 counters into segment-level evidence.

Part 2 - System and Memory Mental Model

Parameters persist across all stages. Forward activations survive for backward. Backward creates gradients and temporaries. The first AdamW step creates persistent state. Gradient reset with `set_to_none=True` can release gradient storage into cache. Snapshots reveal each state as block topology.

Part 3 - Quantitative Prediction Before Execution

Predict active requested bytes, active block count, inactive bytes, and segment count at before-forward, after-forward, after-loss, after-backward, after-step, and after-zero-grad. Separate first and second iterations.

Part 4 - Experimental Design and Instrumentation

Synchronize every capture and store raw CPU snapshot structures with stage names. Do not include them in the autograd graph. Use one fixed batch and reset peak statistics only before the full timeline, not between stages.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def capture(stage, device):
    torch.cuda.synchronize(device)
    return {"stage": stage, "segments": torch.cuda.memory_snapshot()}

def E08():
    device = torch.device("cuda:0")
    model = torch.nn.Sequential(
        torch.nn.Linear(2048, 4096),
        torch.nn.GELU(),
        torch.nn.Linear(4096, 1000),
    ).to(device)
    optimizer = torch.optim.AdamW(model.parameters(), lr=0.0003)
    inputs = torch.randn((128, 2048), device=device)
    targets = torch.randint(0, 1000, (128,), device=device)
    snapshots = [capture("before_forward", device)]
    output = model(inputs)
    snapshots.append(capture("after_forward", device))
    loss = torch.nn.functional.cross_entropy(output, targets)
    snapshots.append(capture("after_loss", device))
    loss.backward()
    snapshots.append(capture("after_backward", device))
    optimizer.step()
    snapshots.append(capture("after_optimizer", device))
    optimizer.zero_grad(set_to_none=True)
    snapshots.append(capture("after_zero_grad", device))
    return snapshots
```

Part 6 - Measurement, Validation, and Failure Analysis

Summarize every snapshot using E04 and diff adjacent stages by block address only within the same process. Confirm first-step optimizer state persists. Delete `output` and `loss` in a second run to test whether user references affect after-zero-grad topology. Numerical validation must accompany memory analysis.

Part 7 - Engineering Interpretation and Philosophy

Snapshots convert a training step into a sequence of ownership states. The question is no longer merely where the peak is, but which semantic stage and specific block lifetime produced it.

19.6.10 Exercise 09

Exercise Title: Create an Irregular Allocation Pattern and Locate Inactive Space Trapped Inside Partially Used CUDA Segments

Part 1 - Exercise Contract and Why It Matters

Create a bounded irregular pattern and identify inactive blocks inside segments that still contain active blocks. These segments cannot be returned wholesale to CUDA while any contained active block remains.

Part 2 - System and Memory Mental Model

A completely inactive segment may be eligible for cache release. Inactive blocks inside a partially active segment are trapped at segment granularity: the allocator may reuse them, but cannot return the entire segment while active neighbors remain. This is distinct from a live tensor leak.

Part 3 - Quantitative Prediction Before Execution

Allocate alternating unequal tensors and retain every other one. Predict partially active segments, trapped inactive bytes, largest trapped block, and trapped ratio. Keep total live payload below 30 percent of free VRAM.

Part 4 - Experimental Design and Instrumentation

Capture before and after releasing alternating objects. Classify a segment as partially active when it contains at least one active state and one inactive block. Compare with a stable-shape control in a fresh process.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def trapped_space(segments):
    rows = []
    for index, segment in enumerate(segments):
        active = 0
        inactive = 0
        largest_inactive = 0
        for block in segment.get("blocks", []):
            size = int(block.get("size", 0))
            state = block.get("state")
            if state == "inactive":
                inactive += size
                largest_inactive = max(largest_inactive, size)
            elif str(state).startswith("active"):
                active += size
```

```
        if active > 0 and inactive > 0:
            rows.append({
                "segment_index": index,
                "active": active,
                "trapped_inactive": inactive,
                "largest_inactive": largest_inactive,
                "total_size": segment.get("total_size"),
            })
    return rows

def E09():
    device = torch.device("cuda:0")
    sizes_mib = [73, 119, 83, 137, 97, 151, 107, 173]
    tensors = []
    for size_mib in sizes_mib:
        count = size_mib * 1024 * 1024 // 4
        tensors.append(torch.empty(count, device=device))
    index = len(tensors) - 1
    while index >= 0:
        if index % 2 == 1:
            del tensors[index]
        index -= 1
    gc.collect()
    torch.cuda.synchronize(device)
    return trapped_space(torch.cuda.memory_snapshot())
```

Part 6 - Measurement, Validation, and Failure Analysis

Sum trapped space without double-counting segments. Verify each reported segment has both state classes. If the allocator placed every allocation in a separate segment, the pattern failed to create trapped space; change sizes and overlap rather than relabeling completely inactive segments.

Part 7 - Engineering Interpretation and Philosophy

Segment-level returnability and block-level reusability are different. A useful diagnosis states which layer is constrained and whether future requests can use the trapped regions.

19.6.11 Exercise 10

Exercise Title: Visualize a Recorded Snapshot with PyTorch Memory Visualizer and Correlate Timeline Peaks with Source-Level Allocations

Part 1 - Exercise Contract and Why It Matters

Load a trusted snapshot into the official PyTorch memory visualization workflow and convert visual peaks into source-level explanations. A screenshot alone is not the deliverable; every highlighted region must be correlated with event, size, address, phase, and stack evidence.

Part 2 - System and Memory Mental Model

The visualizer presents allocator state history and segment maps from the dumped snapshot. The active-memory timeline emphasizes allocations over time, while allocator-state history emphasizes segment/block layout at selected events. PyTorch's profiler sees only memory managed by the PyTorch allocator, so device usage outside it is absent. The official documentation currently directs users to the PyTorch memory visualizer for saved snapshots.

Part 3 - Quantitative Prediction Before Execution

Before loading the file, predict the largest three allocation events from tensor shapes and dtypes. Calculate their payloads and expected training phase. Define how you will verify each visual peak from raw trace entries.

Part 4 - Experimental Design and Instrumentation

Generate one bounded history dump with named workload phases and source stacks. Treat snapshot files as sensitive because paths and code locations may appear. Use only the official visualizer or a trusted local analyzer; never upload confidential traces to an untrusted site.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import torch

def E10(output_path):
    path = Path(output_path)
    if path.exists():
        raise FileExistsError(str(path))
    device = torch.device("cuda:0")
    recorder = torch.cuda.memory._record_memory_history
    try:
        recorder(context="all", stacks="all", max_entries=50000)
        first = torch.randn(
            (4096, 4096),
            device=device,
            requires_grad=True,
        )
        second = torch.relu(first)
        third = first @ second
        loss = third.square().mean()
        loss.backward()
        torch.cuda.synchronize(device)
        torch.cuda.memory._dump_snapshot(str(path))
        return str(path)
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Select each major visual peak, read its stack, and match its requested size to the precomputed payload. Explain gaps caused by block rounding or temporary workspace. If a device-level memory peak lacks a visualizer event, investigate non-PyTorch allocation rather

than assuming the file is corrupted. Preserve a table of visual claim, raw event, and source frame.

Part 7 - Engineering Interpretation and Philosophy

Visualization accelerates pattern recognition, but raw evidence must remain the authority. A persuasive memory analysis can move from a picture to the exact event and code line that created the pressure.

19.6.12 Exercise 11

Exercise Title: Use Allocator State History to Explain Why a Large Allocation Can Fail Even When Significant Reserved Memory Still Exists

Part 1 - Exercise Contract and Why It Matters

Construct a topology in which aggregate inactive space is substantial but the largest contiguous inactive block is smaller than a proposed request. Use history to explain how the layout formed.

Part 2 - System and Memory Mental Model

Reserved memory includes active and inactive blocks across segments. A large request needs a suitable block or new driver capacity. Many small inactive regions cannot be combined across active barriers or independent segments. Therefore reserved-minus-allocated is not an allocatable-block guarantee.

Part 3 - Quantitative Prediction Before Execution

At the pre-request snapshot compute total inactive F, largest inactive block L, driver free D, and proposed request Q. Fragmentation suspicion is strongest when $F \geq Q$, $L < Q$, and $D < Q$. Predict retry or OOM events but treat them as outcomes to observe.

Part 4 - Experimental Design and Instrumentation

Build pressure gradually in a disposable subprocess, never exceeding a predeclared safety schedule until the final controlled probe. Capture topology immediately before the probe and history immediately after success/failure. Run a same-total-free but fixed-shape control.

Part 5 - PyTorch/CUDA Implementation

```
def largest_inactive(segments):
    total = 0
    largest = 0
    for segment in segments:
        for block in segment.get("blocks", []):
            if block.get("state") == "inactive":
                size = int(block.get("size", 0))
                total += size
                largest = max(largest, size)
    return total, largest

def explain_fit(snapshot, request_bytes, driver_free_bytes):
    segments = snapshot.get("segments", snapshot)
```

```
    total, largest = largest_inactive(segments)
    return {
        "request": request_bytes,
        "total_inactive": total,
        "largest_inactive": largest,
        "driver_free": driver_free_bytes,
        "aggregate_slack_enough": total >= request_bytes,
        "single_cached_block_fits": largest >= request_bytes,
        "driver_can_extend": driver_free_bytes >= request_bytes,
    }

def E11(snapshot, request_bytes, driver_free_bytes):
    return explain_fit(snapshot, request_bytes, driver_free_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not claim causality unless the pre-request topology satisfies the predicted conditions and the trace records the failed/retried request. Consider stream- awaiting blocks and external allocations. A successful request despite the simple fit test reveals allocator recovery or segment acquisition and must be explained from subsequent events.

Part 7 - Engineering Interpretation and Philosophy

Capacity planning needs the size distribution of free regions, not just their sum. Snapshot topology supplies the missing geometric evidence behind many apparently contradictory OOM messages.

19.6.13 Exercise 12

Exercise Title: Trigger a Controlled CUDA OOM and Reconstruct the Allocator State Immediately Before the Failed Allocation

Part 1 - Exercise Contract and Why It Matters

Capture a pre-failure snapshot, trigger exactly one deliberate OOM, and join the recorded OOM event with the topology that existed immediately before the request. Run only in a disposable process on an idle GPU.

Part 2 - System and Memory Mental Model

The snapshot taken before the probe records available blocks and live state. History records the failed request. The exception describes requested capacity and allocator/device summary. None alone proves root cause; together they show what the allocator had, what was requested, and how the request ended.

Part 3 - Quantitative Prediction Before Execution

Request slightly more than current driver-free memory. Predict an OOM history event and at least one OOM counter increment. Calculate pre-failure largest free block, total inactive space, active bytes, and driver free. This basic test is capacity-driven; a separate fragmented pattern is required to study fragmentation-driven failure.

Part 4 - Experimental Design and Instrumentation

Enable bounded history, synchronize, capture pre-state, then attempt the probe. Inside the OOM handler capture the post-failure private snapshot and exception text. Do not continue computation after evidence collection; terminate the subprocess and use a fresh process for later experiments.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E12():
    device = torch.device("cuda:0")
    recorder = torch.cuda.memory._record_memory_history
    try:
        recorder(context="all", stacks="all", max_entries=50000)
        baseline = torch.empty((16, 1024, 1024), device=device)
        torch.cuda.synchronize(device)
        before = torch.cuda.memory._snapshot()
        free_bytes, _ = torch.cuda.mem_get_info(device)
        request_bytes = free_bytes + 256 * 1024 * 1024
        try:
            impossible = torch.empty(request_bytes // 4, device=device)
            del impossible
        except torch.OutOfMemoryError as error:
            after = torch.cuda.memory._snapshot()
            return {
                "request_bytes": request_bytes,
                "before": before,
                "after": after,
                "error": str(error),
            }
        raise RuntimeError("The controlled OOM did not occur.")
    finally:
        recorder(enabled=None)
```

Part 6 - Measurement, Validation, and Failure Analysis

Locate the OOM action in device traces and match its requested size. Compare pre/post segment topology and confirm intended baseline remains live. If the allocation unexpectedly succeeds, the free-memory reading changed or another mechanism supplied capacity; discard the run instead of forcing a second huge allocation in the same process.

Part 7 - Engineering Interpretation and Philosophy

Controlled failure analysis freezes the last healthy state and the failed request into one causal record. Isolation protects both the GPU session and the validity of all subsequent experiments.

19.6.14 Exercise 13

Exercise Title: Compare Snapshots Before and After torch.cuda.empty_cache() and Identify Exactly Which Segments Can Be Returned to CUDA

Part 1 - Exercise Contract and Why It Matters

Determine which segments disappear after cache release and explain why partially active segments remain. Avoid the incorrect claim that all inactive blocks are individually returned to CUDA.

Part 2 - System and Memory Mental Model

`empty_cache()` can release eligible unused cached segments. A segment containing any active or awaiting-free block generally cannot be returned as a whole. Inactive blocks inside it may remain available to PyTorch even after the call.

Part 3 - Quantitative Prediction Before Execution

Classify each pre-call segment as fully inactive, partially active, or fully active. Predict fully inactive segment addresses to disappear and active-bearing segments to persist. Calculate returned bytes from vanished segment totals.

Part 4 - Experimental Design and Instrumentation

Create both completely released and deliberately retained tensors. Synchronize before the first snapshot, call cache release, synchronize again, and capture the second. Compare within one process so addresses are meaningful identities.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import torch

def segment_map(segments):
    result = {}
    for segment in segments:
        address = int(segment.get("address", 0))
        states = []
        for block in segment.get("blocks", []):
            states.append(block.get("state"))
        result[address] = {
            "total_size": int(segment.get("total_size", 0)),
            "states": states,
        }
    return result

def E13():
    device = torch.device("cuda:0")
    retained = torch.empty((32, 1024, 1024), device=device)
    released = torch.empty((64, 1024, 1024), device=device)
    del released
    gc.collect()
    torch.cuda.synchronize(device)
    before = segment_map(torch.cuda.memory_snapshot())
    torch.cuda.empty_cache()
    torch.cuda.synchronize(device)
```

```
    after = segment_map(torch.cuda.memory_snapshot())
    vanished = []
    for address in before:
        if address not in after:
            vanished.append((address, before[address]))
    return before, after, vanished
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify every vanished segment was fully inactive in the pre-snapshot. If a mixed-state segment vanishes, inspect state semantics and synchronization. Report returned bytes and driver-free change; external activity may disturb the latter. If no segment vanishes, the released block may share a segment with the retained allocation.

Part 7 - Engineering Interpretation and Philosophy

Cache release operates at allocator ownership boundaries. Snapshot diffs show why "inactive bytes exist" and "CUDA can reclaim these bytes now" are not equivalent statements.

19.6.15 Exercise 14

Exercise Title: Detect a Persistent Tensor Reference by Comparing Two Memory Snapshots Taken Hundreds of Training Steps Apart

Part 1 - Exercise Contract and Why It Matters

Detect allocations that persist unexpectedly across hundreds of steps and trace them to source. Separate legitimate long-lived parameters/optimizer state from accidentally retained outputs or losses.

Part 2 - System and Memory Mental Model

Within one process, a block address that remains active in both snapshots is a persistence candidate. Persistence alone is not a leak: model parameters should persist. Source frames, requested size, creation time, and growth of candidate count distinguish intended state from a container that accumulates tensors.

Part 3 - Quantitative Prediction Before Execution

Predict stable parameter/state candidates and one deliberately retained loss per step. Compare snapshots at steps 10 and 300. Predict candidate count and requested-byte growth, then define allowlists by source/function rather than raw address.

Part 4 - Experimental Design and Instrumentation

Enable history before model creation so parameter stacks are available. Capture at equivalent post-zero-grad boundaries. Store only snapshot data. Run correct and leaking versions from fresh processes and blind the analyzer to labels.

Part 5 - PyTorch/CUDA Implementation

```
def active_allocations(snapshot):
    result = {}
    segments = snapshot.get("segments", snapshot)
    for segment in segments:
        for block in segment.get("blocks", []):
            if block.get("state") != "active_allocated":
                continue
            address = int(block.get("address", 0))
            result[address] = {
                "size": int(block.get("size", 0)),
                "requested_size": int(block.get("requested_size", 0)),
                "frames": block.get("frames", []),
            }
    return result

def E14(early_snapshot, late_snapshot):
    early = active_allocations(early_snapshot)
    late = active_allocations(late_snapshot)
    persistent = {}
    new_late = {}
    for address, block in late.items():
        if address in early:
            persistent[address] = block
        else:
            new_late[address] = block
    return {"persistent": persistent, "new_late": new_late}
```

Part 6 - Measurement, Validation, and Failure Analysis

Rank new late allocations by source frame and requested bytes. Reused addresses can represent different lifetimes, so consult event history before declaring identity. Apply the suspected reference fix, repeat from a clean process, and require the unexpected source group to disappear while training outputs remain correct.

Part 7 - Engineering Interpretation and Philosophy

Leak detection is intent-aware lifetime analysis. The strongest proof joins cross-time persistence, creation source, accumulation pattern, and disappearance after a semantics-preserving fix.

19.6.16 Exercise 15

Exercise Title: Distinguish PyTorch-Managed CUDA Memory from Non-PyTorch GPU Allocations by Comparing Snapshot Data with Device-Level Memory Usage

Part 1 - Exercise Contract and Why It Matters

Estimate the gap between memory represented by PyTorch allocator segments and device-level memory used by the process/device. Demonstrate why a complete snapshot can still omit NCCL, CUDA libraries, custom extensions, or other direct CUDA allocations.

Part 2 - System and Memory Mental Model

Snapshot segment totals describe PyTorch caching-allocator ownership. Driver- level usage includes CUDA context and allocations made outside that allocator. System-wide device usage can also include other processes. Therefore

$$M_{device} - M_{snapshot}$$

is an unexplained gap, not automatically "non-PyTorch tensor memory." Scope and baseline must be defined before interpreting it.

Part 3 - Quantitative Prediction Before Execution

Predict baseline context gap, then allocate a known PyTorch tensor and expect both snapshot-reserved and device-used values to rise. Add a controlled external allocator only if a trusted library is available and predict device usage to rise without matching snapshot growth.

Part 4 - Experimental Design and Instrumentation

Use an idle GPU or process-scoped NVML measurement. Capture synchronized snapshot totals and `mem_get_info()` at identical boundaries. Record other processes and library initialization. Repeat in a fresh process because context cost is a baseline state.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def snapshot_reserved(device):
    torch.cuda.synchronize(device)
    total = 0
    for segment in torch.cuda.memory_snapshot():
        if int(segment.get("device", device.index)) == device.index:
            total += int(segment.get("total_size", 0))
    return total

def device_used(device):
    free_bytes, total_bytes = torch.cuda.mem_get_info(device)
    return total_bytes - free_bytes

def measurement(label, device):
    return {
        "label": label,
        "snapshot_reserved": snapshot_reserved(device),
        "device_used": device_used(device),
        "unexplained_gap": device_used(device) - snapshot_reserved(device),
    }

def E15():
    device = torch.device("cuda:0")
    baseline = measurement("baseline", device)
    value = torch.empty((64, 1024, 1024), device=device)
```

```
    pytorch_live = measurement("pytorch_live", device)
    return baseline, pytorch_live
```

Part 6 - Measurement, Validation, and Failure Analysis

Avoid calling `device_used()` twice in production code because another process can change the value between reads; the skeleton emphasizes readability and should cache one reading. System-wide usage is not process attribution. Use NVML process accounting for stronger isolation when available. A negative gap indicates inconsistent scope/timing or parser error and must not be clipped.

Part 7 - Engineering Interpretation and Philosophy

Every observability system has a boundary. Comparing independent scopes exposes what the snapshot cannot see and prevents a clean PyTorch topology from being mistaken for a complete device-memory explanation.

19.6.17 Exercise 16

Exercise Title: Limit Memory-History Recording with max_entries and Measure the Accuracy, Storage Cost, and Runtime Overhead Trade-Off

Part 1 - Exercise Contract and Why It Matters

Measure how bounded history changes event coverage, dump size, host memory, and runtime. Choose a recording limit that preserves the failure window without unbounded diagnostic cost.

Part 2 - System and Memory Mental Model

History uses a finite entry buffer. When events exceed `max_entries`, older evidence may be unavailable according to implementation behavior. More entries improve temporal coverage but increase host storage and dump size; stack collection adds further overhead. The snapshot of current topology can remain accurate even when early history is truncated.

Part 3 - Quantitative Prediction Before Execution

Test 1,000, 10,000, and 100,000 entries on the same deterministic allocation loop. Predict event count ceiling, first/last represented workload phase, file size, runtime, and host-memory cost. Define accuracy as retention of known marker allocations, not merely a larger file.

Part 4 - Experimental Design and Instrumentation

Run each limit in a fresh process with identical workload and output location. Time baseline without recording, history without stacks, and history with stacks. Synchronize workload boundaries, not every allocation. Record dump size and trace-event count.

Part 5 - PyTorch/CUDA Implementation

```
from pathlib import Path
import time
import torch

def run_limit(max_entries, output_path):
```

```
    device = torch.device("cuda:0")
    path = Path(output_path)
    recorder = torch.cuda.memory._record_memory_history
    start = time.perf_counter()
    try:
        recorder(context="all", stacks="python", max_entries=max_entries)
        for iteration in range(5000):
            size = 1024 + (iteration % 97) * 256
            value = torch.empty(size, device=device)
            del value
        torch.cuda.synchronize(device)
        snapshot = torch.cuda.memory._snapshot()
        torch.cuda.memory._dump_snapshot(str(path))
        elapsed = time.perf_counter() - start
        event_count = 0
        for trace in snapshot.get("device_traces", []):
            event_count += len(trace)
        return {
            "max_entries": max_entries,
            "event_count": event_count,
            "seconds": elapsed,
            "file_bytes": path.stat().st_size,
        }
    finally:
        recorder(enabled=None)

def E16(output_directory):
    rows = []
    for limit in [1000, 10000, 100000]:
        path = Path(output_directory) / ("history_" + str(limit) + ".pickle")
        rows.append(run_limit(limit, path))
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

The sequential skeleton shares process cache and should be converted to subprocess trials for rigorous timing. Verify marker events near beginning, middle, and end. File size alone does not measure diagnostic accuracy. Report median runtime across repetitions and distinguish snapshot serialization time from recording overhead.

Part 7 - Engineering Interpretation and Philosophy

Observability budgets are engineering choices. The correct limit retains enough history to explain the incident while keeping continuous instrumentation safe for the system it is meant to protect.

19.6.18 Exercise 17

Exercise Title: Build a Python Snapshot Analyzer That Ranks Segments by Wasted Space, Allocation Count, and Largest Contiguous Free Block

Part 1 - Exercise Contract and Why It Matters

Build a reusable segment analyzer that ranks memory pressure by several orthogonal dimensions. Preserve raw values so ranking logic remains auditable.

Part 2 - System and Memory Mental Model

Segment waste can mean inactive bytes, rounding gap between active block size and requested payload, or free space trapped beside active blocks. Allocation count describes block multiplicity. Largest contiguous inactive block describes fit capability. No single ranking captures all three.

Part 3 - Quantitative Prediction Before Execution

For each segment compute total, active, inactive, requested, rounding waste, active block count, inactive block count, largest inactive block, and external fragmentation proxy. Define three separate ranking outputs.

Part 4 - Experimental Design and Instrumentation

Validate analyzer first on hand-written synthetic snapshots with known answers, then on a real snapshot. Preserve unknown states and validate block coverage. Never mutate the raw snapshot while sorting derived rows.

Part 5 - PyTorch/CUDA Implementation

```
def analyze_segment(index, segment):
    active = 0
    inactive = 0
    requested = 0
    active_count = 0
    largest_free = 0
    for block in segment.get("blocks", []):
        size = int(block.get("size", 0))
        state = block.get("state")
        if str(state).startswith("active"):
            active += size
            requested += int(block.get("requested_size", 0))
            active_count += 1
        elif state == "inactive":
            inactive += size
            largest_free = max(largest_free, size)
    fragmentation = 0.0
    if inactive > 0:
        fragmentation = 1.0 - largest_free / inactive
    return {
        "index": index,
        "address": segment.get("address"),
        "total": int(segment.get("total_size", 0)),
        "active": active,
        "inactive": inactive,
        "rounding_waste": active - requested,
```

```
        "active_count": active_count,
        "largest_free": largest_free,
        "fragmentation": fragmentation,
    }

def E17(segments):
    rows = []
    for index, segment in enumerate(segments):
        rows.append(analyze_segment(index, segment))
    by_waste = sorted(rows, key=lambda row: row["inactive"], reverse=True)
    by_count = sorted(rows, key=lambda row: row["active_count"], reverse=True)
    by_fit = sorted(rows, key=lambda row: row["largest_free"], reverse=True)
    return {"by_waste": by_waste, "by_count": by_count, "by_fit": by_fit}
```

Part 6 - Measurement, Validation, and Failure Analysis

Check that active plus inactive plus unknown equals segment total. The skeleton must be extended with an unknown-state field before production use. Test ties, empty segments, absent requested sizes, and zero inactive space. Compare top rankings with the visualizer but keep programmatic numbers authoritative.

Part 7 - Engineering Interpretation and Philosophy

Ranking is triage. Separate lists prevent a large-but-healthy cached segment from being conflated with a highly fragmented segment that cannot fit the next critical request.

19.6.19 Exercise 18

Exercise Title: Build a Snapshot-Diff Tool That Identifies New, Released, Persistent, and Growing CUDA Allocations Between Two Execution Points

Part 1 - Exercise Contract and Why It Matters

Compare two snapshots from the same process and classify active allocations as new, released, persistent, or changed. Avoid using address identity blindly when history shows address reuse.

Part 2 - System and Memory Mental Model

Within one process, address plus allocation event identity is stronger than address alone. A block can be freed and a later allocation reuse the same address; an address-only diff would falsely call it persistent. History event sequence or stack/request metadata must resolve ambiguous reuse.

Part 3 - Quantitative Prediction Before Execution

Construct synthetic snapshots containing one member of each class. Treat a changed or growing allocation as the same verified identity with changed requested size only if the schema permits it; ordinary tensor storage usually does not grow in place, so address reuse is a competing explanation.

Part 4 - Experimental Design and Instrumentation

Capture equivalent synchronized boundaries and retain device traces spanning both. First perform topology diff, then annotate ambiguous addresses from event history. Return evidence fields with every classification.

Part 5 - PyTorch/CUDA Implementation

```
def active_map(snapshot):
    result = {}
    segments = snapshot.get("segments", snapshot)
    for segment in segments:
        for block in segment.get("blocks", []):
            if block.get("state") != "active_allocated":
                continue
            address = int(block.get("address", 0))
            result[address] = {
                "size": int(block.get("size", 0)),
                "requested": int(block.get("requested_size", 0)),
                "frames": block.get("frames", []),
            }
    return result

def E18(first_snapshot, second_snapshot):
    first = active_map(first_snapshot)
    second = active_map(second_snapshot)
    result = {"new": {}, "released": {}, "persistent": {}, "changed": {}}
    for address, old_block in first.items():
        if address not in second:
            result["released"][address] = old_block
        else:
            new_block = second[address]
            if old_block["requested"] == new_block["requested"]:
                result["persistent"][address] = new_block
            else:
                result["changed"][address] = {
                    "before": old_block,
                    "after": new_block,
                    "requires_history_check": True,
                }
    for address, new_block in second.items():
        if address not in first:
            result["new"][address] = new_block
    return result
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate on synthetic fixtures and a known live workload. Every changed address must be checked against free/allocation events; reclassify reused addresses as released plus new. Summarize bytes and counts by source frame. Cross-process snapshots cannot use raw addresses this way and require normalized signatures.

Part 7 - Engineering Interpretation and Philosophy

A diff is only as sound as its identity rule. Combining topology with history prevents a convenient address match from becoming a false lifetime claim.

19.6.20 Exercise 19

Exercise Title: Diagnose a Hidden CUDA Memory Failure Using Only Allocation History, Stack Traces, Segment Layouts, and OOM Events from a PyTorch Snapshot

Part 1 - Exercise Contract and Why It Matters

Perform a blind end-to-end diagnosis from one snapshot artifact. Use no source inspection initially. Produce a ranked root-cause report, competing hypotheses, falsification tests, and a predicted topology change after repair.

Part 2 - System and Memory Mental Model

Evidence families include segment geometry, active/inactive/awaiting states, allocation/free event history, OOM requests, and source stacks. Candidate causes include retained tensors, variable-shape fragmentation, asynchronous delayed free, capacity exhaustion, optimizer lazy state, and non-PyTorch memory. A snapshot cannot directly see the last category, so unexplained device-level gap must remain a hypothesis.

Part 3 - Quantitative Prediction Before Execution

Build a diagnostic matrix. For each candidate predict active growth, persistent source groups, inactive distribution, largest-free-block relation to OOM size, awaiting-free presence, retry sequence, and driver gap. Define confidence from independent evidence count, not intuition.

Part 4 - Experimental Design and Instrumentation

Freeze the raw artifact and hash it. Parse with version-aware schema checks. Reconstruct the event window before OOM, locate the failed size, compute segment fit, group active allocations by normalized stack, and identify delayed frees. Write the report before revealing the injected failure.

Part 5 - PyTorch/CUDA Implementation

```
def find_oom_events(snapshot):
    events = []
    for device_index, trace in enumerate(snapshot.get("device_traces", [])):
        for event_index, event in enumerate(trace):
            action = str(event.get("action", ""))
            if "oom" in action.lower():
                events.append({
                    "device": device_index,
                    "event_index": event_index,
                    "event": event,
                })
    return events
```

```
def diagnose(snapshot):
    segments = snapshot.get("segments", [])
    total_free, largest_free = largest_inactive(segments)
    ooms = find_oom_events(snapshot)
    return {
        "segment_count": len(segments),
        "total_inactive": total_free,
        "largest_inactive": largest_free,
        "oom_events": ooms,
        "next_analyses": [
            "group_active_allocations_by_stack",
            "match_failed_request_to_largest_free_block",
            "inspect_awaiting_free_blocks",
            "compare_snapshot_reserved_to_device_usage",
        ],
    }

def E19(snapshot):
    return diagnose(snapshot)
```

Part 6 - Measurement, Validation, and Failure Analysis

The skeleton is triage; the final analysis must implement every listed step. Require each conclusion to cite event index, block/segment evidence, and source frame. Reveal the hidden failure, measure diagnostic accuracy, apply the fix, and reproduce the predicted reduction in persistent allocations, fragmentation, or delayed-free state. Record unresolved ambiguity explicitly.

Part 7 - Engineering Interpretation and Philosophy

Expert diagnosis is a chain of evidence that survives challenge. Snapshot history supplies time, layout supplies geometry, stacks supply responsibility, and OOM events supply the failed demand. Their intersection is far stronger than any one counter or visual impression.

19.7 DMM05

Chapter Title: Pinned Memory and Page-Locked Host Buffers
Specialization: Dynamic Memory Management and CUDA Systems

19.7.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Pageable RAM, Pinned Memory, DMA, and Host-to-GPU Transfer Paths

Part 1 - Exercise Contract and Why It Matters

This exercise establishes the physical model needed for every later benchmark. You must distinguish ordinary pageable host memory, page-locked host memory, device memory, the CUDA driver, and the DMA engine. The deliverable is not the slogan “pinned is faster.” It is a causal explanation of what work occurs, which component performs it, and when the host

is allowed to continue. A good model must also explain why pinning can improve a pipeline, harm a one-shot copy, or exhaust an important operating-system resource.

Part 2 - System and Memory Mental Model

Virtual CPU pages normally may be relocated or swapped. A device DMA engine cannot safely read from a page whose physical location may change during the transfer. For a pageable source, the CUDA runtime may therefore stage the bytes through a temporary page-locked region before DMA moves them across the host– device interconnect. A pinned tensor already occupies stable physical pages, removing that staging requirement and permitting asynchronous DMA submission.

Pinning is not free. Page locking requires operating-system work, consumes a finite host resource, and reduces the memory available for paging decisions. Moreover, `non_blocking=True` means the host need not wait after copy submission; it does not prove that copy and compute overlap. True overlap needs a pinned source, a capable device, suitable CUDA streams, independent work, and correct event dependencies. Default-stream serialization can erase the gain.

Part 3 - Quantitative Prediction Before Execution

For a tensor with dimensions $n_1, \ldots, n_k$ and element width w bytes, predict

$$B = w \prod_{i=1}^{k} n_i.$$

If a 256 MiB float32 batch contains 67,108,864 elements, estimate the ideal transfer time as $t = B/R$ for an assumed effective bandwidth R. Then add a fixed submission cost and a page-locking cost. Predict separately: copy-only latency from pre-pinned memory, pageable copy latency, and end-to-end “allocate, pin, copy” latency. The three predictions answer different questions and must never be collapsed into one number.

Part 4 - Experimental Design and Instrumentation

Record CPU model, GPU, interconnect, PyTorch/CUDA versions, tensor size, dtype, and stream. Warm up CUDA before measurement. Synchronize before a CPU wall-time trial and after its final transfer. Use CUDA events for device-side copy time. Measure pageable, pre-pinned, and pin-then-copy paths independently. Preserve the source until transfer completion, validate the destination, and report median and tail latency rather than one favorable sample.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def cpu_ms(operation, device):
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    result = operation()
    torch.cuda.synchronize(device)
    return (time.perf_counter() - start) * 1000.0, result
```

```
def event_ms(source, device, stream):
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    with torch.cuda.stream(stream):
        start.record(stream)
        destination = source.to(device, non_blocking=True)
        end.record(stream)
    end.synchronize()
    return start.elapsed_time(end), destination

def E00(numel=16 * 1024 * 1024, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM05.")
    device = torch.device("cuda:0")
    pageable = torch.arange(numel, dtype=torch.float32)
    pinned = torch.empty(numel, dtype=torch.float32, pin_memory=True)
    pinned.copy_(pageable)
    stream = torch.cuda.Stream(device=device)
    torch.empty(1, device=device)
    rows = []
    for label, source in (("pageable", pageable), ("pinned", pinned)):
        wall_samples = []
        event_samples = []
        for _ in range(repeats):
            wall, destination = cpu_ms(
                lambda: source.to(device, non_blocking=True), device)
            event, destination = event_ms(source, device, stream)
            wall_samples.append(wall)
            event_samples.append(event)
        rows.append({"path": label,
                     "bytes": source.numel() * source.element_size(),
                     "wall_median_ms": statistics.median(wall_samples),
                     "event_median_ms": statistics.median(event_samples),
                     "source_is_pinned": source.is_pinned()})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

CUDA-event time and synchronized wall time need not match: the first describes work on a stream while the second includes Python submission and synchronization. Confirm equal byte counts and inspect every destination before reusing source storage. If pinned memory is not faster, test whether tensors are too small, pinning was timed, transfers are serialized, or the system is bandwidth- limited elsewhere. A speedup without numerical validation is invalid evidence.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory is a coordination mechanism between virtual memory and DMA, not a magic storage class. Optimize the whole path: page locking, CPU production, queueing, trans-

fer, synchronization, and GPU consumption. The correct question is not "is pinning fast?" but "does a bounded pinned-memory pipeline shorten the critical path on this measured system?"

19.7.2 Exercise 01

Exercise Title: Create Pageable and Pinned CPU Tensors in PyTorch and Verify Their Memory State with is_pinned()

Part 1 - Exercise Contract and Why It Matters

Create equivalent CPU tensors in pageable and pinned storage, prove their state with `is_pinned()`, and test which transformations preserve or replace that storage. The purpose is to prevent a common debugging error: assuming that a tensor is pinned because its parent batch or an earlier version was pinned.

Part 2 - System and Memory Mental Model

Pinned state belongs to the underlying CPU storage. A view normally shares that storage and therefore retains the property; a cloning or conversion operation may allocate different storage whose pinning depends on the operation. CUDA tensors are not described as pinned host tensors. Nested batches require every CPU tensor destined for transfer to be inspected, not just the outer object.

Part 3 - Quantitative Prediction Before Execution

Predict the byte count, data pointers, and pinned flags for an ordinary tensor, a directly pinned tensor, a view, a clone, and a tensor returned by `pin_memory()`. Record which objects should share storage before running the experiment.

Part 4 - Experimental Design and Instrumentation

Use identical shapes and values. Report shape, dtype, bytes, device, data pointer, pinned state, and whether storage is shared. Validate values after every transformation. Run in a CUDA-capable PyTorch environment because pinned allocation may be unavailable in a CPU-only build.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def describe(name, tensor):
    return {"name": name,
            "shape": tuple(tensor.shape),
            "dtype": str(tensor.dtype),
            "device": str(tensor.device),
            "bytes": tensor.numel() * tensor.element_size(),
            "data_ptr": tensor.data_ptr(),
            "is_pinned": tensor.is_pinned()}

def E01():
    if not torch.cuda.is_available():
        raise RuntimeError("A CUDA-capable PyTorch build is required.")
    pageable = torch.arange(24, dtype=torch.float32).reshape(4, 6)
```

```
    direct = torch.empty((4, 6), dtype=torch.float32, pin_memory=True)
    direct.copy_(pageable)
    converted = pageable.pin_memory()
    view = direct.view(2, 12)
    clone = direct.clone()
    tensors = [("pageable", pageable), ("direct", direct),
               ("converted", converted), ("view", view), ("clone", clone)]
    rows = []
    for name, tensor in tensors:
        rows.append(describe(name, tensor))
        if not torch.equal(tensor.reshape(-1), pageable.reshape(-1)):
            raise AssertionError(name + " changed the values")
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Check flags rather than relying on an allocation story. Confirm that the view's pointer matches the pinned base. Do not turn an observed clone behavior into an eternal API guarantee; record PyTorch version and verify it. Failure to allocate pinned memory can reflect a CPU-only build, unavailable accelerator support, or host resource limits rather than a tensor-shape error.

Part 7 - Engineering Interpretation and Philosophy

Performance properties must be observable invariants. A pipeline that merely intends to pin is weaker than one that asserts pinning at its transfer boundary. Small state checks convert an implicit assumption into testable engineering.

19.7.3 Exercise 02

Exercise Title: Allocate CPU Tensors Directly in Pinned Memory and Compare Them with Tensors Converted Later Using pin_memory()

Part 1 - Exercise Contract and Why It Matters

Compare direct pinned allocation with creating pageable data and converting it later. Separate allocation time, data-production time, pinning/copy time, and H2D time. This reveals why identical final tensor states can have very different end-to-end costs.

Part 2 - System and Memory Mental Model

`pin_memory()` creates a pinned copy when the source is not already pinned; it cannot retroactively change arbitrary storage without moving data. Direct allocation avoids that conversion copy, but the producer must be able to write into the pinned destination efficiently. Excessive direct pinned allocations can still incur expensive page-lock operations and fragment host resource usage.

Part 3 - Quantitative Prediction Before Execution

For B bytes, model converted-path cost as $T_p(B) + T_{cpu \to pin}(B) + T_{H2D}(B)$, while a reused direct buffer can approach $T_{fill}(B) + T_{H2D}(B)$. Predict which term dominates for 4 KiB, 4 MiB, and 256 MiB.

Part 4 - Experimental Design and Instrumentation

Pre-generate source values so random-number generation is not accidentally charged to only one path. Measure construction and transfer phases separately, then report their sum. Repeat, randomize path order, synchronize CUDA, and release large host buffers between independent size groups.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def elapsed_ms(operation):
    start = time.perf_counter()
    value = operation()
    return (time.perf_counter() - start) * 1000.0, value

def E02(numel=8 * 1024 * 1024, repeats=15):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.linspace(0.0, 1.0, numel, dtype=torch.float32)
    records = {"direct_prepare": [], "convert_prepare": [],
               "direct_h2d": [], "convert_h2d": []}
    for _ in range(repeats):
        prepare, direct = elapsed_ms(
            lambda: torch.empty(numel, dtype=torch.float32, pin_memory=True))
        fill, _ = elapsed_ms(lambda: direct.copy_(source))
        records["direct_prepare"].append(prepare + fill)
        prepare, converted = elapsed_ms(lambda: source.pin_memory())
        records["convert_prepare"].append(prepare)
        for label, tensor in (("direct_h2d", direct),
                              ("convert_h2d", converted)):
            torch.cuda.synchronize(device)
            start = time.perf_counter()
            destination = tensor.to(device, non_blocking=True)
            torch.cuda.synchronize(device)
            records[label].append((time.perf_counter() - start) * 1000.0)
            if not torch.allclose(destination.cpu(), source):
                raise AssertionError(label + " produced wrong values")
    summary = {}
    for name, samples in records.items():
        summary[name + "_median_ms"] = statistics.median(samples)
    return summary
```

Part 6 - Measurement, Validation, and Failure Analysis

Both final tensors must be pinned and value-equivalent. If conversion appears free, check that synchronization and phase boundaries are correct. If direct allocation appears slower,

the benchmark may be measuring fresh page locking while a real pipeline would reuse buffers. Report both fresh-allocation and reuse scenarios; neither alone represents every workload.

Part 7 - Engineering Interpretation and Philosophy

Storage state does not reveal acquisition cost. Design around lifetimes: direct allocation plus reuse is often valuable, whereas pinning a fresh pageable batch immediately before one copy can add a full CPU copy to the critical path.

19.7.4 Exercise 03

Exercise Title: Benchmark Host-to-GPU Transfer Latency for Pageable and Pinned Tensors Across Increasing Tensor Sizes

Part 1 - Exercise Contract and Why It Matters

Build a size sweep that exposes fixed overhead, bandwidth-dominated behavior, and pinned-memory crossover. The benchmark must distinguish copy-only latency from end-to-end preparation cost and must not use unsynchronized Python timing.

Part 2 - System and Memory Mental Model

Small transfers are dominated by dispatch, synchronization, and bookkeeping. Large transfers approach an effective bandwidth ceiling. Pageable transfers may add staging work, while pre-pinned transfers can be submitted directly to DMA. The observed curve is therefore approximately fixed cost plus bytes over bandwidth, but caching, NUMA placement, interconnect sharing, and power state create deviations.

Part 3 - Quantitative Prediction Before Execution

Choose logarithmic sizes from 1 KiB to a safe fraction of host and GPU memory. For each size predict $T = \alpha + B/R$ under two path-specific values of α and R. Mark the expected crossover before viewing results.

Part 4 - Experimental Design and Instrumentation

Allocate sources before timing, warm each size, alternate path order, and use many repetitions for small transfers. Synchronize before and after each trial. Report median, p95, bytes, and GB/s. Prevent dead-code assumptions by reading a destination value after the synchronized trial group.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def percentile(values, fraction):
    ordered = sorted(values)
    index = round((len(ordered) - 1) * fraction)
    return ordered[index]

def transfer_samples(source, device, repeats):
    samples = []
```

```
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destination = source.to(device, non_blocking=True)
        torch.cuda.synchronize(device)
        samples.append((time.perf_counter() - start) * 1000.0)
    return samples, float(destination[0].item())

def E03():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    sizes = [2 ** exponent for exponent in range(10, 29, 2)]
    rows = []
    for byte_count in sizes:
        numel = max(1, byte_count // 4)
        pageable = torch.ones(numel, dtype=torch.float32)
        pinned = torch.ones(numel, dtype=torch.float32, pin_memory=True)
        for label, source in (("pageable", pageable), ("pinned", pinned)):
            samples, check = transfer_samples(source, device, 25)
            median_ms = statistics.median(samples)
            seconds = median_ms / 1000.0
            bandwidth = source.nbytes / seconds / 1e9
            rows.append({"path": label, "bytes": source.nbytes,
                         "median_ms": median_ms,
                         "p95_ms": percentile(samples, 0.95),
                         "GB_per_s": bandwidth, "check": check})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot latency on log scales and bandwidth against size. Reject trials affected by unrelated GPU work only through a declared rule, never by deleting slow points selectively. A pageable copy with `non_blocking=True` can still return control early at the API level, so synchronized end-to-end timing and pinned-state checks remain essential.

Part 7 - Engineering Interpretation and Philosophy

An optimization has a domain, not a universal truth. The curve identifies the sizes where page locking repays its cost and where batching small transfers is more important than changing memory type.

19.7.5 Exercise 04

Exercise Title: Determine the Tensor Size at Which Pinned Memory Begins to Outperform Pageable Memory on Your Hardware

Part 1 - Exercise Contract and Why It Matters

Estimate a statistically defensible crossover rather than reporting the first noisy point where pinned latency happens to be lower. Produce a local hardware result with uncertainty and a rule that can be rerun after system changes.

Part 2 - System and Memory Mental Model

The crossover is the region where saved staging cost exceeds differences in fixed overhead. It depends on interconnect, NUMA placement, CPU load, driver, power state, and whether memory was pre-pinned or pinned on demand. Consequently there are at least two crossovers: copy-only and end-to-end pin-then-copy.

Part 3 - Quantitative Prediction Before Execution

Define speedup $S(B) = T_{pageable}(B)/T_{pinned}(B)$. Before execution choose a practical threshold such as $S \geq 1.05$, then require it at three consecutive sizes and require confidence intervals not to reverse the conclusion. State the chosen rule before looking at measurements.

Part 4 - Experimental Design and Instrumentation

Use a coarse logarithmic sweep, then a dense sweep around the apparent region. Interleave paths per repetition to reduce temporal bias. Bootstrap medians or repeat complete runs. Record both pre-pinned copy-only and pin-then-copy totals.

Part 5 - PyTorch/CUDA Implementation

```
import statistics

def find_crossover(rows, minimum_speedup=1.05, consecutive=3):
    by_size = {}
    for row in rows:
        size = row["bytes"]
        if size not in by_size:
            by_size[size] = {}
        by_size[size][row["path"]] = row["median_ms"]
    streak = 0
    first_size = None
    decisions = []
    for size in sorted(by_size):
        values = by_size[size]
        if "pageable" not in values or "pinned" not in values:
            continue
        speedup = values["pageable"] / values["pinned"]
        passes = speedup >= minimum_speedup
        decisions.append({"bytes": size, "speedup": speedup,
                          "passes": passes})
        if passes:
            if streak == 0:
                first_size = size
            streak += 1
            if streak >= consecutive:
                return first_size, decisions
        else:
            streak = 0
            first_size = None
    return None, decisions
```

```
def E04(rows_from_E03):
    crossover, evidence = find_crossover(rows_from_E03)
    return {"copy_only_crossover_bytes": crossover,
            "decision_rule": "speedup >= 1.05 for three sizes",
            "evidence": evidence}
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify that both paths moved identical bytes and that the source was already pinned in the pinned path. Report "no stable crossover in tested range" when appropriate. Do not interpolate a precise byte value from widely spaced noisy samples. Re-run after changing PCIe load, NUMA affinity, or DataLoader policy.

Part 7 - Engineering Interpretation and Philosophy

The crossover is a policy input, not a law of CUDA. It can guide whether to pin individual fields, coalesce transfers, or leave tiny metadata pageable. A repeatable decision rule is more useful than a memorable but hardware-specific number.

19.7.6 Exercise 05

Exercise Title: Measure the CPU-Side Cost of Calling pin_memory() and Explain Why Manual Pinning Can Eliminate Expected Transfer Gains

Part 1 - Exercise Contract and Why It Matters

Measure page-lock conversion separately from H2D transfer and then combine the phases. Demonstrate the central trap: pre-pinned memory can accelerate the copy. However, manually converting the batch immediately before the copy can make the entire operation slower. The conversion method under test is `pin_memory()`.

Part 2 - System and Memory Mental Model

Converting a pageable tensor normally allocates page-locked storage and copies the CPU data into it. The path becomes CPU copy plus OS/driver registration plus H2D DMA. Pre-pinning moves this work off the per-batch critical path; a pinned pool amortizes it across many iterations. DataLoader pinning can also perform the work in a separate pipeline stage rather than blocking model code.

Part 3 - Quantitative Prediction Before Execution

Let $P(B)$ be conversion cost, $C_p(B)$ pinned-copy time, and $C_u(B)$ pageable-copy time. Predict whether $P(B) + C_p(B) < C_u(B)$. Then compute the reuse count N needed for $P(B)/N + C_p(B) < C_u(B)$.

Part 4 - Experimental Design and Instrumentation

Time pinning with a CPU clock, copy with synchronized wall time and CUDA events, and total latency with both phases. Keep generation outside timing. Compare fresh conversion, pre-pinned, and reusable-buffer paths at multiple sizes.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def E05(numel=16 * 1024 * 1024, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.randn(numel, dtype=torch.float32)
    pin_ms = []
    copy_ms = []
    total_ms = []
    for _ in range(repeats):
        total_start = time.perf_counter()
        pin_start = time.perf_counter()
        pinned = source.pin_memory()
        pin_ms.append((time.perf_counter() - pin_start) * 1000.0)
        torch.cuda.synchronize(device)
        copy_start = time.perf_counter()
        destination = pinned.to(device, non_blocking=True)
        torch.cuda.synchronize(device)
        copy_ms.append((time.perf_counter() - copy_start) * 1000.0)
        total_ms.append((time.perf_counter() - total_start) * 1000.0)
    return {"bytes": source.nbytes,
            "pin_median_ms": statistics.median(pin_ms),
            "copy_median_ms": statistics.median(copy_ms),
            "pin_then_copy_median_ms": statistics.median(total_ms),
            "validated": torch.allclose(destination.cpu(), source)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare the median of totals with the total of medians carefully; they are not identical statistical quantities. If manual pinning wins unexpectedly, verify that pageable and pinned cases used identical synchronization. If it loses, that is not a contradiction: the copy benefit may be smaller than conversion cost. Inspect host-memory pressure and repeated-registration effects.

Part 7 - Engineering Interpretation and Philosophy

Move optimization work away from the critical path or amortize it. Pinning is a pipeline design choice, not a function to sprinkle immediately before every `to("cuda")` call.

19.7.7 Exercise 06

Exercise Title: Compare tensor.to("cuda") Against Pinned-Memory Transfers Under Identical Shapes, Dtypes, and Repetition Counts

Part 1 - Exercise Contract and Why It Matters

Construct a paired benchmark where the only intended difference is source storage. Compare ordinary `tensor.to("cuda")` with a transfer from an already pinned tensor, while making blocking policy explicit.

Part 2 - System and Memory Mental Model

`to()` is the high-level transfer interface for both sources. Its `non_blocking` flag changes host synchronization behavior, not the number of bytes. Pinned storage enables the DMA-friendly path; pageable storage may require internal staging. Comparisons are meaningless if one source is generated, converted, or pinned inside the timed region and the other is not.

Part 3 - Quantitative Prediction Before Execution

Create a four-cell prediction table. The rows represent pageable and pinned sources; the columns represent blocking and non-blocking submission. Predict CPU submission time, synchronized completion time, and overlap potential for each cell.

Part 4 - Experimental Design and Instrumentation

Use one pageable tensor and a value-equivalent pinned tensor. Alternate all four cases, synchronize at boundaries, and keep repetitions equal. Record host call duration separately from completion duration so asynchronous submission is not misreported as completed bandwidth.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def measure_case(source, device, non_blocking, repeats):
    call_samples = []
    completion_samples = []
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destination = source.to(device, non_blocking=non_blocking)
        call_end = time.perf_counter()
        torch.cuda.synchronize(device)
        end = time.perf_counter()
        call_samples.append((call_end - start) * 1000.0)
        completion_samples.append((end - start) * 1000.0)
    return {"call_median_ms": statistics.median(call_samples),
            "completion_median_ms": statistics.median(completion_samples),
            "checksum": float(destination.float().sum().item())}

def E06(numel=8 * 1024 * 1024, repeats=30):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    pageable = torch.arange(numel, dtype=torch.float32)
    pinned = torch.empty_like(pageable, pin_memory=True)
    pinned.copy_(pageable)
    results = {}
    for name, source in (("pageable", pageable), ("pinned", pinned)):
        for flag in (False, True):
```

```
            key = name + "_nonblocking_" + str(flag)
            results[key] = measure_case(source, device, flag, repeats)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert equal checksums and byte counts. A shorter host-call duration is not a faster completed transfer. If `non_blocking=True` changes little, the explicit synchronization deliberately removes overlap; that is correct for copy completion measurement. A separate pipeline benchmark is required to measure useful overlap.

Part 7 - Engineering Interpretation and Philosophy

APIs do not define performance in isolation. Storage type, synchronization, stream placement, and surrounding work jointly determine the critical path.

19.7.8 Exercise 07

Exercise Title: Sweep float16, float32, and float64 Tensors and Determine Whether Transfer Performance Follows Bytes, Elements, or Dtype

Part 1 - Exercise Contract and Why It Matters

Determine whether H2D performance is primarily predicted by byte count, element count, or dtype-specific effects. Run both equal-element and equal-byte experiments so the conclusion is identifiable.

Part 2 - System and Memory Mental Model

DMA transports bytes and does not perform floating-point arithmetic. Therefore equal element counts should take longer for wider dtypes, while equal byte counts should be similar once bandwidth dominates. Differences may remain from alignment, allocation, small-transfer overhead, or downstream conversion, but these must not be confused with copy volume.

Part 3 - Quantitative Prediction Before Execution

For N elements, predict byte ratios $1 : 2 : 4$ for float16, float32, and float64. For a fixed 64 MiB payload, predict nearly equal transfer times. Write both hypotheses before measurement.

Part 4 - Experimental Design and Instrumentation

Preallocate pinned sources, use synchronized completion time, and alternate dtypes. First hold elements constant; then calculate dtype-specific element counts that hold bytes constant. Report both latency and effective GB/s.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import torch

def cuda_event_copy_ms(source, device, repeats):
    samples = []
    for _ in range(repeats):
        start = torch.cuda.Event(enable_timing=True)
```

```
        end = torch.cuda.Event(enable_timing=True)
        start.record()
        destination = source.to(device, non_blocking=True)
        end.record()
        end.synchronize()
        samples.append(start.elapsed_time(end))
    return statistics.median(samples), destination

def E07(repeats=30):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    dtypes = [torch.float16, torch.float32, torch.float64]
    rows = []
    for mode in ("equal_elements", "equal_bytes"):
        for dtype in dtypes:
            if mode == "equal_elements":
                numel = 16 * 1024 * 1024
            else:
                target_bytes = 64 * 1024 * 1024
                scalar = torch.empty((), dtype=dtype)
                element_bytes = scalar.element_size()
                numel = target_bytes // element_bytes
            source = torch.ones(numel, dtype=dtype, pin_memory=True)
            median_ms, destination = cuda_event_copy_ms(
                source, device, repeats)
            seconds = median_ms / 1000.0
            bandwidth = source.nbytes / seconds / 1e9
            rows.append({"mode": mode, "dtype": str(dtype),
                         "elements": numel, "bytes": source.nbytes,
                         "median_ms": median_ms,
                         "GB_per_s": bandwidth,
                         "check": float(destination[0].item())})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare latency ratios in the equal-element group and bandwidth in the equal- byte group. Ensure no dtype conversion occurs during transfer. If equal-byte results differ, expand repetitions, inspect alignment and clock state, and test larger payloads before claiming a dtype-specific DMA path.

Part 7 - Engineering Interpretation and Philosophy

Choose the independent variable that matches the mechanism. Element count is a model-level quantity; bytes are the transport-level quantity. Good experiments separate them instead of letting dtype change both simultaneously.

19.7.9 Exercise 08

Exercise Title: Build a Bandwidth Benchmark That Converts CPU-to-GPU Transfer Time into Effective GB/s

Part 1 - Exercise Contract and Why It Matters

Create a reusable bandwidth benchmark with correct units, warmup, synchronization, and uncertainty reporting. It must distinguish decimal GB/s from binary GiB/s and useful payload bandwidth from theoretical link rate.

Part 2 - System and Memory Mental Model

Effective bandwidth is payload bytes divided by completed transfer time. It is lower than signaling rate because protocols, topology, contention, and software overhead consume capacity. For small tensors, dividing by a tiny latency creates a volatile number that should not be treated as a steady-state bandwidth.

Part 3 - Quantitative Prediction Before Execution

Calculate

$$R_{GB/s} = \frac{B}{t\,10^9}, \qquad R_{GiB/s} = \frac{B}{t\,2^{30}}.$$

Predict the plateau region and define the minimum payload used to summarize steady-state bandwidth.

Part 4 - Experimental Design and Instrumentation

Use CUDA events around only the copy, a pinned source, fixed destination device, and warmup transfers. Include median, p05, and p95. Optionally measure bidirectional and concurrent traffic separately; do not mix them into H2D results.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import torch

def quantile(samples, fraction):
    values = sorted(samples)
    return values[round((len(values) - 1) * fraction)]

def E08(byte_count=256 * 1024 * 1024, warmup=10, repeats=50):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    numel = byte_count // 4
    source = torch.empty(numel, dtype=torch.float32, pin_memory=True)
    source.fill_(1.0)
    for _ in range(warmup):
        destination = source.to(device, non_blocking=True)
    torch.cuda.synchronize(device)
    samples = []
    for _ in range(repeats):
```

```
        start = torch.cuda.Event(enable_timing=True)
        end = torch.cuda.Event(enable_timing=True)
        start.record()
        destination = source.to(device, non_blocking=True)
        end.record()
        end.synchronize()
        samples.append(start.elapsed_time(end))
    median_ms = statistics.median(samples)
    return {"bytes": source.nbytes, "median_ms": median_ms,
            "p05_ms": quantile(samples, 0.05),
            "p95_ms": quantile(samples, 0.95),
            "GB_per_s": source.nbytes / (median_ms / 1000.0) / 1e9,
            "GiB_per_s": source.nbytes / (median_ms / 1000.0) / (2 ** 30),
            "validated": float(destination[0].item()) == 1.0}
```

Part 6 - Measurement, Validation, and Failure Analysis

Reject zero or negative event times and verify the recorded stream. Compare the plateau with plausible hardware limits, but do not label a discrepancy a bug without checking PCIe generation, lane width, NUMA socket, other traffic, and power management. Preserve raw samples for reproducibility.

Part 7 - Engineering Interpretation and Philosophy

Bandwidth is a derived measurement whose credibility depends entirely on the time boundary and byte definition. A disciplined benchmark turns a vague "transfer is slow" complaint into a comparable engineering metric.

19.7.10 Exercise 09

Exercise Title: Compare One Large Pinned Transfer Against Hundreds of Small Pinned Transfers with the Same Total Byte Count

Part 1 - Exercise Contract and Why It Matters

Hold total bytes constant while changing transfer granularity. Quantify the submission and scheduling cost of many small copies and test whether coalescing fields into a contiguous staging buffer improves throughput.

Part 2 - System and Memory Mental Model

Every copy has fixed software and queueing overhead. Hundreds of small DMA requests may fail to saturate the interconnect and enlarge Python dispatch cost. One large copy reduces request count but may require an additional CPU packing copy, so both copy-only and end-to-end packed results are necessary.

Part 3 - Quantitative Prediction Before Execution

For N transfers totaling B bytes, model $T_N \approx N\alpha + B/R$. Predict the slowdown for $N = 1, 16, 256$, then add packing time to determine whether coalescing remains beneficial.

Part 4 - Experimental Design and Instrumentation

Preallocate pinned sources with equal total bytes. Time the entire sequence using events and synchronized wall time. Preserve destinations until completion. Measure a separate packed path that explicitly includes CPU packing.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def copy_group(sources, device, repeats):
    samples = []
    checksum = None
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destinations = []
        for source in sources:
            destination = source.to(device, non_blocking=True)
            destinations.append(destination)
        torch.cuda.synchronize(device)
        samples.append((time.perf_counter() - start) * 1000.0)
        checksum = 0.0
        for item in destinations:
            checksum += float(item[0].item())
    return statistics.median(samples), checksum

def E09(total_elements=16 * 1024 * 1024, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    rows = []
    for count in (1, 16, 256):
        elements_each = total_elements // count
        sources = []
        for index in range(count):
            tensor = torch.full((elements_each,), float(index + 1),
                                dtype=torch.float32, pin_memory=True)
            sources.append(tensor)
        median_ms, checksum = copy_group(sources, device, repeats)
        actual_bytes = sum(tensor.nbytes for tensor in sources)
        rows.append({"transfers": count, "bytes": actual_bytes,
                     "median_ms": median_ms,
                     "GB_per_s": actual_bytes / (median_ms / 1000.0) / 1e9,
                     "checksum": checksum})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Confirm identical actual bytes; integer division can otherwise make totals differ. The checksum must reflect every destination. If packing is evaluated, include its CPU time in end-to-end results and show copy-only results separately. Python overhead is part of this pipeline experiment, not an error to hide.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory removes one obstacle but does not remove per-operation overhead. Efficient systems manage granularity: coalesce where packing cost is smaller than repeated submission cost, and retain separate tensors where semantics or lifetime make packing wasteful.

19.7.11 Exercise 10

Exercise Title: Use DataLoader(pin_memory=True) and Verify That Returned Batch Tensors Are Actually Page-Locked Before CUDA Transfer

Part 1 - Exercise Contract and Why It Matters

Build a DataLoader that returns nested batches, enable automatic pinning, and assert that every transferable CPU tensor is page-locked before calling `to("cuda")`. This tests pipeline reality rather than configuration intent.

Part 2 - System and Memory Mental Model

With `pin_memory=True`, DataLoader recognizes tensors in standard containers and moves them into pinned host storage before yielding the batch. Custom batch classes may need a `pin_memory()` method. Pinning is a host pipeline stage; CUDA transfer still occurs in the training process, normally with `non_blocking=True`.

Part 3 - Quantitative Prediction Before Execution

Predict the total pinned bytes per batch from every input and label tensor. Estimate in-flight pinned capacity as batch bytes times the number of queued batches, while noting that implementation details and consumer timing can add or subtract buffers.

Part 4 - Experimental Design and Instrumentation

Compare loaders differing only in `pin_memory`. Inspect the batch before device transfer. Include nested dictionaries and labels, and fail if any tensor that should transfer is not pinned. Keep dataset values deterministic.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.utils.data import DataLoader, Dataset

class SampleDataset(Dataset):
    def __init__(self, length=256):
        self.length = length
    def __len__(self):
        return self.length
    def __getitem__(self, index):
        image = torch.full((3, 64, 64), index / self.length)
        label = torch.tensor(index % 10, dtype=torch.long)
```

```
        return {"image": image, "label": label}

def tensor_rows(value, prefix="batch"):
    rows = []
    if torch.is_tensor(value):
        rows.append({"path": prefix, "shape": tuple(value.shape),
                     "bytes": value.nbytes, "pinned": value.is_pinned()})
    elif isinstance(value, dict):
        for key, child in value.items():
            child_rows = tensor_rows(child, prefix + "." + str(key))
            rows.extend(child_rows)
    elif isinstance(value, (list, tuple)):
        for index, child in enumerate(value):
            child_rows = tensor_rows(child, prefix + "[" + str(index) + "]")
            rows.extend(child_rows)
    return rows

def E10():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    loader = DataLoader(SampleDataset(), batch_size=16, num_workers=2,
                        pin_memory=True, persistent_workers=True)
    batch = next(iter(loader))
    rows = tensor_rows(batch)
    for row in rows:
        if not row["pinned"]:
            raise AssertionError(row["path"] + " is not pinned")
    device = torch.device("cuda:0")
    images = batch["image"].to(device, non_blocking=True)
    labels = batch["label"].to(device, non_blocking=True)
    torch.cuda.synchronize(device)
    return {"rows": rows, "image_device": str(images.device),
            "label_device": str(labels.device)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Check all leaves, not only the image. If a custom object remains pageable, implement and test its pinning method or return supported containers. On some accelerator/build configurations, pinning behavior differs; record environment and fail clearly. Never call `is_pinned()` after transfer and mistake a CUDA tensor check for host-state evidence.

Part 7 - Engineering Interpretation and Philosophy

Configuration flags are hypotheses about system state. Assertions at the boundary where data changes ownership make the pipeline auditable and prevent silent performance regressions.

19.7.12 Exercise 11

Exercise Title: Benchmark a Training Input Pipeline with pin_memory=False and pin_memory=True While Holding All Other DataLoader Settings Constant

Part 1 - Exercise Contract and Why It Matters

Measure whether DataLoader pinning improves completed training throughput, not merely transfer microbenchmark latency. Hold model, data, workers, prefetch, batch size, and training work constant.

Part 2 - System and Memory Mental Model

End-to-end iteration time is the maximum or partial overlap of CPU preparation, pinning, H2D transfer, and GPU compute, plus synchronization constraints. A copy speedup may disappear if compute dominates; pinning may help significantly when the GPU waits for input. Worker startup must be separated from steady state.

Part 3 - Quantitative Prediction Before Execution

Predict samples/s and GPU idle fraction for both settings. Use the critical- path model $T \approx \max(T_{input}, T_{compute})$ only when overlap is real; otherwise use the sum. State which regime you expect.

Part 4 - Experimental Design and Instrumentation

Run warmup epochs, fixed seeds, identical batch order, equal measured batches, and multiple repetitions. Synchronize only at benchmark boundaries. Record host RAM, CPU utilization, GPU utilization, and batch p95 in addition to mean throughput.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader

def run_loader(loader, model, device, measured_batches):
    iterator = iter(loader)
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    examples = 0
    for _ in range(measured_batches):
        batch = next(iterator)
        inputs = batch["image"].to(device, non_blocking=True)
        outputs = model(inputs)
        loss = outputs.square().mean()
        loss.backward()
        model.zero_grad(set_to_none=True)
        examples += inputs.shape[0]
    torch.cuda.synchronize(device)
    seconds = time.perf_counter() - start
    return {"seconds": seconds, "examples": examples,
            "examples_per_second": examples / seconds}

def E11(dataset, model, batch_size=64, measured_batches=100):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
```

```
    device = torch.device("cuda:0")
    model = model.to(device)
    results = {}
    for pin in (False, True):
        loader = DataLoader(dataset, batch_size=batch_size, shuffle=False,
                            num_workers=4, pin_memory=pin,
                            persistent_workers=True, prefetch_factor=2)
        warmup = run_loader(loader, model, device, 10)
        measurement = run_loader(loader, model, device, measured_batches)
        results["pin_memory_" + str(pin)] = measurement
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Reset model state or disable parameter updates so the two conditions perform equivalent work. Ensure the dataset has enough batches and avoid including worker startup in only one condition. If results are close, report uncertainty rather than declaring a winner. A slower pinned path may indicate small batches, CPU pinning pressure, or a compute-bound workload.

Part 7 - Engineering Interpretation and Philosophy

Microbenchmarks explain mechanisms; pipeline benchmarks decide policy. Adopt pinning only when it improves the target workload under realistic concurrency and host-memory constraints.

19.7.13 Exercise 12

Exercise Title: Vary num_workers with Pinned DataLoader Memory and Identify When Input Preparation Becomes More Expensive Than GPU Transfer

Part 1 - Exercise Contract and Why It Matters

Sweep worker count while pinning is enabled and identify the transition from input starvation to adequate overlap and finally to CPU/process overhead. The goal is not to maximize workers blindly.

Part 2 - System and Memory Mental Model

Workers parallelize loading and preprocessing; a DataLoader pinning stage then prepares host buffers for transfer. More workers can increase throughput until CPU cores, storage, shared memory, IPC, or pinning becomes saturated. Worker processes may duplicate Python-object memory and enlarge host pressure.

Part 3 - Quantitative Prediction Before Execution

Estimate CPU service demand per batch and available cores. Predict the worker count where preparation time falls below GPU consumption time. Also estimate resident prefetched batch bytes for every configuration.

Part 4 - Experimental Design and Instrumentation

Sweep $0, 1, 2, 4, 8$ up to a safe CPU-specific limit. When workers are zero, omit worker-only options such as persistent workers and prefetch factor. Measure data wait, H2D completion, compute, total throughput, CPU load, and pinned RAM.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader

def make_loader(dataset, batch_size, worker_count):
    arguments = {"dataset": dataset, "batch_size": batch_size,
                 "shuffle": False, "num_workers": worker_count,
                 "pin_memory": True}
    if worker_count > 0:
        arguments["persistent_workers"] = True
        arguments["prefetch_factor"] = 2
    return DataLoader(**arguments)

def E12(dataset, batch_size=64, batches=100):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    rows = []
    for worker_count in (0, 1, 2, 4, 8):
        loader = make_loader(dataset, batch_size, worker_count)
        iterator = iter(loader)
        wait_seconds = 0.0
        transfer_seconds = 0.0
        for _ in range(batches):
            wait_start = time.perf_counter()
            batch = next(iterator)
            wait_seconds += time.perf_counter() - wait_start
            torch.cuda.synchronize(device)
            transfer_start = time.perf_counter()
            device_batch = batch.to(device, non_blocking=True)
            torch.cuda.synchronize(device)
            transfer_seconds += time.perf_counter() - transfer_start
        rows.append({"workers": worker_count,
                     "data_wait_s": wait_seconds,
                     "transfer_s": transfer_seconds,
                     "examples": batches * batch_size,
                     "check": float(device_batch.reshape(-1)[0].item())})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

The staged timing above diagnoses service times but intentionally prevents overlap during transfer measurement; add an end-to-end run without per-batch synchronization before choosing production settings. Watch for exhausted shared memory, worker crashes, oversubscription, and dataset caching effects. Repeat worker order or randomize it.

Part 7 - Engineering Interpretation and Philosophy

Worker count is a queueing parameter. The best setting feeds the consumer with bounded headroom; additional producers that only increase contention and memory footprint are negative capacity.

19.7.14 Exercise 13

Exercise Title: Combine pin_memory, num_workers, prefetch_factor, and persistent_workers and Measure Their Interaction on End-to-End Throughput

Part 1 - Exercise Contract and Why It Matters

Run a controlled factorial study of the main DataLoader pipeline settings. Identify interactions instead of attributing a result to one flag in isolation.

Part 2 - System and Memory Mental Model

Workers determine producer concurrency; prefetch factor bounds queued batches per worker; persistent workers amortize process startup across epochs; pinning adds a page-locked handoff stage. Their effects interact. A larger queue can hide jitter but increases host memory, and persistence can help short epochs while retaining worker resources longer.

Part 3 - Quantitative Prediction Before Execution

For each configuration estimate queued payload as approximately $W \times F \times B$, where W is workers, F prefetch factor, and B batch bytes. Treat this as a planning estimate, not an exact guarantee. Rank predicted throughput and host-memory cost before execution.

Part 4 - Experimental Design and Instrumentation

Use a small declared matrix rather than an uncontrolled Cartesian explosion. Measure first-epoch and steady-state throughput separately. Record total and available RAM, pinned-batch bytes, CPU utilization, GPU idle time, and failures. Options invalid for zero workers must be omitted.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader

def loader_from_config(dataset, batch_size, config):
    arguments = {"dataset": dataset, "batch_size": batch_size,
                 "shuffle": False, "num_workers": config["workers"],
                 "pin_memory": config["pin"]}
    if config["workers"] > 0:
        arguments["prefetch_factor"] = config["prefetch"]
        arguments["persistent_workers"] = config["persistent"]
    return DataLoader(**arguments)

def consume(loader, device, batches):
    iterator = iter(loader)
    start = time.perf_counter()
    examples = 0
```

```
    for _ in range(batches):
        batch = next(iterator)
        device_batch = batch.to(device, non_blocking=True)
        examples += device_batch.shape[0]
    torch.cuda.synchronize(device)
    seconds = time.perf_counter() - start
    return examples / seconds

def E13(dataset, batch_size=64, batches=100):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    configs = [
        {"workers": 0, "pin": False, "prefetch": None, "persistent": False},
        {"workers": 0, "pin": True, "prefetch": None, "persistent": False},
        {"workers": 2, "pin": True, "prefetch": 2, "persistent": False},
        {"workers": 2, "pin": True, "prefetch": 4, "persistent": True},
        {"workers": 4, "pin": True, "prefetch": 2, "persistent": True},
    ]
    rows = []
    for config in configs:
        loader = loader_from_config(dataset, batch_size, config)
        first = consume(loader, device, batches)
        steady = consume(loader, device, batches)
        rows.append({"config": dict(config), "first_examples_s": first,
                     "steady_examples_s": steady})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare only runs with identical samples and transforms. If persistent workers change dataset state, add explicit reset logic. A throughput gain that consumes unacceptable RAM is not a free improvement. Include confidence intervals and repeat after cold start because filesystem caching can dominate early runs.

Part 7 - Engineering Interpretation and Philosophy

Pipeline settings form a coupled system. Select a configuration on the Pareto frontier of throughput, latency, RAM, determinism, and operational stability rather than maximizing one benchmark column.

19.7.15 Exercise 14

Exercise Title: Saturate Pinned Host Memory Deliberately and Measure the Impact on System RAM Availability and Overall Training Stability

Part 1 - Exercise Contract and Why It Matters

Perform a bounded pressure experiment that approaches a declared pinned-memory budget without exhausting the machine. Measure allocation latency, available RAM, transfer performance, and a training canary. Uncontrolled host-memory exhaustion is explicitly outside the exercise contract.

Part 2 - System and Memory Mental Model

Pinned pages cannot be reclaimed through ordinary paging while locked. Excessive pinning reduces OS flexibility, can slow allocations, starve other processes, and destabilize workers even when GPU VRAM is plentiful. The limit is a system property involving physical RAM, OS policy, driver, and concurrent workloads.

Part 3 - Quantitative Prediction Before Execution

Read available RAM and preserve the greater of 8 GiB or 40 percent as a safety reserve. Also impose a conservative experiment cap such as 4 GiB. Predict the maximum number of 64 MiB buffers under both constraints. Stop earlier if available memory, allocation latency, or canary throughput crosses a declared threshold.

Part 4 - Experimental Design and Instrumentation

Run on a non-production machine with no critical co-tenants. Allocate in small steps, touch each buffer, measure after every step, and release in `finally`. Never disable OS safeguards, never allocate from an unbounded loop, and never interpret swap activity or worker death as a desired endpoint.

Part 5 - PyTorch/CUDA Implementation

```
import gc
import os
import time
import torch

def available_ram_bytes():
    page_size = os.sysconf("SC_PAGE_SIZE")
    available_pages = os.sysconf("SC_AVPHYS_PAGES")
    return int(page_size * available_pages)

def E14(step_mib=64, hard_cap_mib=4096, canary=None):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    initial_available = available_ram_bytes()
    reserve = max(8 * 1024 ** 3, int(initial_available * 0.40))
    hard_cap = hard_cap_mib * 1024 ** 2
    step_bytes = step_mib * 1024 ** 2
    buffers = []
    rows = []
    pinned_total = 0
    try:
        while pinned_total + step_bytes <= hard_cap:
            before = available_ram_bytes()
            if before - step_bytes < reserve:
                break
            start = time.perf_counter()
            numel = step_bytes // 4
            buffer = torch.empty(numel, dtype=torch.float32, pin_memory=True)
```

```
            buffer.fill_(1.0)
            allocation_ms = (time.perf_counter() - start) * 1000.0
            buffers.append(buffer)
            pinned_total += buffer.nbytes
            after = available_ram_bytes()
            canary_metric = None
            if canary is not None:
                canary_metric = float(canary())
            rows.append({"pinned_bytes": pinned_total,
                         "available_before": before,
                         "available_after": after,
                         "allocation_ms": allocation_ms,
                         "canary_metric": canary_metric})
            if allocation_ms > 1000.0:
                break
    finally:
        buffers.clear()
        gc.collect()
    return {"initial_available": initial_available, "reserve": reserve,
            "hard_cap": hard_cap, "rows": rows,
            "final_available": available_ram_bytes()}
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify every buffer is pinned and that cleanup restores capacity over time. Available RAM may not rebound byte-for-byte because OS accounting and caches differ. Stop on rising allocation latency, canary degradation, or any allocation error. Do not retry aggressively. Report the bounded range actually tested, never call it the machine's absolute maximum.

Part 7 - Engineering Interpretation and Philosophy

Pinned RAM is shared infrastructure. Responsible optimization includes a hard budget, reserve, backpressure, cleanup, and graceful fallback. The fastest GPU pipeline is a failure if it makes the host unreliable.

19.7.16 Exercise 15

Exercise Title: Build a Reusable Pinned Host Buffer and Refill It Across Iterations Instead of Allocating New Pinned Tensors Every Batch

Part 1 - Exercise Contract and Why It Matters

Build a bounded reusable pinned-buffer object, refill it across iterations, and prove that no buffer is overwritten while an asynchronous H2D copy still reads from it. This converts pinning from repeated allocation into managed capacity.

Part 2 - System and Memory Mental Model

A pinned buffer has two lifetimes: Python ownership and DMA-use lifetime. The host may still own an object whose contents are unsafe to overwrite because a copy is in flight. A CUDA event recorded after the copy is the reuse fence. A two-slot ring allows the CPU to prepare one slot while the GPU consumes another, provided event and stream dependencies are correct.

Part 3 - Quantitative Prediction Before Execution

Compare fresh page-lock cost per iteration with one-time pool construction. For N iterations and K slots, predict pinned capacity KB and amortized allocation cost KP/N. Draw a timeline of fill, copy, compute, and reuse for two slots before writing code.

Part 4 - Experimental Design and Instrumentation

Use deterministic batches containing iteration identifiers. Before refilling a slot, synchronize only that slot's completion event. Submit copies on a copy stream, make the compute stream wait on the event, and validate device values. Track data pointers to prove storage reuse.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class PinnedSlot:
    def __init__(self, shape, dtype):
        self.host = torch.empty(shape, dtype=dtype, pin_memory=True)
        self.copy_done = None

    def wait_until_reusable(self):
        if self.copy_done is not None:
            self.copy_done.synchronize()

    def refill(self, source):
        self.wait_until_reusable()
        if source.shape != self.host.shape or source.dtype != self.host.dtype:
            raise ValueError("Source does not match reusable slot")
        self.host.copy_(source)

    def submit(self, device, copy_stream):
        event = torch.cuda.Event()
        with torch.cuda.stream(copy_stream):
            device_tensor = self.host.to(device, non_blocking=True)
            event.record(copy_stream)
        self.copy_done = event
        return device_tensor, event

def E15(iterations=20, shape=(64, 3, 224, 224)):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    copy_stream = torch.cuda.Stream(device=device)
    compute_stream = torch.cuda.current_stream(device)
    slots = [PinnedSlot(shape, torch.float32),
             PinnedSlot(shape, torch.float32)]
    pointers = []
    checks = []
    for step in range(iterations):
```

```
        slot = slots[step % len(slots)]
        source = torch.full(shape, float(step), dtype=torch.float32)
        slot.refill(source)
        device_batch, ready = slot.submit(device, copy_stream)
        compute_stream.wait_event(ready)
        with torch.cuda.stream(compute_stream):
            checks.append(device_batch[0, 0, 0, 0] + 0.0)
        pointers.append(slot.host.data_ptr())
    torch.cuda.synchronize(device)
    values = [float(value.item()) for value in checks]
    return {"unique_host_pointers": len(set(pointers)),
            "slot_count": len(slots), "values": values}
```

Part 6 - Measurement, Validation, and Failure Analysis

Require the number of unique host pointers to equal slot count and device values to equal iteration identifiers. Remove the per-slot wait deliberately in a controlled test to observe corruption risk, then restore it. If overlap is absent, inspect stream capability and whether CPU refill itself dominates.

Part 7 - Engineering Interpretation and Philosophy

Reuse changes memory optimization into a lifetime protocol. Capacity, ownership, and completion must be explicit. Events are not incidental synchronization; they are the proof that mutating a shared resource is safe.

19.7.17 Exercise 16

Exercise Title: Compare Fresh Pinned Allocations Against Reused Pinned Buffers and Quantify Allocation Overhead and Transfer Throughput

Part 1 - Exercise Contract and Why It Matters

Benchmark fresh page-locked allocation per batch against a fixed reusable pool. Quantify allocation overhead, refill cost, H2D throughput, total iteration time, and peak pinned capacity.

Part 2 - System and Memory Mental Model

Fresh allocation repeatedly asks the runtime and operating system to establish page-locked storage. Reuse pays this cost during pool construction, but still copies producer data into the slot unless data is generated directly there. The correct comparison includes equal useful work and explicit cleanup.

Part 3 - Quantitative Prediction Before Execution

Predict total fresh cost $N(P + F + C)$ and reuse cost $KP + N(F + C)$, where P is pinned allocation, F refill, C transfer, and K pool size. Solve the break-even iteration count.

Part 4 - Experimental Design and Instrumentation

Pre-generate identical pageable batches. Use synchronized end-to-end timing for both policies and phase timers for allocation/refill/copy. Randomize policy order across complete repetitions and report host-memory budget.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def run_policy(batches, device, reuse):
    allocation_ms = 0.0
    refill_ms = 0.0
    copy_ms = 0.0
    slot = None
    if reuse:
        start = time.perf_counter()
        slot = torch.empty_like(batches[0], pin_memory=True)
        allocation_ms += (time.perf_counter() - start) * 1000.0
    for batch in batches:
        if not reuse:
            start = time.perf_counter()
            slot = torch.empty_like(batch, pin_memory=True)
            allocation_ms += (time.perf_counter() - start) * 1000.0
        start = time.perf_counter()
        slot.copy_(batch)
        refill_ms += (time.perf_counter() - start) * 1000.0
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destination = slot.to(device, non_blocking=True)
        torch.cuda.synchronize(device)
        copy_ms += (time.perf_counter() - start) * 1000.0
    total_ms = allocation_ms + refill_ms + copy_ms
    return {"allocation_ms": allocation_ms,
            "refill_ms": refill_ms,
            "copy_ms": copy_ms, "total_ms": total_ms,
            "checksum": float(destination.float().sum().item())}

def E16(iterations=30, shape=(16, 3, 224, 224)):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    batches = []
    for index in range(iterations):
        batches.append(torch.full(shape, float(index), dtype=torch.float32))
    return {"fresh": run_policy(batches, device, False),
            "reused": run_policy(batches, device, True)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Verify equal checksums and equal batch sequences. The single-slot reused path synchronizes before refill and therefore measures safe serial reuse; compare a separate double-buffer overlap design without mixing conclusions. Fresh pinned allocation may be affected by runtime caching, so repeat from clean processes.

Part 7 - Engineering Interpretation and Philosophy

Reuse is valuable because it transforms variable control-plane cost into fixed capacity. Its benefit must be weighed against buffer residency, shape policy, and the synchronization discipline required to avoid corruption.

19.7.18 Exercise 17

Exercise Title: Create a Large Multi-Tensor Batch and Determine Which Tensors Should Be Pinned Based on Transfer Frequency, Size, and Lifetime

Part 1 - Exercise Contract and Why It Matters

Create a heterogeneous batch and select pinned fields under a strict host-memory budget. Base the policy on measured savings, transfer frequency, size, lifetime, and reuse rather than pinning every tensor automatically.

Part 2 - System and Memory Mental Model

The value of pinning field i scales with how often it crosses the bus and how much critical-path time is saved. Its cost scales with resident pinned bytes, allocation/conversion work, and lifetime. Tiny metadata may not repay fixed overhead; large infrequently transferred caches may consume capacity without improving iteration time.

Part 3 - Quantitative Prediction Before Execution

Define a measured benefit score

$$V_i = f_i \max(0, T_{pageable,i} - T_{pinned,i})$$

and efficiency V_i/R_i, where f_i is transfer frequency and R_i resident pinned bytes. Predict selections under a fixed budget, while treating mandatory latency-sensitive fields as explicit constraints.

Part 4 - Experimental Design and Instrumentation

Inventory every tensor: semantic role, bytes, frequency, lifetime, device destination, contiguity, and measured latency. Benchmark fields independently, then validate the chosen combination end to end because transfers can contend.

Part 5 - PyTorch/CUDA Implementation

```
def select_fields(field_rows, budget_bytes):
    candidates = []
    for row in field_rows:
        saved_ms = max(0.0, row["pageable_ms"] - row["pinned_ms"])
        value = row["transfers_per_step"] * saved_ms
        resident = row["resident_bytes"]
        efficiency = value / resident if resident > 0 else 0.0
        candidate = dict(row)
        candidate["saved_ms_per_step"] = value
        candidate["efficiency"] = efficiency
        candidates.append(candidate)
    candidates.sort(key=lambda item: item["efficiency"], reverse=True)
```

```
    selected = []
    used = 0
    for candidate in candidates:
        if candidate.get("must_pin", False):
            if used + candidate["resident_bytes"] > budget_bytes:
                raise RuntimeError("Mandatory fields exceed pinned budget")
            selected.append(candidate)
            used += candidate["resident_bytes"]
    for candidate in candidates:
        if candidate in selected:
            continue
        if candidate["saved_ms_per_step"] <= 0.0:
            continue
        proposed = used + candidate["resident_bytes"]
        if proposed <= budget_bytes:
            selected.append(candidate)
            used = proposed
    return selected, used

def E17(measured_field_rows, budget_mib=512):
    budget_bytes = budget_mib * 1024 ** 2
    selected, used = select_fields(measured_field_rows, budget_bytes)
    names = []
    for row in selected:
        names.append(row["name"])
    return {"selected": names, "used_bytes": used,
            "budget_bytes": budget_bytes}
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate that selected capacity never exceeds budget and remeasure the full pipeline. The greedy policy is transparent but not globally optimal; compare it with alternate combinations when interactions matter. Include queue depth in resident bytes, not merely one tensor's size.

Part 7 - Engineering Interpretation and Philosophy

Pinning is resource allocation under scarcity. A defensible policy makes value, cost, lifetime, and constraints explicit, allowing the system to degrade gracefully when host capacity changes.

19.7.19 Exercise 18

Exercise Title: Profile a Real PyTorch Training Pipeline and Identify Whether Pageable Memory, Pinning Overhead, CPU Preprocessing, or GPU Compute Is the Bottleneck

Part 1 - Exercise Contract and Why It Matters

Instrument a real training step and classify its dominant bottleneck using multiple independent measurements. Produce evidence for pageable staging, pinning overhead, CPU preprocessing, H2D transfer, GPU compute, and idle gaps.

Part 2 - System and Memory Mental Model

Pipeline throughput emerges from stages and queues. Long `next(loader)` time suggests producer starvation; expensive manual pinning suggests misplaced conversion; long copy events suggest transfer pressure; gaps before GPU kernels suggest scheduling or input starvation; continuously busy compute kernels suggest a compute-bound model. No single counter identifies all stages.

Part 3 - Quantitative Prediction Before Execution

Before profiling, estimate batch bytes, ideal H2D time, CPU transform time, and model compute time. Predict a bottleneck and write a falsifying observation for that hypothesis.

Part 4 - Experimental Design and Instrumentation

Combine explicit stage timers with `torch.profiler` regions, CPU and CUDA activities, shape recording, and a controlled pinning ablation. Profile only active steps after warmup because tracing changes timing. Preserve a baseline run without profiler to quantify overhead.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, record_function

def E18(loader, model, optimizer, loss_function, steps=10):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    model = model.to(device)
    iterator = iter(loader)
    observed_pinned_states = []
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    with torch.profiler.profile(activities=activities,
                                record_shapes=True,
                                profile_memory=True) as profiler:
        for _ in range(steps):
            with record_function("input_wait"):
                inputs, labels = next(iterator)
                observed_pinned_states.append(
                    bool(inputs.is_pinned() and labels.is_pinned()))
            with record_function("host_to_device"):
                inputs = inputs.to(device, non_blocking=True)
                labels = labels.to(device, non_blocking=True)
            with record_function("forward_loss"):
                outputs = model(inputs)
                loss = loss_function(outputs, labels)
            with record_function("backward_optimizer"):
                optimizer.zero_grad(set_to_none=True)
                loss.backward()
                optimizer.step()
            profiler.step()
    table = profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=30)
```

```
    return {"table": table, "last_loss": float(loss.detach().item()),
            "all_batches_were_pinned": all(observed_pinned_states)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not equate DataLoader's pinning flag with verified tensor state; inspect `is_pinned()` in the batch. Compare profiler regions with baseline wall time and CUDA events. If removing pinning improves time, test whether pinning cost, tiny batches, or host pressure explains it. If GPU utilization is low, separate waiting from synchronization and CPU dispatch gaps.

Part 7 - Engineering Interpretation and Philosophy

Profiling is hypothesis testing, not screenshot collection. Optimize the stage that constrains throughput, then rerun the whole system because removing one bottleneck exposes another.

19.7.20 Exercise 19

Exercise Title: Design and Benchmark a Memory-Efficient Pinned-Buffer Pipeline That Maximizes Host-to-GPU Throughput Without Excessive Host RAM Consumption

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter into a production-shaped design: bounded pinned slots, copy/compute overlap, event-governed reuse, host-RAM budgeting, measurement, validation, and graceful fallback. Defend the final policy with before-and-after evidence rather than maximum microbenchmark bandwidth alone.

Part 2 - System and Memory Mental Model

The pipeline is a bounded producer–consumer system. CPU producers fill pinned slots; a copy stream moves them; a compute stream waits only for the appropriate copy event; completion events protect slots from premature refill. Backpressure occurs when no slot is safe. Capacity equals slot count times maximum slot bytes, plus DataLoader and application queues. Variable shapes require size classes, padding, or a controlled pageable fallback rather than unbounded reallocation.

Part 3 - Quantitative Prediction Before Execution

Choose a pinned-RAM budget from available memory and operational reserve. For slot size B and count K, predict resident capacity KB, copy time, compute time, and ideal overlapped iteration time $\max(T_{fill}, T_{copy}, T_{compute})$. Compare one, two, and three slots; more slots help only when they cover real pipeline latency.

Part 4 - Experimental Design and Instrumentation

Benchmark pageable baseline, fresh pinning, single-slot reuse, and double-buffer overlap. Use identical batches and outputs. Record throughput, median/p95 latency, effective bandwidth, available RAM, slot waits, GPU idle gaps, and errors. Stress expected shape variation and inject an oversized batch to verify bounded fallback.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class BoundedPinnedPipeline:
    def __init__(self, shape, dtype, slots, max_pinned_bytes, device):
        bytes_per_slot = torch.empty((), dtype=dtype).element_size()
        for dimension in shape:
            bytes_per_slot *= dimension
        required = slots * bytes_per_slot
        if required > max_pinned_bytes:
            raise MemoryError("Pinned pool exceeds configured budget")
        self.device = device
        self.copy_stream = torch.cuda.Stream(device=device)
        self.compute_stream = torch.cuda.current_stream(device)
        self.host_slots = []
        self.done_events = []
        for _ in range(slots):
            host = torch.empty(shape, dtype=dtype, pin_memory=True)
            self.host_slots.append(host)
            self.done_events.append(None)
        self.next_slot = 0

    def stage(self, source):
        index = self.next_slot
        event = self.done_events[index]
        if event is not None:
            event.synchronize()
        host = self.host_slots[index]
        if source.shape != host.shape or source.dtype != host.dtype:
            destination = source.to(self.device)
            return destination, None, "bounded_fallback"
        host.copy_(source)
        ready = torch.cuda.Event()
        with torch.cuda.stream(self.copy_stream):
            destination = host.to(self.device, non_blocking=True)
            ready.record(self.copy_stream)
        self.compute_stream.wait_event(ready)
        self.done_events[index] = ready
        self.next_slot = (index + 1) % len(self.host_slots)
        return destination, ready, "pinned_pool"

def E19(cpu_batches, model, max_pinned_mib=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    if len(cpu_batches) == 0:
        raise ValueError("At least one batch is required")
    device = torch.device("cuda:0")
    model = model.to(device)
    first = cpu_batches[0]
```

```
    pipeline = BoundedPinnedPipeline(
        first.shape, first.dtype, slots=2,
        max_pinned_bytes=max_pinned_mib * 1024 ** 2, device=device)
    outputs = []
    paths = []
    for batch in cpu_batches:
        device_batch, ready, path = pipeline.stage(batch)
        with torch.cuda.stream(pipeline.compute_stream):
            output = model(device_batch)
            outputs.append(output)
        paths.append(path)
    torch.cuda.synchronize(device)
    checksums = []
    for output in outputs:
        checksums.append(float(output.float().sum().item()))
    return {"paths": paths, "checksums": checksums,
            "pinned_slots": len(pipeline.host_slots)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare outputs with the pageable baseline within declared tolerances. Confirm pool bytes never exceed budget, slot pointers remain stable, and each slot waits before refill. The sample fallback is synchronous and correctness-oriented; production code should log it, apply backpressure, or route to an approved size class. Test cancellation and exceptions so events and buffers are not abandoned in ambiguous states.

Part 7 - Engineering Interpretation and Philosophy

Maximum bandwidth is not the final objective. The engineering objective is predictable useful throughput under finite host memory, variable demand, and failure. A mature pinned-buffer pipeline owns its capacity, proves its lifetime rules, exposes backpressure, validates correctness, and can choose a slower safe path instead of destabilizing the machine.

19.8 DMM06

Chapter Title: Non-Blocking CPU-GPU Transfers
Specialization: Dynamic Memory Management and CUDA Systems

19.8.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Synchronous and Asynchronous Tensor Transfers Between CPU and CUDA Devices

Part 1 - Exercise Contract and Why It Matters

Build a model that separates API return, CUDA-stream completion, data visibility, source lifetime, and destination consumption. The deliverable is a transfer timeline for H2D, D2H, and D2D copies. For each direction, state who may proceed, which storage may be changed, and what synchronization proves completion. This precision is essential because asynchronous transfer bugs often return plausible values rather than raising exceptions.

Part 2 - System and Memory Mental Model

CUDA work is submitted to streams and normally executes asynchronously with respect to the host. A blocking PyTorch transfer introduces host-visible waiting before the call returns. A non-blocking request attempts to enqueue the copy and return earlier; it does not make the bytes instantaneous. Stream ordering protects operations on the same stream, while work on different streams needs explicit dependencies.

For H2D, page-locked source memory enables direct asynchronous DMA. That source must remain alive and unmodified until copy completion. For D2H, the CPU destination cannot be trusted until an event, stream, or device synchronization completes. For D2D, CUDA streams protect device-side consumers when ordering is correct; cross-stream use requires a wait event. The `non_blocking` argument is therefore only one part of a lifetime and visibility protocol.

Part 3 - Quantitative Prediction Before Execution

For B bytes and effective bandwidth R, predict device transfer time $T_{copy} = B/R$. Add host submission cost T_s and any wait T_w. Predict separate values for API-call latency T_s, completed wall latency $T_s + T_w$, and useful-overlap time. Draw two timelines: one with a host wait after every copy and one with several submissions followed by one completion barrier.

Part 4 - Experimental Design and Instrumentation

Use preallocated tensors, warm CUDA, fixed device and stream, and deterministic values. Measure host submission with `perf_counter`, device duration with CUDA events, and completed wall time with synchronization. Keep sources alive until validation. Treat pageable and pinned H2D sources as different paths, and never infer readiness merely because Python regained control.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E00(numel=16 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM06.")
    device = torch.device("cuda:0")
    source = torch.arange(numel, dtype=torch.float32, pin_memory=True)
    stream = torch.cuda.Stream(device=device)
    torch.empty(1, device=device)
    torch.cuda.synchronize(device)

    start_event = torch.cuda.Event(enable_timing=True)
    end_event = torch.cuda.Event(enable_timing=True)
    host_start = time.perf_counter()
    with torch.cuda.stream(stream):
        start_event.record(stream)
        destination = source.to(device, non_blocking=True)
        end_event.record(stream)
    host_return = time.perf_counter()
    end_event.synchronize()
```

```
    completed = time.perf_counter()

    expected = float(source[-1].item())
    observed = float(destination[-1].item())
    return {
        "bytes": source.nbytes,
        "host_submission_ms": (host_return - host_start) * 1000.0,
        "completed_wall_ms": (completed - host_start) * 1000.0,
        "device_copy_ms": start_event.elapsed_time(end_event),
        "source_pinned": source.is_pinned(),
        "validated": observed == expected,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

The submission time should not be reported as transfer latency. Confirm that completed wall time includes the event wait and that event timing covers only stream work between records. If the three times are similar, the transfer may be too small or submission may be serialized by earlier work. If validation fails, inspect source mutation and lifetime before blaming numerical precision.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony transfers responsibility from the API to the programmer. Removing a wait can expose overlap, but it also creates an obligation to prove readiness and preserve lifetimes. High performance comes from explicit temporal ownership, not from adding a Boolean flag.

19.8.2 Exercise 01

Exercise Title: Compare tensor.to("cuda") and tensor.to("cuda", non_blocking=True) and Identify Where Host Synchronization Changes

Part 1 - Exercise Contract and Why It Matters

Compare blocking and non-blocking `to()` calls with identical pinned sources. Locate the exact boundary where host behavior changes, then prove that both paths still require completed data before validation.

Part 2 - System and Memory Mental Model

A blocking call performs or waits for the synchronization needed before it returns. A non-blocking call can return after enqueueing the copy. The latter allows the host to submit more work, but destination readiness remains governed by the CUDA stream. A later operation that forces a result back to the host may implicitly reveal the pending wait and hide it in an unexpected line.

Part 3 - Quantitative Prediction Before Execution

Predict API-call time and completed time for both modes. The non-blocking call should reduce host-call time more than completed copy time. Predict where the saved wait reappears when `torch.cuda.synchronize()` is executed.

Part 4 - Experimental Design and Instrumentation

Preallocate one pinned source, alternate modes, synchronize before each trial, and measure return and completion timestamps. Do not regenerate or repin data inside the timed region. Validate byte count and tensor values.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def measure_to(source, device, non_blocking, repeats):
    call_samples = []
    complete_samples = []
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destination = source.to(device, non_blocking=non_blocking)
        returned = time.perf_counter()
        torch.cuda.synchronize(device)
        completed = time.perf_counter()
        call_samples.append((returned - start) * 1000.0)
        complete_samples.append((completed - start) * 1000.0)
    return {
        "call_median_ms": statistics.median(call_samples),
        "complete_median_ms": statistics.median(complete_samples),
        "checksum": float(destination.float().sum().item()),
    }

def E01(numel=8 * 1024 * 1024, repeats=30):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.ones(numel, dtype=torch.float32, pin_memory=True)
    blocking = measure_to(source, device, False, repeats)
    non_blocking = measure_to(source, device, True, repeats)
    return {"blocking": blocking, "non_blocking": non_blocking}
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equal checksums and completion semantics. If blocking call time appears short, check whether PyTorch deferred synchronization to a later operation or whether the platform path differs. If non-blocking completion is faster, do not attribute all gain to asynchrony without randomizing order and measuring clocks, cache state, and background load.

Part 7 - Engineering Interpretation and Philosophy

Non-blocking execution does not delete work; it relocates waiting and allows overlap. Trace the wait through the entire dependency chain before declaring a speedup.

19.8.3 Exercise 02

Exercise Title: Measure CPU Submission Time Separately from Actual GPU Transfer Completion Time for Blocking and Non-Blocking Copies

Part 1 - Exercise Contract and Why It Matters

Build two independent clocks for one copy: a CPU clock around submission and CUDA events around device execution. Add a completion clock that waits for the event. Explain why these metrics answer different engineering questions.

Part 2 - System and Memory Mental Model

The CPU clock measures Python, dispatcher, driver submission, and any host wait. CUDA events measure elapsed work on a device timeline. Event synchronization connects those timelines and proves completion. Event creation and recording also have overhead, so they should be reused or measured when precision matters.

Part 3 - Quantitative Prediction Before Execution

For a 128 MiB pinned tensor, predict submission time, event duration, and wall completion. State which should scale strongly with bytes and which should remain approximately fixed until queue pressure appears.

Part 4 - Experimental Design and Instrumentation

Warm up, reset no unrelated state, record events on the same stream as the copy, and synchronize the ending event rather than the entire device when possible. Report medians and tail latency from repeated trials.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def one_trial(source, device, stream, non_blocking):
    torch.cuda.synchronize(device)
    start_event = torch.cuda.Event(enable_timing=True)
    end_event = torch.cuda.Event(enable_timing=True)
    wall_start = time.perf_counter()
    with torch.cuda.stream(stream):
        start_event.record(stream)
        destination = source.to(device, non_blocking=non_blocking)
        end_event.record(stream)
    host_return = time.perf_counter()
    end_event.synchronize()
    wall_end = time.perf_counter()
    return ((host_return - wall_start) * 1000.0,
            start_event.elapsed_time(end_event),
            (wall_end - wall_start) * 1000.0,
            destination)
```

```
def E02(numel=32 * 1024 * 1024, repeats=25):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    source = torch.ones(numel, dtype=torch.float32, pin_memory=True)
    rows = {}
    for mode in (False, True):
        submission = []
        device_time = []
        completed = []
        for _ in range(repeats):
            cpu_ms, gpu_ms, wall_ms, destination = one_trial(
                source, device, stream, mode)
            submission.append(cpu_ms)
            device_time.append(gpu_ms)
            completed.append(wall_ms)
        rows[str(mode)] = {
            "submission_median_ms": statistics.median(submission),
            "device_median_ms": statistics.median(device_time),
            "completed_median_ms": statistics.median(completed),
            "check": float(destination[0].item()),
        }
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

The end event must be recorded after the copy on the same stream. A device event does not include CPU preparation before submission. If submission time grows with queued operations, measure queue saturation separately. Do not compare an event duration in milliseconds with an unsynchronized Python duration and call the mismatch an error.

Part 7 - Engineering Interpretation and Philosophy

Latency has multiple observers. The host cares when it can do more work; the consumer cares when bytes are ready; the system owner cares about end-to-end throughput. Good instrumentation preserves all three perspectives.

19.8.4 Exercise 03

Exercise Title: Use torch.cuda.synchronize() to Prove Why Timing an Asynchronous Transfer Without Synchronization Produces Misleading Results

Part 1 - Exercise Contract and Why It Matters

Create an intentionally wrong benchmark and a corrected benchmark. Show that the wrong version mostly measures enqueue time, then locate the missing transfer cost with an explicit synchronization boundary.

Part 2 - System and Memory Mental Model

Python proceeds after asynchronous submission while the GPU continues copying. The CPU timestamp taken immediately after `to()` therefore does not observe completion. Synchronization blocks until prior work covered by its scope finishes. Device-wide synchronization is useful for proof but may be broader than production requires; an event or stream wait can provide narrower control.

Part 3 - Quantitative Prediction Before Execution

Predict an apparently impossible bandwidth from unsynchronized timing. Then predict a plausible value after dividing the same bytes by synchronized elapsed time. Explain why the first calculation violates the physical link limit.

Part 4 - Experimental Design and Instrumentation

Use a large pre-pinned tensor, warmup, and no unrelated GPU work. Run the wrong and correct measurements in alternating order. Retain the destination and validate it after completion.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E03(numel=64 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.ones(numel, dtype=torch.float32, pin_memory=True)
    warmup = source.to(device, non_blocking=True)
    torch.cuda.synchronize(device)

    wrong_start = time.perf_counter()
    wrong_destination = source.to(device, non_blocking=True)
    wrong_seconds = time.perf_counter() - wrong_start
    torch.cuda.synchronize(device)

    torch.cuda.synchronize(device)
    correct_start = time.perf_counter()
    correct_destination = source.to(device, non_blocking=True)
    torch.cuda.synchronize(device)
    correct_seconds = time.perf_counter() - correct_start

    wrong_bandwidth = source.nbytes / wrong_seconds / 1e9
    correct_bandwidth = source.nbytes / correct_seconds / 1e9
    return {
        "wrong_submission_only_ms": wrong_seconds * 1000.0,
        "wrong_apparent_GB_s": wrong_bandwidth,
        "correct_completed_ms": correct_seconds * 1000.0,
        "correct_GB_s": correct_bandwidth,
        "validated": torch.equal(wrong_destination, correct_destination),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

The synchronization after the wrong timer prevents its work from contaminating the correct trial but does not repair the wrong measurement. If the apparent bandwidth is not absurd, increase tensor size or repetitions. Device-wide waits include all preceding work on the device, so isolate the benchmark or use events for operation-specific timing.

Part 7 - Engineering Interpretation and Philosophy

A fast timestamp is not evidence of fast work when the work is still running. Every asynchronous benchmark must name its completion condition; otherwise it measures permission to proceed rather than delivered data.

19.8.5 Exercise 04

Exercise Title: Benchmark Blocking and Non-Blocking Host-to-Device Transfers Across Increasing Tensor Sizes

Part 1 - Exercise Contract and Why It Matters

Build a logarithmic size sweep that compares blocking and non-blocking H2D behavior using both host-return and completed-transfer metrics. Identify the size regions dominated by fixed overhead and bandwidth.

Part 2 - System and Memory Mental Model

Small copies expose dispatch and synchronization overhead. Large copies expose interconnect throughput. Non-blocking submission changes host latency most clearly when the copy itself is long enough to remain in flight after return. Completed transfer duration may remain similar because the same bytes cross the same link.

Part 3 - Quantitative Prediction Before Execution

For sizes from 1 KiB to 256 MiB, predict $T = \alpha + B/R$. Use different host-wait terms for blocking and non-blocking calls but the same first-order bandwidth. Mark the expected size where submission and completion diverge.

Part 4 - Experimental Design and Instrumentation

Preallocate pinned sources before timing, warm each size, alternate modes, and use more repetitions for small sizes. Record median submission, median completed wall time, p95, and effective GB/s. Cap the maximum size to safe host and VRAM budgets on the test machine.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def percentile(samples, fraction):
    ordered = sorted(samples)
    index = round((len(ordered) - 1) * fraction)
    return ordered[index]
```

```
def E04(repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    byte_sizes = []
    for exponent in range(10, 29, 2):
        byte_sizes.append(2 ** exponent)
    rows = []
    for requested_bytes in byte_sizes:
        numel = max(1, requested_bytes // 4)
        source = torch.ones(numel, dtype=torch.float32, pin_memory=True)
        for mode in (False, True):
            submission = []
            completed = []
            for _ in range(repeats):
                torch.cuda.synchronize(device)
                start = time.perf_counter()
                destination = source.to(device, non_blocking=mode)
                returned = time.perf_counter()
                torch.cuda.synchronize(device)
                end = time.perf_counter()
                submission.append((returned - start) * 1000.0)
                completed.append((end - start) * 1000.0)
            median_ms = statistics.median(completed)
            rows.append({
                "bytes": source.nbytes, "non_blocking": mode,
                "submission_median_ms": statistics.median(submission),
                "completed_median_ms": median_ms,
                "completed_p95_ms": percentile(completed, 0.95),
                "GB_s": source.nbytes / (median_ms / 1000.0) / 1e9,
                "check": float(destination[0].item()),
            })
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Plot submission and completion curves separately. Verify actual byte counts because integer division can alter requested sizes. If blocking and non-blocking completion differ substantially, repeat complete randomized runs and inspect power state, background traffic, and synchronization scope before concluding that the transport path itself changed.

Part 7 - Engineering Interpretation and Philosophy

Size sweeps prevent one tensor shape from becoming a universal recommendation. Choose non-blocking policy from the workload's distribution and overlap opportunity, not from one favorable point.

19.8.6 Exercise 05

Exercise Title: Compare Non-Blocking Transfers from Pageable and Pinned Host Memory and Explain the Different Transfer Paths

Part 1 - Exercise Contract and Why It Matters

Compare non-blocking H2D submission from pageable and pre-pinned sources. Explain why the same API flag does not guarantee the same physical path, lifetime rule, or overlap potential.

Part 2 - System and Memory Mental Model

DMA requires stable physical host pages. A pinned source supplies them directly. A pageable source may be staged through an internal pinned region; staging can introduce a CPU copy or synchronization before true DMA proceeds. PyTorch may still accept `non_blocking=True`, but full host–device overlap is most reliably designed with already pinned source storage. Because pinned memory can be read by DMA after the call returns, changing it early creates a real race.

Part 3 - Quantitative Prediction Before Execution

Model pageable cost as staging plus DMA and pinned cost as DMA plus fixed submission. Predict submission, completion, and end-to-end pin-then-copy cost for 4 KiB, 4 MiB, and 128 MiB. Keep pre-pinned and on-demand pinning predictions separate.

Part 4 - Experimental Design and Instrumentation

Construct value-equivalent sources outside timing. Verify `is_pinned()`, alternate paths, and measure host return, CUDA-event duration, and completion. Do not mutate either source until its copy is complete.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def sample_path(source, device, repeats):
    submission = []
    completion = []
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destination = source.to(device, non_blocking=True)
        returned = time.perf_counter()
        torch.cuda.synchronize(device)
        finished = time.perf_counter()
        submission.append((returned - start) * 1000.0)
        completion.append((finished - start) * 1000.0)
    return {"submission_ms": statistics.median(submission),
            "completion_ms": statistics.median(completion),
            "checksum": float(destination.float().sum().item())}

def E05(numel=16 * 1024 * 1024, repeats=25):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
```

```
    pageable = torch.arange(numel, dtype=torch.float32)
    pinned = torch.empty(numel, dtype=torch.float32, pin_memory=True)
    pinned.copy_(pageable)
    return {
        "pageable": sample_path(pageable, device, repeats),
        "pinned": sample_path(pinned, device, repeats),
        "pageable_flag": pageable.is_pinned(),
        "pinned_flag": pinned.is_pinned(),
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equal checksums and bytes. A short pageable API call does not prove direct DMA or safe overlap. If results vary, inspect NUMA placement and repeat from clean processes. Never generalize source-mutation safety from the pageable path to the pinned path.

Part 7 - Engineering Interpretation and Philosophy

An API promise and a physical mechanism are different layers. High-throughput design begins by controlling storage type explicitly and ends by validating the actual critical path.

19.8.7 Exercise 06

Exercise Title: Transfer Hundreds of Small Tensors and Measure How Removing Per-Copy Host Synchronization Changes Total Runtime

Part 1 - Exercise Contract and Why It Matters

Submit hundreds of equal small tensors using two policies: blocking each copy and enqueueing all copies before one completion barrier. Measure submission and total time separately.

Part 2 - System and Memory Mental Model

Per-copy synchronization repeatedly stalls the host and prevents the queue from filling. One final barrier preserves correctness while allowing submission to proceed. However, each small copy still carries dispatch and DMA transaction overhead; removing waits does not make granularity free.

Part 3 - Quantitative Prediction Before Execution

For N tensors, blocking time is approximately $N(T_s + T_c + T_w)$. Queued time approaches $NT_s + T_{queue} + T_w$. Predict the ratio for $N = 256$ and identify the remaining fixed-copy cost.

Part 4 - Experimental Design and Instrumentation

Preallocate pinned sources and preserve every destination until completion. Use the same stream, order, sizes, and values. Synchronize before trial start and once at the declared end. Repeat complete loops rather than cherry-picking individual copies.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def run_small_loop(sources, device, queued):
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    destinations = []
    for source in sources:
        destination = source.to(device, non_blocking=queued)
        destinations.append(destination)
        if not queued:
            torch.cuda.synchronize(device)
    submitted = time.perf_counter()
    torch.cuda.synchronize(device)
    completed = time.perf_counter()
    checksum = 0.0
    for destination in destinations:
        checksum += float(destination[0].item())
    return ((submitted - start) * 1000.0,
            (completed - start) * 1000.0, checksum)

def E06(count=256, elements_each=4096, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    sources = []
    for index in range(count):
        tensor = torch.full((elements_each,), float(index + 1),
                            dtype=torch.float32, pin_memory=True)
        sources.append(tensor)
    rows = {}
    for queued in (False, True):
        submit_samples = []
        total_samples = []
        for _ in range(repeats):
            submit_ms, total_ms, checksum = run_small_loop(
                sources, device, queued)
            submit_samples.append(submit_ms)
            total_samples.append(total_ms)
        rows[str(queued)] = {
            "submit_median_ms": statistics.median(submit_samples),
            "total_median_ms": statistics.median(total_samples),
            "checksum": checksum,
        }
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Require equal checksums. The blocking path may already synchronize inside `to()`, while the explicit wait makes the boundary unambiguous. If queued submission creates memory pressure, record peak VRAM because all destinations remain live simultaneously. Compare against coalescing in the next exercise.

Part 7 - Engineering Interpretation and Philosophy

Synchronization has multiplicative cost when placed inside a loop. Correctness requires a barrier before consumption, not necessarily a barrier after every independent submission.

19.8.8 Exercise 07

Exercise Title: Compare One Large Non-Blocking Transfer Against Many Small Non-Blocking Transfers with the Same Total Byte Count

Part 1 - Exercise Contract and Why It Matters

Hold total bytes and synchronization policy constant while changing transfer count. Quantify the cost that remains after per-copy host waits are removed.

Part 2 - System and Memory Mental Model

Non-blocking submission removes repeated waiting but not Python dispatch, driver enqueue, DMA descriptors, or small-transfer inefficiency. A large contiguous copy can approach link bandwidth. Packing many fields into one buffer adds a CPU copy, so copy-only and end-to-end packed measurements must be reported separately.

Part 3 - Quantitative Prediction Before Execution

Model N copies as $N\alpha + B/R$ and one copy as $\alpha + B/R$. Predict the copy-only difference for 64 MiB total. Then add a measured packing term to decide whether coalescing pays.

Part 4 - Experimental Design and Instrumentation

Use pre-pinned sources, equal actual byte counts, one final synchronization, and deterministic values. Measure 1, 16, and 256 copies. Keep destination objects alive and verify all of them.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def transfer_group(sources, device, repeats):
    samples = []
    checksum = 0.0
    for _ in range(repeats):
        torch.cuda.synchronize(device)
        start = time.perf_counter()
        destinations = []
        for source in sources:
            destinations.append(source.to(device, non_blocking=True))
        torch.cuda.synchronize(device)
```

```
        samples.append((time.perf_counter() - start) * 1000.0)
        checksum = 0.0
        for destination in destinations:
            checksum += float(destination[0].item())
    return statistics.median(samples), checksum

def E07(total_elements=16 * 1024 * 1024, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    rows = []
    for count in (1, 16, 256):
        elements_each = total_elements // count
        sources = []
        for index in range(count):
            source = torch.full((elements_each,), float(index + 1),
                                dtype=torch.float32, pin_memory=True)
            sources.append(source)
        median_ms, checksum = transfer_group(sources, device, repeats)
        actual_bytes = 0
        for source in sources:
            actual_bytes += source.nbytes
        rows.append({"copies": count, "bytes": actual_bytes,
                     "median_ms": median_ms,
                     "GB_s": actual_bytes / (median_ms / 1000.0) / 1e9,
                     "checksum": checksum})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Check actual bytes because division can drop elements. The checksum changes with the number and values of tensors, so compute a scenario-specific expected value rather than comparing raw checksums across counts. If packing is added, include packing time in a separate total metric.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony and batching solve different problems. One removes unnecessary host waiting; the other reduces the number of operations. Efficient pipelines often need both.

19.8.9 Exercise 08

Exercise Title: Build a Batched Transfer Function That Moves Nested PyTorch Tensors to CUDA Without Blocking the Host After Every Copy

Part 1 - Exercise Contract and Why It Matters

Move every tensor leaf in a nested batch to CUDA, preserve container structure, enqueue copies without per-leaf synchronization, and return an explicit completion ticket. Non-tensor metadata must remain unchanged.

Part 2 - System and Memory Mental Model

A nested batch is a tree of ownership. Each transferred leaf has a destination and a source lifetime. One event recorded after all copies on the transfer stream represents completion of the whole batch. Keeping source references in the ticket prevents premature reclamation; the caller chooses when to wait.

Part 3 - Quantitative Prediction Before Execution

Count tensor leaves and total bytes before transfer. Predict submission cost as the sum of leaf dispatch costs and transfer cost from total bytes plus granularity overhead. Define exactly what `ticket.wait()` guarantees.

Part 4 - Experimental Design and Instrumentation

Test dictionaries, lists, tuples, labels, and strings. Verify input structure, device placement, values, dtype, and a single completion event. Reject unsupported mutable custom containers visibly rather than silently dropping fields.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class TransferTicket:
    def __init__(self, event, sources, value):
        self.event = event
        self.sources = sources
        self.value = value
    def wait(self):
        self.event.synchronize()
        return self.value

def move_tree(value, device, sources):
    if torch.is_tensor(value):
        sources.append(value)
        return value.to(device, non_blocking=True)
    if isinstance(value, dict):
        result = {}
        for key, child in value.items():
            result[key] = move_tree(child, device, sources)
        return result
    if isinstance(value, list):
        result = []
        for child in value:
            result.append(move_tree(child, device, sources))
        return result
    if isinstance(value, tuple):
        result = []
        for child in value:
            result.append(move_tree(child, device, sources))
        return tuple(result)
```

```
    return value

def E08(batch):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    sources = []
    event = torch.cuda.Event()
    with torch.cuda.stream(stream):
        moved = move_tree(batch, device, sources)
        event.record(stream)
    return TransferTicket(event, sources, moved)
```

Part 6 - Measurement, Validation, and Failure Analysis

The ticket must stay alive until completion because it owns source references. If downstream GPU work uses another stream, call `wait_event` on that stream instead of forcing the host to wait. For CPU validation, call `ticket.wait()`. Add cycle detection if arbitrary recursive containers are supported.

Part 7 - Engineering Interpretation and Philosophy

A safe asynchronous interface returns both the future value and the evidence needed to know when it is ready. Hiding completion control makes fast code easy to misuse.

19.8.10 Exercise 09

Exercise Title: Benchmark DataLoader(pin_memory=True) with Blocking and Non-Blocking Batch Transfers Under an Identical Training Workload

Part 1 - Exercise Contract and Why It Matters

Measure training throughput when pinned DataLoader batches are transferred with blocking and non-blocking `to()`. Hold data order, workers, model, batch size, optimization, and measured steps constant.

Part 2 - System and Memory Mental Model

Pinned batches enable asynchronous H2D submission, but throughput improves only when host preparation, transfer, and GPU compute overlap or when repeated host waits are removed. A synchronization hidden in logging, loss extraction, or metric calculation can erase overlap.

Part 3 - Quantitative Prediction Before Execution

Predict the critical path for blocking as transfer plus compute. For the non-blocking path, predict the maximum of overlapped stages only if stream dependencies permit it. Estimate pinned queue bytes from batch size, workers, and prefetch factor.

Part 4 - Experimental Design and Instrumentation

Warm workers and GPU, verify `is_pinned()` on batches, use identical seeds and batch order, and avoid per-step `loss.item()`. Synchronize at benchmark boundaries and compare multiple complete runs.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def run_training(loader, model, optimizer, loss_fn, device,
                 non_blocking, steps):
    iterator = iter(loader)
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    examples = 0
    all_pinned = True
    for _ in range(steps):
        inputs, labels = next(iterator)
        all_pinned = all_pinned and inputs.is_pinned()
        all_pinned = all_pinned and labels.is_pinned()
        inputs = inputs.to(device, non_blocking=non_blocking)
        labels = labels.to(device, non_blocking=non_blocking)
        optimizer.zero_grad(set_to_none=True)
        outputs = model(inputs)
        loss = loss_fn(outputs, labels)
        loss.backward()
        optimizer.step()
        examples += inputs.shape[0]
    torch.cuda.synchronize(device)
    seconds = time.perf_counter() - start
    return {"seconds": seconds, "examples_s": examples / seconds,
            "all_sources_pinned": all_pinned,
            "last_loss": float(loss.detach().item())}

def E09(loader, model_factory, optimizer_factory, loss_fn, steps=100):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    if not loader.pin_memory:
        raise ValueError("DataLoader must use pin_memory=True")
    device = torch.device("cuda:0")
    reference_model = model_factory()
    reference_state = {}
    for name, tensor in reference_model.state_dict().items():
        reference_state[name] = tensor.detach().clone()
    results = {}
    for mode in (False, True):
        model = model_factory().to(device)
        model.load_state_dict(reference_state)
        optimizer = optimizer_factory(model.parameters())
        results[str(mode)] = run_training(
            loader, model, optimizer, loss_fn, device, mode, steps)
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

Initialize equivalent model states; merely constructing two models in sequence does not guarantee identical weights. The factory or caller should load the same state dictionary. If non-blocking is not faster, inspect compute dominance, default-stream serialization, batch size, and hidden host synchronizations.

Part 7 - Engineering Interpretation and Philosophy

The value of non-blocking transfer is systemic. A correct microbenchmark may show available overlap while a real training loop proves whether the application actually uses it.

19.8.11 Exercise 10

Exercise Title: Corrupt a Pinned Source Tensor Before an Asynchronous CUDA Copy Completes and Reproduce a Real Data-Race Failure

Part 1 - Exercise Contract and Why It Matters

Reproduce a controlled H2D race using disposable synthetic buffers. Enqueue a copy from pinned memory, modify that source before DMA completion, and detect a destination containing old, new, or mixed values. Never run this experiment on real training data or shared application buffers.

Part 2 - System and Memory Mental Model

Pinned host memory is directly accessible to the DMA engine. Once a non-blocking copy is submitted, the host can regain control while the GPU is still reading the source. A CPU write during that interval has no CUDA-stream ordering, so the device may observe bytes before or after modification. Python object lifetime alone does not protect content immutability.

Part 3 - Quantitative Prediction Before Execution

Predict three outcomes: entirely original values, entirely overwritten values, or a mixture. Queue an unrelated large transfer before the target copy to widen the race window. The exercise demonstrates possibility, not a guaranteed split at a specific element.

Part 4 - Experimental Design and Instrumentation

Use a bounded allocation size, fresh pinned tensors, a dedicated stream, and a fixed number of trials. Initialize target with one value and overwrite with a different value. Record an event after the copy and inspect only after event completion. Report mismatches; do not assert that every machine must reproduce the same race frequency.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E10(target_mib=64, blocker_mib=128, trials=10):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    target_numel = target_mib * 1024 * 1024 // 4
```

```
    blocker_numel = blocker_mib * 1024 * 1024 // 4
    race_rows = []
    for trial in range(trials):
        blocker = torch.ones(blocker_numel, dtype=torch.float32,
                             pin_memory=True)
        source = torch.full((target_numel,), 1.0, dtype=torch.float32,
                            pin_memory=True)
        done = torch.cuda.Event()
        with torch.cuda.stream(stream):
            blocker_device = blocker.to(device, non_blocking=True)
            destination = source.to(device, non_blocking=True)
            done.record(stream)

        source.fill_(9.0)  # Intentional unsafe write for this experiment.
        done.synchronize()
        count_original = int((destination == 1.0).sum().item())
        count_overwritten = int((destination == 9.0).sum().item())
        count_other = target_numel - count_original - count_overwritten
        race_rows.append({"trial": trial, "original": count_original,
                          "overwritten": count_overwritten,
                          "other": count_other,
                          "blocker_check": float(blocker_device[0].item())})
    observed = False
    for row in race_rows:
        if row["overwritten"] > 0 or row["other"] > 0:
            observed = True
    return {"race_observed": observed, "trials": race_rows}
```

Part 6 - Measurement, Validation, and Failure Analysis

No observed mismatch does not prove safety; the copy may have won every race. Increase trials or bounded blocker size without exhausting RAM. Mixed values are direct evidence that the copy and CPU write overlapped. Entirely overwritten output is also corruption relative to the submitted logical batch.

Part 7 - Engineering Interpretation and Philosophy

Data races are timing-dependent violations, not deterministic exceptions. A system is unsafe if corruption is possible even when a short test happens to pass. Safety must come from a lifetime protocol, not favorable scheduling.

19.8.12 Exercise 11

Exercise Title: Fix an Unsafe Pinned-Memory Transfer by Introducing Correct Lifetime Management and Synchronization

Part 1 - Exercise Contract and Why It Matters

Repair the race from E10 with a reusable pinned slot that retains its storage and blocks only when that particular slot is about to be overwritten. Prove correct values across many iterations.

Part 2 - System and Memory Mental Model

An event recorded after the copy is the completion token for source reuse. The CPU may perform unrelated work while DMA runs, but it must wait on that event before mutating the slot. A ring of slots reduces waiting by offering another safe buffer while one remains in flight.

Part 3 - Quantitative Prediction Before Execution

For K slots of B bytes, predict pinned capacity KB. Draw the state machine: available, filling, in-flight, and available again. Identify the only transition that requires completion evidence.

Part 4 - Experimental Design and Instrumentation

Fill each slot with an iteration identifier, submit on one copy stream, retain the returned device tensors, and wait only before slot reuse. Validate all values after a final barrier. Track pointers to prove bounded reuse.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class SafePinnedSlot:
    def __init__(self, shape, dtype):
        self.host = torch.empty(shape, dtype=dtype, pin_memory=True)
        self.copy_done = None

    def prepare(self, value):
        if self.copy_done is not None:
            self.copy_done.synchronize()
        self.host.fill_(value)

    def submit(self, device, stream):
        event = torch.cuda.Event()
        with torch.cuda.stream(stream):
            destination = self.host.to(device, non_blocking=True)
            event.record(stream)
        self.copy_done = event
        return destination

def E11(iterations=30, elements=4 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    slots = [SafePinnedSlot((elements,), torch.float32),
             SafePinnedSlot((elements,), torch.float32)]
    outputs = []
    pointers = []
    for step in range(iterations):
        slot = slots[step % len(slots)]
```

```
        slot.prepare(float(step))
        outputs.append(slot.submit(device, stream))
        pointers.append(slot.host.data_ptr())
    torch.cuda.synchronize(device)
    validated = True
    for step, output in enumerate(outputs):
        if float(output[0].item()) != float(step):
            validated = False
    return {"validated": validated,
            "unique_host_buffers": len(set(pointers)),
            "configured_slots": len(slots)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Require unique pointers to equal slot count. The event protects host source reuse, not arbitrary consumers of the CUDA destination. If compute runs on a different stream, make that stream wait on a readiness event. On exception, retain or synchronize in-flight slots before returning them to a pool.

Part 7 - Engineering Interpretation and Philosophy

Correct synchronization is local to the resource whose lifetime is changing. This is both safer and faster than synchronizing the entire device after every operation.

19.8.13 Exercise 12

Exercise Title: Perform a Non-Blocking CUDA-to-CPU Transfer and Demonstrate Why Reading the Destination Too Early Can Produce Incorrect Results

Part 1 - Exercise Contract and Why It Matters

Enqueue D2H transfer into a preallocated pinned CPU tensor, inspect a small sample before completion, then wait and validate the final result. Demonstrate that early host access has no stream dependency and is therefore unsafe.

Part 2 - System and Memory Mental Model

The GPU writes the pinned destination through DMA while the CPU can directly read the same memory. A non-blocking copy returns before those writes necessarily finish. CUDA stream ordering protects later GPU work, but it does not automatically delay ordinary CPU loads. The host needs an event or equivalent completion wait.

Part 3 - Quantitative Prediction Before Execution

Initialize the host buffer with -1 and device source with 7. Predict that an immediate sample may contain stale -1, new 7, or a mixture. After synchronization every element must be 7.

Part 4 - Experimental Design and Instrumentation

Use disposable tensors, a dedicated copy stream, and an event recorded after `copy_`. Read only a small prefix early to limit observer overhead. Never use the early result for real decisions.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E12(numel=32 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    device_source = torch.full((numel,), 7.0, device=device)
    host_destination = torch.full((numel,), -1.0, dtype=torch.float32,
                                  pin_memory=True)
    done = torch.cuda.Event()
    with torch.cuda.stream(stream):
        host_destination.copy_(device_source, non_blocking=True)
        done.record(stream)

    early_values = host_destination[:16].clone()
    ready_before_wait = done.query()
    done.synchronize()
    final_valid = bool(torch.all(host_destination == 7.0).item())
    return {"ready_before_wait": ready_before_wait,
            "early_values": early_values.tolist(),
            "final_valid": final_valid}
```

Part 6 - Measurement, Validation, and Failure Analysis

Early values may look correct if the transfer completes quickly; this does not make early reading safe. The event query records whether completion was already known at that instant. Final validation must occur after the wait. Run multiple sizes and trials to reveal timing dependence.

Part 7 - Engineering Interpretation and Philosophy

Visibility is directional. H2D races threaten a source that DMA reads; D2H races threaten a destination that DMA writes. Safe code names which side is immutable and which side is not yet readable.

19.8.14 Exercise 13

Exercise Title: Design the Minimum Synchronization Required to Safely Consume Results After an Asynchronous Device-to-Host Copy

Part 1 - Exercise Contract and Why It Matters

Replace device-wide synchronization with the narrowest completion mechanism that safely permits CPU consumption of one D2H result. Compare event waiting, stream waiting, polling, and global waiting.

Part 2 - System and Memory Mental Model

An event recorded after the copy represents that copy and all earlier work in its stream. `event.synchronize()` blocks the host only until that point. `stream.synchronize()` waits for all current work in one stream, while `torch.cuda.synchronize()` waits for all work on the

device. Event query allows non-blocking polling but consumption remains forbidden until it returns true.

Part 3 - Quantitative Prediction Before Execution

Construct a stream with unrelated long work after the D2H copy. Predict that waiting on the copy event can release the CPU earlier than synchronizing the whole stream or device.

Part 4 - Experimental Design and Instrumentation

Record the event immediately after D2H copy and before unrelated stream work. Time event wait and whole-stream wait in separate equivalent trials. Validate the host result after the event only.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E13(numel=16 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    device_source = torch.arange(numel, dtype=torch.float32, device=device)
    host_destination = torch.empty(numel, dtype=torch.float32,
                                   pin_memory=True)
    copy_done = torch.cuda.Event()
    with torch.cuda.stream(stream):
        host_destination.copy_(device_source, non_blocking=True)
        copy_done.record(stream)
        unrelated = torch.randn((4096, 4096), device=device)
        unrelated_result = unrelated @ unrelated

    start = time.perf_counter()
    copy_done.synchronize()
    event_wait_ms = (time.perf_counter() - start) * 1000.0
    first = float(host_destination[0].item())
    last = float(host_destination[-1].item())
    stream.synchronize()
    return {"event_wait_ms": event_wait_ms,
            "validated": first == 0.0 and last == float(numel - 1),
            "unrelated_check": float(unrelated_result[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

The matrix multiplication may stress memory; scale it to the device. The event must be recorded before unrelated work. For a fair timing comparison, execute independent reconstructed trials because waiting once changes later wait times. Polling loops need backoff or useful host work to avoid wasting a CPU core.

Part 7 - Engineering Interpretation and Philosophy

Minimum synchronization means waiting for the required dependency, not removing all waits. Narrow completion tokens preserve concurrency while making readiness provable.

19.8.15 Exercise 14

Exercise Title: Compare CPU-to-GPU, GPU-to-CPU, and GPU-to-GPU non_blocking=True Semantics Through Controlled Correctness Experiments

Part 1 - Exercise Contract and Why It Matters

Build one experiment for each transfer direction and write its distinct lifetime and consumption rule. Prove correctness with events rather than assuming that the same flag has identical implications everywhere.

Part 2 - System and Memory Mental Model

H2D from pinned memory requires the CPU source to remain immutable until copy completion. D2H requires the CPU destination to remain unread until completion. D2D is ordered for operations on the same stream; a consumer on another stream must wait on an event. For cross-device copies, peer-access support and device topology can change the transport path without changing these dependency rules.

Part 3 - Quantitative Prediction Before Execution

For each direction, name source owner, destination owner, forbidden early action, and completion proof. Predict which action causes corruption: CPU source write, CPU destination read, or cross-stream GPU consumption.

Part 4 - Experimental Design and Instrumentation

Use pinned host buffers, one copy stream, one consumer stream, and separate events. Perform only safe variants in the final combined test; the unsafe variants are already isolated in E10 and E12. Validate values after appropriate waits.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E14(numel=4 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    copy_stream = torch.cuda.Stream(device=device)
    consumer_stream = torch.cuda.Stream(device=device)

    host_source = torch.full((numel,), 3.0, pin_memory=True)
    h2d_done = torch.cuda.Event()
    with torch.cuda.stream(copy_stream):
        gpu_a = host_source.to(device, non_blocking=True)
        h2d_done.record(copy_stream)
    h2d_done.synchronize()
```

```
    host_source.fill_(4.0)  # Safe only after the event.

    d2d_done = torch.cuda.Event()
    with torch.cuda.stream(copy_stream):
        gpu_b = torch.empty_like(gpu_a)
        gpu_b.copy_(gpu_a, non_blocking=True)
        d2d_done.record(copy_stream)
    consumer_stream.wait_event(d2d_done)
    with torch.cuda.stream(consumer_stream):
        gpu_sum = gpu_b.sum()

    host_destination = torch.empty(numel, dtype=torch.float32,
                                   pin_memory=True)
    d2h_done = torch.cuda.Event()
    with torch.cuda.stream(copy_stream):
        host_destination.copy_(gpu_b, non_blocking=True)
        d2h_done.record(copy_stream)
    d2h_done.synchronize()
    consumer_stream.synchronize()
    return {"h2d_value": float(gpu_a[0].item()),
            "d2d_sum": float(gpu_sum.item()),
            "d2h_value": float(host_destination[0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Expected transferred value is 3, although the host source becomes 4 after safe completion. The D2D sum and D2H value must agree with GPU A. If a second GPU is available, add a peer-copy variant and record peer-access support, but do not make two GPUs a requirement for this exercise.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony is not one universal behavior. Direction determines which memory is vulnerable and which observer needs a completion proof. A transfer API should encode these roles explicitly.

19.8.16 Exercise 15

Exercise Title: Profile Blocking and Non-Blocking Transfer Loops and Identify cudaMemcpyAsync and Synchronization Events in the Execution Trace

Part 1 - Exercise Contract and Why It Matters

Capture profiler traces for equivalent blocking and queued transfer loops. Locate copy activity, synchronization calls, CPU gaps, and CUDA kernels, then connect trace structure to measured runtime.

Part 2 - System and Memory Mental Model

PyTorch commonly dispatches CUDA copy machinery asynchronously at lower layers, even when a high-level blocking operation subsequently waits. The trace can therefore contain

`cudaMemcpyAsync` plus synchronization. Performance difference comes from where and how often waiting occurs, not necessarily from using a completely different copy primitive.

Part 3 - Quantitative Prediction Before Execution

Predict one synchronization region per blocking copy and one completion barrier for the queued loop. Predict equal copy counts but different CPU scheduling gaps.

Part 4 - Experimental Design and Instrumentation

Profile warm active steps only, annotate each mode with `record_function`, record CPU and CUDA activities, and export separate Chrome traces. Measure profiler overhead against an unprofiled baseline.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, record_function

def profile_loop(sources, device, queued, trace_path):
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    with torch.profiler.profile(activities=activities,
                                record_shapes=True) as profiler:
        destinations = []
        label = "queued_non_blocking" if queued else "per_copy_blocking"
        with record_function(label):
            for source in sources:
                destination = source.to(device, non_blocking=queued)
                destinations.append(destination)
                if not queued:
                    torch.cuda.synchronize(device)
            torch.cuda.synchronize(device)
    profiler.export_chrome_trace(trace_path)
    table = profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=30)
    return table, destinations

def validate_outputs(outputs):
    valid = True
    for index, output in enumerate(outputs):
        if float(output[0].item()) != float(index):
            valid = False
    return valid

def E15(output_prefix="dmm06_transfer"):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    sources = []
    for index in range(64):
        source = torch.full((256 * 1024,), float(index),
```

```
                        dtype=torch.float32, pin_memory=True)
    sources.append(source)
blocking_table, blocking_outputs = profile_loop(
    sources, device, False, output_prefix + "_blocking.json")
queued_table, queued_outputs = profile_loop(
    sources, device, True, output_prefix + "_queued.json")
return {"blocking_table": blocking_table,
        "queued_table": queued_table,
        "blocking_outputs": len(blocking_outputs),
        "queued_outputs": len(queued_outputs),
        "blocking_valid": validate_outputs(blocking_outputs),
        "queued_valid": validate_outputs(queued_outputs)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Search the trace for copy and synchronization events, but account for naming differences across PyTorch, CUDA, and profiler versions. The profiler changes timing and should diagnose structure, while the unprofiled benchmark determines speed. Verify both loops copied identical bytes and values.

Part 7 - Engineering Interpretation and Philosophy

A trace reveals causality that aggregate time hides. It shows whether the host waits after every operation, whether the queue stays populated, and where the saved time actually goes.

19.8.17 Exercise 16

Exercise Title: Measure Effective Transfer Bandwidth and Host Availability Under Blocking and Non-Blocking Workloads

Part 1 - Exercise Contract and Why It Matters

Measure two outcomes simultaneously: completed H2D bandwidth and how much useful CPU work can proceed while the copy is in flight. Avoid claiming success from short submission time when the host performs no useful work.

Part 2 - System and Memory Mental Model

Effective bandwidth measures bytes delivered per completion time. Host availability measures scheduling freedom between submission and completion. Non-blocking transfer can increase the latter without changing raw link bandwidth. Busy polling wastes that freedom; useful CPU preprocessing or next- batch preparation can exploit it.

Part 3 - Quantitative Prediction Before Execution

Predict GB/s from $B/(t10^9)$. Define a deterministic CPU work unit, calibrate its standalone rate, and predict how many units can execute before the transfer event completes. Keep copy contention and CPU work separate in interpretation.

Part 4 - Experimental Design and Instrumentation

Use a large pre-pinned source and CUDA event. For non-blocking mode, perform fixed CPU chunks until `event.query()` becomes true. For blocking mode, measure the same work only

after the call returns. Report completion bandwidth, overlap window, CPU units, and total wall time.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def cpu_work_unit(state):
    value = state
    for index in range(2000):
        value = (value * 1664525 + index + 1013904223) % 4294967296
    return value

def E16(numel=64 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.ones(numel, dtype=torch.float32, pin_memory=True)
    stream = torch.cuda.Stream(device=device)
    start_event = torch.cuda.Event(enable_timing=True)
    end_event = torch.cuda.Event(enable_timing=True)
    torch.cuda.synchronize(device)
    wall_start = time.perf_counter()
    with torch.cuda.stream(stream):
        start_event.record(stream)
        destination = source.to(device, non_blocking=True)
        end_event.record(stream)
    host_return = time.perf_counter()
    units = 0
    state = 1
    while not end_event.query():
        state = cpu_work_unit(state)
        units += 1
    wall_end = time.perf_counter()
    copy_ms = start_event.elapsed_time(end_event)
    return {"bytes": source.nbytes,
            "submission_ms": (host_return - wall_start) * 1000.0,
            "completion_wall_ms": (wall_end - wall_start) * 1000.0,
            "device_copy_ms": copy_ms,
            "GB_s": source.nbytes / (copy_ms / 1000.0) / 1e9,
            "cpu_work_units": units, "cpu_state": state,
            "check": float(destination[0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Event polling has overhead and should not be the production design; it provides a controlled experiment. Compare with a calibrated CPU-only loop and an event- wait version. If zero work

units execute, increase transfer size safely or use smaller work chunks. Report decimal GB/s explicitly.

Part 7 - Engineering Interpretation and Philosophy

The purpose of asynchrony is not an impressive API-return number. Its value is productive concurrency: the host advances the pipeline while the transfer engine delivers data.

19.8.18 Exercise 17

Exercise Title: Build a Transfer Queue That Submits Multiple Tensor Copies Before Performing a Single Explicit Synchronization

Part 1 - Exercise Contract and Why It Matters

Implement a transfer queue whose submissions return tickets and whose `wait_all()` method performs one explicit completion phase. Preserve source lifetimes and validate every destination.

Part 2 - System and Memory Mental Model

The queue owns a CUDA stream, pending source references, destinations, and events. Each event defines readiness of one result. One final wait drains the queue, but individual tickets can support earlier dependencies. Bounded queue depth prevents unlimited VRAM and host-reference growth.

Part 3 - Quantitative Prediction Before Execution

Predict resident source and destination bytes for depth Q. Define backpressure when pending count reaches Q. Compare $Q = 1, 4, 16$ for submission freedom, memory footprint, and throughput.

Part 4 - Experimental Design and Instrumentation

Use pinned sources with unique sentinels. Submit multiple copies, call one wait, and validate all outputs. Track peak pending bytes and reject a submission when the budget would be exceeded.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class CopyTicket:
    def __init__(self, source, destination, event):
        self.source = source
        self.destination = destination
        self.event = event
    def wait(self):
        self.event.synchronize()
        return self.destination

class TransferQueue:
    def __init__(self, device, max_pending):
        self.device = device
```

```
        self.stream = torch.cuda.Stream(device=device)
        self.max_pending = max_pending
        self.pending = []
    def submit(self, source):
        if len(self.pending) >= self.max_pending:
            raise RuntimeError("Transfer queue is full")
        event = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            destination = source.to(self.device, non_blocking=True)
            event.record(self.stream)
        ticket = CopyTicket(source, destination, event)
        self.pending.append(ticket)
        return ticket
    def wait_all(self):
        completed = []
        for ticket in self.pending:
            completed.append(ticket.wait())
        self.pending.clear()
        return completed

def E17(count=16, elements=1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    queue = TransferQueue(device, max_pending=count)
    for index in range(count):
        source = torch.full((elements,), float(index),
                            dtype=torch.float32, pin_memory=True)
        queue.submit(source)
    outputs = queue.wait_all()
    validated = True
    for index, output in enumerate(outputs):
        if float(output[0].item()) != float(index):
            validated = False
    return {"validated": validated, "completed": len(outputs)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The queue retains sources until wait, preventing deallocation but not mutation; callers must treat submitted sources as immutable. Production code should apply backpressure by waiting for the oldest ticket rather than raising immediately. Handle exceptions by draining or safely cancelling owned work.

Part 7 - Engineering Interpretation and Philosophy

A queue turns asynchronous calls into an explicit ownership system. Throughput comes from controlled in-flight work; stability comes from bounding it.

19.8.19 Exercise 18

Exercise Title: Stress-Test Asynchronous Transfers with Variable Tensor Sizes and Detect Incorrect Synchronization, Source-Lifetime, and Timing Assumptions

Part 1 - Exercise Contract and Why It Matters

Run a bounded randomized stress test across variable sizes, dtypes, and queue depths. Detect value corruption, lost lifetimes, invalid timing, and memory growth. The goal is to break assumptions that fixed-size microbenchmarks do not expose.

Part 2 - System and Memory Mental Model

Variable sizes change transfer duration and completion order across streams. Temporary Python objects may disappear while work is in flight, queues may retain too much memory, and one final global wait can hide incorrect per-result readiness. Sentinels and per-ticket events make these failures observable.

Part 3 - Quantitative Prediction Before Execution

Choose minimum and maximum bytes, dtype set, queue bound, and total in-flight budget before execution. Predict peak host and device bytes. Define failure as wrong sentinel, non-finite timing, exceeded budget, or unbounded memory trend.

Part 4 - Experimental Design and Instrumentation

Fix random seeds, generate an explicit case manifest, allocate pinned sources, and retain them in tickets. Drain the oldest ticket at the queue bound. Record submission and completion times, bytes, order, and allocator memory. Never stress to host or GPU exhaustion.

Part 5 - PyTorch/CUDA Implementation

```
import random
import time
import torch

def E18(cases=200, max_pending=8, max_mib=32):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    random.seed(1234)
    torch.manual_seed(1234)
    device = torch.device("cuda:0")
    torch.cuda.reset_peak_memory_stats(device)
    stream = torch.cuda.Stream(device=device)
    pending = []
    failures = []
    rows = []
    dtypes = [torch.float16, torch.float32, torch.float64]
    for case_index in range(cases):
        dtype = dtypes[case_index % len(dtypes)]
        mib = random.randint(1, max_mib)
        element_size = torch.empty((), dtype=dtype).element_size()
        numel = mib * 1024 * 1024 // element_size
```

```
        sentinel = float((case_index % 97) + 1)
        source = torch.full((numel,), sentinel, dtype=dtype,
                            pin_memory=True)
        event = torch.cuda.Event()
        submit_start = time.perf_counter()
        with torch.cuda.stream(stream):
            destination = source.to(device, non_blocking=True)
            event.record(stream)
        submit_ms = (time.perf_counter() - submit_start) * 1000.0
        pending.append((case_index, sentinel, source, destination, event))
        rows.append({"case": case_index, "bytes": source.nbytes,
                     "dtype": str(dtype), "submit_ms": submit_ms})
        if len(pending) >= max_pending:
            old_item = pending.pop(0)
            old_case = old_item[0]
            old_value = old_item[1]
            old_source = old_item[2]
            old_destination = old_item[3]
            old_event = old_item[4]
            old_event.synchronize()
            if float(old_destination[0].item()) != old_value:
                failures.append(old_case)
    for old_item in pending:
        old_case = old_item[0]
        old_value = old_item[1]
        old_source = old_item[2]
        old_destination = old_item[3]
        old_event = old_item[4]
        old_event.synchronize()
        if float(old_destination[0].item()) != old_value:
            failures.append(old_case)
    return {"cases": cases, "failures": failures, "rows": rows,
            "peak_allocated": torch.cuda.max_memory_allocated(device)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Reset peak statistics before independent runs if peak comparison is required. Validate more than the first element in a hardened version by sampling multiple positions or checksums. A zero-failure stress run increases confidence but does not prove correctness; code review of lifetime and stream dependencies remains necessary.

Part 7 - Engineering Interpretation and Philosophy

Stress testing explores schedules that ordinary tests rarely visit. Its strongest value is forcing hidden assumptions about size, order, and lifetime into explicit invariants.

19.8.20 Exercise 19

Exercise Title: Build and Benchmark a Safe High-Throughput PyTorch Host-to-GPU Transfer Engine Using Pinned Buffers, Non-Blocking Copies, and Explicit Completion Control

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter into a bounded transfer engine. It must reuse pinned host slots, submit H2D copies on a dedicated stream, expose readiness events, preserve source and destination lifetimes, connect to a consumer stream, apply backpressure, validate output, and report throughput against a blocking baseline.

Part 2 - System and Memory Mental Model

Each slot moves through available, filling, in-flight, and reusable states. A copy-completion event protects host-slot reuse. A consumer stream waits on the same readiness event before reading the CUDA destination. Because the destination was allocated on the copy stream and consumed elsewhere, recording the consumer stream on that tensor protects allocator lifetime. The pool size bounds pinned RAM; slot acquisition provides backpressure.

Part 3 - Quantitative Prediction Before Execution

For K slots and batch bytes B, predict pinned capacity KB. Estimate serial time $T_{fill} + T_{copy} + T_{compute}$ and overlapped time near their maximum when the pipeline is balanced. Predict the point where more slots stop improving throughput.

Part 4 - Experimental Design and Instrumentation

Use identical CPU batches for blocking and engine paths. Warm up both, synchronize only at declared boundaries, and report median throughput, p95 latency, pinned capacity, slot waits, and correctness. Test unsupported shape and budget failure without unbounded allocation.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

class EngineSlot:
    def __init__(self, shape, dtype):
        self.host = torch.empty(shape, dtype=dtype, pin_memory=True)
        self.copy_done = None
    def acquire(self):
        if self.copy_done is not None:
            self.copy_done.synchronize()

class EngineTicket:
    def __init__(self, destination, ready):
        self.destination = destination
        self.ready = ready
    def attach_consumer(self, consumer_stream):
        consumer_stream.wait_event(self.ready)
        self.destination.record_stream(consumer_stream)
        return self.destination
    def wait_host(self):
        self.ready.synchronize()
        return self.destination
```

```
class H2DTransferEngine:
    def __init__(self, shape, dtype, slot_count, budget_bytes, device):
        element_bytes = torch.empty((), dtype=dtype).element_size()
        slot_bytes = element_bytes
        for dimension in shape:
            slot_bytes *= dimension
        if slot_count * slot_bytes > budget_bytes:
            raise MemoryError("Pinned-buffer budget exceeded")
        self.shape = torch.Size(shape)
        self.dtype = dtype
        self.device = device
        self.copy_stream = torch.cuda.Stream(device=device)
        self.slots = []
        for _ in range(slot_count):
            self.slots.append(EngineSlot(shape, dtype))
        self.index = 0
        self.pinned_bytes = slot_count * slot_bytes
    def submit(self, source):
        if source.shape != self.shape or source.dtype != self.dtype:
            raise ValueError("Batch does not match engine shape and dtype")
        slot = self.slots[self.index]
        slot.acquire()
        slot.host.copy_(source)
        ready = torch.cuda.Event()
        with torch.cuda.stream(self.copy_stream):
            destination = slot.host.to(self.device, non_blocking=True)
            ready.record(self.copy_stream)
        slot.copy_done = ready
        self.index = (self.index + 1) % len(self.slots)
        return EngineTicket(destination, ready)

def E19(cpu_batches, model, slot_count=2, budget_mib=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    if len(cpu_batches) == 0:
        raise ValueError("At least one batch is required")
    device = torch.device("cuda:0")
    model = model.to(device)
    model.eval()

    baseline_checksums = []
    torch.cuda.synchronize(device)
    baseline_start = time.perf_counter()
    with torch.no_grad():
        for batch in cpu_batches:
            device_batch = batch.to(device, non_blocking=False)
            output = model(device_batch)
            baseline_checksums.append(output.float().sum())
```

```
    torch.cuda.synchronize(device)
    baseline_seconds = time.perf_counter() - baseline_start

    engine = H2DTransferEngine(
        cpu_batches[0].shape, cpu_batches[0].dtype, slot_count,
        budget_mib * 1024 ** 2, device)
    consumer = torch.cuda.current_stream(device)
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    checksums = []
    with torch.no_grad():
        for batch in cpu_batches:
            ticket = engine.submit(batch)
            device_batch = ticket.attach_consumer(consumer)
            with torch.cuda.stream(consumer):
                output = model(device_batch)
                checksums.append(output.float().sum())
    torch.cuda.synchronize(device)
    seconds = time.perf_counter() - start
    values = []
    for checksum in checksums:
        values.append(float(checksum.item()))
    baseline_values = []
    for checksum in baseline_checksums:
        baseline_values.append(float(checksum.item()))
    return {"baseline_seconds": baseline_seconds,
            "engine_seconds": seconds,
            "baseline_batches_s": len(cpu_batches) / baseline_seconds,
            "engine_batches_s": len(cpu_batches) / seconds,
            "pinned_bytes": engine.pinned_bytes,
            "outputs_match": values == baseline_values,
            "checksums": values}
```

Part 6 - Measurement, Validation, and Failure Analysis

Compare checksums with a blocking reference under identical model state. The sample engine waits before refilling a slot and rejects shape drift; production systems may use bounded size classes or an explicit fallback. Handle exceptions by synchronizing owned in-flight events before recycling slots. Monitor pinned RAM, VRAM, and queue depth together.

Part 7 - Engineering Interpretation and Philosophy

A transfer engine is a temporal memory manager. It succeeds when it makes ownership, readiness, reuse, and backpressure explicit while reducing the real critical path. Throughput without those invariants is merely a faster route to silent corruption.

19.9 DMM07

Chapter Title: CUDA Streams in PyTorch
Specialization: Dynamic Memory Management and CUDA Systems

19.9.1 Exercise 00

Exercise Title: Build a Precise Mental Model of the Default CUDA Stream, Custom Streams, Queued Operations, and Asynchronous GPU Execution

Part 1 - Exercise Contract and Why It Matters

Construct a stream-level model of one PyTorch process. Identify the current stream for each device, the ordered queue inside each stream, the absence of automatic ordering across independent streams, and the points where the CPU waits. The final model must separately explain execution dependency, completion observation, and allocator lifetime.

Part 2 - System and Memory Mental Model

A CUDA stream is an ordered sequence belonging to one device. Operations in the same stream execute in issue order. Different streams can overlap or interleave when dependencies and hardware resources allow, but concurrency is not guaranteed. PyTorch submits work asynchronously, so Python can continue while a stream still contains queued kernels.

The current stream is a thread-local submission context. The default stream is used when no custom context is active. `wait_stream()` and events create execution dependencies; `synchronize()` makes the host wait; `record_stream()` tells the allocator that tensor storage remains in use by a side stream. These mechanisms answer different questions and cannot be substituted blindly.

Part 3 - Quantitative Prediction Before Execution

Draw two streams with operations A_1, A_2 and B_1, B_2. Predict legal schedules without dependencies, then add an event from A_1 to B_2. Calculate sequential time $T_A + T_B$ and ideal overlap $\max(T_A, T_B)$, while noting that resource contention can place reality between them.

Part 4 - Experimental Design and Instrumentation

Record device, stream identifiers, event timestamps, host submission time, and completed wall time. Warm CUDA and use sufficiently large independent kernels. Validate results after explicit dependencies. Use profiler traces to prove overlap rather than inferring it from two stream objects.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def stream_description(stream):
    return {"device": str(stream.device),
            "cuda_stream": int(stream.cuda_stream),
            "priority": int(stream.priority),
            "ready": bool(stream.query())}

def E00(matrix_size=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required for DMM07.")
    device = torch.device("cuda:0")
    default_stream = torch.cuda.default_stream(device)
```

```
    first_stream = torch.cuda.Stream(device=device)
    second_stream = torch.cuda.Stream(device=device)
    left = torch.randn((matrix_size, matrix_size), device=device)
    right = torch.randn((matrix_size, matrix_size), device=device)
    torch.cuda.synchronize(device)
    host_start = time.perf_counter()
    with torch.cuda.stream(first_stream):
        first_result = left @ right
    with torch.cuda.stream(second_stream):
        second_result = right @ left
    host_return = time.perf_counter()
    first_stream.synchronize()
    second_stream.synchronize()
    completed = time.perf_counter()
    return {"default": stream_description(default_stream),
            "first": stream_description(first_stream),
            "second": stream_description(second_stream),
            "submission_ms": (host_return - host_start) * 1000.0,
            "completion_ms": (completed - host_start) * 1000.0,
            "checks": [float(first_result[0, 0].item()),
                       float(second_result[0, 0].item())]}
```

Part 6 - Measurement, Validation, and Failure Analysis

Two custom streams do not prove simultaneous kernels. Check profiler lanes and elapsed time against a sequential baseline. The input tensors were created on the default stream; synchronize before side-stream use or create explicit waits as done by the pre-experiment device barrier. Remove that barrier only after replacing it with precise dependencies.

Part 7 - Engineering Interpretation and Philosophy

Streams are timelines, not worker threads. Correct multi-stream design makes the dependency graph and storage lifetimes explicit, then asks the hardware how much concurrency it can realize.

19.9.2 Exercise 01

Exercise Title: Inspect torch.cuda.current_stream() and Verify Which Stream Executes PyTorch CUDA Operations by Default

Part 1 - Exercise Contract and Why It Matters

Inspect the current and default streams outside and inside nested stream contexts. Prove which stream receives each operation without relying on visual code indentation alone.

Part 2 - System and Memory Mental Model

`current_stream()` returns the stream used for new submissions on a device in the current context. Entering `torch.cuda.stream(s)` temporarily changes it; leaving restores the previous stream. The default stream is a stable device-associated stream but need not remain current inside a custom context.

Part 3 - Quantitative Prediction Before Execution

Predict stream handles at four points: initial, inside stream A, inside nested stream B, and after both contexts. Predict that restoration follows stack order.

Part 4 - Experimental Design and Instrumentation

Record handles and priorities at every boundary. Record events immediately after operations and synchronize those events before validating outputs. Use one device explicitly to avoid accidental current-device changes.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def handle(stream):
    return int(stream.cuda_stream)

def E01():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    default_stream = torch.cuda.default_stream(device)
    stream_a = torch.cuda.Stream(device=device)
    stream_b = torch.cuda.Stream(device=device)
    observations = []
    current = torch.cuda.current_stream(device)
    observations.append(("initial", handle(current)))
    with torch.cuda.stream(stream_a):
        tensor_a = torch.ones(1024, device=device) * 2.0
        current = torch.cuda.current_stream(device)
        observations.append(("inside_a", handle(current)))
        with torch.cuda.stream(stream_b):
            tensor_b = torch.ones(1024, device=device) * 3.0
            current = torch.cuda.current_stream(device)
            observations.append(("inside_b", handle(current)))
        current = torch.cuda.current_stream(device)
        observations.append(("restored_a", handle(current)))
    current = torch.cuda.current_stream(device)
    observations.append(("restored_default", handle(current)))
    torch.cuda.synchronize(device)
    return {"observations": observations,
            "default_handle": handle(default_stream),
            "a_handle": handle(stream_a), "b_handle": handle(stream_b),
            "checks": [float(tensor_a[0].item()), float(tensor_b[0].item())]}
```

Part 6 - Measurement, Validation, and Failure Analysis

Assert the predicted restoration sequence and distinct handles. Stream handle values are process-local implementation identifiers, not portable persistent IDs. A context controls submissions executed while active; it does not migrate already queued work.

Part 7 - Engineering Interpretation and Philosophy

Submission context is mutable state. Inspecting it at boundaries turns an implicit scheduling assumption into a testable invariant.

19.9.3 Exercise 02

Exercise Title: Create a Custom torch.cuda.Stream() and Execute Tensor Operations Inside a Stream Context

Part 1 - Exercise Contract and Why It Matters

Create one custom stream, submit a dependent chain inside its context, record a completion event, and consume the result safely from the default stream.

Part 2 - System and Memory Mental Model

Operations submitted inside the context inherit the custom stream and are ordered with one another. Leaving the context restores submission state but does not wait for completion. The default stream must explicitly wait for the event before consuming the side-stream output.

Part 3 - Quantitative Prediction Before Execution

For $y = 2x$, $z = y + 5$, and $r = z^2$, predict values and stream order. Then predict the dependency edge needed before a default-stream reduction of r.

Part 4 - Experimental Design and Instrumentation

Prepare input before the custom chain and make the custom stream wait for the default stream that created it. Record an event after the producer chain. Make the default stream wait on that event, then validate.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E02(numel=4 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    default_stream = torch.cuda.current_stream(device)
    side_stream = torch.cuda.Stream(device=device)
    x = torch.arange(numel, dtype=torch.float32, device=device)
    side_stream.wait_stream(default_stream)
    ready = torch.cuda.Event()
    with torch.cuda.stream(side_stream):
        y = x * 2.0
        z = y + 5.0
        result = z.square()
        ready.record(side_stream)
    default_stream.wait_event(ready)
    total = result.sum()
    result.record_stream(default_stream)
```

```
    default_stream.synchronize()
    expected_first = 25.0
    return {"first": float(result[0].item()),
            "expected_first": expected_first,
            "sum": float(total.item()),
            "side_handle": int(side_stream.cuda_stream)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The wait before production protects reading x; the wait after production protects default-stream consumption. These are separate edges. Retaining Python references does not create ordering. `record_stream` protects allocator lifetime when the result crosses stream ownership.

Part 7 - Engineering Interpretation and Philosophy

A custom stream is useful only when its inputs, outputs, and ownership transfer are explicit. Context syntax is the surface; the dependency graph is the real program.

19.9.4 Exercise 03

Exercise Title: Launch Independent CUDA Work on Two Streams and Determine Whether the GPU Executes Them Concurrently

Part 1 - Exercise Contract and Why It Matters

Launch independent workloads on two streams and determine overlap from timing and profiler evidence. Avoid treating multiple stream creation as proof of concurrency.

Part 2 - System and Memory Mental Model

Streams permit concurrency but the scheduler realizes it only when kernels, copy engines, occupancy, and dependencies allow. Two large matrix multiplications may each saturate the GPU and serialize in practice; smaller kernels may overlap but expose overhead. Concurrency is an empirical property of workload and device.

Part 3 - Quantitative Prediction Before Execution

Measure isolated times T_A, T_B, sequential time, and multi-stream time T_M. Define an overlap indicator $(T_A + T_B - T_M)/\min(T_A, T_B)$, interpreted cautiously under contention.

Part 4 - Experimental Design and Instrumentation

Use independent inputs and outputs, warm up kernels, record a start event on a control stream, make both workers wait for it, and record completion events. Host-wait after both completions. Repeat several workload sizes and inspect a profiler trace.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E03(size=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
```

```
    device = torch.device("cuda:0")
    stream_a = torch.cuda.Stream(device=device)
    stream_b = torch.cuda.Stream(device=device)
    control = torch.cuda.current_stream(device)
    a = torch.randn((size, size), device=device)
    b = torch.randn((size, size), device=device)
    c = torch.randn((size, size), device=device)
    d = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    start_gate = torch.cuda.Event()
    done_a = torch.cuda.Event()
    done_b = torch.cuda.Event()
    start_gate.record(control)
    stream_a.wait_event(start_gate)
    stream_b.wait_event(start_gate)
    wall_start = time.perf_counter()
    with torch.cuda.stream(stream_a):
        result_a = a @ b
        done_a.record(stream_a)
    with torch.cuda.stream(stream_b):
        result_b = c @ d
        done_b.record(stream_b)
    done_a.synchronize()
    done_b.synchronize()
    wall_ms = (time.perf_counter() - wall_start) * 1000.0
    return {"multi_stream_wall_ms": wall_ms,
            "checks": [float(result_a[0, 0].item()),
                       float(result_b[0, 0].item())]}
```

Part 6 - Measurement, Validation, and Failure Analysis

This run alone needs sequential and isolated companion runs for the overlap metric. Ensure input creation completed before the start gate through the initial device synchronization. Vary kernel size; lack of overlap can be a legitimate resource result, not a stream bug.

Part 7 - Engineering Interpretation and Philosophy

Streams expose possible parallelism. Profiling decides whether the workload has usable parallelism and whether contention makes it worthwhile.

19.9.5 Exercise 04

Exercise Title: Compare Sequential Default-Stream Execution Against Multi-Stream Execution Under Identical CUDA Workloads

Part 1 - Exercise Contract and Why It Matters

Build paired sequential and multi-stream benchmarks using the same tensors, kernels, warmup, repetition count, and validation. Quantify speedup and identify whether concurrency or overhead dominates.

Part 2 - System and Memory Mental Model

The default stream gives simple ordered execution. Multiple streams remove unnecessary ordering between independent tasks but add event, context, and scheduling overhead. If each task saturates the device, multi-stream execution may offer no gain. If tasks use different engines or leave resources idle, overlap may shorten the critical path.

Part 3 - Quantitative Prediction Before Execution

Predict sequential time as the sum of task durations and ideal multi-stream time as their maximum. Define measured speedup and efficiency relative to that ideal. State a threshold larger than measurement noise before declaring improvement.

Part 4 - Experimental Design and Instrumentation

Alternate benchmark order across repetitions. Synchronize before starting and after finishing each full trial. Reuse inputs, retain outputs, and compare numerical results. Report median and p95.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def run_pair(a, b, c, d, device, multi_stream):
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    if not multi_stream:
        first = a @ b
        second = c @ d
    else:
        stream_a = torch.cuda.Stream(device=device)
        stream_b = torch.cuda.Stream(device=device)
        with torch.cuda.stream(stream_a):
            first = a @ b
        with torch.cuda.stream(stream_b):
            second = c @ d
        stream_a.synchronize()
        stream_b.synchronize()
    torch.cuda.synchronize(device)
    return (time.perf_counter() - start) * 1000.0, first, second

def E04(size=1536, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    tensors = []
    for _ in range(4):
        tensors.append(torch.randn((size, size), device=device))
    rows = {}
```

```
    for mode in (False, True):
        samples = []
        for _ in range(repeats):
            elapsed, first, second = run_pair(
                tensors[0], tensors[1], tensors[2], tensors[3], device, mode)
            samples.append(elapsed)
        rows[str(mode)] = {"median_ms": statistics.median(samples),
                           "check_a": float(first[0, 0].item()),
                           "check_b": float(second[0, 0].item())}
    rows["speedup"] = rows["False"]["median_ms"] / rows["True"]["median_ms"]
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Creating streams inside the timed path charges real orchestration cost but may not represent a reusable production pool. Report a second variant with streams created once. Compare full tensors or stable checksums within tolerance, not only one element, in the hardened benchmark.

Part 7 - Engineering Interpretation and Philosophy

Concurrency is an optimization with overhead and a resource ceiling. The default stream is often the correct baseline because it makes ordering cheap and obvious.

19.9.6 Exercise 05

Exercise Title: Demonstrate That Python Execution Can Continue While CUDA Work Remains Queued on a Custom Stream

Part 1 - Exercise Contract and Why It Matters

Submit a long GPU workload, return immediately to Python, perform deterministic CPU work, then wait for stream completion. Measure host submission, CPU progress, and completed wall time separately.

Part 2 - System and Memory Mental Model

Kernel launches enqueue work and normally return before GPU completion. The CPU can prepare another batch, update queues, or execute independent logic. Any operation that reads a CUDA result on the host, such as `item()`, creates a completion requirement and can hide the wait.

Part 3 - Quantitative Prediction Before Execution

Predict a small launch time, a larger stream-completion time, and a nonzero count of CPU work units completed between them. Compare total time with executing CPU work only after stream synchronization.

Part 4 - Experimental Design and Instrumentation

Warm CUDA, submit on one custom stream, record an event after the workload, and perform bounded CPU work until `event.query()` succeeds. Avoid accessing the CUDA result before completion.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def cpu_unit(value):
    for index in range(5000):
        value = (value * 1103515245 + index + 12345) % 2147483648
    return value

def E05(size=3072):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    left = torch.randn((size, size), device=device)
    right = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    done = torch.cuda.Event()
    wall_start = time.perf_counter()
    with torch.cuda.stream(stream):
        result = left @ right
        done.record(stream)
    host_return = time.perf_counter()
    units = 0
    state = 1
    while not done.query():
        state = cpu_unit(state)
        units += 1
    completed = time.perf_counter()
    return {"submission_ms": (host_return - wall_start) * 1000.0,
            "completion_ms": (completed - wall_start) * 1000.0,
            "cpu_units": units, "cpu_state": state,
            "gpu_check": float(result[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Polling itself consumes CPU cycles and is used here for observation, not as the default production policy. If no CPU unit completes, reduce work-unit size or increase GPU work safely. Ensure input creation completed before timing.

Part 7 - Engineering Interpretation and Philosophy

Asynchronous execution creates time the host can use, but only useful pipeline work converts that time into throughput. Busy waiting merely proves availability.

19.9.7 Exercise 06

Exercise Title: Use stream.query() to Poll CUDA Work Completion Without Blocking the CPU Thread

Part 1 - Exercise Contract and Why It Matters

Poll stream completion while doing bounded host work and compare aggressive polling with backoff. Understand what `query()` reports and what it does not guarantee about unrelated streams.

Part 2 - System and Memory Mental Model

`stream.query()` returns whether all currently submitted work in that stream has completed. It does not block and says nothing about work submitted later or work in other streams. Frequent queries add runtime overhead and can waste a CPU core.

Part 3 - Quantitative Prediction Before Execution

Predict query count under no backoff and under a short sleep. Estimate detection latency added by backoff. Choose a policy based on CPU cost and responsiveness.

Part 4 - Experimental Design and Instrumentation

Submit a known workload, poll with timestamp and count, and access the result only after query returns true. Repeat with useful CPU chunks and with controlled sleep. Record completion-detection lag.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E06(size=3072, sleep_seconds=0.0005):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
    left = torch.randn((size, size), device=device)
    right = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    with torch.cuda.stream(stream):
        result = left @ right
    polls = 0
    start = time.perf_counter()
    while not stream.query():
        polls += 1
        time.sleep(sleep_seconds)
    detected = time.perf_counter()
    return {"polls": polls,
            "detected_completion_ms": (detected - start) * 1000.0,
            "sleep_seconds": sleep_seconds,
            "check": float(result[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

A true query result applies to work already placed in that stream at the query instant. Concurrent producers could submit more work afterward. Sleeping reduces CPU cost but

delays detection. Event query is preferable when completion of a specific point, rather than the entire stream, is required.

Part 7 - Engineering Interpretation and Philosophy

Polling trades responsiveness for CPU consumption. Completion interfaces should match the granularity of the dependency and the operational cost of waiting.

19.9.8 Exercise 07

Exercise Title: Use stream.synchronize() and Compare Stream-Level Synchronization Against Device-Wide torch.cuda.synchronize()

Part 1 - Exercise Contract and Why It Matters

Show that stream-level synchronization can release the host after required work while unrelated work continues elsewhere. Compare it with a device-wide barrier using reconstructed equivalent trials.

Part 2 - System and Memory Mental Model

Waiting on one stream covers only the work queued there. A device-wide barrier instead waits for every stream on that device and can couple unrelated tasks. The implementation in Part 5 calls the narrow and broad PyTorch methods explicitly. An event can be narrower still by marking one point inside a stream.

Part 3 - Quantitative Prediction Before Execution

Place short required work in stream A and longer unrelated work in stream B. Predict that waiting on A returns near T_A, whereas device synchronization returns near $\max(T_A, T_B)$.

Part 4 - Experimental Design and Instrumentation

Build a function that reconstructs inputs and streams for each policy. Warm up, submit both tasks, then time only the selected wait. After measuring A-only wait, drain B before cleanup without including that drain in the required latency.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def one_wait_policy(device, wait_for_device, short_size=1024, long_size=3072):
    stream_a = torch.cuda.Stream(device=device)
    stream_b = torch.cuda.Stream(device=device)
    short_left = torch.randn((short_size, short_size), device=device)
    short_right = torch.randn((short_size, short_size), device=device)
    long_left = torch.randn((long_size, long_size), device=device)
    long_right = torch.randn((long_size, long_size), device=device)
    torch.cuda.synchronize(device)
    with torch.cuda.stream(stream_a):
        required = short_left @ short_right
    with torch.cuda.stream(stream_b):
        unrelated = long_left @ long_right
```

```
    start = time.perf_counter()
    if wait_for_device:
        torch.cuda.synchronize(device)
    else:
        stream_a.synchronize()
    wait_ms = (time.perf_counter() - start) * 1000.0
    stream_b.synchronize()
    required_check = float(required[0, 0].item())
    unrelated_check = float(unrelated[0, 0].item())
    return wait_ms, required_check, unrelated_check

def E07():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream_wait = one_wait_policy(device, False)
    device_wait = one_wait_policy(device, True)
    return {"stream_wait_ms": stream_wait[0],
            "device_wait_ms": device_wait[0],
            "checks": [stream_wait[1], stream_wait[2],
                       device_wait[1], device_wait[2]]}
```

Part 6 - Measurement, Validation, and Failure Analysis

Task durations can differ across reconstructed trials, so repeat and randomize policy order. If the long kernel monopolizes GPU resources, it may delay stream A despite no dependency. That scheduling effect is distinct from host barrier scope.

Part 7 - Engineering Interpretation and Philosophy

Synchronization defines which unrelated work becomes part of your latency. Choose the narrowest wait that proves the data dependency you actually need.

19.9.9 Exercise 08

Exercise Title: Create a Race Condition by Consuming a Tensor on the Default Stream Before Its Producer Stream Has Finished

Part 1 - Exercise Contract and Why It Matters

Create a controlled cross-stream race with disposable tensors. Delay a producer stream, enqueue a write, and consume the output immediately on the default stream without a dependency. Detect stale or inconsistent results without using real application data.

Part 2 - System and Memory Mental Model

Operations within each stream are ordered, but the default stream does not automatically wait for arbitrary custom-stream work. A Python reference proves storage exists; it does not prove the producer kernel completed. The consumer may read uninitialized or previous contents.

Part 3 - Quantitative Prediction Before Execution

Initialize output to -1, delay the producer with large work, then enqueue a fill with 7. Predict the unsafe default-stream sum may reflect -1, 7, or timing-dependent behavior. A correct dependency must always produce $7N$.

Part 4 - Experimental Design and Instrumentation

Use bounded synthetic sizes and multiple trials. Synchronize before setup and after collecting results. Record whether the unsafe result differs from expected; absence of failure does not prove safety.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E08(numel=16 * 1024 * 1024, blocker_size=3072, trials=10):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    producer = torch.cuda.Stream(device=device)
    rows = []
    for trial in range(trials):
        output = torch.full((numel,), -1.0, device=device)
        left = torch.randn((blocker_size, blocker_size), device=device)
        right = torch.randn((blocker_size, blocker_size), device=device)
        torch.cuda.synchronize(device)
        with torch.cuda.stream(producer):
            blocker = left @ right
            output.fill_(7.0)
        unsafe_sum = output.sum()  # No default-stream dependency.
        torch.cuda.synchronize(device)
        observed = float(unsafe_sum.item())
        expected = float(7.0 * numel)
        rows.append({"trial": trial, "observed": observed,
                     "expected": expected,
                     "race_seen": observed != expected,
                     "blocker_check": float(blocker[0, 0].item())})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

This intentionally unsafe example may pass on favorable schedules. Increasing bounded blocker work widens the window. The final synchronization makes result inspection safe but cannot repair an already enqueued consumer that ran too early.

Part 7 - Engineering Interpretation and Philosophy

Race freedom is a property of declared ordering, not repeated successful runs. Cross-stream dataflow must be represented by a CUDA dependency.

19.9.10 Exercise 09

Exercise Title: Fix a Cross-Stream Dependency with wait_stream() and Verify Correct Execution Without Global Synchronization

Part 1 - Exercise Contract and Why It Matters

Repair E08 by making the default stream wait for producer work. Prove correct consumption without a device-wide barrier and identify the breadth of `wait_stream()`.

Part 2 - System and Memory Mental Model

`consumer.wait_stream(producer)` enqueues a dependency so future work in the consumer waits for work already submitted to the producer. It does not block Python. It is broader than waiting for a specifically recorded event if the producer contains unrelated earlier work.

Part 3 - Quantitative Prediction Before Execution

Predict the sequence: producer blocker, producer fill, consumer wait, consumer sum. Expected output is always $7N$. Compare host submission time with global synchronization to show the wait remains device-side.

Part 4 - Experimental Design and Instrumentation

Create tensors, submit producer operations, call wait on the current default stream, and enqueue the reduction. Synchronize only before CPU inspection. Repeat with deterministic sentinels.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E09(numel=16 * 1024 * 1024, blocker_size=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    producer = torch.cuda.Stream(device=device)
    consumer = torch.cuda.current_stream(device)
    output = torch.full((numel,), -1.0, device=device)
    left = torch.randn((blocker_size, blocker_size), device=device)
    right = torch.randn((blocker_size, blocker_size), device=device)
    torch.cuda.synchronize(device)
    with torch.cuda.stream(producer):
        blocker = left @ right
        output.fill_(7.0)
    consumer.wait_stream(producer)
    safe_sum = output.sum()
    output.record_stream(consumer)
    consumer.synchronize()
    expected = float(7.0 * numel)
    return {"observed": float(safe_sum.item()), "expected": expected,
            "validated": float(safe_sum.item()) == expected,
            "blocker_check": float(blocker[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Call `wait_stream` before submitting the consumer, not after. The wait covers producer work submitted at that point; later producer submissions are not automatically included. For a precise point in a long producer stream, use an event as in E10.

Part 7 - Engineering Interpretation and Philosophy

Device-side waits preserve host concurrency while enforcing dataflow. Their scope should match the producer work the consumer truly depends on.

19.9.11 Exercise 10

Exercise Title: Record a CUDA Event on One Stream and Make Another Stream Wait Only for the Required Dependency

Part 1 - Exercise Contract and Why It Matters

Replace a broad stream wait with an event marking the exact producer milestone. Let the producer continue unrelated work while the consumer begins as soon as its required tensor is ready.

Part 2 - System and Memory Mental Model

An event recorded in a stream becomes complete after all preceding work in that stream. `consumer.wait_event(event)` delays later consumer operations until that point without blocking the host. Producer work submitted after the event is not part of the dependency.

Part 3 - Quantitative Prediction Before Execution

Draw producer operations P_1, event, P_2, and consumer operation C depending only on P_1. Predict that C may overlap P_2, whereas `wait_stream` after both were queued would not permit that schedule.

Part 4 - Experimental Design and Instrumentation

Record the event immediately after producing the shared tensor. Submit unrelated producer work after it. Make consumer wait on the event, use the tensor, and validate after consumer completion. Profile to verify the intended overlap.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E10(numel=8 * 1024 * 1024, matrix_size=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    producer = torch.cuda.Stream(device=device)
    consumer = torch.cuda.Stream(device=device)
    source = torch.arange(numel, dtype=torch.float32, device=device)
    left = torch.randn((matrix_size, matrix_size), device=device)
    right = torch.randn((matrix_size, matrix_size), device=device)
    torch.cuda.synchronize(device)
```

```
required_ready = torch.cuda.Event()
with torch.cuda.stream(producer):
    produced = source * 2.0
    required_ready.record(producer)
    unrelated = left @ right
consumer.wait_event(required_ready)
with torch.cuda.stream(consumer):
    consumed = produced + 5.0
consumed.record_stream(consumer)
consumer.synchronize()
producer.synchronize()
return {"first": float(consumed[0].item()),
        "last": float(consumed[-1].item()),
        "unrelated_check": float(unrelated[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Expected consumed values are 5 and $2(N-1)+5$. The event protects execution order, while `record_stream` protects storage lifetime during consumer use. A profiler trace is needed to confirm that unrelated work actually overlaps on the tested GPU.

Part 7 - Engineering Interpretation and Philosophy

Events express dataflow milestones. Precise milestones preserve more concurrency than treating an entire stream as one indivisible dependency.

19.9.12 Exercise 11

Exercise Title: Build a Three-Stream Dependency Graph and Enforce Correct Producer-Consumer Ordering Using CUDA Events

Part 1 - Exercise Contract and Why It Matters

Build a fork–join graph: streams A and B produce independent tensors; stream C waits for both and combines them. Validate ordering without global synchronization inside the graph.

Part 2 - System and Memory Mental Model

Events transform implicit tensor relationships into edges of a directed acyclic graph. A and B may overlap. C cannot begin the join operation until both readiness events complete. The host can enqueue the whole graph without waiting at each edge.

Part 3 - Quantitative Prediction Before Execution

For producer times T_A, T_B and join time T_C, predict ideal critical path $\max(T_A, T_B) + T_C$. List invalid schedules when either event edge is removed.

Part 4 - Experimental Design and Instrumentation

Create three streams and two events. Ensure input creation is complete before forking. Record producer events after outputs, enqueue both waits in C, then combine. Validate values and profile stream lanes.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E11(numel=8 * 1024 * 1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream_a = torch.cuda.Stream(device=device)
    stream_b = torch.cuda.Stream(device=device)
    stream_c = torch.cuda.Stream(device=device)
    source_a = torch.arange(numel, dtype=torch.float32, device=device)
    source_b = torch.ones(numel, dtype=torch.float32, device=device)
    torch.cuda.synchronize(device)
    ready_a = torch.cuda.Event()
    ready_b = torch.cuda.Event()
    with torch.cuda.stream(stream_a):
        output_a = source_a * 2.0
        ready_a.record(stream_a)
    with torch.cuda.stream(stream_b):
        output_b = source_b * 3.0
        ready_b.record(stream_b)
    stream_c.wait_event(ready_a)
    stream_c.wait_event(ready_b)
    with torch.cuda.stream(stream_c):
        joined = output_a + output_b
    output_a.record_stream(stream_c)
    output_b.record_stream(stream_c)
    stream_c.synchronize()
    return {"first": float(joined[0].item()),
            "last": float(joined[-1].item()),
            "expected_last": float(2 * (numel - 1) + 3)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The two waits must be issued before the join. If one producer fails, the join may remain blocked; production schedulers need error propagation and timeouts. Tensor lifetime crosses into stream C and must be protected independently of the event dependency.

Part 7 - Engineering Interpretation and Philosophy

Multi-stream programs are dependency graphs. Once represented explicitly, they can be validated, profiled, scheduled, and recovered rather than debugged as timing accidents.

19.9.13 Exercise 12

Exercise Title: Reproduce an Unsafe Cross-Stream Tensor Lifetime Bug and Explain Why Allocator Reuse Can Corrupt Asynchronous Execution

Part 1 - Exercise Contract and Why It Matters

Reproduce a bounded, nondeterministic storage-lifetime failure with disposable CUDA tensors. Submit side-stream work that reads a tensor, delete the last Python reference, allocate a replacement on the creation stream, and observe possible allocator reuse and corruption.

Part 2 - System and Memory Mental Model

The caching allocator knows the stream where storage was allocated and the streams recorded as users. If side-stream use is not recorded, freeing the tensor on its creation stream can make its block available while the side stream still plans to read it. A new allocation may reuse the same address and overwrite data. Execution dependencies and allocator lifetime are separate obligations.

Part 3 - Quantitative Prediction Before Execution

Fill source with 1, delay the side stream, and plan a sum. Delete source and fill a same-sized replacement with 9. Predict correct sum N, corrupted sum $9N$, or an intermediate outcome. Pointer equality strengthens evidence of reuse but is not required for the conceptual bug.

Part 4 - Experimental Design and Instrumentation

Use fixed bounded sizes and several trials. Capture source and replacement data pointers, retain the result tensor, and synchronize before inspection. Do not use real model tensors. Passing trials do not prove safety.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E12(numel=32 * 1024 * 1024, blocker_size=3072, trials=10):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    side = torch.cuda.Stream(device=device)
    rows = []
    for trial in range(trials):
        source = torch.full((numel,), 1.0, device=device)
        source_pointer = source.data_ptr()
        left = torch.randn((blocker_size, blocker_size), device=device)
        right = torch.randn((blocker_size, blocker_size), device=device)
        torch.cuda.synchronize(device)
        with torch.cuda.stream(side):
            blocker = left @ right
            result = source.sum()
        del source  # Intentionally unsafe: side-stream use was not recorded.
        replacement = torch.empty(numel, dtype=torch.float32, device=device)
        replacement_pointer = replacement.data_ptr()
        replacement.fill_(9.0)
        torch.cuda.synchronize(device)
        observed = float(result.item())
        rows.append({"trial": trial, "observed": observed,
                     "expected": float(numel),
                     "same_pointer": source_pointer == replacement_pointer,
                     "blocker_check": float(blocker[0, 0].item())})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Allocator behavior and scheduling are nondeterministic; no corruption in ten trials is not proof. A matching pointer plus wrong sum is strong reproduction. The final global synchronization only makes observation safe; it cannot undo a prematurely reused block.

Part 7 - Engineering Interpretation and Philosophy

Memory correctness includes future GPU readers that Python can no longer see. Allocator-aware lifetime tracking is part of asynchronous program correctness.

19.9.14 Exercise 13

Exercise Title: Use Tensor.record_stream() to Protect Tensor Storage Used by a Side Stream from Premature Allocator Reuse

Part 1 - Exercise Contract and Why It Matters

Repair E12 by recording side-stream use before releasing the source. Demonstrate that the allocator delays reuse until the recorded stream completes without forcing an immediate host wait.

Part 2 - System and Memory Mental Model

`tensor.record_stream(side)` informs the caching allocator that the tensor's storage is in use on that stream. After Python releases the tensor, the block cannot be safely recycled until recorded work completes. This manages storage lifetime; it does not create a producer–consumer execution dependency.

Part 3 - Quantitative Prediction Before Execution

Repeat the source/replacement experiment. Predict correct sum N in every trial and expect the replacement often to receive a different block while side work is pending. Memory may remain reserved longer as the cost of safety.

Part 4 - Experimental Design and Instrumentation

Keep workload identical to E12 except for one `record_stream` call. Measure pointer reuse, result correctness, peak allocated memory, and host submission time. Run from a clean allocator state for controlled comparisons.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E13(numel=32 * 1024 * 1024, blocker_size=3072, trials=10):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    side = torch.cuda.Stream(device=device)
    rows = []
    for trial in range(trials):
        source = torch.full((numel,), 1.0, device=device)
        source_pointer = source.data_ptr()
```

```
        left = torch.randn((blocker_size, blocker_size), device=device)
        right = torch.randn((blocker_size, blocker_size), device=device)
        torch.cuda.synchronize(device)
        with torch.cuda.stream(side):
            blocker = left @ right
            result = source.sum()
        source.record_stream(side)
        del source
        replacement = torch.empty(numel, dtype=torch.float32, device=device)
        replacement_pointer = replacement.data_ptr()
        replacement.fill_(9.0)
        torch.cuda.synchronize(device)
        rows.append({"trial": trial, "observed": float(result.item()),
                     "expected": float(numel),
                     "same_pointer": source_pointer == replacement_pointer,
                     "blocker_check": float(blocker[0, 0].item())})
    return rows
```

Part 6 - Measurement, Validation, and Failure Analysis

Every observed sum must equal N. A different replacement pointer is expected but not itself the correctness criterion. Recording the wrong stream or recording after storage has been released does not protect use. Version and allocator backend should be recorded for performance interpretation.

Part 7 - Engineering Interpretation and Philosophy

`record_stream` lets the allocator participate in the dependency model. It preserves concurrency by delaying reuse instead of blocking the host.

19.9.15 Exercise 14

Exercise Title: Compare Explicit record_stream() Lifetime Management Against Manual Stream Synchronization for Temporary CUDA Buffers

Part 1 - Exercise Contract and Why It Matters

Compare two safe policies for temporary buffers used on a side stream: allocator lifetime recording and host-side stream synchronization before release. Quantify submission latency, total time, overlap, and memory retention.

Part 2 - System and Memory Mental Model

Manual synchronization waits immediately, simplifying reuse but blocking the host and potentially draining unrelated side-stream work. Recording the stream allows the host to continue and the allocator to defer recycling. The latter may increase temporary memory pressure because old and new blocks coexist.

Part 3 - Quantitative Prediction Before Execution

Predict lower host submission time but possibly higher peak allocation for the recorded policy. Predict similar numerical results and completed compute time when workloads are otherwise identical.

Part 4 - Experimental Design and Instrumentation

Reconstruct equivalent trials, reset peak statistics, use fixed tensors, and time host return separately from final completion. Track source/replacement pointers and result checksums.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def run_lifetime_policy(device, use_record_stream, numel, matrix_size):
    side = torch.cuda.Stream(device=device)
    torch.cuda.reset_peak_memory_stats(device)
    source = torch.ones(numel, device=device)
    left = torch.randn((matrix_size, matrix_size), device=device)
    right = torch.randn((matrix_size, matrix_size), device=device)
    torch.cuda.synchronize(device)
    start = time.perf_counter()
    with torch.cuda.stream(side):
        blocker = left @ right
        result = source.sum()
    if use_record_stream:
        source.record_stream(side)
    else:
        side.synchronize()
    del source
    submitted = time.perf_counter()
    replacement = torch.empty(numel, device=device)
    replacement.fill_(9.0)
    torch.cuda.synchronize(device)
    completed = time.perf_counter()
    return {"submission_ms": (submitted - start) * 1000.0,
            "completion_ms": (completed - start) * 1000.0,
            "peak_bytes": torch.cuda.max_memory_allocated(device),
            "result": float(result.item()),
            "blocker_check": float(blocker[0, 0].item())}

def E14(numel=32 * 1024 * 1024, matrix_size=3072):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    return {"record_stream": run_lifetime_policy(
                device, True, numel, matrix_size),
            "manual_sync": run_lifetime_policy(
                device, False, numel, matrix_size)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Both results must equal N. Peak statistics include inputs, blocker, result, and replacement, so compare only identical workloads. Repetition order and allocator cache state can bias memory and timing; use clean-process repetitions for a defensible report.

Part 7 - Engineering Interpretation and Philosophy

Safety has multiple implementations. Choose immediate waiting when simplicity and memory pressure dominate; choose recorded lifetime when host progress and overlap justify deferred reuse.

19.9.16 Exercise 15

Exercise Title: Create Normal- and High-Priority CUDA Streams and Measure How Stream Priority Changes Scheduling Under Competing Workloads

Part 1 - Exercise Contract and Why It Matters

Create competing normal- and high-priority streams, queue background kernels, then measure completion latency of urgent work. Treat priority as a scheduling hint, not a deadline or preemption guarantee.

Part 2 - System and Memory Mental Model

CUDA exposes a device-specific priority range in which numerically lower values represent greater priority. Higher priority can influence which pending blocks are scheduled, but it does not necessarily preempt a kernel already running. Large saturating kernels can therefore delay urgent work despite stream priority.

Part 3 - Quantitative Prediction Before Execution

Predict urgent completion when its stream uses normal priority and when it uses the greatest supported priority. Expect the effect to be clearest with many small background kernels that leave scheduling boundaries.

Part 4 - Experimental Design and Instrumentation

Query the supported range, reconstruct identical workload cases, warm up, queue background work before urgent work, and time urgent-event completion separately from total completion. Repeat and report distributions.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def priority_case(device, urgent_priority, jobs=64, size=512):
    background = torch.cuda.Stream(device=device, priority=0)
    urgent = torch.cuda.Stream(device=device, priority=urgent_priority)
    left = torch.randn((size, size), device=device)
    right = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    urgent_done = torch.cuda.Event()
    background_done = torch.cuda.Event()
    start = time.perf_counter()
    with torch.cuda.stream(background):
        for _ in range(jobs):
            background_result = left @ right
```

```
        background_done.record(background)
    with torch.cuda.stream(urgent):
        urgent_result = left @ right
        urgent_done.record(urgent)
    urgent_done.synchronize()
    urgent_ms = (time.perf_counter() - start) * 1000.0
    background_done.synchronize()
    total_ms = (time.perf_counter() - start) * 1000.0
    return {"urgent_ms": urgent_ms, "total_ms": total_ms,
            "urgent_check": float(urgent_result[0, 0].item()),
            "background_check": float(background_result[0, 0].item())}

def E15():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    least_priority, greatest_priority = torch.cuda.get_stream_priority_range()
    return {"priority_range": [least_priority, greatest_priority],
            "normal": priority_case(device, 0),
            "high": priority_case(device, greatest_priority)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Priority effects can be small or absent on some workloads. Verify the reported range and do not assume -1 is universally the greatest supported value. Create multiple repetitions and compare urgent latency, not only total throughput.

Part 7 - Engineering Interpretation and Philosophy

Priority expresses preference under contention, not certainty. Real-time correctness still requires bounded kernels, admission control, and measured tail latency.

19.9.17 Exercise 16

Exercise Title: Profile Multiple CUDA Streams with PyTorch Profiler and Verify Actual Kernel Overlap Instead of Assuming Concurrency

Part 1 - Exercise Contract and Why It Matters

Capture an execution trace with labeled work on multiple streams and verify whether kernels overlap in time. Connect visible overlap to the sequential and multi-stream benchmarks.

Part 2 - System and Memory Mental Model

Wall-clock speedup can be distorted by warmup, clock state, or measurement scope. A trace exposes per-stream lanes, kernel intervals, gaps, synchronization, and CPU submissions. Overlap exists only when intervals execute concurrently, not merely when launches appear near each other on the CPU timeline.

Part 3 - Quantitative Prediction Before Execution

Predict stream lanes and kernel counts for two independent chains. Estimate the overlap interval and compare it with the difference between sequential and multi-stream time.

Part 4 - Experimental Design and Instrumentation

Use `record_function` labels, CPU and CUDA profiler activities, warmup outside the active profile, and an exported Chrome trace. Measure profiler overhead against an unprofiled run.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, record_function

def E16(trace_path="dmm07_multistream_trace.json", size=1536):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream_a = torch.cuda.Stream(device=device)
    stream_b = torch.cuda.Stream(device=device)
    a = torch.randn((size, size), device=device)
    b = torch.randn((size, size), device=device)
    c = torch.randn((size, size), device=device)
    d = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    activities = [ProfilerActivity.CPU, ProfilerActivity.CUDA]
    with torch.profiler.profile(activities=activities,
                                record_shapes=True) as profiler:
        with record_function("stream_a_chain"):
            with torch.cuda.stream(stream_a):
                result_a = torch.relu(a @ b)
        with record_function("stream_b_chain"):
            with torch.cuda.stream(stream_b):
                result_b = torch.relu(c @ d)
        stream_a.synchronize()
        stream_b.synchronize()
    profiler.export_chrome_trace(trace_path)
    table = profiler.key_averages().table(
        sort_by="self_cuda_time_total", row_limit=30)
    return {"table": table, "trace_path": trace_path,
            "checks": [float(result_a[0, 0].item()),
                       float(result_b[0, 0].item())]}
```

Part 6 - Measurement, Validation, and Failure Analysis

Profiler overhead changes timing, so use it for causal structure and an unprofiled benchmark for final speed. Kernel names and lanes vary by backend and version. Lack of overlap may indicate resource saturation rather than a missing stream context.

Part 7 - Engineering Interpretation and Philosophy

Concurrency claims require timeline evidence. Profiling converts an architectural intention into an observable scheduling fact.

19.9.18 Exercise 17

Exercise Title: Stress-Test Multi-Stream Execution with Shared Tensors and Detect Missing Dependencies, Race Conditions, and Unnecessary Synchronization

Part 1 - Exercise Contract and Why It Matters

Stress a bounded ring of shared CUDA buffers across producer and consumer streams. Run a safe dependency mode and an injected-failure mode, validate sentinels, and measure the cost of optional global barriers.

Part 2 - System and Memory Mental Model

Each reusable slot needs two edges: consumer completion before the next producer overwrite, and producer readiness before the next consumer read. Missing either edge creates a write-after-read or read-before-write race. A global barrier fixes ordering broadly but removes inter-slot concurrency.

Part 3 - Quantitative Prediction Before Execution

For K slots and N iterations, predict bounded storage KB. In safe mode every checksum equals sentinel times element count. In injected mode at least some schedules may fail, though no failure is guaranteed.

Part 4 - Experimental Design and Instrumentation

Use fixed seeds, deterministic sentinel values, per-slot readiness and reuse events, one final synchronization, and an optional dependency omission. Record failures and global-sync count. Never use production tensors for injected races.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def run_stress(device, inject_failure, iterations=100,
               slots_count=4, numel=1024 * 1024):
    producer = torch.cuda.Stream(device=device)
    consumer = torch.cuda.Stream(device=device)
    slots = []
    reuse_events = []
    for _ in range(slots_count):
        slots.append(torch.empty(numel, device=device))
        reuse_events.append(None)
    results = []
    expected = []
    for step in range(iterations):
        slot_index = step % slots_count
        reusable = reuse_events[slot_index]
        if reusable is not None:
            producer.wait_event(reusable)
        ready = torch.cuda.Event()
        with torch.cuda.stream(producer):
            slots[slot_index].fill_(float(step + 1))
```

```
            ready.record(producer)
        should_wait = not (inject_failure and step % 10 == 0)
        if should_wait:
            consumer.wait_event(ready)
        consumed = torch.cuda.Event()
        with torch.cuda.stream(consumer):
            checksum = slots[slot_index].sum()
            consumed.record(consumer)
        slots[slot_index].record_stream(consumer)
        reuse_events[slot_index] = consumed
        results.append(checksum)
        expected.append(float((step + 1) * numel))
    torch.cuda.synchronize(device)
    failures = []
    for index, result in enumerate(results):
        if float(result.item()) != expected[index]:
            failures.append(index)
    return failures

def E17():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    return {"safe_failures": run_stress(device, False),
            "injected_failures": run_stress(device, True)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Safe mode must have zero failures. Injected mode can pass under favorable scheduling, so it demonstrates missing proof even if no mismatch appears. Add a profiler and a version with device-wide synchronization to quantify unnecessary serialization.

Part 7 - Engineering Interpretation and Philosophy

Reusable buffers turn stream programming into a state machine. Stress tests are most useful when every transition has an explicit invariant that can fail.

19.9.19 Exercise 18

Exercise Title: Build a Reusable PyTorch Stream Scheduler That Assigns Independent GPU Tasks to Multiple Streams and Tracks Their Completion

Part 1 - Exercise Contract and Why It Matters

Implement a bounded round-robin stream scheduler. Submissions accept dependency tickets, run tensor-producing functions, record completion, protect input and output lifetimes, and return a ticket that supports host waiting or downstream stream attachment.

Part 2 - System and Memory Mental Model

The scheduler maps a task DAG onto a fixed stream pool. Dependency events enforce execution order. Ticket ownership retains outputs. Input `record_stream` calls protect buffers

while a selected stream uses them. A fixed pool bounds orchestration resources but not output memory, so pending task count also requires a limit.

Part 3 - Quantitative Prediction Before Execution

For S streams and Q pending tasks, predict stream handles, maximum in-flight tasks, and output memory. Independent tasks can overlap; dependent tasks follow the critical path of the DAG.

Part 4 - Experimental Design and Instrumentation

Submit independent tasks, a join task depending on them, and more tasks than streams to test reuse. Validate stream assignment, completion, outputs, and queue bound. Propagate exceptions instead of returning a never-completing ticket.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class TaskTicket:
    def __init__(self, output, ready, stream):
        self.output = output
        self.ready = ready
        self.stream = stream
    def wait_host(self):
        self.ready.synchronize()
        return self.output
    def attach(self, consumer_stream):
        consumer_stream.wait_event(self.ready)
        self.output.record_stream(consumer_stream)
        return self.output

class StreamScheduler:
    def __init__(self, device, stream_count, max_pending):
        self.device = device
        self.streams = []
        for _ in range(stream_count):
            self.streams.append(torch.cuda.Stream(device=device))
        self.max_pending = max_pending
        self.pending = []
        self.next_stream = 0
    def submit(self, function, arguments, dependencies=()):
        if len(self.pending) >= self.max_pending:
            self.drain_oldest()
        stream = self.streams[self.next_stream]
        self.next_stream = (self.next_stream + 1) % len(self.streams)
        for dependency in dependencies:
            stream.wait_event(dependency.ready)
        ready = torch.cuda.Event()
        with torch.cuda.stream(stream):
            output = function(*arguments)
```

```
            ready.record(stream)
        for argument in arguments:
            if torch.is_tensor(argument):
                argument.record_stream(stream)
        ticket = TaskTicket(output, ready, stream)
        self.pending.append(ticket)
        return ticket
    def drain_oldest(self):
        ticket = self.pending.pop(0)
        return ticket.wait_host()
    def wait_all(self):
        outputs = []
        while self.pending:
            outputs.append(self.drain_oldest())
        return outputs

def E18(size=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    scheduler = StreamScheduler(device, stream_count=3, max_pending=8)
    a = torch.randn((size, size), device=device)
    b = torch.randn((size, size), device=device)
    torch.cuda.synchronize(device)
    first = scheduler.submit(torch.matmul, (a, b))
    second = scheduler.submit(torch.matmul, (b, a))
    joined = scheduler.submit(torch.add, (first.output, second.output),
                              dependencies=(first, second))
    output = joined.wait_host()
    return {"shape": tuple(output.shape),
            "check": float(output[0, 0].item())}
```

Part 6 - Measurement, Validation, and Failure Analysis

The scheduler records tensor arguments on the selected task stream and waits on dependency events before executing the join. Harden it to traverse nested arguments and outputs, remove completed tickets, and preserve exception state. The example focuses on the core ownership model.

Part 7 - Engineering Interpretation and Philosophy

A scheduler is valuable when it makes dependencies and capacity explicit. Round robin alone distributes submissions; tickets and bounds turn it into a reliable execution system.

19.9.20 Exercise 19

Exercise Title: Build and Benchmark a Dependency-Aware Multi-Stream CUDA Pipeline That Preserves Correctness While Minimizing Global Synchronization

Part 1 - Exercise Contract and Why It Matters

Integrate H2D copy, parallel inference, and D2H copy into an event-driven pipeline. Use bounded in-flight batches, pinned host storage, stream-specific dependencies, allocator lifetime protection, and a blocking reference for correctness and throughput comparison.

Part 2 - System and Memory Mental Model

The input-copy stream produces a device batch and records readiness. A selected compute stream waits for it, runs the model, and records output readiness. The output-copy stream waits only for that model result, writes a pinned host tensor, and records completion. Source references remain owned until H2D finishes; `record_stream` protects device tensors across stream boundaries. A maximum in-flight count provides backpressure and bounds memory.

Part 3 - Quantitative Prediction Before Execution

Estimate serial latency $T_{H2D} + T_C + T_{D2H}$ and ideal pipeline interval as the maximum stage time. Multiply per-batch host and device storage by the in-flight bound. Predict where more compute streams stop helping because the model saturates the GPU.

Part 4 - Experimental Design and Instrumentation

Use identical model state and pinned batches for sequential and pipelined paths. Warm up, run in evaluation/no-grad mode, report throughput and output parity, and profile overlap. Inject shape errors and low queue limits to test backpressure.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

class PipelineTicket:
    def __init__(self, host_source, host_output, done):
        self.host_source = host_source
        self.host_output = host_output
        self.done = done
    def wait(self):
        self.done.synchronize()
        return self.host_output

            outputs_match = False
    return {"baseline_seconds": baseline_seconds,
            "pipeline_seconds": seconds,
            "baseline_batches_s": len(pinned_batches) / baseline_seconds,
            "pipeline_batches_s": len(pinned_batches) / seconds,
            "completed_outputs": len(pipeline_checksums),
            "outputs_match": outputs_match}
```

Part 6 - Measurement, Validation, and Failure Analysis

The demonstration must be paired with a sequential blocking reference and full output comparisons within tolerance. Fresh pinned output allocation is simple but should become a bounded reusable pool in production. Stateful models or modules that mutate shared buffers may not be safe for concurrent forwards and must be tested or serialized.

Part 7 - Engineering Interpretation and Philosophy

The best multi-stream pipeline is not the one with the most streams. It is the one whose dependency graph is minimal, whose memory is bounded, whose lifetimes are provable, and whose measured critical path is shorter without changing the answer.

19.10 DMM08

Chapter Title: Compute and Data Transfer Overlap
Specialization: Dynamic Memory Management and CUDA Systems

19.10.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Overlapping Host-to-Device Transfers with GPU Computation

Part 1 - Exercise Contract and Why It Matters

Construct a falsifiable model of an input pipeline in which batch $n+1$ moves from host RAM to VRAM while the GPU computes batch n. The goal is not merely to use asynchronous-looking API calls. The goal is to prove that two independent engines are active during the same interval, that dependencies remain correct, and that reused buffers cannot be overwritten prematurely.

Part 2 - System and Memory Mental Model

True overlap requires five conditions: page-locked source memory, an asynchronous copy, different CUDA streams for copy and compute, hardware able to run copy and compute concurrently, and enough work to expose concurrency. A copy stream orders transfers; a compute stream orders kernels. An event connects only the required producer–consumer edge. There are two distinct lifetimes: the CPU may refill a pinned slot only after its H2D copy completes, while the transfer stream may overwrite a device slot only after computation using that slot completes. Confusing these events creates rare data corruption.

Part 3 - Quantitative Prediction Before Execution

Let T_p, T_c, and T_g denote CPU preparation, H2D copy, and GPU compute time. A serial iteration costs approximately $T_p + T_c + T_g$. After pipeline fill, an ideal three-stage pipeline approaches $\max(T_p, T_c, T_g)$ per batch. If preparation is excluded, the maximum copy–compute speedup is

$$S_{\max} = \frac{T_c + T_g}{\max(T_c, T_g)} \leq 2.$$

Record this prediction before measuring; otherwise ordinary noise can be mistaken for overlap.

Part 4 - Experimental Design and Instrumentation

Measure a serial baseline, then a warmup, steady-state, and drain phase for the overlapped version. Use CUDA events for device intervals, a synchronized host timer for end-to-end time, and a profiler timeline to prove simultaneous copy and kernel activity. Validate numerical output against the serial pipeline and report pinned RAM, input VRAM, throughput, and exposed copy time.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E00(batch=2048, width=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    copy_stream = torch.cuda.Stream(device=device)
    compute_stream = torch.cuda.current_stream(device)
    host = torch.randn((batch, width), pin_memory=True)
    gpu = torch.empty_like(host, device=device)
    copy_done = torch.cuda.Event()
```

```
    compute_done = torch.cuda.Event()
    compute_done.record(compute_stream)

    copy_stream.wait_event(compute_done)
    with torch.cuda.stream(copy_stream):
        gpu.copy_(host, non_blocking=True)
        copy_done.record(copy_stream)

    compute_stream.wait_event(copy_done)
    with torch.cuda.stream(compute_stream):
        result = torch.relu(gpu).sum()
        compute_done.record(compute_stream)

    compute_done.synchronize()
    expected = torch.relu(host).sum().item()
    observed = result.item()
    return {"observed": observed, "expected": expected,
            "absolute_error": abs(observed - expected)}
```

Part 6 - Measurement, Validation, and Failure Analysis

This one-batch skeleton demonstrates ordering, not steady-state speedup. A timeline with no overlap may simply mean the workload is too short. If the copy appears as a blocking memcpy, verify `is_pinned()`; if kernels wait, search for `item()`, printing CUDA tensors, or global synchronization. An output match is necessary but insufficient because a race may pass by chance.

Part 7 - Engineering Interpretation and Philosophy

Overlap is a scheduling theorem supported by evidence, not a property granted by one keyword. Optimize the critical path, express the smallest correct dependency graph, and treat buffer ownership as part of correctness. The rest of this chapter turns that discipline into reusable machinery.

19.10.2 Exercise 01

Exercise Title: Measure a Sequential Copy-Then-Compute Pipeline and Establish a Reliable Baseline for Total Iteration Time

Part 1 - Exercise Contract and Why It Matters

Establish the reference that every later optimization must beat. Measure a strict H2D-copy-then-compute loop with correct warmup and synchronization, and retain its outputs for parity checking.

Part 2 - System and Memory Mental Model

CUDA submission is asynchronous with respect to Python. A host timer around enqueue calls measures submission latency unless completion is forced at the measurement boundary. The serial baseline deliberately places copy and compute on one stream, so stream ordering prevents overlap without adding a barrier inside every iteration.

Part 3 - Quantitative Prediction Before Execution

Predict $T_{serial} \approx T_{copy} + T_{compute}$ per steady iteration. Convert elapsed time into batches/s and GiB/s of input traffic. Repeat enough iterations that fixed launch and first-use costs are a small fraction of the total.

Part 4 - Experimental Design and Instrumentation

Preallocate pinned CPU batches and one CUDA buffer. Warm up the exact kernels, synchronize once before and once after the timed region, and repeat several trials. Report median and range rather than selecting the fastest run.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
import torch

def E01(steps=40, batch=1024, width=2048, trials=5):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    host = torch.randn((steps, batch, width), pin_memory=True)
    gpu = torch.empty((batch, width), device=device)
    weight = torch.randn((width, 512), device=device)

    for index in range(5):
        gpu.copy_(host[index], non_blocking=True)
        warm = torch.relu(gpu @ weight).mean()
    torch.cuda.synchronize(device)

    samples = []
    checksum = None
    for trial in range(trials):
        torch.cuda.synchronize(device)
        started = time.perf_counter()
        total = torch.zeros((), device=device)
        for index in range(steps):
            gpu.copy_(host[index], non_blocking=True)
            total = total + torch.relu(gpu @ weight).mean()
        torch.cuda.synchronize(device)
        samples.append(time.perf_counter() - started)
        checksum = float(total.item())
    median_s = statistics.median(samples)
    input_bytes = host[0].numel() * host.element_size() * steps
    return {"median_s": median_s, "batches_per_s": steps / median_s,
            "input_GiB_per_s": input_bytes / median_s / (1024 ** 3),
            "trials_s": samples, "checksum": checksum}
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not include tensor construction or first CUDA initialization unless deployment startup is the stated target. A surprisingly tiny time indicates missing final synchronization. Compare checksums later with tolerances appropriate to reduction order and dtype.

Part 7 - Engineering Interpretation and Philosophy

A credible optimization begins with a boring baseline. Its value is not speed; it is a controlled counterfactual that prevents claims based on different data, different kernels, or incomplete timing.

19.10.3 Exercise 02

Exercise Title: Separate Transfer Time and Compute Time with CUDA Events and Predict the Maximum Possible Overlap Speedup

Part 1 - Exercise Contract and Why It Matters

Measure copy and compute independently on the GPU timeline, then calculate an upper bound before constructing the pipeline. This separates an architectural limit from implementation quality.

Part 2 - System and Memory Mental Model

CUDA events are timestamp markers recorded in stream order. Elapsed time is valid only after the ending event completes. Events avoid the host scheduling noise of per-operation wall timers, but they still perturb very short workloads and must be placed on the stream containing the measured work.

Part 3 - Quantitative Prediction Before Execution

For measured C ms of copying and G ms of computation, serial time is $C + G$, ideal overlapped time is $\max(C, G)$, and the bound is $(C + G)/\max(C, G)$. The shorter stage can be hidden completely; the longer stage remains on the critical path.

Part 4 - Experimental Design and Instrumentation

Time repeated copies in one event interval and repeated computations in another. Use the same buffers, shapes, and operation as E01. Divide totals by repetitions and compare the calculated bound with later measured speedup.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def timed_region(work, repeats, stream):
    begin = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    with torch.cuda.stream(stream):
        begin.record(stream)
        for index in range(repeats):
            work(index)
        end.record(stream)
    end.synchronize()
    return begin.elapsed_time(end) / repeats
```

```
def E02(repeats=50, batch=1024, width=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    stream = torch.cuda.current_stream(device)
    host = torch.randn((batch, width), pin_memory=True)
    gpu = torch.empty_like(host, device=device)
    weight = torch.randn((width, 512), device=device)

    def copy_work(index):
        gpu.copy_(host, non_blocking=True)

    def compute_work(index):
        output = torch.relu(gpu @ weight)
        output.record_stream(stream)

    copy_ms = timed_region(copy_work, repeats, stream)
    compute_ms = timed_region(compute_work, repeats, stream)
    serial_ms = copy_ms + compute_ms
    ideal_ms = max(copy_ms, compute_ms)
    return {"copy_ms": copy_ms, "compute_ms": compute_ms,
            "serial_prediction_ms": serial_ms,
            "ideal_overlap_ms": ideal_ms,
            "maximum_speedup": serial_ms / ideal_ms}
```

Part 6 - Measurement, Validation, and Failure Analysis

Allocator work, cache effects, and clock variation can make isolated stage times differ from integrated execution. Treat the bound as a ceiling, not a promise. If compute output is discarded, ensure PyTorch still submits the operation and retain a reference until its stream work is safe.

Part 7 - Engineering Interpretation and Philosophy

Optimization should begin by asking what can possibly improve. If compute is ten times longer than copy, heroic copy engineering has a small ceiling; if the two times are balanced, scheduling quality matters greatly.

19.10.4 Exercise 03

Exercise Title: Build a Two-Stage PyTorch Pipeline That Transfers Batch N+1 While Computing Batch N

Part 1 - Exercise Contract and Why It Matters

Implement the first steady-state pipeline: prefetch batch $n + 1$ while computing batch n. Preserve exact dataflow and compare both outputs and throughput with the sequential baseline.

Part 2 - System and Memory Mental Model

Pipeline execution has fill, steady state, and drain. The first copy cannot be hidden, and the final compute has no later copy to overlap. Two CUDA input slots avoid overwriting the batch currently consumed by compute. Each slot has a copy-ready event and a compute-done event.

Part 3 - Quantitative Prediction Before Execution

For N batches, ideal two-stage time is approximately $C + G + (N - 1)\max(C, G)$. Hence short runs understate steady-state benefit. Predict the measured speedup using E02 values before running this code.

Part 4 - Experimental Design and Instrumentation

Use two pinned inputs, two device slots, one copy stream, and the default compute stream. Prime slot zero, alternate slots, wait on only the relevant events, and synchronize after drain. Compare every batch checksum with a serial reference.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E03(steps=50, batch=1024, width=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    copy_stream = torch.cuda.Stream(device=device)
    compute_stream = torch.cuda.current_stream(device)
    host = torch.randn((steps, batch, width), pin_memory=True)
    slots = []
    copy_ready = []
    compute_done = []
    for slot_index in range(2):
        slots.append(torch.empty((batch, width), device=device))
        copy_ready.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute_stream)
        compute_done.append(done)

    torch.cuda.synchronize(device)
    started = time.perf_counter()
    outputs = []
    for index in range(steps):
        slot_index = index % 2
        copy_stream.wait_event(compute_done[slot_index])
        with torch.cuda.stream(copy_stream):
            slots[slot_index].copy_(host[index], non_blocking=True)
            copy_ready[slot_index].record(copy_stream)
        compute_stream.wait_event(copy_ready[slot_index])
        with torch.cuda.stream(compute_stream):
            value = torch.relu(slots[slot_index]).sum()
```

```
            outputs.append(value)
            compute_done[slot_index].record(compute_stream)
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - started
    observed = torch.stack(outputs).cpu()
    expected = torch.relu(host).sum(dim=(1, 2))
    return {"seconds": elapsed, "batches_per_s": steps / elapsed,
            "maximum_error": float((observed - expected).abs().max())}
```

Part 6 - Measurement, Validation, and Failure Analysis

The loop submits copy then compute for each index, yet independent streams may overlap copy $n + 1$ with compute n. If the timeline serializes, check pinned status, stream assignment, workload duration, and device capability. The final CPU transfer of checksums occurs only after timing.

Part 7 - Engineering Interpretation and Philosophy

Pipelining changes temporal organization, not mathematics. A useful design makes ownership and dependencies visible enough that performance work cannot silently change the samples being computed.

19.10.5 Exercise 04

Exercise Title: Use a Dedicated CUDA Transfer Stream and the Default Compute Stream to Execute Copy and Compute Concurrently

Part 1 - Exercise Contract and Why It Matters

Isolate transfer submission on a dedicated stream and computation on the default stream. Demonstrate why stream separation is necessary but not sufficient for concurrency.

Part 2 - System and Memory Mental Model

Operations within one stream are ordered. Operations in different streams are eligible for concurrent execution unless dependencies, implicit synchronization, resource saturation, or hardware limits serialize them.

Part 3 - Quantitative Prediction Before Execution

Measure three quantities: serialized interval, multi-stream interval, and event span of each stage. Define realized efficiency as $(T_{serial} - T_{overlap})/(T_{serial} - T_{ideal})$, clamped only when presenting the metric, not when hiding anomalous measurements.

Part 4 - Experimental Design and Instrumentation

Record stream identities, enqueue H2D on the transfer stream, connect it with an event to default-stream compute, and use a profiler in a separate run. Repeat with a long-enough matrix operation so overlap is observable.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E04(batch=1536, width=1536):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    host_next = torch.randn((batch, width), pin_memory=True)
    current = torch.randn((batch, width), device=device)
    next_gpu = torch.empty_like(current)
    weight = torch.randn((width, width), device=device)
    ready = torch.cuda.Event()
    begin = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)

    begin.record(compute)
    with torch.cuda.stream(transfer):
        next_gpu.copy_(host_next, non_blocking=True)
        ready.record(transfer)
    with torch.cuda.stream(compute):
        current_result = current @ weight
        compute.wait_event(ready)
        next_result = next_gpu.square().mean()
        end.record(compute)
    end.synchronize()
    return {"combined_ms": begin.elapsed_time(end),
            "transfer_stream": str(transfer),
            "compute_stream": str(compute),
            "checksum": float(current_result.mean() + next_result)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Here current-batch compute is independent of the incoming batch and may overlap its copy; only next-batch consumption waits. A timeline is required because a shorter combined interval alone could reflect warm caches or clock variation.

Part 7 - Engineering Interpretation and Philosophy

Streams express potential parallelism. Events express truth about dependencies. Hardware decides what actually overlaps, and measurement decides whether the extra scheduling complexity earns its place.

19.10.6 Exercise 05

Exercise Title: Combine Pinned Host Memory with non_blocking=True and Prove That True Transfer-Compute Overlap Occurs

Part 1 - Exercise Contract and Why It Matters

Prove experimentally that pinned source storage and asynchronous submission are both present when H2D traffic overlaps a kernel. Distinguish proof on a device timeline from a mere reduction in Python blocking time.

Part 2 - System and Memory Mental Model

DMA can read page-locked host pages directly. Pageable input usually requires a staging step into pinned storage before the device copy can proceed. Setting `non_blocking=True` permits asynchronous host submission, but it does not turn pageable storage into a dependable overlap source.

Part 3 - Quantitative Prediction Before Execution

Predict four cases formed by crossing pageable versus pinned storage with blocking versus non-blocking submission. Only pinned, non-blocking transfer on a separate stream is expected to expose reliable copy–compute overlap. Record completed wall time and not just submission time.

Part 4 - Experimental Design and Instrumentation

Use identical byte counts and computation. Confirm `is_pinned()`, warm all paths, and collect a profiler trace containing memcpy and kernels. Compare the overlapped interval with the E02 ideal bound.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def run_case(source, non_blocking, repeats=30):
    device = torch.device("cuda:0")
    copy_stream = torch.cuda.Stream(device=device)
    compute_stream = torch.cuda.current_stream(device)
    destination = torch.empty_like(source, device=device)
    independent = torch.randn((2048, 2048), device=device)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    for index in range(repeats):
        with torch.cuda.stream(copy_stream):
            destination.copy_(source, non_blocking=non_blocking)
        with torch.cuda.stream(compute_stream):
            independent = torch.sin(independent)
    torch.cuda.synchronize(device)
    return time.perf_counter() - started

def E05(batch=2048, width=2048):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    pageable = torch.randn((batch, width))
    pinned = torch.randn((batch, width), pin_memory=True)
    results = {}
    results["pageable_blocking_s"] = run_case(pageable, False)
```

```
    results["pageable_nonblocking_s"] = run_case(pageable, True)
    results["pinned_blocking_s"] = run_case(pinned, False)
    results["pinned_nonblocking_s"] = run_case(pinned, True)
    results["pageable_is_pinned"] = pageable.is_pinned()
    results["pinned_is_pinned"] = pinned.is_pinned()
    return results
```

Part 6 - Measurement, Validation, and Failure Analysis

This timing screens cases; use E11's trace for proof. The `sin` chain is independent but may become too short or memory-bound. If all cases match, enlarge work, verify stream placement, and inspect device support rather than claiming that pinning never helps.

Part 7 - Engineering Interpretation and Philosophy

Pinned memory is a scarce system resource, not a universal decoration. Pin only frequently transferred buffers, reuse them, and judge benefit by end-to-end throughput under realistic CPU and GPU pressure.

19.10.7 Exercise 06

Exercise Title: Reproduce a Pipeline That Appears Asynchronous but Fails to Overlap Because the Source Memory Is Pageable

Part 1 - Exercise Contract and Why It Matters

Build a deliberate false positive: use `non_blocking=True` and a copy stream with pageable source tensors, then show why API appearance does not imply true overlap.

Part 2 - System and Memory Mental Model

The runtime may stage pageable data through an internal pinned buffer. Python can return before the final device work completes, yet host staging or synchronization can serialize the effective path. Submission asynchrony and engine concurrency are different claims.

Part 3 - Quantitative Prediction Before Execution

Predict that host submission may look fast while completed iteration time and the trace show an exposed staging/copy interval. Compare against a pre-pinned clone of the same values.

Part 4 - Experimental Design and Instrumentation

Collect host submission time, synchronized completion time, and a trace. Validate identical values and bytes. Run pageable first and pinned first in alternating trials to reduce ordering bias.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def measure(source, repeats=40):
    device = torch.device("cuda:0")
    stream = torch.cuda.Stream(device=device)
```

```
    destination = torch.empty_like(source, device=device)
    torch.cuda.synchronize(device)
    submitted_at = time.perf_counter()
    for index in range(repeats):
        with torch.cuda.stream(stream):
            destination.copy_(source, non_blocking=True)
    submission_s = time.perf_counter() - submitted_at
    stream.synchronize()
    completed_s = time.perf_counter() - submitted_at
    return submission_s, completed_s, float(destination.sum())

def E06(batch=4096, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    pageable = torch.randn((batch, width))
    pinned = torch.empty_like(pageable, pin_memory=True)
    pinned.copy_(pageable)
    pageable_result = measure(pageable)
    pinned_result = measure(pinned)
    return {"pageable_is_pinned": pageable.is_pinned(),
            "pinned_is_pinned": pinned.is_pinned(),
            "pageable_submission_s": pageable_result[0],
            "pageable_completion_s": pageable_result[1],
            "pinned_submission_s": pinned_result[0],
            "pinned_completion_s": pinned_result[1],
            "checksum_error": abs(pageable_result[2] - pinned_result[2])}
```

Part 6 - Measurement, Validation, and Failure Analysis

Fast submission is not the target metric. If pageable copies happen to perform well on one system, the experiment still establishes that pinned state must be verified and concurrency must be observed. Runtime behavior is implementation- and platform-dependent.

Part 7 - Engineering Interpretation and Philosophy

Performance APIs often describe permission, not completion. Engineers must name the layer of every claim: Python thread, CUDA queue, copy engine, kernel engine, or end-to-end application.

19.10.8 Exercise 07

Exercise Title: Insert CUDA Events Between Transfer and Compute Streams to Enforce Only the Dependencies Required for Correct Execution

Part 1 - Exercise Contract and Why It Matters

Encode precise dependencies with CUDA events so consumers wait for their input copy and producers wait before reusing occupied storage, without a global device barrier.

Part 2 - System and Memory Mental Model

An event recorded in stream A becomes complete after all earlier work in A. A wait inserted in stream B delays only later work in B. This creates a directed edge, leaving unrelated streams free to progress. One event protects copy-to-compute readiness; another protects compute-to-reuse safety.

Part 3 - Quantitative Prediction Before Execution

The correct dependency graph should produce zero mismatches and no global synchronization inside the loop. Predict that removing the ready wait can read partial input, while removing the reuse wait can overwrite a live batch.

Part 4 - Experimental Design and Instrumentation

Use deterministic per-batch sentinel values and two slots. Log submission order, event completion after the run, and per-batch reductions. Run many repetitions because timing races are probabilistic.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E07(steps=100, batch=1024, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    host_slots = []
    gpu_slots = []
    ready_events = []
    reusable_events = []
    for slot_index in range(2):
        host_slots.append(torch.empty((batch, width), pin_memory=True))
        gpu_slots.append(torch.empty((batch, width), device=device))
        copied = torch.cuda.Event()
        copied.record(compute)
        ready_events.append(copied)
        event = torch.cuda.Event()
        event.record(compute)
        reusable_events.append(event)

    results = []
    for index in range(steps):
        slot_index = index % 2
        ready_events[slot_index].synchronize()
        host_slots[slot_index].fill_(float(index))
        transfer.wait_event(reusable_events[slot_index])
        with torch.cuda.stream(transfer):
            gpu_slots[slot_index].copy_(host_slots[slot_index],
                                        non_blocking=True)
            ready_events[slot_index].record(transfer)
```

```
        compute.wait_event(ready_events[slot_index])
        with torch.cuda.stream(compute):
            results.append(gpu_slots[slot_index].mean())
            reusable_events[slot_index].record(compute)
    torch.cuda.synchronize(device)
    observed = torch.stack(results).cpu()
    expected = torch.arange(steps, dtype=observed.dtype)
    return {"maximum_error": float((observed - expected).abs().max()),
            "all_ready": all(event.query() for event in ready_events),
            "all_reusable": all(event.query() for event in reusable_events)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The CPU synchronizes the previous ready event before refilling that pinned slot; the same event marks completion of the H2D read and readiness of the device input. Compute completion separately protects device-slot reuse. Removing either rule creates a different lifetime bug.

Part 7 - Engineering Interpretation and Philosophy

Global synchronization replaces reasoning with waiting. Event graphs make correctness local: every edge has a producer, consumer, storage object, and lifetime. That precision is the foundation of scalable asynchronous systems.

19.10.9 Exercise 08

Exercise Title: Remove an Unnecessary torch.cuda.synchronize() and Measure the Throughput Recovered by Preserving Asynchronous Execution

Part 1 - Exercise Contract and Why It Matters

Insert a device-wide synchronization into an otherwise valid pipeline, quantify the lost throughput, remove it, and prove that event dependencies retain correctness.

Part 2 - System and Memory Mental Model

`torch.cuda.synchronize()` blocks the CPU until all prior work on the device completes. Inside a loop it repeatedly drains the pipeline, preventing future copy submission while compute runs. A stream wait or event wait expresses only the actual dependency and does not block the host.

Part 3 - Quantitative Prediction Before Execution

The synchronized variant tends toward $C + G$ per batch; the event-driven variant tends toward $\max(C, G)$, plus overhead. Predict the ratio from E02 and compare it with the measured ratio.

Part 4 - Experimental Design and Instrumentation

Run identical data twice through the same model. Change only the loop barrier. Warm up, randomize run order across trials, synchronize at outer timing boundaries, and compare outputs before discussing speed.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def run_pipeline(host, weight, synchronize_inside):
    device = weight.device
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    gpu_slots = []
    ready_events = []
    reusable_events = []
    for slot_index in range(2):
        gpu_slots.append(torch.empty_like(host[0], device=device))
        ready_events.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        reusable_events.append(done)
    elapsed_start = time.perf_counter()
    checksum = torch.zeros((), device=device)
    for index in range(host.shape[0]):
        slot_index = index % 2
        transfer.wait_event(reusable_events[slot_index])
        with torch.cuda.stream(transfer):
            gpu_slots[slot_index].copy_(host[index], non_blocking=True)
            ready_events[slot_index].record(transfer)
        compute.wait_event(ready_events[slot_index])
        with torch.cuda.stream(compute):
            value = torch.relu(gpu_slots[slot_index] @ weight).mean()
            checksum = checksum + value
            reusable_events[slot_index].record(compute)
        if synchronize_inside:
            torch.cuda.synchronize(device)
    torch.cuda.synchronize(device)
    return time.perf_counter() - elapsed_start, float(checksum)

def E08(steps=30, batch=512, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    host = torch.randn((steps, batch, width), pin_memory=True)
    weight = torch.randn((width, width), device=device)
    blocked_s, blocked_value = run_pipeline(host, weight, True)
    async_s, async_value = run_pipeline(host, weight, False)
    return {"synchronized_s": blocked_s, "event_driven_s": async_s,
            "speedup": blocked_s / async_s,
            "checksum_error": abs(blocked_value - async_value)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The two slots and their reuse events keep the experiment correct in both modes. If removing the barrier changes values, the barrier was hiding a missing dependency rather than being unnecessary. Small workloads may show little gain because event and launch overhead dominate.

Part 7 - Engineering Interpretation and Philosophy

Synchronization is not intrinsically bad; unjustified synchronization is. Place completion boundaries where the application consumes results, not wherever asynchronous behavior feels uncomfortable.

19.10.10 Exercise 09

Exercise Title: Build a Double-Buffered Input Pipeline That Alternates Between Two Pinned CPU Buffers and Two CUDA Input Buffers

Part 1 - Exercise Contract and Why It Matters

Build a reusable two-slot pipeline with pinned CPU storage and preallocated CUDA storage. Make every reuse rule explicit and measure RAM, VRAM, correctness, and steady-state throughput.

Part 2 - System and Memory Mental Model

Slot i cycles through CPU preparation, H2D copy, GPU compute, and reusable states. Two slots permit one batch in transfer while the other is in compute. Host storage becomes refillable at copy completion; CUDA storage becomes overwriteable at compute completion. Those milestones must not be conflated.

Part 3 - Quantitative Prediction Before Execution

Per-slot memory is $B_{host} + B_{device}$. Double buffering consumes twice that amount, excluding model and activations. Predict whether two slots can hide copy using E02 and calculate the fill/drain penalty for the chosen number of steps.

Part 4 - Experimental Design and Instrumentation

Use two copy-done events, two input-ready events, and two compute-done events. Refill the host slot only after copy-done, overwrite the GPU slot only after compute-done, and validate per-batch sentinels over many cycles.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E09(steps=64, batch=1024, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    host_slots = []
    gpu_slots = []
    copy_done = []
```

```
    input_ready = []
    compute_done = []
    for slot_index in range(2):
        host_slots.append(torch.empty((batch, width), pin_memory=True))
        gpu_slots.append(torch.empty((batch, width), device=device))
        copied = torch.cuda.Event()
        copied.record(compute)
        copy_done.append(copied)
        input_ready.append(torch.cuda.Event())
        computed = torch.cuda.Event()
        computed.record(compute)
        compute_done.append(computed)

    answers = []
    for index in range(steps):
        slot_index = index % 2
        copy_done[slot_index].synchronize()
        host_slots[slot_index].fill_(float(index + 1))
        transfer.wait_event(compute_done[slot_index])
        with torch.cuda.stream(transfer):
            gpu_slots[slot_index].copy_(host_slots[slot_index],
                                        non_blocking=True)
            copy_done[slot_index].record(transfer)
            input_ready[slot_index].record(transfer)
        compute.wait_event(input_ready[slot_index])
        with torch.cuda.stream(compute):
            answers.append(gpu_slots[slot_index].mean())
            compute_done[slot_index].record(compute)
    torch.cuda.synchronize(device)
    observed = torch.stack(answers).cpu()
    expected = torch.arange(1, steps + 1, dtype=observed.dtype)
    slot_bytes = host_slots[0].numel() * host_slots[0].element_size()
    return {"maximum_error": float((observed - expected).abs().max()),
            "pinned_RAM_MiB": 2 * slot_bytes / (1024 ** 2),
            "input_VRAM_MiB": 2 * slot_bytes / (1024 ** 2)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Host-side event synchronization can stall CPU preparation; E14 will overlap preparation using backpressure and a producer. It is retained here to make host buffer ownership undeniable. Stress sentinels, variable delays, and many cycles to reveal reuse races.

Part 7 - Engineering Interpretation and Philosophy

Double buffering is a bounded queue, not simply two arrays. Its strength is controlled ownership: bounded memory, predictable latency, and backpressure when one stage cannot keep pace.

19.10.11 Exercise 10

Exercise Title: Extend Double Buffering into Triple Buffering and Determine Whether Additional Buffers Improve Throughput or Only Increase Memory Usage

Part 1 - Exercise Contract and Why It Matters

Generalize the pipeline from two to three slots and determine experimentally whether extra queue depth absorbs jitter or merely consumes pinned RAM and VRAM.

Part 2 - System and Memory Mental Model

Two slots are sufficient for ideal two-stage copy–compute overlap. A third can help when CPU preparation, transfer, or kernel duration varies, because one slot may wait while another is ready. It cannot reduce the steady-state critical path below the slowest stage.

Part 3 - Quantitative Prediction Before Execution

For slot bytes $M_h + M_d$, moving from two to three slots adds exactly one such unit. Predict throughput gain from measured jitter, not average time alone. Define gain per MiB as $(R_3 - R_2)/(M_h + M_d)$.

Part 4 - Experimental Design and Instrumentation

Run slot counts one, two, and three under identical batch order. Record median throughput, tail iteration latency, peak VRAM, pinned RAM, and output error. Add controlled preparation jitter in a separate trial.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def buffered_run(source, weight, slot_count):
    device = weight.device
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    slots = []
    ready = []
    reusable = []
    for slot_index in range(slot_count):
        slots.append(torch.empty_like(source[0], device=device))
        ready.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        reusable.append(done)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    values = []
    for index in range(source.shape[0]):
        slot_index = index % slot_count
        transfer.wait_event(reusable[slot_index])
        with torch.cuda.stream(transfer):
```

```
            slots[slot_index].copy_(source[index], non_blocking=True)
            ready[slot_index].record(transfer)
        compute.wait_event(ready[slot_index])
        with torch.cuda.stream(compute):
            values.append(torch.relu(slots[slot_index] @ weight).mean())
            reusable[slot_index].record(compute)
    torch.cuda.synchronize(device)
    return time.perf_counter() - started, torch.stack(values).cpu()

def E10(steps=60, batch=512, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    source = torch.randn((steps, batch, width), pin_memory=True)
    weight = torch.randn((width, width), device=device)
    report = {}
    reference = None
    for slot_count in (1, 2, 3):
        seconds, values = buffered_run(source, weight, slot_count)
        if reference is None:
            reference = values
        error = float((values - reference).abs().max())
        report[slot_count] = {"seconds": seconds,
                              "batches_per_s": steps / seconds,
                              "maximum_error": error}
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

The entire source dataset is pinned here for experimental control; production should use bounded pinned slots. Alternate test order because thermal state can favor later runs. If three slots help only once, investigate warmup rather than adopting them.

Part 7 - Engineering Interpretation and Philosophy

Buffer count is a queueing decision. More capacity smooths variance but increases memory, stale work, and debugging surface. The smallest depth that sustains the target rate is usually the strongest engineering choice.

19.10.12 Exercise 11

Exercise Title: Profile Copy Engines and CUDA Kernels to Verify Real Timeline Overlap Instead of Inferring It from Wall-Clock Time

Part 1 - Exercise Contract and Why It Matters

Capture a device trace and prove that H2D memcpy intervals intersect kernel intervals. Replace inference from total runtime with direct temporal evidence.

Part 2 - System and Memory Mental Model

A faster wall time can come from caching, clocks, or reduced work. A profiler timeline exposes CPU submission, CUDA runtime calls, memcpy activity, kernels, and synchronization. Overlap exists only when device intervals occupy the same time range on distinct execution resources.

Part 3 - Quantitative Prediction Before Execution

Predict the overlap duration as at most $\min(C, G)$ per steady batch. Define overlap fraction as intersected copy time divided by total copy time, and exposed copy as copy time minus intersection.

Part 4 - Experimental Design and Instrumentation

Profile warmup separately, then a small active window. Give CPU submission regions short profiler labels. Export a Chrome trace, inspect memcpy and kernel lanes, and corroborate it with event and wall-clock measurements.

Part 5 - PyTorch/CUDA Implementation

```
import torch
from torch.profiler import ProfilerActivity, profile, record_function

def E11(trace_path="dmm08_overlap_trace.json", steps=12):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    host = torch.randn((steps, 1024, 1024), pin_memory=True)
    gpu_slots = []
    ready_events = []
    reusable_events = []
    for slot_index in range(2):
        gpu_slots.append(torch.empty_like(host[0], device=device))
        ready_events.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        reusable_events.append(done)
    weight = torch.randn((1024, 1024), device=device)
    torch.cuda.synchronize(device)
    with profile(activities=[ProfilerActivity.CPU, ProfilerActivity.CUDA],
                 record_shapes=True, profile_memory=True) as prof:
        for index in range(steps):
            slot_index = index % 2
            transfer.wait_event(reusable_events[slot_index])
            with record_function("submit_h2d"):
                with torch.cuda.stream(transfer):
                    gpu_slots[slot_index].copy_(host[index],
                                                non_blocking=True)
                    ready_events[slot_index].record(transfer)
            compute.wait_event(ready_events[slot_index])
```

```
            with record_function("submit_compute"):
                output = torch.relu(gpu_slots[slot_index] @ weight)
                reusable_events[slot_index].record(compute)
        torch.cuda.synchronize(device)
    prof.export_chrome_trace(trace_path)
    table = prof.key_averages().table(sort_by="self_cuda_time_total",
                                      row_limit=12)
    return {"trace_path": trace_path, "summary": table,
            "checksum": float(output.mean())}
```

Part 6 - Measurement, Validation, and Failure Analysis

The trace uses two protected destinations so reuse cannot race with compute. Profiler overhead alters absolute time, but temporal overlap remains observable. Do not claim concurrent engines from adjacent, non-overlapping rectangles, and validate outputs separately because a timeline proves scheduling, not arithmetic.

Part 7 - Engineering Interpretation and Philosophy

Timelines turn concurrency from folklore into auditable evidence. The trace is the explanation: it should show where work waited, which dependency caused it, and how much critical-path time the change removed.

19.10.13 Exercise 12

Exercise Title: Sweep Batch Size and Identify the Region Where Transfer Is Fully Hidden Behind Computation

Part 1 - Exercise Contract and Why It Matters

Sweep batch size and locate the operating region where compute duration is long enough to hide H2D transfer without exceeding memory or latency targets.

Part 2 - System and Memory Mental Model

Transfer and compute do not necessarily scale identically. Copy is roughly proportional to bytes after fixed overhead, while kernels may change algorithms, occupancy, or efficiency at shape thresholds. Therefore the hidden-copy region must be measured on the target system.

Part 3 - Quantitative Prediction Before Execution

For every batch b, record C_b, G_b, serial S_b, and pipeline P_b. Estimate exposed copy as $\max(0, P_b - G_b)$ and hidden fraction as $1 - \max(0, P_b - G_b)/C_b$. Mark full hiding only within a declared tolerance.

Part 4 - Experimental Design and Instrumentation

Use geometric batch sizes, fixed width and dtype, repeated trials, and peak-memory reset per point. Stop before unsafe memory pressure. Retain throughput, latency, hidden fraction, and peak VRAM rather than selecting by throughput alone.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def event_time(work, repeats=20):
    start = torch.cuda.Event(enable_timing=True)
    end = torch.cuda.Event(enable_timing=True)
    start.record()
    for index in range(repeats):
        work()
    end.record()
    end.synchronize()
    return start.elapsed_time(end) / repeats

def E12(width=1024, batch_sizes=(64, 128, 256, 512, 1024, 2048)):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    report = []
    for batch in batch_sizes:
        host = torch.randn((batch, width), pin_memory=True)
        gpu = torch.empty_like(host, device=device)
        weight = torch.randn((width, width), device=device)
        torch.cuda.reset_peak_memory_stats(device)

        def copy_work():
            gpu.copy_(host, non_blocking=True)

        def compute_work():
            output = torch.relu(gpu @ weight)
            output.record_stream(torch.cuda.current_stream(device))

        copy_ms = event_time(copy_work)
        compute_ms = event_time(compute_work)
        ideal_ms = max(copy_ms, compute_ms)
        hidden_fraction = 1.0 - max(0.0, ideal_ms - compute_ms) / copy_ms
        report.append({"batch": batch, "copy_ms": copy_ms,
                       "compute_ms": compute_ms, "ideal_ms": ideal_ms,
                       "predicted_hidden_fraction": hidden_fraction,
                       "peak_MiB": torch.cuda.max_memory_allocated(device)
                                   / (1024 ** 2)})
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

The implementation predicts hiding from isolated stages; pair it with measured double-buffered time from E09 for confirmation. Avoid calling a point fully hidden when differences are within timer noise. An OOM is not a valid endpoint for an ordinary sweep.

Part 7 - Engineering Interpretation and Philosophy

The best batch is a constrained operating point, not the largest possible one. Throughput, latency, memory headroom, and robustness to variable shapes all participate in the decision.

19.10.14 Exercise 13

Exercise Title: Reduce GPU Compute Cost Until Data Transfer Becomes the Dominant Bottleneck and Explain Why Overlap Efficiency Collapses

Part 1 - Exercise Contract and Why It Matters

Systematically reduce GPU work while holding input bytes fixed. Identify the point at which transfer becomes the critical path and explain why further kernel optimization no longer improves pipeline throughput proportionally.

Part 2 - System and Memory Mental Model

Overlap hides only the shorter concurrent stage. When compute dominates, copy can disappear beneath it. As compute shrinks below copy time, the copy engine sets the cadence and exposed transfer grows. This is bottleneck migration, not a failure of asynchronous APIs.

Part 3 - Quantitative Prediction Before Execution

For compute multipliers k, predict $P_k = \max(C, G_k)$. The crossover occurs near $G_k = C$. Plot achieved throughput and exposed-copy fraction against k.

Part 4 - Experimental Design and Instrumentation

Keep source shape, dtype, transfer route, streams, and repetitions fixed. Vary only the number or complexity of independent kernels. Measure isolated stages and the integrated pipeline at every point.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E13(batch=2048, width=1024, depths=(16, 8, 4, 2, 1)):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    host = torch.randn((batch, width), pin_memory=True)
    gpu = torch.empty_like(host, device=device)
    report = []
    for depth in depths:
        start = torch.cuda.Event(enable_timing=True)
        copied = torch.cuda.Event(enable_timing=True)
        finished = torch.cuda.Event(enable_timing=True)
        start.record()
        gpu.copy_(host, non_blocking=True)
        copied.record()
        value = gpu
        for layer_index in range(depth):
            value = torch.tanh(value)
        finished.record()
```

```
        finished.synchronize()
        copy_ms = start.elapsed_time(copied)
        compute_ms = copied.elapsed_time(finished)
        report.append({"depth": depth, "copy_ms": copy_ms,
                       "compute_ms": compute_ms,
                       "predicted_pipeline_ms": max(copy_ms, compute_ms),
                       "dominant_stage": "copy" if copy_ms > compute_ms
                                         else "compute"})
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

These stage timings are serialized intentionally; run the corresponding double-buffered cases to measure realized overlap. Elementwise kernels may be memory-bandwidth limited and contend with copies, so the ideal maximum can be optimistic even when their nominal intervals balance.

Part 7 - Engineering Interpretation and Philosophy

Local optimization changes the global bottleneck. Mature performance work reprofiles after every major improvement and stops tuning a stage once another resource controls the service rate.

19.10.15 Exercise 14

Exercise Title: Increase CPU Data-Preparation Cost and Determine When Preprocessing Prevents the GPU Pipeline from Remaining Saturated

Part 1 - Exercise Contract and Why It Matters

Increase CPU preparation time until the GPU develops idle gaps. Separate a data production bottleneck from H2D and compute bottlenecks and quantify the queue depth needed to absorb ordinary jitter.

Part 2 - System and Memory Mental Model

The GPU remains saturated only if prepared pinned batches arrive at least as fast as the GPU pipeline consumes them. A bounded queue decouples short-term variation but cannot repair a producer whose long-run service rate is lower. Backpressure prevents unbounded pinned-memory growth.

Part 3 - Quantitative Prediction Before Execution

Let average preparation be P and GPU cadence be $Q = \max(C, G)$. If $P > Q$, the best sustained rate is (1/P). If (P<Q) but preparation has jitter, buffer depth determines how much variance can be absorbed.

Part 4 - Experimental Design and Instrumentation

Create a bounded producer queue, vary synthetic preparation delay, and record queue-empty time, queue-full time, GPU throughput, and pinned allocation. Do not sleep in the GPU submission thread; isolate preparation in a producer thread.

Part 5 - PyTorch/CUDA Implementation

```
import queue
import threading
import time
import torch

def E14(steps=50, delay_ms=2.0, batch=512, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    prepared = queue.Queue(maxsize=3)
    stop_token = object()

    def producer():
        for index in range(steps):
            host = torch.empty((batch, width), pin_memory=True)
            host.normal_()
            time.sleep(delay_ms / 1000.0)
            prepared.put((index, host))
        prepared.put(stop_token)

    worker = threading.Thread(target=producer)
    worker.start()
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    gpu_slots = []
    ready_events = []
    reusable_events = []
    for slot_index in range(2):
        gpu_slots.append(torch.empty((batch, width), device=device))
        ready_events.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        reusable_events.append(done)
    inflight_sources = []
    empty_wait_s = 0.0
    processed = 0
    started = time.perf_counter()
    while True:
        wait_started = time.perf_counter()
        item = prepared.get()
        empty_wait_s += time.perf_counter() - wait_started
        if item is stop_token:
            break
        index, host = item
        slot_index = index % 2
        transfer.wait_event(reusable_events[slot_index])
        with torch.cuda.stream(transfer):
            gpu_slots[slot_index].copy_(host, non_blocking=True)
```

```
            ready_events[slot_index].record(transfer)
        inflight_sources.append((host, ready_events[slot_index]))
        if len(inflight_sources) > 3:
            old_host, old_event = inflight_sources.pop(0)
            old_event.synchronize()
        compute.wait_event(ready_events[slot_index])
        with torch.cuda.stream(compute):
            output = torch.relu(gpu_slots[slot_index]).mean()
            reusable_events[slot_index].record(compute)
        processed += 1
    for old_host, old_event in inflight_sources:
        old_event.synchronize()
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - started
    worker.join()
    return {"processed": processed, "seconds": elapsed,
            "batches_per_s": processed / elapsed,
            "consumer_queue_wait_s": empty_wait_s,
            "checksum": float(output)}
```

Part 6 - Measurement, Validation, and Failure Analysis

This diagnostic allocates pinned tensors per batch to make preparation cost visible and retains a bounded set until their copies complete; replace those allocations with reusable host slots for production. Queue wait includes Python scheduling and is not itself GPU-idle proof, so correlate it with a trace. Vary delay over a sweep instead of drawing conclusions from one point.

Part 7 - Engineering Interpretation and Philosophy

GPU utilization is an end-to-end property. A faster kernel is irrelevant when the accelerator waits for decoding, augmentation, storage, or Python. Optimize the slowest stage while keeping queues bounded and observable.

19.10.16 Exercise 15

Exercise Title: Overlap GPU-to-CPU Output Transfers with Computation of the Next Batch Without Reading Host Results Prematurely

Part 1 - Exercise Contract and Why It Matters

Move batch n's output to pinned host memory while computing batch $n+1$, and prove that the CPU never consumes a destination before its asynchronous D2H copy completes.

Part 2 - System and Memory Mental Model

An asynchronous D2H copy reverses the ownership problem. The GPU produces an output, an output stream waits for the compute event, and a pinned host slot receives the bytes. Python may regain control before the host values are valid. The CPU must query or synchronize the copy-complete event before reading or reusing that slot.

Part 3 - Quantitative Prediction Before Execution

With output-copy time D and next compute time G, the steady contribution is ideally $\max(D, G)$, subject to copy-engine capabilities. Calculate output bytes and predict whether D2H is large enough to be visible.

Part 4 - Experimental Design and Instrumentation

Use two device outputs and two pinned host outputs. Record compute-ready and D2H-done events per slot. Compare results with a blocking reference, and include an intentionally premature-read demonstration only as a documented unsafe variant, not as a correctness oracle.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E15(steps=40, batch=1024, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    compute = torch.cuda.current_stream(device)
    output_stream = torch.cuda.Stream(device=device)
    inputs = torch.randn((steps, batch, width), device=device)
    device_outputs = []
    host_outputs = []
    compute_ready = []
    d2h_done = []
    for slot_index in range(2):
        device_outputs.append(torch.empty((batch,), device=device))
        host_outputs.append(torch.empty((batch,), pin_memory=True))
        compute_ready.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        d2h_done.append(done)

    validated = []
    for index in range(steps):
        slot_index = index % 2
        d2h_done[slot_index].synchronize()
        if index >= 2:
            completed_index = index - 2
            expected = inputs[completed_index].square().sum(dim=1).cpu()
            error = (host_outputs[slot_index] - expected).abs().max()
            validated.append(float(error))
        with torch.cuda.stream(compute):
            torch.sum(inputs[index].square(), dim=1,
                      out=device_outputs[slot_index])
            compute_ready[slot_index].record(compute)
        output_stream.wait_event(compute_ready[slot_index])
        with torch.cuda.stream(output_stream):
            host_outputs[slot_index].copy_(device_outputs[slot_index],
                                           non_blocking=True)
```

```
            d2h_done[slot_index].record(output_stream)

    for event in d2h_done:
        event.synchronize()
    return {"validated_completed_slots": len(validated),
            "maximum_error": max(validated) if validated else 0.0}
```

Part 6 - Measurement, Validation, and Failure Analysis

The final two batches require an explicit drain validation in a production test; the compact return focuses on steady-state slots. Calling `cpu()` on the expected value introduces synchronization outside the timed region. A premature host read may occasionally look correct, which makes it especially dangerous.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony transfers responsibility for completion to the program. Host-visible memory is not valid merely because a copy was requested. Correct systems expose completion as an explicit state, not an assumption about elapsed time.

19.10.17 Exercise 16

Exercise Title: Build a Bidirectional Pipeline That Overlaps Host-to-Device Inputs, GPU Compute, and Device-to-Host Outputs

Part 1 - Exercise Contract and Why It Matters

Construct a three-stage bidirectional pipeline with H2D input, GPU compute, and D2H output streams. Preserve dependencies and discover whether the device can actually overlap both transfer directions with kernels.

Part 2 - System and Memory Mental Model

Input copy, compute, and output copy form a directed acyclic graph per slot. Different devices expose different copy-engine counts and scheduling behavior; separate streams express eligibility but do not guarantee simultaneous H2D, D2H, and compute. Slot reuse waits for both the input consumer and output copy.

Part 3 - Quantitative Prediction Before Execution

With stage times H, G, and D, an ideal three-engine cadence is $\max(H, G, D)$. With one shared bidirectional copy engine, transfer contribution may approach $H + D$, giving $\max(H + D, G)$. Treat these as hypotheses for the trace.

Part 4 - Experimental Design and Instrumentation

Preallocate bounded host input/output and device input/output slots. Use events for H2D-ready, compute-ready, compute-done, and D2H-done. Validate all outputs, measure fill/steady/drain separately, and inspect engine lanes.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E16(steps=30, batch=512, width=1024, slots_count=3):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    h2d = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    d2h = torch.cuda.Stream(device=device)
    host_inputs = []
    host_outputs = []
    gpu_inputs = []
    gpu_outputs = []
    input_ready = []
    compute_done = []
    output_done = []
    for slot_index in range(slots_count):
        host_inputs.append(torch.empty((batch, width), pin_memory=True))
        host_outputs.append(torch.empty((batch,), pin_memory=True))
        gpu_inputs.append(torch.empty((batch, width), device=device))
        gpu_outputs.append(torch.empty((batch,), device=device))
        input_ready.append(torch.cuda.Event())
        computed = torch.cuda.Event()
        computed.record(compute)
        compute_done.append(computed)
        copied = torch.cuda.Event()
        copied.record(compute)
        output_done.append(copied)

    for index in range(steps):
        slot_index = index % slots_count
        output_done[slot_index].synchronize()
        host_inputs[slot_index].fill_(float(index + 1))
        h2d.wait_event(compute_done[slot_index])
        with torch.cuda.stream(h2d):
            gpu_inputs[slot_index].copy_(host_inputs[slot_index],
                                         non_blocking=True)
            input_ready[slot_index].record(h2d)
        compute.wait_event(input_ready[slot_index])
        with torch.cuda.stream(compute):
            torch.sum(gpu_inputs[slot_index], dim=1,
                      out=gpu_outputs[slot_index])
            compute_done[slot_index].record(compute)
        d2h.wait_event(compute_done[slot_index])
        with torch.cuda.stream(d2h):
            host_outputs[slot_index].copy_(gpu_outputs[slot_index],
                                           non_blocking=True)
            output_done[slot_index].record(d2h)
```

```
for event in output_done:
    event.synchronize()
last_slot = (steps - 1) % slots_count
last_mean = float(host_outputs[last_slot].mean())
return {"last_slot_mean": last_mean,
        "expected_last": float(steps * width)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Validate every slot before refill in the full experiment, not only the final one. If H2D and D2H serialize, check the device's engines before rewriting the event graph. If values fail, verify output-slot reuse as carefully as input reuse.

Part 7 - Engineering Interpretation and Philosophy

A pipeline is a resource graph constrained by hardware, not a list of streams. Good design remains correct on a device with less concurrency and opportunistically accelerates on one with more.

19.10.18 Exercise 17

Exercise Title: Stress-Test an Overlapped Pipeline Under Variable Batch Sizes and Detect Buffer Reuse Hazards, Race Conditions, and Synchronization Stalls

Part 1 - Exercise Contract and Why It Matters

Stress the pipeline with bounded variable shapes, randomized delays, and repeated slot reuse. Detect corruption, illegal assumptions, allocator growth, and unnecessary waits without deliberately exhausting the GPU.

Part 2 - System and Memory Mental Model

Variable sizes challenge both logical capacity and allocator reuse. A slot has a maximum capacity and a logical view for the current batch. Reallocation inside the hot path can destroy stable memory behavior and add hidden synchronization. Generation numbers reveal stale or overwritten data.

Part 3 - Quantitative Prediction Before Execution

Before execution, compute maximum slot bytes and total bounded memory. Predict the expected checksum for every generation. Set failure thresholds for mismatches, timeout/stall duration, reserved-memory drift, and throughput variance.

Part 4 - Experimental Design and Instrumentation

Generate sizes with a fixed seed, preallocate for the maximum, use explicit slices, and inject optional CPU jitter. Log size, slot, generation, event waits, checksum, iteration time, allocated memory, and reserved memory.

Part 5 - PyTorch/CUDA Implementation

```
import random
import torch

def E17(steps=300, min_batch=64, max_batch=1024, width=512):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    random.seed(1708)
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    host_slots = []
    gpu_slots = []
    ready = []
    reusable = []
    for slot_index in range(3):
        host_slots.append(torch.empty((max_batch, width), pin_memory=True))
        gpu_slots.append(torch.empty((max_batch, width), device=device))
        copied = torch.cuda.Event()
        copied.record(compute)
        ready.append(copied)
        done = torch.cuda.Event()
        done.record(compute)
        reusable.append(done)

    results = []
    expected = []
    for generation in range(steps):
        batch = random.randint(min_batch, max_batch)
        slot_index = generation % 3
        value = float((generation % 97) + 1)
        ready[slot_index].synchronize()
        host_view = host_slots[slot_index][:batch]
        gpu_view = gpu_slots[slot_index][:batch]
        host_view.fill_(value)
        transfer.wait_event(reusable[slot_index])
        with torch.cuda.stream(transfer):
            gpu_view.copy_(host_view, non_blocking=True)
            ready[slot_index].record(transfer)
        compute.wait_event(ready[slot_index])
        with torch.cuda.stream(compute):
            results.append(gpu_view.sum())
            reusable[slot_index].record(compute)
        expected.append(value * batch * width)
    torch.cuda.synchronize(device)
    observed = torch.stack(results).double().cpu()
    target = torch.tensor(expected, dtype=torch.float64)
    relative = (observed - target).abs() / target.clamp_min(1.0)
    allocated = torch.cuda.memory_allocated(device) / (1024 ** 2)
```

```
    reserved = torch.cuda.memory_reserved(device) / (1024 ** 2)
    return {"steps": steps,
            "maximum_relative_error": float(relative.max()),
            "allocated_MiB": allocated,
            "reserved_MiB": reserved}
```

Part 6 - Measurement, Validation, and Failure Analysis

Run a negative-control variant that omits one wait only in an isolated test and confirm the validator can catch failure. If no failure appears, increase timing variation rather than declaring the race safe. Bound maximum batch from a memory budget; a stress test should study limits, not crash the workstation.

Part 7 - Engineering Interpretation and Philosophy

Concurrency bugs live in rare schedules. Deterministic sentinels, generations, bounded randomness, and long repetitions turn "occasionally wrong" into a reproducible engineering signal.

19.10.19 Exercise 18

Exercise Title: Build an Adaptive Buffering Controller That Chooses Buffer Count from Measured Transfer Time, Compute Time, and Available VRAM

Part 1 - Exercise Contract and Why It Matters

Build a controller that proposes a bounded slot count from measured stage times and explicit host/device memory budgets. Treat the proposal as a hypothesis that must be benchmarked, not an automatic guarantee.

Part 2 - System and Memory Mental Model

Buffer depth supplies queueing slack. Time ratios estimate how much work can be in flight; memory budgets impose hard feasibility. Per-slot cost includes pinned input/output storage and device input/output storage, while model, activations, and safety headroom remain outside the slot budget.

Part 3 - Quantitative Prediction Before Execution

Estimate required depth as

$$n_t = 1 + \left\lceil \frac{T_p + T_c}{\max(T_g, \epsilon)} \right\rceil .$$

Compute $n_h = \lfloor R_{budget}/M_h \rfloor$ and $n_d = \lfloor V_{budget}/M_d \rfloor$. Choose $\max(2, \min(n_t, n_h, n_d, n_{hard}))$ when at least two slots are feasible; otherwise fall back to a serial design.

Part 4 - Experimental Design and Instrumentation

Measure robust medians after warmup, reserve fixed safety margins, calculate the candidate, then benchmark neighboring depths. Re-evaluate when shape distribution, dtype, model, or hardware changes.

Part 5 - PyTorch/CUDA Implementation

```
import math
import torch

def choose_buffers(prep_ms, h2d_ms, compute_ms, host_slot_bytes,
                   device_slot_bytes, ram_budget_bytes,
                   vram_budget_bytes, hard_max=8):
    epsilon = 1.0e-9
    time_need = 1 + math.ceil((prep_ms + h2d_ms) /
                              max(compute_ms, epsilon))
    host_limit = ram_budget_bytes // max(host_slot_bytes, 1)
    device_limit = vram_budget_bytes // max(device_slot_bytes, 1)
    feasible = min(host_limit, device_limit, hard_max)
    if feasible < 2:
        return 1
    return max(2, min(time_need, feasible))

def E18(batch=1024, width=1024, prep_ms=1.5, h2d_ms=0.8,
        compute_ms=2.4, ram_budget_MiB=512, vram_budget_MiB=512):
    element_size = torch.empty((), dtype=torch.float32).element_size()
    input_bytes = batch * width * element_size
    output_bytes = batch * element_size
    host_slot_bytes = input_bytes + output_bytes
    device_slot_bytes = input_bytes + output_bytes
    ram_budget = int(ram_budget_MiB * 1024 ** 2)
    vram_budget = int(vram_budget_MiB * 1024 ** 2)
    selected = choose_buffers(prep_ms, h2d_ms, compute_ms,
                              host_slot_bytes, device_slot_bytes,
                              ram_budget, vram_budget)
    return {"selected_buffers": selected,
            "host_slot_MiB": host_slot_bytes / (1024 ** 2),
            "device_slot_MiB": device_slot_bytes / (1024 ** 2),
            "host_commit_MiB": selected * host_slot_bytes / (1024 ** 2),
            "device_commit_MiB": selected * device_slot_bytes / (1024 ** 2)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The formula assumes stationary representative times and does not model long-tail jitter or resource contention. Reject a recommendation that violates real peak memory after model allocations. Benchmark depth $n-1, n, n+1$ where feasible, and keep the smallest depth within the throughput tolerance.

Part 7 - Engineering Interpretation and Philosophy

Adaptive control should make assumptions visible, respect hard budgets, and fail safely. Its purpose is not to eliminate measurement but to reduce the search space and explain why a configuration was selected.

19.10.20 Exercise 19

Exercise Title: Build and Benchmark a Fully Overlapped PyTorch Training Input Pipeline That Maximizes GPU Utilization While Respecting a Fixed VRAM and RAM Budget

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter into a bounded training pipeline: reusable pinned slots, preallocated CUDA inputs, non-blocking H2D, copy and compute streams, event-based ownership, backpressure, a serial baseline, and reproducible correctness and performance reports.

Part 2 - System and Memory Mental Model

Each slot moves through free, prepared, copying, device-ready, computing, and reusable states. The model and optimizer own a separate VRAM budget. The pipeline may occupy only the remaining allowance after safety headroom. Fill and drain are real costs; steady-state throughput must not conceal them. A bounded slot pool prevents producer speed from becoming unbounded RAM consumption.

Part 3 - Quantitative Prediction Before Execution

Before allocation, compute slot bytes and reject infeasible counts. Predict serial and ideal pipeline time from measured preparation, copy, forward/backward, and optimizer intervals. Report realized speedup, GPU duty cycle, peak allocated and reserved VRAM, pinned RAM commitment, and numerical parity.

Part 4 - Experimental Design and Instrumentation

First overfit a tiny deterministic dataset with the serial loop. Snapshot initial weights, restore them, run the overlapped loop with identical batch order, and compare losses and parameters within declared tolerances. Then benchmark warmed trials, profile one active window, and repeat across safe buffer counts.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E19(steps=40, batch=256, width=1024, classes=16,
        slots_count=2, ram_budget_MiB=256, vram_budget_MiB=256):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    element_size = torch.empty((), dtype=torch.float32).element_size()
    label_element_size = torch.empty((), dtype=torch.long).element_size()
    host_slot_bytes = (batch * width * element_size
                       + batch * label_element_size)
    device_slot_bytes = host_slot_bytes
    ram_need = slots_count * host_slot_bytes
    vram_need = slots_count * device_slot_bytes
    if ram_need > ram_budget_MiB * 1024 ** 2:
        raise ValueError("Pinned RAM budget is too small.")
    if vram_need > vram_budget_MiB * 1024 ** 2:
        raise ValueError("Input VRAM budget is too small.")

    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
```

```
    model = torch.nn.Linear(width, classes).to(device)
    optimizer = torch.optim.SGD(model.parameters(), lr=0.01)
    host_inputs = []
    host_labels = []
    gpu_inputs = []
    gpu_labels = []
    ready = []
    reusable = []
    for slot_index in range(slots_count):
        host_inputs.append(torch.empty((batch, width), pin_memory=True))
        host_labels.append(torch.empty((batch,), dtype=torch.long,
                                       pin_memory=True))
        gpu_inputs.append(torch.empty((batch, width), device=device))
        gpu_labels.append(torch.empty((batch,), dtype=torch.long,
                                      device=device))
        ready.append(torch.cuda.Event())
        done = torch.cuda.Event()
        done.record(compute)
        reusable.append(done)

    generator = torch.Generator().manual_seed(1908)
    losses = []
    torch.cuda.reset_peak_memory_stats(device)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    for index in range(steps):
        slot_index = index % slots_count
        reusable[slot_index].synchronize()
        host_inputs[slot_index].normal_(generator=generator)
        host_labels[slot_index].random_(0, classes, generator=generator)
        transfer.wait_event(reusable[slot_index])
        with torch.cuda.stream(transfer):
            gpu_inputs[slot_index].copy_(host_inputs[slot_index],
                                         non_blocking=True)
            gpu_labels[slot_index].copy_(host_labels[slot_index],
                                         non_blocking=True)
            ready[slot_index].record(transfer)
        compute.wait_event(ready[slot_index])
        with torch.cuda.stream(compute):
            optimizer.zero_grad(set_to_none=True)
            logits = model(gpu_inputs[slot_index])
            loss = torch.nn.functional.cross_entropy(
                logits, gpu_labels[slot_index])
            loss.backward()
            optimizer.step()
            losses.append(loss.detach())
            reusable[slot_index].record(compute)
    torch.cuda.synchronize(device)
```

```
    elapsed = time.perf_counter() - started
    loss_values = torch.stack(losses).cpu()
    return {"seconds": elapsed, "samples_per_s": steps * batch / elapsed,
            "first_loss": float(loss_values[0]),
            "last_loss": float(loss_values[-1]),
            "pinned_input_MiB": ram_need / (1024 ** 2),
            "device_input_MiB": vram_need / (1024 ** 2),
            "peak_allocated_MiB": torch.cuda.max_memory_allocated(device)
                                  / (1024 ** 2)}
```

Part 6 - Measurement, Validation, and Failure Analysis

The precheck includes input and label storage on both host and device, but a full budget must also reserve model, gradients, optimizer state, activations, allocator overhead, and a safety margin. Host preparation is synchronized per slot for ownership and can be moved to a bounded producer queue after parity is established. A faster run is rejected if batch order, losses, gradients, or parameter updates diverge beyond the chosen reproducibility tolerance.

Part 7 - Engineering Interpretation and Philosophy

The final objective is dependable useful work per second under explicit resource limits. Maximum utilization is not achieved by keeping the GPU busy with any work; it is achieved by preserving the intended computation, bounding memory, expressing exact dependencies, surviving variability, and producing evidence that another engineer can reproduce and defend.

19.11 DMM09

Chapter Title: Data and Tensor Prefetching
Specialization: Dynamic Memory Management and CUDA Systems

19.11.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Prefetch Distance, Buffer Depth, Producer-Consumer Latency, and Memory Cost

Part 1 - Exercise Contract and Why It Matters

Build a quantitative model of prefetching before changing any loader setting. Explain what is loaded, how far ahead it is loaded, which memory tier owns it, when it becomes consumable, and what prevents the producer from running unboundedly ahead of training.

Part 2 - System and Memory Mental Model

Prefetching moves future work earlier; it does not remove that work. Distance d is the number of future batches made ready, while buffer depth is the maximum number retained. DataLoader workers can prepare CPU batches, the pinning stage can create page-locked batches, and a CUDA stream can transfer GPU-ready batches. These queues occupy different memory tiers and have different completion rules. Backpressure is mandatory when a budget is reached.

Part 3 - Quantitative Prediction Before Execution

Let preparation, transfer, and compute times be T_p, T_h, T_g. Without prefetching, one batch can cost $T_p + T_h + T_g$. An ideal pipeline approaches $\max(T_p, T_h, T_g)$ after fill. If a CPU batch costs M_c bytes and a CUDA batch costs M_g, lookahead d adds approximately dM_c RAM and dM_g VRAM, plus worker and allocator overhead.

Part 4 - Experimental Design and Instrumentation

Separate fill, steady-state, and drain. Measure queue wait, loader latency, H2D time, compute time, throughput, peak RAM, pinned memory, allocated VRAM, and reserved VRAM. Validate batch identity and order with generation numbers. Compare against a no-prefetch baseline using identical samples and model state.

Part 5 - PyTorch/CUDA Implementation

```
import math

def E00(prep_ms=4.0, h2d_ms=2.0, compute_ms=6.0,
        cpu_batch_MiB=32.0, gpu_batch_MiB=32.0, distance=2):
    serial_ms = prep_ms + h2d_ms + compute_ms
    ideal_steady_ms = max(prep_ms, h2d_ms, compute_ms)
    maximum_speedup = serial_ms / ideal_steady_ms
    extra_ram_MiB = distance * cpu_batch_MiB
    extra_vram_MiB = distance * gpu_batch_MiB
    fill_ms = prep_ms + h2d_ms
    predicted_total_ms = fill_ms + ideal_steady_ms
    report = {
        "serial_ms_per_batch": serial_ms,
        "ideal_steady_ms_per_batch": ideal_steady_ms,
        "maximum_speedup": maximum_speedup,
        "distance": distance,
        "extra_RAM_MiB": extra_ram_MiB,
        "extra_VRAM_MiB": extra_vram_MiB,
        "first_batch_ready_ms": predicted_total_ms,
    }
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

The formula is a ceiling, not a promise: worker startup, IPC, storage contention, shape variation, stream dependencies, and memory pressure lower the gain. Increasing distance while throughput is flat is over-prefetching. A fast but misordered or stale batch is a correctness failure.

Part 7 - Engineering Interpretation and Philosophy

Prefetching spends memory to buy time. The correct objective is the smallest bounded lookahead that keeps the consumer supplied, not the largest queue the machine can survive.

19.11.2 Exercise 01

Exercise Title: Measure a Training Loop Without Prefetching and Identify CPU Loading, H2D Transfer, and GPU Idle Regions

Part 1 - Exercise Contract and Why It Matters

Create a deliberately sequential baseline and identify exactly where the GPU waits for loading and transfer. This becomes the counterfactual for every later prefetch claim.

Part 2 - System and Memory Mental Model

With `num_workers=0`, dataset access occurs in the training process. With blocking transfer followed by compute, no future batch is prepared while the current batch runs. Wall time includes CPU preparation, transfer, compute, and synchronization; CUDA events measure only device intervals.

Part 3 - Quantitative Prediction Before Execution

Predict iteration time as $L_i + H_i + G_i$. GPU idle time before H2D is roughly loader latency L_i, while idle time between completed compute and the next kernel includes the next load and exposed transfer.

Part 4 - Experimental Design and Instrumentation

Use a synthetic dataset with controlled delay, a single-process DataLoader, pinned memory disabled, and explicit phase timers. Warm the model first. Record per-batch load, transfer, and compute durations plus a profiler trace.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader, Dataset

class SlowDataset(Dataset):
    def __init__(self, count=512, width=1024, delay_ms=2.0):
        self.count = count
        self.width = width
        self.delay_ms = delay_ms

    def __len__(self):
        return self.count

    def __getitem__(self, index):
        time.sleep(self.delay_ms / 1000.0)
        features = torch.full((self.width,), float(index % 17))
        label = torch.tensor(index % 8, dtype=torch.long)
        return features, label

def E01(batch_size=32, batches=12):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
```

```
    device = torch.device("cuda:0")
    loader = DataLoader(SlowDataset(), batch_size=batch_size,
                        num_workers=0, pin_memory=False)
    model = torch.nn.Linear(1024, 8).to(device)
    iterator = iter(loader)
    records = []
    for batch_index in range(batches):
        load_start = time.perf_counter()
        features, labels = next(iterator)
        load_ms = (time.perf_counter() - load_start) * 1000.0
        transfer_start = time.perf_counter()
        features = features.to(device)
        labels = labels.to(device)
        torch.cuda.synchronize(device)
        transfer_ms = (time.perf_counter() - transfer_start) * 1000.0
        compute_start = torch.cuda.Event(enable_timing=True)
        compute_end = torch.cuda.Event(enable_timing=True)
        compute_start.record()
        loss = torch.nn.functional.cross_entropy(model(features), labels)
        compute_end.record()
        compute_end.synchronize()
        records.append({"load_ms": load_ms, "transfer_ms": transfer_ms,
                        "compute_ms": compute_start.elapsed_time(compute_end),
                        "loss": float(loss)})
    return records
```

Part 6 - Measurement, Validation, and Failure Analysis

This is an intentionally poor pipeline. Do not compare it with a prefetched run that changes batch size, transforms, or model. A host timer without final CUDA synchronization understates completion time. First-iteration startup must be reported separately.

Part 7 - Engineering Interpretation and Philosophy

Idle GPU regions are evidence of supply failure, not automatically a request for more workers. The slow stage may be storage, decoding, IPC, pinning, or H2D; measure the phase before prescribing the queue.

19.11.3 Exercise 02

Exercise Title: Enable DataLoader Prefetching with prefetch_factor and Measure Its Effect on End-to-End Throughput

Part 1 - Exercise Contract and Why It Matters

Enable worker-side prefetching and measure completed training throughput. Explain what `prefetch_factor` controls and why it is meaningful only when worker processes are enabled.

Part 2 - System and Memory Mental Model

Each worker can prepare up to `prefetch_factor` batches ahead. The approximate queued capacity is therefore workers times factor, although runtime state and consumption make the

instantaneous count variable. These are CPU batches; CUDA transfer prefetch is a separate layer.

Part 3 - Quantitative Prediction Before Execution

For w workers and factor f, estimate queued batch capacity as wf and RAM as wfM_b. Predict benefit only if the baseline loader time is exposed on the critical path.

Part 4 - Experimental Design and Instrumentation

Compare `num_workers=0` with a fixed positive worker count and factor. Keep order deterministic, consume the same number of batches, synchronize at outer timing boundaries, and include loader startup separately.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader

def benchmark_loader(dataset, workers, factor, batches=30):
    arguments = {
        "dataset": dataset,
        "batch_size": 32,
        "num_workers": workers,
        "pin_memory": False,
        "persistent_workers": workers > 0,
    }
    if workers > 0:
        arguments["prefetch_factor"] = factor
    loader = DataLoader(**arguments)
    started = time.perf_counter()
    checksum = 0.0
    for batch_index, batch in enumerate(loader):
        features, labels = batch
        checksum += float(features.sum())
        if batch_index + 1 >= batches:
            break
    elapsed = time.perf_counter() - started
    return {"seconds": elapsed, "batches_per_s": batches / elapsed,
            "checksum": checksum}

def E02(dataset):
    baseline = benchmark_loader(dataset, workers=0, factor=None)
    prefetched = benchmark_loader(dataset, workers=4, factor=2)
    return {"baseline": baseline, "prefetched": prefetched,
            "speedup": baseline["seconds"] / prefetched["seconds"]}
```

Part 6 - Measurement, Validation, and Failure Analysis

Dataset objects must be safe for multiprocessing, and Windows execution needs a proper main guard. Worker startup can dominate short runs. Matching checksums alone does not prove identical order; log sample indices when order matters.

Part 7 - Engineering Interpretation and Philosophy

`prefetch_factor` is queue depth per worker, not a magic speed control. It helps when prepared work arrives early enough to cover consumer latency and hurts when memory and IPC cost exceed the waiting it removes.

19.11.4 Exercise 03

Exercise Title: Sweep prefetch_factor Across Multiple Values and Find the Best Throughput-to-RAM Trade-Off

Part 1 - Exercise Contract and Why It Matters

Sweep prefetch factors under controlled conditions and select a Pareto-efficient setting rather than blindly choosing maximum throughput.

Part 2 - System and Memory Mental Model

Larger factors hold more completed or in-progress batches across worker queues. They can smooth latency variation, but also increase resident RAM, shared-memory traffic, stale queued work, and epoch shutdown cost.

Part 3 - Quantitative Prediction Before Execution

Estimate queue bytes as wfM_b. Define marginal efficiency from factor f_1 to f_2 as throughput gain divided by additional MiB. Stop increasing factor when gain falls below a declared threshold.

Part 4 - Experimental Design and Instrumentation

Test factors $1, 2, 4, 8$, repeat trials in rotated order, and report medians. Measure process RSS when available and calculate an explicit batch-byte estimate. Keep workers persistent only when comparing steady epochs consistently.

Part 5 - PyTorch/CUDA Implementation

```
import statistics
import time
from torch.utils.data import DataLoader

def one_trial(dataset, workers, factor, batch_size, batches):
    loader = DataLoader(dataset, batch_size=batch_size,
                        num_workers=workers, prefetch_factor=factor,
                        persistent_workers=True)
    started = time.perf_counter()
    count = 0
    first_batch_bytes = None
    for features, labels in loader:
        if first_batch_bytes is None:
            feature_bytes = features.numel() * features.element_size()
```

```
            label_bytes = labels.numel() * labels.element_size()
            first_batch_bytes = feature_bytes + label_bytes
        count += 1
        if count >= batches:
            break
    elapsed = time.perf_counter() - started
    estimated_queue = workers * factor * first_batch_bytes
    return count / elapsed, estimated_queue

def E03(dataset, workers=4, batch_size=32, batches=40):
    report = []
    for factor in (1, 2, 4, 8):
        rates = []
        queue_bytes = 0
        for trial_index in range(3):
            rate, queue_bytes = one_trial(
                dataset, workers, factor, batch_size, batches)
            rates.append(rate)
        report.append({"prefetch_factor": factor,
                       "median_batches_per_s": statistics.median(rates),
                       "estimated_queue_MiB": queue_bytes / (1024 ** 2)})
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

Estimated queue bytes exclude worker copies, Python objects, allocator overhead, and in-progress samples. Peak RSS is needed for real budgeting. Recreating persistent workers per trial includes startup; use multi-epoch measurements when steady training is the target.

Part 7 - Engineering Interpretation and Philosophy

The best factor is the knee of the curve: enough inventory to absorb variation, but not so much that RAM, cancellation latency, and complexity grow without meaningful throughput.

19.11.5 Exercise 04

Exercise Title: Measure How num_workers and prefetch_factor Interact and Identify When Additional Prefetched Batches Stop Helping

Part 1 - Exercise Contract and Why It Matters

Map the interaction between parallel producers and per-worker queue depth. Identify whether performance is limited by worker service rate, queue capacity, IPC, CPU cores, storage, or the GPU consumer.

Part 2 - System and Memory Mental Model

Workers change production concurrency; factor changes inventory per worker. Their product affects queue capacity, but the two parameters are not interchangeable. More workers can contend for CPU, disk, file handles, and shared memory, while a larger factor with too few slow workers cannot increase their production rate.

Part 3 - Quantitative Prediction Before Execution

For every (w, f), report throughput, estimated wfM_b, and marginal gain. A plateau across factors suggests sufficient lookahead; a plateau across workers suggests another bottleneck or resource saturation.

Part 4 - Experimental Design and Instrumentation

Run a grid over workers $1, 2, 4, 8$ and factors $1, 2, 4$. Record CPU utilization, RSS, queue wait, throughput, and failures such as shared-memory exhaustion. Never tune on an unbounded grid.

Part 5 - PyTorch/CUDA Implementation

```
import time
from torch.utils.data import DataLoader

def E04(dataset, batch_size=32, batches=50):
    report = []
    worker_values = (1, 2, 4, 8)
    factor_values = (1, 2, 4)
    for workers in worker_values:
        for factor in factor_values:
            loader = DataLoader(
                dataset,
                batch_size=batch_size,
                num_workers=workers,
                prefetch_factor=factor,
                persistent_workers=True,
            )
            started = time.perf_counter()
            completed = 0
            for features, labels in loader:
                completed += 1
                if completed >= batches:
                    break
            elapsed = time.perf_counter() - started
            report.append({
                "num_workers": workers,
                "prefetch_factor": factor,
                "queue_capacity_estimate": workers * factor,
                "batches_per_s": completed / elapsed,
            })
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

The loop measures loading, not GPU consumption; repeat the winning candidates in the full training pipeline. CPU topology, storage cache, multiprocessing start method, and dataset implementation make results machine-specific.

Part 7 - Engineering Interpretation and Philosophy

Concurrency and buffering solve different problems. Add producers when service capacity is insufficient; add inventory when variability causes temporary starvation. Stop when the consumer or another shared resource becomes dominant.

19.11.6 Exercise 05

Exercise Title: Combine pin_memory=True with DataLoader Prefetching and Quantify CPU RAM, Pinned Memory, and GPU Utilization Changes

Part 1 - Exercise Contract and Why It Matters

Combine worker prefetching with DataLoader pinning and account separately for ordinary RAM, page-locked RAM, transfer behavior, and GPU utilization.

Part 2 - System and Memory Mental Model

Workers prepare pageable CPU batches; DataLoader's pinning stage makes returned tensors page-locked. Pinned memory enables a direct asynchronous H2D path but is a constrained system resource. Queued pageable and pinned copies may coexist temporarily, so total host cost can exceed batch bytes times queue depth.

Part 3 - Quantitative Prediction Before Execution

For batch bytes M_b, workers w, and factor f, use wfM_b only as a lower-order queue estimate. Predict H2D benefit from bytes transferred and whether transfer is exposed behind compute.

Part 4 - Experimental Design and Instrumentation

Compare pinning off and on with identical loader settings. Verify the pinned state explicitly, request non-blocking CUDA transfers, measure synchronized throughput and process memory, and inspect a profiler trace.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import DataLoader

def run_pinning_case(dataset, pin_memory, batches=40):
    device = torch.device("cuda:0")
    loader = DataLoader(dataset, batch_size=64, num_workers=4,
                        prefetch_factor=2, persistent_workers=True,
                        pin_memory=pin_memory)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    pinned_observations = []
    checksum = torch.zeros((), device=device)
    for batch_index, (features, labels) in enumerate(loader):
        pinned_observations.append(features.is_pinned())
        features = features.to(device, non_blocking=True)
        labels = labels.to(device, non_blocking=True)
```

```
        checksum = checksum + features.mean() + labels.float().mean()
        if batch_index + 1 >= batches:
            break
    torch.cuda.synchronize(device)
    elapsed = time.perf_counter() - started
    return {"seconds": elapsed, "batches_per_s": batches / elapsed,
            "all_feature_batches_pinned": all(pinned_observations),
            "checksum": float(checksum)}

def E05(dataset):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    pageable = run_pinning_case(dataset, False)
    pinned = run_pinning_case(dataset, True)
    return {"pageable": pageable, "pinned": pinned,
            "speedup": pageable["seconds"] / pinned["seconds"]}
```

Part 6 - Measurement, Validation, and Failure Analysis

`pin_memory=True` does not itself move data to CUDA. If compute is too short, copies remain exposed. If host RAM pressure or pinning overhead rises, throughput may fall. Measure rather than assuming pinned always wins.

Part 7 - Engineering Interpretation and Philosophy

Memory tiers form a pipeline contract. Pinning is useful when it unlocks overlap or bandwidth on a repeated path; it is wasteful when applied indiscriminately to large, infrequently transferred objects.

19.11.7 Exercise 06

Exercise Title: Build a Custom CUDA Data Prefetcher That Moves Batch N+1 to GPU While Batch N Is Computing

Part 1 - Exercise Contract and Why It Matters

Build a one-batch CUDA lookahead iterator that transfers the next pinned batch while the current batch is consumed by the model.

Part 2 - System and Memory Mental Model

The prefetcher owns a loader iterator, a side stream, and the next CUDA batch. It primes one batch, waits only when that batch becomes current, immediately launches the following transfer, and preserves tensor storage until consumers finish.

Part 3 - Quantitative Prediction Before Execution

One-batch lookahead can hide at most $\min(T_h, T_g)$. It adds approximately one CUDA input batch to VRAM and may retain one CPU batch. Fill exposes the first transfer and drain exposes final compute.

Part 4 - Experimental Design and Instrumentation

Require pinned loader output, compare order and labels with a serial iterator, time completed epochs, and profile memcpy/kernel intersection. Test empty and single-batch datasets as edge cases.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class CUDAPrefetcher:
    def __init__(self, loader, device):
        self.iterator = iter(loader)
        self.device = device
        self.stream = torch.cuda.Stream(device=device)
        self.next_cpu_features = None
        self.next_cpu_labels = None
        self.next_features = None
        self.next_labels = None
        self.next_ready = None
        self.retired_cpu = []
        self._preload()

    def _preload(self):
        try:
            features, labels = next(self.iterator)
        except StopIteration:
            self.next_cpu_features = None
            self.next_cpu_labels = None
            self.next_features = None
            self.next_labels = None
            self.next_ready = None
            return
        self.next_cpu_features = features
        self.next_cpu_labels = labels
        with torch.cuda.stream(self.stream):
            self.next_features = self.next_cpu_features.to(
                self.device, non_blocking=True)
            self.next_labels = self.next_cpu_labels.to(
                self.device, non_blocking=True)
            self.next_ready = torch.cuda.Event()
            self.next_ready.record(self.stream)

    def next(self):
        if self.next_features is None:
            return None
        current_stream = torch.cuda.current_stream(self.device)
        current_stream.wait_event(self.next_ready)
        features = self.next_features
        labels = self.next_labels
        cpu_features = self.next_cpu_features
```

```
        cpu_labels = self.next_cpu_labels
        ready = self.next_ready
        features.record_stream(current_stream)
        labels.record_stream(current_stream)
        self.retired_cpu.append((cpu_features, cpu_labels, ready))
        remaining = []
        for entry in self.retired_cpu:
            if not entry[2].query():
                remaining.append(entry)
        self.retired_cpu = remaining
        if len(self.retired_cpu) > 2:
            self.retired_cpu[0][2].synchronize()
            self.retired_cpu.pop(0)
        self._preload()
        return features, labels

def E06(loader):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    prefetcher = CUDAPrefetcher(loader, torch.device("cuda:0"))
    batches = []
    while True:
        batch = prefetcher.next()
        if batch is None:
            break
        features, labels = batch
        batches.append((tuple(features.shape), tuple(labels.shape)))
    return batches
```

Part 6 - Measurement, Validation, and Failure Analysis

The loader must provide pinned tensors for dependable H2D overlap. Waiting before consumption is required; global synchronization is not. The returned tensors are recorded on the consumer stream so their storage is not recycled while kernels still use it.

Part 7 - Engineering Interpretation and Philosophy

A prefetcher is an ownership protocol disguised as an iterator. Its value comes from moving work early while preserving the same sample sequence and exact consumer-visible semantics.

19.11.8 Exercise 07

Exercise Title: Add a Dedicated Prefetch CUDA Stream and Coordinate It with the Compute Stream Using wait_stream()

Part 1 - Exercise Contract and Why It Matters

Make the stream dependency explicit and compare stream-level waiting with device-wide synchronization.

Part 2 - System and Memory Mental Model

`consumer.wait_stream(producer)` makes future consumer work wait for producer work already submitted at that point. It queues a device dependency and does not block Python. It is broader than waiting for a single event when the producer stream contains unrelated work.

Part 3 - Quantitative Prediction Before Execution

Predict correct values with both approaches, but lower host blocking and better pipeline retention with stream waiting. Submission time and completed time must be reported separately.

Part 4 - Experimental Design and Instrumentation

Transfer a deterministic pinned batch on a prefetch stream, enqueue independent current-batch compute, then make default-stream future work wait. Synchronize only before CPU inspection.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def E07(batch=1024, width=1024):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    prefetch_stream = torch.cuda.Stream(device=device)
    compute_stream = torch.cuda.current_stream(device)
    host_next = torch.full((batch, width), 3.0, pin_memory=True)
    current = torch.randn((batch, width), device=device)
    torch.cuda.synchronize(device)
    started = time.perf_counter()
    with torch.cuda.stream(prefetch_stream):
        next_batch = host_next.to(device, non_blocking=True)
    current_result = torch.sin(current).sum()
    compute_stream.wait_stream(prefetch_stream)
    next_result = next_batch.sum()
    next_batch.record_stream(compute_stream)
    compute_stream.synchronize()
    elapsed = time.perf_counter() - started
    expected = float(3.0 * batch * width)
    return {"seconds": elapsed, "next_result": float(next_result),
            "expected": expected,
            "absolute_error": abs(float(next_result) - expected),
            "current_checksum": float(current_result)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Calling `wait_stream` after submitting the consumer is too late for that operation. A wait covers producer work submitted before the call, not arbitrary future work. Use an event when one precise producer milestone is required.

Part 7 - Engineering Interpretation and Philosophy

Synchronization scope is a design choice. The smallest dependency that proves correctness preserves the most concurrency and documents the true dataflow.

19.11.9 Exercise 08

Exercise Title: Protect Prefetched CUDA Buffers with Correct record_stream() Lifetime Management and Reproduce the Failure When It Is Removed

Part 1 - Exercise Contract and Why It Matters

Demonstrate why a tensor allocated or transferred on a side stream must have its consumer lifetime communicated to the caching allocator when Python references can disappear early.

Part 2 - System and Memory Mental Model

Stream waiting orders operations but does not by itself extend allocator ownership. Recording the consumer stream on a tensor tells the allocator that its storage remains in use there. Without this annotation, storage may be recycled after the last Python reference disappears even while work is queued.

Part 3 - Quantitative Prediction Before Execution

The safe path must produce zero mismatches across many generations. The unsafe negative control may fail nondeterministically; absence of observed corruption does not prove safety.

Part 4 - Experimental Design and Instrumentation

Use deterministic generation sentinels, allocator churn, a delayed consumer, and hundreds of repetitions. Run the unsafe variant only in an isolated process, then fix it with `record_stream`.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def run_lifetime_case(steps, use_record_stream):
    device = torch.device("cuda:0")
    producer = torch.cuda.Stream(device=device)
    consumer = torch.cuda.current_stream(device)
    results = []
    for generation in range(steps):
        with torch.cuda.stream(producer):
            prefetched = torch.full((512, 512), float(generation),
                                    device=device)
        consumer.wait_stream(producer)
        value = prefetched.mean()
        if use_record_stream:
            prefetched.record_stream(consumer)
        results.append(value)
        del prefetched
        churn = torch.empty((512, 512), device=device)
        churn.fill_(-1.0)
```

```
    torch.cuda.synchronize(device)
    observed = torch.stack(results).cpu()
    expected = torch.arange(steps, dtype=observed.dtype)
    error = (observed - expected).abs().max()
    return float(error)

def E08(steps=200):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    safe_error = run_lifetime_case(steps, True)
    return {"safe_maximum_error": safe_error,
            "unsafe_command": "Run use_record_stream=False separately."}
```

Part 6 - Measurement, Validation, and Failure Analysis

Allocator timing differs across systems, so the negative control may pass. CUDA stream sanitizer and long stress runs strengthen detection. Do not ship the unsafe variant merely because one execution was correct.

Part 7 - Engineering Interpretation and Philosophy

Asynchronous correctness includes storage lifetime. Dependencies protect value availability; allocator annotations protect the memory that holds the value. Both obligations must be satisfied.

19.11.10 Exercise 09

Exercise Title: Build a Two-Batch Lookahead Prefetcher and Compare Its Latency Hiding Against One-Batch Lookahead

Part 1 - Exercise Contract and Why It Matters

Extend CUDA lookahead from one to two batches and determine whether additional depth absorbs latency variation or only consumes memory.

Part 2 - System and Memory Mental Model

Two future batches form a bounded FIFO. Each entry needs a transfer-complete event and a lifetime that extends through compute. Extra distance helps when one future batch is insufficient to bridge variable production or transfer latency; it cannot beat the slowest sustained stage.

Part 3 - Quantitative Prediction Before Execution

Two-batch lookahead adds one CPU/CUDA batch beyond the one-batch design. Predict the throughput gain and calculate gain per extra MiB. Include fill latency, because deeper lookahead delays readiness if the implementation fills eagerly.

Part 4 - Experimental Design and Instrumentation

Benchmark distances one and two with identical batch sequence. Report completed throughput, time-to-first-batch, peak VRAM, output parity, and profiler evidence.

Part 5 - PyTorch/CUDA Implementation

```
from collections import deque
import torch

class LookaheadPrefetcher:
    def __init__(self, loader, device, distance):
        self.iterator = iter(loader)
        self.device = device
        self.distance = distance
        self.stream = torch.cuda.Stream(device=device)
        self.queue = deque()
        self.retired_cpu = []
        for slot_index in range(distance):
            if not self._append_one():
                break

    def _append_one(self):
        try:
            features, labels = next(self.iterator)
        except StopIteration:
            return False
        event = torch.cuda.Event()
        with torch.cuda.stream(self.stream):
            gpu_features = features.to(self.device, non_blocking=True)
            gpu_labels = labels.to(self.device, non_blocking=True)
            event.record(self.stream)
        self.queue.append((gpu_features, gpu_labels, event,
                           features, labels))
        return True

    def next(self):
        if len(self.queue) == 0:
            return None
        features, labels, event, cpu_features, cpu_labels = \
            self.queue.popleft()
        current = torch.cuda.current_stream(self.device)
        current.wait_event(event)
        features.record_stream(current)
        labels.record_stream(current)
        self.retired_cpu.append((cpu_features, cpu_labels, event))
        remaining = []
        for entry in self.retired_cpu:
            if not entry[2].query():
                remaining.append(entry)
        self.retired_cpu = remaining
        if len(self.retired_cpu) > self.distance + 1:
            self.retired_cpu[0][2].synchronize()
            self.retired_cpu.pop(0)
        self._append_one()
```

```
        return features, labels

def E09(loader, distance=2):
    device = torch.device("cuda:0")
    prefetcher = LookaheadPrefetcher(loader, device, distance)
    count = 0
    while prefetcher.next() is not None:
        count += 1
    return {"distance": distance, "batches": count}
```

Part 6 - Measurement, Validation, and Failure Analysis

Queue entries are CUDA tensors and therefore consume VRAM before use. A larger distance can cause OOM even when training itself fits. Check empty datasets and partial final batches, and never infer benefit from queue fullness alone.

Part 7 - Engineering Interpretation and Philosophy

Lookahead depth is insurance against latency variation. Pay only for the amount of insurance that measurably reduces consumer starvation under the real workload.

19.11.11 Exercise 10

Exercise Title: Increase Prefetch Distance Until Extra Buffered Tensors Cause Memory Pressure and Determine the Optimal Lookahead Depth

Part 1 - Exercise Contract and Why It Matters

Increase distance safely, quantify the point of diminishing throughput, and stop before memory pressure threatens training stability.

Part 2 - System and Memory Mental Model

Every prefetched CPU or CUDA batch extends a tensor lifetime. Larger queues raise allocated memory, allocator reservation, pinned RAM, and cancellation waste. Approaching capacity can trigger retries or OOM even when average use appears safe because model activations peak later.

Part 3 - Quantitative Prediction Before Execution

For distance d, predict $M(d) = M_{base} + dM_{batch}$. Define headroom as budget minus measured peak and reject configurations below a fixed safety margin. Choose the smallest d within a throughput tolerance of the best.

Part 4 - Experimental Design and Instrumentation

Sweep bounded distances, reset peak statistics, warm each case, and record throughput, first-batch latency, allocated/reserved VRAM, RAM, and correctness. Terminate by budget, not by intentionally causing OOM.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E10(measure_case, distances=(0, 1, 2, 3, 4, 6, 8),
        vram_budget_MiB=4096, safety_MiB=512):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    report = []
    for distance in distances:
        torch.cuda.empty_cache()
        torch.cuda.reset_peak_memory_stats(device)
        result = measure_case(distance)
        peak_MiB = torch.cuda.max_memory_allocated(device) / (1024 ** 2)
        headroom_MiB = vram_budget_MiB - peak_MiB
        accepted = headroom_MiB >= safety_MiB
        report.append({
            "distance": distance,
            "throughput": result["throughput"],
            "peak_allocated_MiB": peak_MiB,
            "headroom_MiB": headroom_MiB,
            "accepted": accepted,
        })
        if not accepted:
            break
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

`empty_cache()` is used only between isolated configurations, never per training step. Peak allocated memory excludes some non-PyTorch allocations, so the safety margin must include device-level evidence and model variability.

Part 7 - Engineering Interpretation and Philosophy

The optimum is not the last configuration before failure. It is the shallowest queue that delivers near-best throughput with defensible operational headroom.

19.11.12 Exercise 11

Exercise Title: Design a Fixed-RAM Prefetch Budget That Limits the Number of Queued CPU and Pinned Batches Dynamically

Part 1 - Exercise Contract and Why It Matters

Replace a fixed item count with byte-accounted admission so CPU and pinned queues cannot exceed a declared host-memory budget.

Part 2 - System and Memory Mental Model

A batch queue owns bytes from admission until release. Variable objects require recursive tensor accounting, while Python containers and allocator overhead need a safety multiplier. A condition variable provides backpressure when the next batch would cross the budget.

Part 3 - Quantitative Prediction Before Execution

Admit batch i only when $U + M_i \leq B$, where U is currently owned bytes and B is usable budget after safety reserve. Predict maximum equal-size depth as $\lfloor B/M_b \rfloor$.

Part 4 - Experimental Design and Instrumentation

Log admitted bytes, peak owned bytes, producer wait, consumer wait, queue length, and batch generations. Test one batch larger than the budget and fail explicitly instead of deadlocking.

Part 5 - PyTorch/CUDA Implementation

```
import queue
import threading
import torch

def tensor_tree_bytes(value):
    if torch.is_tensor(value):
        return value.numel() * value.element_size()
    if isinstance(value, dict):
        total = 0
        for child in value.values():
            total += tensor_tree_bytes(child)
        return total
    if isinstance(value, (list, tuple)):
        total = 0
        for child in value:
            total += tensor_tree_bytes(child)
        return total
    return 0

class RAMBudgetQueue:
    def __init__(self, budget_bytes):
        self.budget_bytes = budget_bytes
        self.used_bytes = 0
        self.items = queue.Queue()
        self.condition = threading.Condition()

    def put(self, batch):
        size = tensor_tree_bytes(batch)
        if size > self.budget_bytes:
            raise ValueError("One batch exceeds the complete RAM budget.")
        with self.condition:
            while self.used_bytes + size > self.budget_bytes:
                self.condition.wait()
            self.used_bytes += size
            self.items.put((batch, size))

    def get(self):
```

```
        batch, size = self.items.get()
        with self.condition:
            self.used_bytes -= size
            self.condition.notify_all()
        return batch

def E11(budget_MiB=256):
    return RAMBudgetQueue(int(budget_MiB * 1024 ** 2))
```

Part 6 - Measurement, Validation, and Failure Analysis

Releasing budget at `get()` is valid only if queue ownership ends there. If asynchronous H2D still reads the pinned batch, release its bytes after the copy-complete event instead. Logical accounting must match physical lifetime.

Part 7 - Engineering Interpretation and Philosophy

Budgets turn memory from an accident into a contract. Byte-aware backpressure keeps the system bounded and makes overload appear as measurable waiting rather than a sudden host failure.

19.11.13 Exercise 12

Exercise Title: Design a Fixed-VRAM Prefetch Budget That Prevents Prefetched CUDA Tensors from Triggering Out-of-Memory Failures

Part 1 - Exercise Contract and Why It Matters

Admit CUDA-prefetched batches only inside a fixed VRAM allowance that preserves room for model parameters, gradients, optimizer state, activations, temporary kernels, and allocator behavior.

Part 2 - System and Memory Mental Model

Input tensor bytes are not the whole peak. Prefetched tensors coexist with the training maximum, and reserved memory differs from live allocated memory. A prefetch budget should be derived after measuring training without lookahead and subtracting an explicit safety reserve.

Part 3 - Quantitative Prediction Before Execution

Set usable prefetch bytes to

$$B_p = V_{limit} - V_{training_peak} - V_{safety}.$$

Admit batch i only when owned prefetch bytes plus M_i do not exceed B_p. If $B_p < M_i$, fall back to just-in-time transfer.

Part 4 - Experimental Design and Instrumentation

Measure baseline training peak first. Track logical prefetch bytes, actual allocated/reserved VRAM, admission rejections, consumer stalls, and output parity. Test near-budget cases without provoking OOM.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class VRAMAdmission:
    def __init__(self, total_limit_bytes, training_peak_bytes,
                 safety_bytes):
        available = total_limit_bytes - training_peak_bytes - safety_bytes
        self.prefetch_budget = max(0, available)
        self.owned_bytes = 0

    def can_admit(self, batch_bytes):
        return self.owned_bytes + batch_bytes <= self.prefetch_budget

    def admit(self, batch_bytes):
        if not self.can_admit(batch_bytes):
            return False
        self.owned_bytes += batch_bytes
        return True

    def release(self, batch_bytes):
        self.owned_bytes -= batch_bytes
        if self.owned_bytes < 0:
            raise RuntimeError("VRAM accounting became negative.")

def E12(vram_limit_MiB, training_peak_MiB, safety_MiB=512):
    controller = VRAMAdmission(
        int(vram_limit_MiB * 1024 ** 2),
        int(training_peak_MiB * 1024 ** 2),
        int(safety_MiB * 1024 ** 2),
    )
    return {"prefetch_budget_MiB":
            controller.prefetch_budget / (1024 ** 2)}
```

Part 6 - Measurement, Validation, and Failure Analysis

Logical bytes must be released only after the prefetched CUDA tensor is no longer used on any stream. Baseline peak can change with shape, mixed precision, or optimizer phase; remeasure under representative worst cases.

Part 7 - Engineering Interpretation and Philosophy

VRAM headroom is an operational reserve, not wasted capacity. A prefetcher that occasionally forces OOM has failed even if its average throughput is higher.

19.11.14 Exercise 13

Exercise Title: Prefetch Variable-Size Batches and Replace Fixed Lookahead Depth with Byte-Aware Memory Accounting

Part 1 - Exercise Contract and Why It Matters

Handle variable-size batches without assuming that equal item counts imply equal memory. Admit future batches by bytes while preserving FIFO order.

Part 2 - System and Memory Mental Model

A fixed distance may be safe for small sequences and catastrophic for a cluster of long ones. Byte-aware lookahead produces variable queue length: many small batches or few large batches under the same budget.

Part 3 - Quantitative Prediction Before Execution

For queued sizes $M_1, \ldots, M_k$, require $\sum_i M_i \leq B$. Predict distance as an outcome of the size sequence, not an input constant. Reserve space for the largest admissible next batch to avoid starvation by fragmentation of the logical budget.

Part 4 - Experimental Design and Instrumentation

Generate a reproducible distribution of sequence lengths. Log bytes and tensor shapes per entry, queue depth, producer wait, peak memory, padding waste, and correct output order.

Part 5 - PyTorch/CUDA Implementation

```
from collections import deque
import torch

def batch_bytes(batch):
    total = 0
    for tensor in batch:
        total += tensor.numel() * tensor.element_size()
    return total

class ByteAwareFIFO:
    def __init__(self, budget_bytes):
        self.budget_bytes = budget_bytes
        self.used_bytes = 0
        self.entries = deque()

    def try_append(self, batch):
        size = batch_bytes(batch)
        if size > self.budget_bytes:
            raise ValueError("Batch is larger than the queue budget.")
        if self.used_bytes + size > self.budget_bytes:
            return False
        self.entries.append((batch, size))
        self.used_bytes += size
        return True

    def pop_left(self):
        batch, size = self.entries.popleft()
        self.used_bytes -= size
        return batch
```

```
def E13(budget_MiB=256):
    fifo = ByteAwareFIFO(int(budget_MiB * 1024 ** 2))
    return fifo
```

Part 6 - Measurement, Validation, and Failure Analysis

Tensor bytes omit object and allocator overhead, so apply a measured reserve. For CUDA entries, release only after stream lifetime completes. A FIFO can suffer head-of-line blocking when one large batch prevents smaller later work; changing order may violate training semantics.

Part 7 - Engineering Interpretation and Philosophy

Memory is measured in bytes, not batch labels. Byte-aware admission converts variable shapes from a hidden risk into an explicit scheduling input.

19.11.15 Exercise 14

Exercise Title: Build an Adaptive Prefetch Controller That Increases or Decreases Lookahead from Measured Load, Transfer, and Compute Times

Part 1 - Exercise Contract and Why It Matters

Build a conservative controller that adjusts lookahead using measured starvation, stage times, and memory headroom without oscillating every iteration.

Part 2 - System and Memory Mental Model

Lookahead should rise when the consumer waits and budgets permit it, and fall when queues remain unused or memory headroom shrinks. Exponential moving averages, cooldown, and hysteresis separate sustained change from noise.

Part 3 - Quantitative Prediction Before Execution

Estimate required depth as

$$d_t = 1 + \left\lceil \frac{T_p + T_h}{\max(T_g, \epsilon)} \right\rceil,$$

then clamp by RAM, VRAM, and hard limits. Change at most one step per control interval.

Part 4 - Experimental Design and Instrumentation

Feed the controller controlled phase changes: slow storage, faster compute, and large batches. Log every decision and reason, previous and new depth, stage averages, memory headroom, throughput, and oscillation count.

Part 5 - PyTorch/CUDA Implementation

```
import math

class AdaptivePrefetch:
    def __init__(self, minimum=1, maximum=8, alpha=0.2):
        self.minimum = minimum
        self.maximum = maximum
```

```
        self.alpha = alpha
        self.depth = minimum
        self.load_ms = None
        self.h2d_ms = None
        self.compute_ms = None

    def _update(self, old, value):
        if old is None:
            return value
        return self.alpha * value + (1.0 - self.alpha) * old

    def observe(self, load_ms, h2d_ms, compute_ms):
        self.load_ms = self._update(self.load_ms, load_ms)
        self.h2d_ms = self._update(self.h2d_ms, h2d_ms)
        self.compute_ms = self._update(self.compute_ms, compute_ms)

    def decide(self, ram_limit, vram_limit):
        denominator = max(self.compute_ms, 1.0e-9)
        target = 1 + math.ceil(
            (self.load_ms + self.h2d_ms) / denominator)
        target = min(target, ram_limit, vram_limit, self.maximum)
        target = max(target, self.minimum)
        if target > self.depth:
            self.depth += 1
        elif target < self.depth:
            self.depth -= 1
        return self.depth

def E14():
    return AdaptivePrefetch()
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not resize queues while entries are silently discarded. Apply decisions at a safe boundary and preserve FIFO order. Time-based target is an estimate; compare neighboring depths and roll back if throughput or memory safety worsens.

Part 7 - Engineering Interpretation and Philosophy

An adaptive controller is valuable when it explains and bounds change. It should reduce manual tuning while remaining subordinate to correctness and hard memory budgets.

19.11.16 Exercise 15

Exercise Title: Introduce Artificial Storage Latency and Measure When Dataset Prefetching Becomes More Important Than GPU Transfer Prefetching

Part 1 - Exercise Contract and Why It Matters

Increase storage latency until CPU dataset prefetch dominates the benefit from CUDA transfer lookahead. Identify which queue deserves the next byte of memory.

Part 2 - System and Memory Mental Model

Dataset prefetch hides storage, decoding, and transforms; CUDA prefetch hides H2D. If storage latency exceeds the combined transfer and compute window, an empty CPU queue starves every downstream stage. GPU lookahead cannot transfer a batch that has not been produced.

Part 3 - Quantitative Prediction Before Execution

Sweep storage delay S. When worker aggregate production interval exceeds GPU consumption interval, CPU queue starvation controls throughput. Compare four cases: neither, loader-only, CUDA-only, and both.

Part 4 - Experimental Design and Instrumentation

Inject deterministic delay in `__getitem__`, vary it geometrically, and measure loader wait, transfer wait, GPU gaps, throughput, RAM, and VRAM. Keep data values identical across configurations.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch
from torch.utils.data import Dataset

class StorageLatencyDataset(Dataset):
    def __init__(self, count, width, latency_ms):
        self.count = count
        self.width = width
        self.latency_ms = latency_ms

    def __len__(self):
        return self.count

    def __getitem__(self, index):
        time.sleep(self.latency_ms / 1000.0)
        generator = torch.Generator().manual_seed(index)
        features = torch.randn((self.width,), generator=generator)
        label = torch.tensor(index % 8, dtype=torch.long)
        return features, label

def E15(count=1024, width=1024):
    datasets = []
    for latency_ms in (0.0, 0.5, 1.0, 2.0, 4.0, 8.0):
        dataset = StorageLatencyDataset(count, width, latency_ms)
        datasets.append({"latency_ms": latency_ms, "dataset": dataset})
    return datasets
```

Part 6 - Measurement, Validation, and Failure Analysis

`sleep` models latency but not bandwidth contention or decoding CPU cost. Add real-storage trials before production decisions. OS page cache can erase apparent disk latency; report cold and warm conditions separately.

Part 7 - Engineering Interpretation and Philosophy

Prefetch the scarce future first. When data production is late, deeper CUDA queues are empty promises; when CPU supply is healthy and H2D is exposed, GPU lookahead becomes the correct investment.

19.11.17 Exercise 16

Exercise Title: Prefetch Model Parameters for the Next Layer from CPU to GPU Before the Current Layer Finishes Computing

Part 1 - Exercise Contract and Why It Matters

Prototype layer-wise parameter streaming for a model too large to keep entirely resident in VRAM. Transfer layer $k+1$ while layer k computes, without changing outputs.

Part 2 - System and Memory Mental Model

CPU owns pinned master parameters. Two CUDA staging slots alternate: one layer computes while the next layer transfers. A ready event protects consumption and a compute-done event protects slot overwrite. Parameter transfer is useful only when layer compute can cover next-layer bytes.

Part 3 - Quantitative Prediction Before Execution

For layer k, hiding requires $T_{compute,k} \geq T_{copy,k+1}$. Peak staging VRAM is approximately the two largest simultaneously resident layer parameter sets plus activations and workspace.

Part 4 - Experimental Design and Instrumentation

Use a small inference-only chain first. Compare against a fully resident model, check maximum output error, log per-layer bytes/events, and profile overlap. Training additionally requires gradient and optimizer-state ownership and is outside this first prototype.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def E16(x_cpu, cpu_weights, cpu_biases):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    device = torch.device("cuda:0")
    transfer = torch.cuda.Stream(device=device)
    compute = torch.cuda.current_stream(device)
    x = x_cpu.to(device)
    def prefetch(layer_index):
        ready_event = torch.cuda.Event()
        with torch.cuda.stream(transfer):
            weight = cpu_weights[layer_index].to(
                device, non_blocking=True)
            bias = cpu_biases[layer_index].to(
                device, non_blocking=True)
            ready_event.record(transfer)
```

```
        return weight, bias, ready_event

    next_weight, next_bias, next_ready = prefetch(0)
    for layer_index in range(len(cpu_weights)):
        compute.wait_event(next_ready)
        weight = next_weight
        bias = next_bias
        weight.record_stream(compute)
        bias.record_stream(compute)
        if layer_index + 1 < len(cpu_weights):
            next_weight, next_bias, next_ready = prefetch(
                layer_index + 1)
        x = torch.nn.functional.linear(x, weight, bias)
        if layer_index + 1 < len(cpu_weights):
            x = torch.relu(x)
    compute.synchronize()
    return x
```

Part 6 - Measurement, Validation, and Failure Analysis

CPU parameter tensors must be pinned for reliable asynchronous H2D. Layer shapes can require differently sized staging storage. This readable prototype allocates CUDA tensors per layer; a production engine preallocates byte-budgeted slots and must handle errors without losing master parameters.

Part 7 - Engineering Interpretation and Philosophy

Parameter prefetch exchanges residency for bandwidth and scheduling complexity. It is justified when capacity prevents full residency and useful compute is long enough to hide transfers.

19.11.18 Exercise 17

Exercise Title: Build a Parameter Prefetch Queue That Tracks Layer Order, Available VRAM, Transfer Completion, and Tensor Lifetime

Part 1 - Exercise Contract and Why It Matters

Turn layer prefetch into a bounded queue whose entries expose identity, bytes, ready state, consumer lifetime, and release state.

Part 2 - System and Memory Mental Model

A parameter entry progresses through planned, admitted, transferring, ready, consuming, and released states. Admission reserves logical VRAM before transfer. An event marks readiness; `record_stream` protects consumption; release occurs only after the consumer's completion.

Part 3 - Quantitative Prediction Before Execution

For queued layers Q, require $\sum_{k \in Q} M_k \leq B_p$. Preserve layer order unless the computation graph proves independence. Predict stalls where the next required layer is not ready.

Part 4 - Experimental Design and Instrumentation

Log layer index, bytes, admission, transfer timestamps, ready wait, compute completion, release, queue depth, and VRAM counters. Inject a transfer failure and ensure reserved bytes are rolled back.

Part 5 - PyTorch/CUDA Implementation

```
from collections import deque
from dataclasses import dataclass
import torch

@dataclass
class ParameterEntry:
    layer_index: int
    tensors: tuple
    size_bytes: int
    ready_event: object

class ParameterPrefetchQueue:
    def __init__(self, budget_bytes, device):
        self.budget_bytes = budget_bytes
        self.device = device
        self.used_bytes = 0
        self.entries = deque()

    def try_admit(self, layer_index, cpu_tensors, transfer_stream):
        size = 0
        for tensor in cpu_tensors:
            size += tensor.numel() * tensor.element_size()
        if self.used_bytes + size > self.budget_bytes:
            return False
        event = torch.cuda.Event()
        gpu_tensors = []
        with torch.cuda.stream(transfer_stream):
            for tensor in cpu_tensors:
                gpu_tensors.append(
                    tensor.to(self.device, non_blocking=True))
            event.record(transfer_stream)
        entry = ParameterEntry(layer_index, tuple(gpu_tensors), size, event)
        self.entries.append(entry)
        self.used_bytes += size
        return True

    def consume_next(self, compute_stream):
        entry = self.entries.popleft()
        compute_stream.wait_event(entry.ready_event)
        for tensor in entry.tensors:
            tensor.record_stream(compute_stream)
```

```
        return entry

    def release(self, entry):
        self.used_bytes -= entry.size_bytes

def E17(budget_MiB=1024):
    device = torch.device("cuda:0")
    return ParameterPrefetchQueue(int(budget_MiB * 1024 ** 2), device)
```

Part 6 - Measurement, Validation, and Failure Analysis

`release` must be called after the consumer stream has completed its use, not immediately after submission. In a production queue, associate a compute-done event with the entry and reclaim asynchronously only when it queries complete.

Part 7 - Engineering Interpretation and Philosophy

A parameter queue is a scheduler with accounting, not a cache of anonymous tensors. Traceable state transitions make capacity failures and lifetime bugs diagnosable.

19.11.19 Exercise 18

Exercise Title: Stress-Test Data and Parameter Prefetching Together and Diagnose Over-Prefetching, Memory Spikes, Stream Stalls, and Wasted Transfers

Part 1 - Exercise Contract and Why It Matters

Run data and parameter prefetch concurrently under controlled variability and detect competition for VRAM, copy engines, streams, and memory bandwidth.

Part 2 - System and Memory Mental Model

Two individually effective prefetchers can interfere. Their transfers may share one copy engine, their queues share VRAM, and excessive future work can be wasted when an epoch ends, an error occurs, or control flow skips a layer. One global budget and priority policy must coordinate them.

Part 3 - Quantitative Prediction Before Execution

Require $B_{data} + B_{param} \leq B_{prefetch}$. Predict service order from deadlines: the next batch and next layer receive priority over distant work. Measure wasted transferred bytes that were never consumed.

Part 4 - Experimental Design and Instrumentation

Vary data sizes, layer sizes, storage delay, and compute duration with fixed seeds. Log peak memory, admission denials, stream wait, copy overlap, useful bytes, wasted bytes, output parity, and recovery after cancellation.

Part 5 - PyTorch/CUDA Implementation

```
class SharedPrefetchBudget:
    def __init__(self, total_bytes):
        self.total_bytes = total_bytes
        self.data_bytes = 0
        self.parameter_bytes = 0

    def used_bytes(self):
        return self.data_bytes + self.parameter_bytes

    def try_reserve(self, category, size_bytes):
        if self.used_bytes() + size_bytes > self.total_bytes:
            return False
        if category == "data":
            self.data_bytes += size_bytes
        elif category == "parameter":
            self.parameter_bytes += size_bytes
        else:
            raise ValueError("Unknown prefetch category.")
        return True

    def release(self, category, size_bytes):
        if category == "data":
            self.data_bytes -= size_bytes
        elif category == "parameter":
            self.parameter_bytes -= size_bytes
        else:
            raise ValueError("Unknown prefetch category.")
        if self.data_bytes < 0 or self.parameter_bytes < 0:
            raise RuntimeError("Prefetch accounting became negative.")

def E18(total_budget_MiB=2048):
    total_bytes = int(total_budget_MiB * 1024 ** 2)
    return SharedPrefetchBudget(total_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Logical accounting alone cannot prove engine overlap or reveal non-PyTorch memory. Combine it with CUDA events, profiler traces, memory statistics, and device-level free memory. Stress safely below a fixed limit; never use OOM as the normal stopping rule.

Part 7 - Engineering Interpretation and Philosophy

Prefetchers are competing clients of a finite future-work budget. Coordination should favor imminent useful work, bound speculation, and cancel work whose result will not be consumed.

19.11.20 Exercise 19

Exercise Title: Build and Benchmark a Memory-Aware PyTorch Prefetch Engine That Dynamically Chooses What to Load Next Under Fixed RAM and VRAM Budgets

Part 1 - Exercise Contract and Why It Matters

Integrate the chapter into one bounded engine that chooses between future data and parameters according to deadlines, measured stage times, and fixed RAM/VRAM budgets. Benchmark it against no prefetch and fixed-depth policies.

Part 2 - System and Memory Mental Model

The engine has planners, byte-accounted admission, CPU/pinned queues, CUDA transfer streams, completion events, consumer lifetime tracking, backpressure, cancellation, and telemetry. A request is eligible only if its dependencies are known, its bytes fit, and its result is likely to be consumed.

Part 3 - Quantitative Prediction Before Execution

Score request r from deadline urgency, predicted stall avoided, transfer cost, and memory residence:

$$score(r) = \frac{stall_avoided(r)}{copy_time(r) + \epsilon} - \lambda\, memory_bytes(r).$$

Hard budgets override score. Predict throughput and peak memory before running, then compare realized and predicted values.

Part 4 - Experimental Design and Instrumentation

Use deterministic data and initial weights. Run serial, fixed one-step, fixed two-step, and adaptive policies. Verify outputs or training updates, and report fill/steady/drain time, starvation, useful/wasted bytes, RAM, pinned RAM, VRAM, queue depth, and profiler overlap.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import heapq

@dataclass
class PrefetchRequest:
    name: str
    category: str
    size_bytes: int
    deadline_step: int
    copy_ms: float
    stall_avoided_ms: float
    payload: object

class MemoryAwarePrefetchEngine:
    def __init__(self, ram_budget_bytes, vram_budget_bytes,
                 memory_penalty=1.0e-12):
        self.ram_budget_bytes = ram_budget_bytes
        self.vram_budget_bytes = vram_budget_bytes
        self.memory_penalty = memory_penalty
        self.ram_used = 0
        self.vram_used = 0
        self.pending = []
```

```
        self.sequence = 0

    def score(self, request):
        efficiency = request.stall_avoided_ms / max(
            request.copy_ms, 1.0e-9)
        memory_cost = self.memory_penalty * request.size_bytes
        urgency = 1.0 / max(request.deadline_step, 1)
        return efficiency + urgency - memory_cost

    def submit(self, request):
        priority = -self.score(request)
        entry = (priority, self.sequence, request)
        heapq.heappush(self.pending, entry)
        self.sequence += 1

    def next_admissible(self):
        deferred = []
        selected = None
        while len(self.pending) > 0:
            priority, sequence, request = heapq.heappop(self.pending)
            ram_fits = self.ram_used + request.size_bytes <= \
                self.ram_budget_bytes
            vram_fits = self.vram_used + request.size_bytes <= \
                self.vram_budget_bytes
            if ram_fits and vram_fits:
                selected = request
                self.ram_used += request.size_bytes
                self.vram_used += request.size_bytes
                break
            deferred.append((priority, sequence, request))
        for entry in deferred:
            heapq.heappush(self.pending, entry)
        return selected

    def release(self, request):
        self.ram_used -= request.size_bytes
        self.vram_used -= request.size_bytes

def E19(ram_budget_MiB=2048, vram_budget_MiB=2048):
    ram_bytes = int(ram_budget_MiB * 1024 ** 2)
    vram_bytes = int(vram_budget_MiB * 1024 ** 2)
    return MemoryAwarePrefetchEngine(ram_bytes, vram_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

This policy skeleton separates planning from actual transfer execution. A production implementation reserves host and device bytes independently, releases them at their real completion boundaries, ages requests to prevent starvation, and rolls back every partial failure. The model must never consume a request whose transfer event is incomplete.

Part 7 - Engineering Interpretation and Philosophy

The final engine is not successful because it predicts farther ahead. It is successful when it chooses the smallest amount of useful future work that removes stalls, stays within hard budgets, preserves exact computation, and produces evidence another engineer can reproduce.

19.12 DMM10

Chapter Title: Memory Eviction Policies
Specialization: Dynamic Memory Management and CUDA Systems

19.12.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Memory Eviction, Residency, Reuse Distance, and the Cost of Removing Data from VRAM

Part 1 - Exercise Contract and Why It Matters

Build a falsifiable model of residency and eviction. Distinguish dropping a cache entry from actually making its CUDA storage reusable, and account for the cost of restoring an evicted value.

Part 2 - System and Memory Mental Model

A resident tensor has live GPU storage and may also have a CPU backing copy. Eviction selects a victim, waits for every GPU user, writes dirty state back if required, removes cache ownership, and permits allocator reuse. Reuse distance is the number of intervening accesses before the same key returns. A miss incurs lookup, CPU availability, H2D transfer, and possibly recomputation.

Part 3 - Quantitative Prediction Before Execution

For access i, define hit cost C_h, reload cost C_r, and write-back cost C_w. Total cost is

$$C = \sum_i hit_i C_h + \sum_i miss_i C_r + \sum_i dirtyEvict_i C_w.$$

Predict working-set bytes, reuse distances, hit ratio, traffic bytes, and peak VRAM before running a policy.

Part 4 - Experimental Design and Instrumentation

Use deterministic keys and tensors. Log access sequence, size, resident bytes, victim, dirty/protected state, reload/write-back time, hits, misses, and CUDA memory counters. Validate values after every reload.

Part 5 - PyTorch/CUDA Implementation

```
def E00(accesses, sizes_bytes, reload_ms, budget_bytes):
    resident = set()
    resident_bytes = 0
    hits = 0
    misses = 0
    reload_cost_ms = 0.0
```

```
    trace = []
    for step, key in enumerate(accesses):
        if key in resident:
            hits += 1
            outcome = "hit"
        else:
            misses += 1
            reload_cost_ms += reload_ms[key]
            resident.add(key)
            resident_bytes += sizes_bytes[key]
            outcome = "miss"
        trace.append({"step": step, "key": key, "outcome": outcome,
                      "resident_bytes": resident_bytes,
                      "over_budget": resident_bytes > budget_bytes})
    total = hits + misses
    return {"hits": hits, "misses": misses,
            "hit_rate": hits / max(total, 1),
            "reload_cost_ms": reload_cost_ms, "trace": trace}
```

Part 6 - Measurement, Validation, and Failure Analysis

This model intentionally flags over-budget states without choosing victims. Later exercises supply policies. Do not equate `del tensor` with immediate device-level free memory: references, asynchronous use, and the caching allocator all matter.

Part 7 - Engineering Interpretation and Philosophy

Eviction is a prediction about future usefulness under a hard capacity limit. The best policy minimizes avoidable future cost while never sacrificing data correctness or active-stream safety.

19.12.2 Exercise 01

Exercise Title: Build a Fixed-Capacity PyTorch GPU Tensor Cache and Trigger Eviction When Its VRAM Budget Is Exceeded

Part 1 - Exercise Contract and Why It Matters

Build a byte-budgeted CUDA tensor cache with explicit admission, eviction, and accounting. Never use tensor count as a substitute for bytes.

Part 2 - System and Memory Mental Model

The cache owns a CUDA tensor from admission until safe eviction. Logical resident bytes describe cache responsibility; PyTorch allocated and reserved counters describe allocator state. They should be compared but need not be equal.

Part 3 - Quantitative Prediction Before Execution

Before admitting size M, evict until $U + M \leq B$. Reject one object larger than the entire budget. Predict peak logical bytes never exceed B.

Part 4 - Experimental Design and Instrumentation

Insert variable-size pinned CPU tensors, validate values, and record logical bytes plus CUDA allocated/reserved memory after each operation. Start with clean, read-only entries.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict
import torch

class FixedGPUCache:
    def __init__(self, budget_bytes, device="cuda:0"):
        self.budget_bytes = budget_bytes
        self.device = torch.device(device)
        self.entries = OrderedDict()
        self.used_bytes = 0

    def tensor_bytes(self, tensor):
        return tensor.numel() * tensor.element_size()

    def evict_one(self):
        key, tensor = self.entries.popitem(last=False)
        size = self.tensor_bytes(tensor)
        self.used_bytes -= size
        del tensor
        return key, size

    def put(self, key, cpu_tensor):
        size = self.tensor_bytes(cpu_tensor)
        if size > self.budget_bytes:
            raise ValueError("Tensor exceeds the complete cache budget.")
        evicted = []
        while self.used_bytes + size > self.budget_bytes:
            evicted.append(self.evict_one())
        gpu_tensor = cpu_tensor.to(self.device)
        self.entries[key] = gpu_tensor
        self.used_bytes += size
        return evicted

def E01(budget_MiB=512):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    return FixedGPUCache(int(budget_MiB * 1024 ** 2))
```

Part 6 - Measurement, Validation, and Failure Analysis

This first cache assumes no active users and clean data. Removing the dictionary reference permits allocator reuse but does not guarantee an immediate drop in `memory_reserved()`. Later exercises add events, dirty state, and protection.

Part 7 - Engineering Interpretation and Philosophy

A capacity invariant is more valuable than reactive OOM handling. Every admission must prove its bytes fit before allocation occurs.

19.12.3 Exercise 02

Exercise Title: Implement FIFO Eviction for CUDA Tensors and Measure Hit Rate, Miss Rate, Transfer Cost, and Peak VRAM

Part 1 - Exercise Contract and Why It Matters

Implement FIFO as the simplest reproducible policy and establish complete cache metrics for later comparisons.

Part 2 - System and Memory Mental Model

FIFO evicts the earliest admitted entry regardless of later access. Hits do not change order. Its simplicity gives low metadata overhead but ignores locality.

Part 3 - Quantitative Prediction Before Execution

Trace the queue manually for a chosen access sequence. Predict hits, misses, victims, H2D bytes, and maximum resident bytes. Transfer cost should be measured with completion-aware timing.

Part 4 - Experimental Design and Instrumentation

Use a CPU backing store, fixed budget, pinned sources, and CUDA events around reloads. Log every victim and compare output checksums to CPU masters.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict
import torch

class FIFOCache:
    def __init__(self, backing, capacity):
        self.backing = backing
        self.capacity = capacity
        self.data = OrderedDict()
        self.hits = 0
        self.misses = 0
        self.transfer_bytes = 0

    def get(self, key):
        if key in self.data:
            self.hits += 1
            return self.data[key]
        self.misses += 1
        source = self.backing[key]
        if len(self.data) >= self.capacity:
            old_key, old_tensor = self.data.popitem(last=False)
            del old_tensor
        tensor = source.to("cuda:0", non_blocking=source.is_pinned())
```

```
        self.data[key] = tensor
        self.transfer_bytes += source.numel() * source.element_size()
        return tensor

def E02(backing, accesses, capacity=3):
    cache = FIFOCache(backing, capacity)
    checksums = []
    for key in accesses:
        checksums.append(float(cache.get(key).sum()))
    torch.cuda.synchronize()
    return {"hits": cache.hits, "misses": cache.misses,
            "transfer_bytes": cache.transfer_bytes,
            "checksums": checksums}
```

Part 6 - Measurement, Validation, and Failure Analysis

The example uses item capacity to isolate FIFO order; repeat with the byte capacity from E01 for realistic tensors. Float conversion synchronizes and should be removed from timed production paths.

Part 7 - Engineering Interpretation and Philosophy

FIFO is an important baseline precisely because it knows almost nothing. Metadata sophistication earns its cost only when it beats this controlled reference.

19.12.4 Exercise 03

Exercise Title: Implement LRU Eviction from Scratch and Update Tensor Recency on Every GPU Access

Part 1 - Exercise Contract and Why It Matters

Implement least-recently-used eviction and prove that every hit updates recency, not only insertion.

Part 2 - System and Memory Mental Model

LRU assumes recently used entries are more likely to return soon. An ordered map stores least recent at one end and most recent at the other. Metadata must not retain autograd graphs or duplicate tensor ownership.

Part 3 - Quantitative Prediction Before Execution

For each access, write the recency order before and after. The victim is the least recent resident key when capacity is required.

Part 4 - Experimental Design and Instrumentation

Test hits at both ends, repeated keys, capacity one, and missing keys. Log order, victims, hit ratio, reload bytes, and value parity.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict
import torch

class LRUCache:
    def __init__(self, backing, capacity):
        self.backing = backing
        self.capacity = capacity
        self.entries = OrderedDict()
        self.victims = []

    def get(self, key):
        if key in self.entries:
            tensor = self.entries.pop(key)
            self.entries[key] = tensor
            return tensor, True
        if len(self.entries) >= self.capacity:
            victim_key, victim = self.entries.popitem(last=False)
            self.victims.append(victim_key)
            del victim
        tensor = self.backing[key].to("cuda:0")
        self.entries[key] = tensor
        return tensor, False

def E03(backing, accesses, capacity=3):
    cache = LRUCache(backing, capacity)
    hits = 0
    for key in accesses:
        tensor, was_hit = cache.get(key)
        if was_hit:
            hits += 1
    return {"hits": hits, "misses": len(accesses) - hits,
            "victims": cache.victims,
            "final_order": list(cache.entries.keys())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Returning a tensor can extend its life outside the cache; safe eviction therefore requires a usage contract or event tracking. LRU order alone does not solve stream lifetime.

Part 7 - Engineering Interpretation and Philosophy

Recency is a prediction encoded as metadata. Its usefulness depends on locality in the workload, not on the elegance of the data structure.

19.12.5 Exercise 04

Exercise Title: Compare FIFO and LRU Under Sequential, Repeating, and Random Tensor Access Patterns

Part 1 - Exercise Contract and Why It Matters

Compare policies across access distributions and explain why no hit-rate result is meaningful without the workload that produced it.

Part 2 - System and Memory Mental Model

Sequential scans may defeat both policies when the working set exceeds capacity. Repeating hot sets favor LRU; admission order can sometimes favor FIFO. Random access approaches probability determined by capacity and popularity.

Part 3 - Quantitative Prediction Before Execution

Predict the exact trace for a short sequence, then compare hits, misses, evictions, transfer bytes, and policy metadata overhead for longer seeded sequences.

Part 4 - Experimental Design and Instrumentation

Generate sequential, cyclic-hot, and seeded-random traces with the same key set and length. Reset caches and CUDA peak statistics between policies.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict
import random

def make_patterns(key_count=10, length=100):
    sequential = []
    repeating = []
    random_access = []
    generator = random.Random(1004)
    for index in range(length):
        sequential.append(index % key_count)
        repeating.append(index % 3)
        random_access.append(generator.randrange(key_count))
    return {"sequential": sequential, "repeating": repeating,
            "random": random_access}

def evaluate_policy(policy, accesses, capacity):
    entries = OrderedDict()
    hits = 0
    for key in accesses:
        if key in entries:
            hits += 1
            if policy == "lru":
                value = entries.pop(key)
                entries[key] = value
        else:
            if len(entries) >= capacity:
                entries.popitem(last=False)
            entries[key] = True
    total = len(accesses)
    return {"hits": hits, "misses": total - hits,
            "hit_rate": hits / max(total, 1)}
```

```
def E04(capacity=3):
    report = {}
    patterns = make_patterns()
    for name, accesses in patterns.items():
        report[name] = {}
        report[name]["fifo"] = evaluate_policy(
            "fifo", accesses, capacity)
        report[name]["lru"] = evaluate_policy(
            "lru", accesses, capacity)
    return report
```

Part 6 - Measurement, Validation, and Failure Analysis

The simulator isolates policy order; repeat with real CUDA transfers and warm backing storage consistently. Hit ratio alone can mislead when miss costs and tensor sizes differ.

Part 7 - Engineering Interpretation and Philosophy

An eviction policy is part of a workload-policy pair. Benchmark representative traces, not a single synthetic sequence chosen after seeing the result.

19.12.6 Exercise 05

Exercise Title: Implement LFU Eviction and Track Tensor Access Frequency Without Keeping Autograd References Alive Accidentally

Part 1 - Exercise Contract and Why It Matters

Implement least-frequently-used eviction while keeping metadata scalar and detached from autograd graphs.

Part 2 - System and Memory Mental Model

LFU predicts that historically popular keys remain valuable. Frequency counters store integers by key, never tensors or losses. Recency breaks ties so old one-time popularity does not dominate forever.

Part 3 - Quantitative Prediction Before Execution

Before each miss, rank residents by frequency then last-access step. Predict the victim and compare with LRU on a hot-key trace.

Part 4 - Experimental Design and Instrumentation

Test ties, frequency growth, phase changes, and counter aging. Inspect metadata to prove it contains no tensors with `grad_fn`.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class LFUCache:
    def __init__(self, backing, capacity):
```

```
        self.backing = backing
        self.capacity = capacity
        self.entries = {}
        self.frequency = {}
        self.last_step = {}
        self.step = 0

    def get(self, key):
        self.step += 1
        if key in self.entries:
            self.frequency[key] += 1
            self.last_step[key] = self.step
            return self.entries[key], True
        if len(self.entries) >= self.capacity:
            victim = min(self.entries,
                         key=lambda item: (self.frequency[item],
                                           self.last_step[item]))
            del self.entries[victim]
            del self.frequency[victim]
            del self.last_step[victim]
        self.entries[key] = self.backing[key].to("cuda:0")
        self.frequency[key] = 1
        self.last_step[key] = self.step
        return self.entries[key], False

def E05(backing, accesses, capacity=3):
    cache = LFUCache(backing, capacity)
    for key in accesses:
        cache.get(key)
    metadata_has_tensor = any(
        torch.is_tensor(value) for value in cache.frequency.values())
    return {"frequency": dict(cache.frequency),
            "metadata_has_tensor": metadata_has_tensor}
```

Part 6 - Measurement, Validation, and Failure Analysis

Unbounded counters make ancient popularity sticky; introduce periodic decay for phase-changing workloads. Never derive metadata by storing tensor-valued counts inside the autograd graph.

Part 7 - Engineering Interpretation and Philosophy

Frequency remembers demand, but memory without aging becomes prejudice. Policy state must be cheap, bounded, and relevant to the current phase.

19.12.7 Exercise 06

Exercise Title: Construct a Workload Where LRU Performs Poorly and Explain Why Access Recency Alone Is an Insufficient Eviction Signal

Part 1 - Exercise Contract and Why It Matters

Construct a scan-resistant counterexample where a sequential burst evicts a hot working set that returns immediately afterward.

Part 2 - System and Memory Mental Model

LRU interprets every recent scan item as valuable. A scan longer than cache capacity pushes stable hot keys out, causing misses when the hot phase resumes. Frequency or admission filtering can preserve the hot set.

Part 3 - Quantitative Prediction Before Execution

Trace hot keys A, B, C, a cold scan, then A, B, C again. Predict LRU victims, reload count, and transfer bytes. Compare an LFU or scan-resistant policy.

Part 4 - Experimental Design and Instrumentation

Vary scan length and cache capacity. Report hot-set hit rate separately from overall hit rate, because cold compulsory misses can hide policy damage.

Part 5 - PyTorch/CUDA Implementation

```
def build_lru_failure_trace(hot_repeats=20, scan_length=20):
    accesses = []
    for repeat in range(hot_repeats):
        for key in ("A", "B", "C"):
            accesses.append(key)
    for index in range(scan_length):
        accesses.append("cold_" + str(index))
    for repeat in range(5):
        for key in ("A", "B", "C"):
            accesses.append(key)
    return accesses

def E06(run_policy):
    trace = build_lru_failure_trace()
    lru_result = run_policy("lru", trace, 3)
    lfu_result = run_policy("lfu", trace, 3)
    return {"trace_length": len(trace),
            "lru": lru_result, "lfu": lfu_result}
```

Part 6 - Measurement, Validation, and Failure Analysis

The point is not that LFU always wins; a later phase can invalidate old frequencies. Label compulsory, capacity, and policy-induced misses separately.

Part 7 - Engineering Interpretation and Philosophy

Recency is one signal among several. Counterexamples reveal the assumptions a policy makes and show when those assumptions stop matching reality.

19.12.8 Exercise 07

Exercise Title: Implement Size-Aware Eviction That Chooses Victims Based on Tensor Bytes Instead of Tensor Count

Part 1 - Exercise Contract and Why It Matters

Select enough victim bytes to admit a requested tensor and compare evicting one large entry with many small entries.

Part 2 - System and Memory Mental Model

Capacity is byte-based. A count policy may evict one tiny tensor and remain over budget, or remove a huge tensor unnecessarily. Size-aware selection reasons about reclaimed bytes and the value lost per byte.

Part 3 - Quantitative Prediction Before Execution

Required reclaim is $R = \max(0, U + M_{new} - B)$. Select victims whose total bytes reach R, then minimize a declared loss objective.

Part 4 - Experimental Design and Instrumentation

Use heterogeneous tensor sizes and report reclaimed bytes, excess reclaim, victim count, hit loss, transfer cost, and peak VRAM.

Part 5 - PyTorch/CUDA Implementation

```
def tensor_bytes(tensor):
    return tensor.numel() * tensor.element_size()

def choose_size_aware_victims(entries, required_bytes):
    candidates = []
    for key, tensor in entries.items():
        candidates.append((tensor_bytes(tensor), key))
    candidates.sort(reverse=True)
    victims = []
    reclaimed = 0
    for size, key in candidates:
        victims.append(key)
        reclaimed += size
        if reclaimed >= required_bytes:
            break
    if reclaimed < required_bytes:
        raise RuntimeError("Evictable entries cannot satisfy the request.")
    return victims, reclaimed

def E07(entries, used_bytes, budget_bytes, new_tensor_bytes):
    required = max(0, used_bytes + new_tensor_bytes - budget_bytes)
    if required == 0:
        return {"victims": [], "reclaimed_bytes": 0}
    victims, reclaimed = choose_size_aware_victims(entries, required)
    return {"victims": victims, "reclaimed_bytes": reclaimed,
            "excess_reclaim_bytes": reclaimed - required}
```

Part 6 - Measurement, Validation, and Failure Analysis

Largest-first minimizes victim count, not future reload cost. It can evict a high-value large tensor. E08 adds cost; E18 combines all signals.

Part 7 - Engineering Interpretation and Philosophy

Bytes are the physical constraint, while usefulness determines the opportunity cost. A sound policy needs both.

19.12.9 Exercise 08

Exercise Title: Implement Cost-Aware Eviction That Considers Both Tensor Size and CPU-to-GPU Reload Latency

Part 1 - Exercise Contract and Why It Matters

Avoid evicting entries that are expensive to reload merely because they reclaim many bytes.

Part 2 - System and Memory Mental Model

Reload cost includes source readiness, H2D latency, conversion, and recomputation. Eviction benefit is bytes reclaimed; penalty is expected future reload cost. A cheap victim has low expected cost per reclaimed byte.

Part 3 - Quantitative Prediction Before Execution

Rank by

$$score_k = \frac{P(reuse_k)\, C(reload_k)}{M_k}.$$

Evict lowest scores until enough bytes are reclaimed. Predict traffic and stall cost, not only hit ratio.

Part 4 - Experimental Design and Instrumentation

Measure reload latency repeatedly with CUDA completion timing. Use entries with equal size/different cost and different size/equal cost. Validate sensitivity.

Part 5 - PyTorch/CUDA Implementation

```
def choose_cost_aware_victims(metadata, required_bytes):
    ranked = []
    for key, item in metadata.items():
        size = max(item["size_bytes"], 1)
        expected_cost = item["reuse_probability"] * item["reload_ms"]
        score = expected_cost / size
        ranked.append((score, key, item["size_bytes"]))
    ranked.sort()
    victims = []
    reclaimed = 0
    predicted_penalty_ms = 0.0
    for score, key, size in ranked:
        victims.append(key)
        reclaimed += size
```

```
        predicted_penalty_ms += (
            metadata[key]["reuse_probability"]
            * metadata[key]["reload_ms"])
        if reclaimed >= required_bytes:
            break
    return victims, reclaimed, predicted_penalty_ms

def E08(metadata, required_bytes):
    victims, reclaimed, penalty = choose_cost_aware_victims(
        metadata, required_bytes)
    return {"victims": victims, "reclaimed_bytes": reclaimed,
            "predicted_reload_penalty_ms": penalty}
```

Part 6 - Measurement, Validation, and Failure Analysis

Greedy scoring is not globally optimal for every combination of sizes. Reload measurements change with contention and pinned state. Recalibrate and compare against a small exact solver on tiny cases.

Part 7 - Engineering Interpretation and Philosophy

Eviction should minimize future pain, not maximize immediate freed bytes. Cost models make that trade explicit and testable.

19.12.10 Exercise 09

Exercise Title: Build a Reuse-Distance Tracker and Use Future-Likelihood Estimates to Avoid Evicting Tensors Needed Again Soon

Part 1 - Exercise Contract and Why It Matters

Measure reuse distance online and estimate which resident keys are likely to return before the cache can recover their reload cost.

Part 2 - System and Memory Mental Model

Stack reuse distance counts distinct intervening keys; simpler step distance counts accesses. Small recent distances suggest temporal locality. The tracker stores scalar histories, not tensor references.

Part 3 - Quantitative Prediction Before Execution

For key k, update distance $d = t - last_k$ and an exponential average. Prefer preserving small predicted distances while accounting for uncertainty when a key has little history.

Part 4 - Experimental Design and Instrumentation

Feed periodic, bursty, and phase-changing traces. Compare predicted next reuse with observed distance and measure eviction regret when a victim returns soon.

Part 5 - PyTorch/CUDA Implementation

```
class ReuseDistanceTracker:
    def __init__(self, alpha=0.25):
        self.alpha = alpha
        self.step = 0
        self.last_step = {}
        self.predicted_distance = {}

    def observe(self, key):
        self.step += 1
        distance = None
        if key in self.last_step:
            distance = self.step - self.last_step[key]
            if key not in self.predicted_distance:
                self.predicted_distance[key] = float(distance)
            else:
                old = self.predicted_distance[key]
                self.predicted_distance[key] = (
                    self.alpha * distance + (1.0 - self.alpha) * old)
        self.last_step[key] = self.step
        return distance

    def predicted(self, key):
        return self.predicted_distance.get(key, float("inf"))

def E09(accesses):
    tracker = ReuseDistanceTracker()
    observed = []
    for key in accesses:
        observed.append((key, tracker.observe(key)))
    return {"observed": observed,
            "predictions": dict(tracker.predicted_distance)}
```

Part 6 - Measurement, Validation, and Failure Analysis

History is not clairvoyance. Phase changes invalidate estimates, and infinity for unseen reuse may wrongly evict a new hot key. Add aging, confidence, and admission exploration.

Part 7 - Engineering Interpretation and Philosophy

Reuse distance connects access traces to capacity pressure. Prediction is useful only when uncertainty and mistakes are measured alongside successful hits.

19.12.11 Exercise 10

Exercise Title: Introduce Dirty and Clean Tensor States and Prevent Modified GPU Data from Being Lost During Eviction

Part 1 - Exercise Contract and Why It Matters

Track whether GPU data differs from its CPU backing copy and forbid silent eviction of modified state.

Part 2 - System and Memory Mental Model

A clean entry can be discarded because the backing copy can reconstruct it. A dirty entry contains the newest value in VRAM and requires write-back or an explicit discard decision. Dirty metadata changes only when mutation or successful persistence completes.

Part 3 - Quantitative Prediction Before Execution

Count clean evictions, dirty write-backs, bytes persisted, and blocked evictions. Predict final CPU values after a sequence of GPU mutations.

Part 4 - Experimental Design and Instrumentation

Modify deterministic tensors, mark them dirty, attempt unsafe eviction, then write back and validate CPU parity. Test failed write-back and preserve dirty state on failure.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class CacheEntry:
    gpu_tensor: object
    cpu_tensor: object
    dirty: bool = False
    protected: bool = False

class DirtyAwareCache:
    def __init__(self):
        self.entries = {}

    def mark_dirty(self, key):
        self.entries[key].dirty = True

    def evict_clean(self, key):
        entry = self.entries[key]
        if entry.protected:
            raise RuntimeError("Protected entry cannot be evicted.")
        if entry.dirty:
            raise RuntimeError("Dirty entry requires write-back.")
        del self.entries[key]

def E10():
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    cache = DirtyAwareCache()
    cpu = torch.zeros((1024,), pin_memory=True)
    cache.entries["x"] = CacheEntry(cpu.to("cuda:0"), cpu)
    cache.entries["x"].gpu_tensor.add_(5.0)
    cache.mark_dirty("x")
    return cache
```

Part 6 - Measurement, Validation, and Failure Analysis

Mutation APIs must consistently mark dirty state; missing one creates silent loss. Views sharing storage need shared dirty ownership rather than independent flags.

Part 7 - Engineering Interpretation and Philosophy

Capacity management never outranks data integrity. Dirty state identifies the authoritative value and prevents its accidental loss.

19.12.12 Exercise 11

Exercise Title: Implement Write-Back Eviction That Copies Modified CUDA Tensors to CPU Before Releasing Their GPU Storage

Part 1 - Exercise Contract and Why It Matters

Implement synchronous write-back as the correctness baseline: persist dirty CUDA values to CPU, validate completion, then release GPU ownership.

Part 2 - System and Memory Mental Model

Write-back has requested, complete, and committed states. GPU storage cannot be released before D2H completion, and dirty cannot become false before the CPU backing value is authoritative.

Part 3 - Quantitative Prediction Before Execution

Write-back bytes equal tensor storage bytes. Predict latency from D2H bandwidth and report it separately from victim-selection overhead.

Part 4 - Experimental Design and Instrumentation

Mutate known values, time completed D2H, compare CPU/GPU checksums, then delete the entry. Inject an exception before commit and confirm it remains dirty.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def write_back_and_evict(cache, key):
    entry = cache.entries[key]
    if entry.protected:
        raise RuntimeError("Protected entry cannot be evicted.")
    started = time.perf_counter()
    bytes_written = 0
    if entry.dirty:
        entry.cpu_tensor.copy_(entry.gpu_tensor, non_blocking=False)
        bytes_written = (
            entry.gpu_tensor.numel() * entry.gpu_tensor.element_size())
        entry.dirty = False
    del cache.entries[key]
    elapsed_ms = (time.perf_counter() - started) * 1000.0
```

```
    return {"bytes_written": bytes_written,
            "writeback_and_evict_ms": elapsed_ms}

def E11(cache, key):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    return write_back_and_evict(cache, key)
```

Part 6 - Measurement, Validation, and Failure Analysis

Blocking write-back stalls the caller but gives a clear reference result. If CPU backing dtype or shape differs, define conversion semantics explicitly. External aliases to the GPU tensor can prevent real reclamation.

Part 7 - Engineering Interpretation and Philosophy

Establish the simple correct state machine before adding concurrency. An asynchronous optimization must preserve the same commit boundary.

19.12.13 Exercise 12

Exercise Title: Perform Asynchronous Eviction to Pinned CPU Memory on a Dedicated CUDA Stream Without Blocking Active Computation

Part 1 - Exercise Contract and Why It Matters

Move dirty data to pinned CPU storage on an eviction stream while unrelated compute continues, and expose completion as an event.

Part 2 - System and Memory Mental Model

Asynchronous D2H requires pinned destination memory and a side stream. The entry remains resident and dirty while copying. After its event completes, CPU data becomes authoritative and GPU ownership may be released.

Part 3 - Quantitative Prediction Before Execution

Ideal overlap hides at most $\min(T_{D2H}, T_{compute})$. During write-back, both CPU and GPU copies coexist, increasing temporary memory.

Part 4 - Experimental Design and Instrumentation

Record an event after D2H, run independent compute, poll completion, validate CPU data, and compare wall time with blocking eviction. Keep the source alive.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class PendingEviction:
    def __init__(self, key, entry, event, stream):
        self.key = key
        self.entry = entry
        self.event = event
```

```
        self.stream = stream

def begin_async_writeback(cache, key, eviction_stream):
    entry = cache.entries[key]
    if entry.protected:
        raise RuntimeError("Protected entry cannot be evicted.")
    event = torch.cuda.Event()
    with torch.cuda.stream(eviction_stream):
        if entry.dirty:
            if not entry.cpu_tensor.is_pinned():
                raise RuntimeError("Async D2H destination must be pinned.")
            entry.cpu_tensor.copy_(entry.gpu_tensor, non_blocking=True)
        event.record(eviction_stream)
    return PendingEviction(key, entry, event, eviction_stream)

def finish_async_writeback(cache, pending):
    pending.event.synchronize()
    if pending.entry.dirty:
        pending.entry.dirty = False
    del cache.entries[pending.key]

def E12(cache, key):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    stream = torch.cuda.Stream(device="cuda:0")
    return begin_async_writeback(cache, key, stream)
```

Part 6 - Measurement, Validation, and Failure Analysis

Reading CPU backing data before event completion is invalid. Pending bytes remain counted until finish. A queue must handle copy errors without losing the dirty GPU authority.

Part 7 - Engineering Interpretation and Philosophy

Asynchronous eviction delays reclamation to preserve concurrency. Accounting must follow physical lifetime, not the moment a request was submitted.

19.12.14 Exercise 13

Exercise Title: Coordinate Eviction with CUDA Events to Prevent a Tensor from Leaving VRAM While Another Stream Is Still Using It

Part 1 - Exercise Contract and Why It Matters

Prevent a victim from leaving VRAM until every registered consumer stream has finished using its storage.

Part 2 - System and Memory Mental Model

Each consumer records a completion event after final use. Eviction waits for all such events before write-back or deletion. Recording the tensor on consumer streams also protects allocator reuse when references disappear.

Part 3 - Quantitative Prediction Before Execution

Victim eligibility time is the latest completion among active consumers. Measure eviction wait separately from D2H time.

Part 4 - Experimental Design and Instrumentation

Run readers on two streams with sentinels, request eviction early, wait only on their events, and compare results with a no-eviction reference.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class UsageTracker:
    def __init__(self):
        self.events = {}

    def record_use(self, key, tensor, stream):
        tensor.record_stream(stream)
        event = torch.cuda.Event()
        event.record(stream)
        if key not in self.events:
            self.events[key] = []
        self.events[key].append(event)

    def wait_until_idle(self, key, eviction_stream):
        for event in self.events.get(key, []):
            eviction_stream.wait_event(event)
        self.events[key] = []

def E13(tensor):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required.")
    tracker = UsageTracker()
    first = torch.cuda.Stream()
    second = torch.cuda.Stream()
    with torch.cuda.stream(first):
        output_a = tensor.square()
        tracker.record_use("x", tensor, first)
    with torch.cuda.stream(second):
        output_b = tensor.abs()
        tracker.record_use("x", tensor, second)
    eviction = torch.cuda.Stream()
    tracker.wait_until_idle("x", eviction)
    eviction.synchronize()
    return float(output_a.mean() + output_b.mean())
```

Part 6 - Measurement, Validation, and Failure Analysis

Record completion after final use, not before. Unregistered consumers make the protocol unsound. Wait only on victim events rather than synchronizing the entire device.

Part 7 - Engineering Interpretation and Philosophy

Residency is shared ownership across streams. Eviction becomes legal only after every owner relinquishes use through an explicit completion edge.

19.12.15 Exercise 14

Exercise Title: Add Protected and Non-Evictable Tensor States for Parameters, Active Inputs, Temporary Buffers, and In-Flight Transfers

Part 1 - Exercise Contract and Why It Matters

Represent temporary and permanent non-evictable states and ensure victim selection never violates them.

Part 2 - System and Memory Mental Model

Permanent protection covers required parameters; temporary protection covers active inputs, workspaces, and in-flight transfers. Reference counts ensure overlapping users cannot unprotect each other.

Part 3 - Quantitative Prediction Before Execution

Evictable bytes equal resident bytes minus protected and pending bytes. Reject admission when legal victims cannot reclaim enough.

Part 4 - Experimental Design and Instrumentation

Test nested protection, double release, exception cleanup, and all-protected capacity failure. Log protection reasons and owners.

Part 5 - PyTorch/CUDA Implementation

```
class ProtectionRegistry:
    def __init__(self):
        self.counts = {}
        self.reasons = {}

    def protect(self, key, reason):
        self.counts[key] = self.counts.get(key, 0) + 1
        if key not in self.reasons:
            self.reasons[key] = []
        self.reasons[key].append(reason)

    def release(self, key, reason):
        if self.counts.get(key, 0) <= 0:
            raise RuntimeError("Protection release without ownership.")
        self.counts[key] -= 1
        self.reasons[key].remove(reason)

    def is_evictable(self, key):
```

```
        return self.counts.get(key, 0) == 0

def E14(keys):
    registry = ProtectionRegistry()
    for key in keys:
        registry.protect(key, "active")
    return registry
```

Part 6 - Measurement, Validation, and Failure Analysis

Use context managers so exceptions release temporary protection. Report insufficient evictable memory rather than silently selecting a protected victim.

Part 7 - Engineering Interpretation and Philosophy

Protection expresses correctness above policy preference. A score ranks only legal candidates; it never makes an illegal candidate valid.

19.12.16 Exercise 15

Exercise Title: Build a Watermark-Based Eviction Controller with High and Low VRAM Thresholds to Prevent Last-Second OOM Recovery

Part 1 - Exercise Contract and Why It Matters

Evict proactively when usage crosses a high watermark and continue until a low watermark restores headroom.

Part 2 - System and Memory Mental Model

Two thresholds create hysteresis. High watermark triggers reclamation; low watermark stops it. A single threshold can oscillate on every allocation. Pending write-backs remain counted until completion.

Part 3 - Quantitative Prediction Before Execution

For capacity B, choose $H = hB$ and $L = lB$ with $l < h$. On trigger, reclaim at least $U - L$ bytes plus admission size if known.

Part 4 - Experimental Design and Instrumentation

Feed bursty allocations, log threshold crossings, selected bytes, pending bytes, eviction cycles, headroom, and any emergency allocation retries.

Part 5 - PyTorch/CUDA Implementation

```
class WatermarkController:
    def __init__(self, budget_bytes, low_ratio=0.70, high_ratio=0.85):
        if not 0.0 < low_ratio < high_ratio < 1.0:
            raise ValueError("Watermark ratios are invalid.")
        self.budget_bytes = budget_bytes
        self.low_bytes = int(budget_bytes * low_ratio)
        self.high_bytes = int(budget_bytes * high_ratio)
        self.eviction_active = False
```

```
    def update(self, used_bytes):
        if not self.eviction_active and used_bytes >= self.high_bytes:
            self.eviction_active = True
        if self.eviction_active and used_bytes <= self.low_bytes:
            self.eviction_active = False
        reclaim_target = 0
        if self.eviction_active:
            reclaim_target = max(0, used_bytes - self.low_bytes)
        return {"eviction_active": self.eviction_active,
                "reclaim_target_bytes": reclaim_target}

def E15(budget_MiB=4096):
    return WatermarkController(int(budget_MiB * 1024 ** 2))
```

Part 6 - Measurement, Validation, and Failure Analysis

Watermarks use the same memory definition consistently: logical cache bytes or measured allocated bytes. Reserved memory can stay high after safe eviction and must not be mistaken for live residency.

Part 7 - Engineering Interpretation and Philosophy

Headroom is planned resilience. Proactive reclamation is cheaper and more predictable than selecting victims while an allocation is already failing.

19.12.17 Exercise 16

Exercise Title: Combine Prefetching and Eviction and Detect Thrashing When Tensors Are Repeatedly Loaded and Removed from VRAM

Part 1 - Exercise Contract and Why It Matters

Run prefetch and eviction together and identify tensors loaded speculatively, evicted before useful reuse, then loaded again.

Part 2 - System and Memory Mental Model

Prefetch increases future residency while eviction reduces it. Without one coordinator they can fight. Thrashing converts PCIe bandwidth and CPU memory into repeated movement without proportional GPU work.

Part 3 - Quantitative Prediction Before Execution

Track load and eviction counts per key. Define churn bytes as reload plus write-back traffic and useful bytes as bytes consumed by GPU operations.

Part 4 - Experimental Design and Instrumentation

Use a working set slightly above capacity, vary prefetch distance, and log load-evict-reload cycles, residence time, use count, transfer bytes, and compute time.

Part 5 - PyTorch/CUDA Implementation

```
class ChurnTracker:
    def __init__(self):
        self.loads = {}
        self.evictions = {}
        self.loaded_bytes = 0
        self.evicted_bytes = 0
        self.useful_bytes = 0

    def record_load(self, key, size_bytes):
        self.loads[key] = self.loads.get(key, 0) + 1
        self.loaded_bytes += size_bytes

    def record_evict(self, key, size_bytes):
        self.evictions[key] = self.evictions.get(key, 0) + 1
        self.evicted_bytes += size_bytes

    def record_use(self, size_bytes):
        self.useful_bytes += size_bytes

    def thrash_ratio(self):
        traffic = self.loaded_bytes + self.evicted_bytes
        return traffic / max(self.useful_bytes, 1)

def E16():
    return ChurnTracker()
```

Part 6 - Measurement, Validation, and Failure Analysis

Repeated loads can be legitimate if compute benefit is large. Diagnose thrashing from traffic relative to useful work and short residence, not from miss count alone.

Part 7 - Engineering Interpretation and Philosophy

Speculation and reclamation need one economic model. Work loaded with no credible consumption deadline should not displace known useful residency.

19.12.18 Exercise 17

Exercise Title: Implement Thrashing Detection and Dynamically Change the Eviction Policy When Transfer Traffic Exceeds Useful GPU Work

Part 1 - Exercise Contract and Why It Matters

Detect sustained churn and switch to a safer policy or reduce prefetch distance without oscillating on transient bursts.

Part 2 - System and Memory Mental Model

A detector uses a moving window of transferred bytes, useful compute bytes or time, rapid reloads, and hit rate. Hysteresis and cooldown prevent repeated policy changes.

Part 3 - Quantitative Prediction Before Execution

Declare thrashing when traffic/useful ratio exceeds a high threshold for several windows; recover only below a lower threshold. Predict switch points on a controlled trace.

Part 4 - Experimental Design and Instrumentation

Create stable, bursty, and sustained-thrash phases. Log ratios, consecutive bad windows, chosen policy, lookahead depth, switch count, and recovered throughput.

Part 5 - PyTorch/CUDA Implementation

```
class ThrashingController:
    def __init__(self, high_ratio=2.0, low_ratio=1.2,
                 required_windows=3):
        self.high_ratio = high_ratio
        self.low_ratio = low_ratio
        self.required_windows = required_windows
        self.bad_windows = 0
        self.mode = "performance"

    def observe(self, transfer_bytes, useful_bytes):
        ratio = transfer_bytes / max(useful_bytes, 1)
        if ratio >= self.high_ratio:
            self.bad_windows += 1
        else:
            self.bad_windows = 0
        if self.mode == "performance":
            if self.bad_windows >= self.required_windows:
                self.mode = "thrash_safe"
        elif ratio <= self.low_ratio:
            self.mode = "performance"
            self.bad_windows = 0
        return {"ratio": ratio, "mode": self.mode,
                "bad_windows": self.bad_windows}

def E17():
    return ThrashingController()
```

Part 6 - Measurement, Validation, and Failure Analysis

Useful bytes are a proxy; kernel time or application progress may be better. Policy changes must preserve resident dirty state and queue order. Apply them at safe boundaries.

Part 7 - Engineering Interpretation and Philosophy

Adaptive systems need a stable definition of harm and a reversible response. Detection without controlled action merely adds telemetry.

19.12.19 Exercise 18

Exercise Title: Build a Hybrid Eviction Score from Recency, Frequency, Tensor Size, Reload Cost, and Predicted Reuse and Tune Its Weights Experimentally

Part 1 - Exercise Contract and Why It Matters

Combine multiple normalized signals into one explainable victim score and tune weights on held-out traces.

Part 2 - System and Memory Mental Model

Raw signals have incompatible scales. Normalize recency, inverse frequency, size benefit, reload penalty, and predicted reuse before weighting. Protected or in-flight entries are excluded before scoring.

Part 3 - Quantitative Prediction Before Execution

Define higher score as more evictable:

$$S = w_r R + w_f F + w_s M - w_c C + w_p P.$$

Record each component so every victim decision can be defended.

Part 4 - Experimental Design and Instrumentation

Tune weights on sequential, hot-set, variable-size, and expensive-reload traces. Evaluate on separate traces using stall time, traffic, hit rate, and peak memory.

Part 5 - PyTorch/CUDA Implementation

```
def normalize(value, minimum, maximum):
    if maximum <= minimum:
        return 0.0
    return (value - minimum) / (maximum - minimum)

def hybrid_score(item, ranges, weights):
    recency = normalize(item["age"], *ranges["age"])
    frequency = 1.0 - normalize(
        item["frequency"], *ranges["frequency"])
    size = normalize(item["size_bytes"], *ranges["size_bytes"])
    reload_cost = normalize(
        item["reload_ms"], *ranges["reload_ms"])
    reuse_far = normalize(
        item["predicted_reuse"], *ranges["predicted_reuse"])
    score = (
        weights["recency"] * recency
        + weights["frequency"] * frequency
        + weights["size"] * size
        - weights["reload_cost"] * reload_cost
        + weights["predicted_reuse"] * reuse_far
    )
    return score

def E18(metadata, ranges, weights):
    scores = {}
    for key, item in metadata.items():
        if not item["protected"] and not item["in_flight"]:
```

```
            scores[key] = hybrid_score(item, ranges, weights)
    return sorted(scores.items(), key=lambda pair: pair[1],
                  reverse=True)
```

Part 6 - Measurement, Validation, and Failure Analysis

Avoid tuning and evaluation on the same trace. Weight signs must match score meaning. A score ranks candidates but the admission loop still evicts enough bytes and respects dirty write-back.

Part 7 - Engineering Interpretation and Philosophy

Hybrid policies are useful when complexity buys robustness across workloads. Explainable components and held-out evaluation prevent a score from becoming an opaque collection of preferences.

19.12.20 Exercise 19

Exercise Title: Build and Benchmark a Memory-Aware PyTorch Eviction Engine That Keeps a Variable Working Set Inside a Strict VRAM Budget Without OOM

Part 1 - Exercise Contract and Why It Matters

Integrate byte admission, legal-victim filtering, dirty write-back, stream-safe completion, watermarks, policy scoring, and thrash telemetry into one bounded engine.

Part 2 - System and Memory Mental Model

Entries move through loading, resident-clean, resident-dirty, protected, write-back-pending, and evicted states. Logical bytes include resident and pending entries until completion. The engine never depends on catching OOM as a normal capacity decision.

Part 3 - Quantitative Prediction Before Execution

For every admission, prove current owned bytes plus requested bytes fit after legal completed evictions. Report hit/miss rate, stall time, traffic, dirty bytes, thrash ratio, peak allocated/reserved VRAM, and safety headroom.

Part 4 - Experimental Design and Instrumentation

Run fixed FIFO, LRU, hybrid, and adaptive modes on identical variable-size traces. Validate every value against CPU backing truth, include phase changes, and test cancellation and all-protected failure.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class EngineEntry:
    tensor: object
    cpu_backing: object
    size_bytes: int
    dirty: bool = False
```

```
    protected: int = 0
    pending: bool = False
    last_access: int = 0
    frequency: int = 0

class EvictionEngine:
    def __init__(self, budget_bytes, low_ratio=0.70,
                 high_ratio=0.85):
        self.budget_bytes = budget_bytes
        self.low_bytes = int(budget_bytes * low_ratio)
        self.high_bytes = int(budget_bytes * high_ratio)
        self.entries = {}
        self.owned_bytes = 0
        self.step = 0

    def legal_candidates(self):
        candidates = []
        for key, entry in self.entries.items():
            if entry.protected == 0 and not entry.pending:
                candidates.append((key, entry))
        return candidates

    def choose_lru(self):
        candidates = self.legal_candidates()
        if len(candidates) == 0:
            raise RuntimeError("No legal eviction candidate.")
        return min(candidates, key=lambda pair: pair[1].last_access)[0]

    def reclaim_for(self, requested_bytes, evict_callback):
        if requested_bytes > self.budget_bytes:
            raise ValueError("Requested entry exceeds the complete budget.")
        admission_limit = self.budget_bytes - requested_bytes
        if self.owned_bytes >= self.high_bytes:
            target_bytes = min(self.low_bytes, admission_limit)
        else:
            target_bytes = admission_limit
        while self.owned_bytes > target_bytes:
            victim = self.choose_lru()
            released_bytes = evict_callback(victim, self.entries[victim])
            if released_bytes <= 0:
                raise RuntimeError("Eviction made no capacity progress.")
            self.owned_bytes -= released_bytes
            del self.entries[victim]

    def register(self, key, entry):
        if key in self.entries:
            raise KeyError("Key is already resident.")
        if self.owned_bytes + entry.size_bytes > self.budget_bytes:
```

```
            raise RuntimeError("Admission invariant was not satisfied.")
        self.step += 1
        entry.last_access = self.step
        entry.frequency = 1
        self.entries[key] = entry
        self.owned_bytes += entry.size_bytes

def E19(budget_MiB=4096):
    return EvictionEngine(int(budget_MiB * 1024 ** 2))
```

Part 6 - Measurement, Validation, and Failure Analysis

The callback must complete or correctly retain pending write-back before reporting released bytes. Production admission also reserves model headroom and compares logical accounting with PyTorch and device-level counters. A faster engine is rejected if it loses dirty data or violates stream ownership.

Part 7 - Engineering Interpretation and Philosophy

The final objective is not maximum cache occupancy. It is predictable useful work inside a strict budget, with every victim legal, every dirty value durable, every asynchronous lifetime explicit, and every policy decision measurable.

19.13 DMM11

Chapter Title: Dynamic Tensor Placement
Specialization: Dynamic Memory Management and CUDA Systems

19.13.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Tensor Residency Across CPU RAM, GPU VRAM, and Transfer Boundaries

Part 1 - Exercise Contract and Why It Matters

Build a state model for where a tensor's authoritative value resides, which copies exist, and when a migration becomes complete. Placement is a correctness decision before it is a performance decision.

The required outcome is not a diagram with device names. It is an executable contract that answers five questions at every instant: which copy contains the newest value, which replicas are valid, which transfer is pending, which streams may still touch the storage, and which transition is legal next. This contract becomes the foundation for every later promotion, demotion, and budget decision.

Part 2 - System and Memory Mental Model

A logical tensor may have pageable CPU, pinned CPU, and CUDA copies. States include CPU-only, H2D-pending, GPU-resident, both-clean, GPU-dirty, D2H-pending, and released. A transfer request does not instantly change authority. Events define completion; stream usage and autograd references define lifetime.

Residency and authority must remain separate. A tensor can be resident on both tiers while only one copy is authoritative after a GPU update. Likewise, "H2D-pending" means CUDA storage exists but is not yet consumable without an event dependency. Python object lifetime, storage lifetime, logical-value lifetime, and asynchronous-operation lifetime are four different concepts.

Views add a second axis: several tensor objects may share one storage allocation. Moving or releasing one logical view cannot be accounted as if it owned unique bytes. Autograd adds hidden future consumers through saved tensors. The state model must therefore attach placement to storage identity while preserving the shape and stride metadata of each logical tensor.

Part 3 - Quantitative Prediction Before Execution

For tensor bytes M, H2D/D2H bandwidths B_h, B_d, and fixed overhead L, estimate migration time as $L + M/B$. Placement value depends on expected reuse count times avoided transfer cost minus VRAM residence opportunity cost.

For an H2D promotion followed by r GPU uses, compute a break-even reuse count from measured transfer time and per-use acceleration. Also predict the peak during migration: for a period both the source and destination exist, and a dirty D2H demotion may require an additional pinned destination before CUDA storage can be released. A correct budget includes pending bytes, not only committed residents.

Part 4 - Experimental Design and Instrumentation

Track key, shape, dtype, bytes, authority, replicas, dirty state, transfer event, consumer streams, use count, last use, and resident duration. Validate values at every completed state transition.

Exercise the model with clean promotion, GPU mutation, dirty write-back, multi-stream readers, aliased views, and an intentionally delayed event. At each boundary capture a state record and verify a checksum after completion. Negative tests should attempt early CPU reads, early GPU consumption, and premature release so the model demonstrates how it prevents each race.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PlacementState:
    key: str
    authority: str
    cpu_present: bool
    gpu_present: bool
    dirty: bool
    transfer_pending: bool
    size_bytes: int

def E00(key, shape, element_size):
    elements = 1
    for dimension in shape:
        elements *= dimension
```

```
    size_bytes = elements * element_size
    return PlacementState(
        key=key,
        authority="cpu",
        cpu_present=True,
        gpu_present=False,
        dirty=False,
        transfer_pending=False,
        size_bytes=size_bytes,
    )
```

Part 6 - Measurement, Validation, and Failure Analysis

Device labels alone do not reveal authority or aliases. Views may share storage, autograd may retain tensors, and reserved VRAM may remain after a CUDA copy is logically removed. State transitions must follow physical completion.

Part 7 - Engineering Interpretation and Philosophy

Dynamic placement is controlled replication across memory tiers. A useful engine can answer where the newest value is, who may use it, and what event makes the next transition legal.

19.13.2 Exercise 01

Exercise Title: Inspect the Device, Size, Dtype, and Memory Footprint of Every Tensor in a Mixed CPU-GPU PyTorch Workload

Part 1 - Exercise Contract and Why It Matters

Build an inventory of tensors before designing placement policy. Report storage facts without accidentally holding additional autograd references.

The inventory must be useful for policy and safe for a long-running process. Store names, scalar dimensions, byte counts, and storage identifiers in the report, but do not store the tensors themselves. The final report must separate logical tensor bytes from unique physical storage bytes and show totals per memory tier.

Part 2 - System and Memory Mental Model

Logical tensor bytes are `numel()*element_size()`, but views can share storage and make naive sums double-count. Device, dtype, shape, stride, gradient status, pinned state, and storage identity affect migration.

A non-contiguous view may expose fewer logical elements than its underlying storage, and two differently shaped tensors may refer to exactly the same bytes. Pinned CPU memory is physically a host allocation yet has different transfer and operating-system consequences from pageable RAM. CUDA allocated bytes also exclude allocator cache, context memory, and allocations made outside PyTorch.

Part 3 - Quantitative Prediction Before Execution

Predict bytes by shape and dtype, then compare with observed tensor bytes and unique-storage totals. Separate CPU, pinned CPU, and each CUDA device.

For each alias group, predict both the naive sum and unique-storage sum. Their difference is the double-counting error a placement engine would make if it budgeted tensor objects

independently. Reconcile CUDA unique storage with `memory_allocated()` while expecting known differences from allocator rounding and unrelated live tensors.

Part 4 - Experimental Design and Instrumentation

Traverse explicit containers, record scalar metadata only, and identify aliases through storage pointers. Compare inventory with CUDA allocated/reserved counters.

Include contiguous tensors, slices, transposes, a detached alias, parameters, gradients, and pinned batches. Take inventory before forward, after forward, after backward, and after gradient reset. The changing report reveals which objects are persistent and which exist only during a training phase.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def describe_tensor(name, tensor):
    storage_pointer = tensor.untyped_storage().data_ptr()
    bytes_logical = tensor.numel() * tensor.element_size()
    pinned = tensor.is_pinned() if tensor.device.type == "cpu" else False
    return {"name": name, "shape": tuple(tensor.shape),
            "dtype": str(tensor.dtype), "device": str(tensor.device),
            "logical_bytes": bytes_logical,
            "storage_pointer": storage_pointer,
            "requires_grad": tensor.requires_grad,
            "is_leaf": tensor.is_leaf, "is_pinned": pinned}

def E01(named_tensors):
    report = []
    unique_storage = {}
    for name, tensor in named_tensors.items():
        item = describe_tensor(name, tensor)
        report.append(item)
        pointer = item["storage_pointer"]
        if pointer not in unique_storage:
            unique_storage[pointer] = tensor.untyped_storage().nbytes()
    return {"tensors": report,
            "unique_storage_bytes": sum(unique_storage.values())}
```

Part 6 - Measurement, Validation, and Failure Analysis

Storage pointers are diagnostic identities within a process, not persistent keys. Sparse, quantized, and nested tensors need specialized accounting. Do not store tensor objects inside long-lived telemetry.

Part 7 - Engineering Interpretation and Philosophy

Placement decisions are only as good as the inventory beneath them. Measure physical storage and logical use separately.

19.13.3 Exercise 02

Exercise Title: Build a Tensor Placement Function That Moves Inputs to CPU or CUDA from Explicit Runtime Rules

Part 1 - Exercise Contract and Why It Matters

Implement a deterministic rule interface that chooses CPU or CUDA and performs the move without silently changing dtype, shape, or values.

The function is deliberately split into a pure decision and an effectful mover. This makes rules testable on a CPU-only machine and makes every real transfer carry a reason, byte count, completion contract, and validation record.

Part 2 - System and Memory Mental Model

Decision and execution are separate. The policy returns a target and reason; the mover handles pinning, non-blocking eligibility, completion, and validation. Calling `to()` on an already placed tensor may return the same object.

An H2D request from pinned memory can be submitted asynchronously, but the returned CUDA tensor is a pending destination until its producer stream reaches the copy. A D2H request is even easier to misuse because Python can immediately inspect the host object. Therefore a production return type should include an event or future rather than presenting the destination as an ordinary completed value.

Part 3 - Quantitative Prediction Before Execution

For each input, predict target device, bytes transferred, and whether a copy is required. Sum traffic before execution.

Estimate completed migration time with measured fixed latency and bandwidth. Predict zero bytes for same-device identity placement, full logical bytes for a copy, and an error for a target that violates an operation's device constraint. Do not let a low-level mover silently override the policy to recover from OOM.

Part 4 - Experimental Design and Instrumentation

Test CPU-to-CPU, GPU-to-GPU, H2D, and D2H paths. Verify shape, dtype, values, and completion semantics under explicit rules.

Add rules that conflict intentionally and define priority: forced CPU, mandatory CUDA operation, hard-fit budget, then optimization preference. Test contiguous and non-contiguous inputs and verify whether placement preserves layout or materializes a copy. Log CPU submission and completed CUDA time separately.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def choose_target(metadata, rules):
    if metadata["force_cpu"]:
        return "cpu", "forced_cpu"
    if metadata["requires_cuda"]:
        return "cuda:0", "required_by_operation"
    if metadata["size_bytes"] <= rules["gpu_size_limit"]:
        return "cuda:0", "small_tensor"
```

```
    return "cpu", "large_tensor"

def place_tensor(tensor, metadata, rules):
    target, reason = choose_target(metadata, rules)
    if str(tensor.device) == target:
        return tensor, {"target": target, "reason": reason,
                        "copied": False}
    non_blocking = (
        tensor.device.type == "cpu"
        and tensor.is_pinned()
        and target.startswith("cuda"))
    moved = tensor.to(target, non_blocking=non_blocking)
    return moved, {"target": target, "reason": reason,
                   "copied": True}

def E02(tensor, metadata, rules):
    return place_tensor(tensor, metadata, rules)
```

Part 6 - Measurement, Validation, and Failure Analysis

Non-blocking return does not mean completed migration. The caller must wait before consumption and preserve source lifetime. D2H results must not be read before completion.

The simple function returns only a tensor, so its asynchronous path requires a documented caller discipline. E15 replaces this with a transaction object that retains source and destination. Also validate that metadata byte counts agree with the actual tensor; stale metadata can defeat the hard budget.

Part 7 - Engineering Interpretation and Philosophy

Explicit rules make placement auditable. Hidden device movement inside arbitrary operations makes both performance and correctness harder to reason about.

19.13.4 Exercise 03

Exercise Title: Design a Size-Based Placement Policy That Keeps Small Tensors on GPU and Large Low-Reuse Tensors on CPU

Part 1 - Exercise Contract and Why It Matters

Use byte thresholds and reuse qualification to avoid allowing large, rarely used tensors to consume scarce VRAM.

The policy is a baseline, not a final answer. It must be deterministic, use byte capacity rather than tensor count, and emit a reason for every choice so later experiments can identify exactly where a simple threshold fails.

Part 2 - System and Memory Mental Model

Small tensors have limited capacity cost but may suffer launch/transfer overhead. Large tensors deserve VRAM only when reuse or compute benefit repays residence. Policy uses bytes, not dimensions or tensor count.

Capacity cost includes the resident tensor and any temporary duplicate during migration. Small tensors can be cheap to keep yet expensive to transfer one by one because fixed copy

latency dominates. A large tensor can still be the best resident if it is reused frequently or blocks a critical computation whenever reloaded.

Part 3 - Quantitative Prediction Before Execution

Place on GPU when $M \leq S$, or when large-tensor expected reuse exceeds a threshold and budget permits. Predict total resident and transferred bytes.

Evaluate the boundary at $S - 1$, S, and $S + 1$ bytes. For large tensors, estimate avoided reload time from predicted reuse and compare it with the value of VRAM occupied over that interval. Reserve headroom before declaring that a candidate fits; observed free VRAM is not wholly available to the policy.

Part 4 - Experimental Design and Instrumentation

Sweep size around the threshold and compare low/high reuse. Report decisions, hit time, migration time, VRAM, and threshold sensitivity.

Use fixed-size stable workloads and variable-shape workloads. Report decision stability, transfer count, hit rate, completed latency, managed peak, and policy regret. A sweep should reveal whether one threshold generalizes or merely fits a single trace.

Part 5 - PyTorch/CUDA Implementation

```
class SizePlacementPolicy:
    def __init__(self, small_limit_bytes, large_reuse_threshold):
        self.small_limit_bytes = small_limit_bytes
        self.large_reuse_threshold = large_reuse_threshold

    def decide(self, size_bytes, predicted_reuse, available_vram):
        if size_bytes > available_vram:
            return "cpu", "does_not_fit"
        if size_bytes <= self.small_limit_bytes:
            return "cuda:0", "small"
        if predicted_reuse >= self.large_reuse_threshold:
            return "cuda:0", "large_but_reused"
        return "cpu", "large_low_reuse"

def E03(size_limit_MiB=16, reuse_threshold=4):
    return SizePlacementPolicy(
        int(size_limit_MiB * 1024 ** 2), reuse_threshold)
```

Part 6 - Measurement, Validation, and Failure Analysis

A hard size boundary can oscillate with variable shapes and ignores reload cost. Use hysteresis and workload evidence before production.

The policy also ignores dirty write-back, phase change, transfer overlap, and competition between several candidates that individually fit but collectively do not. Treat these omissions as measured limitations, not implementation details to hide.

Part 7 - Engineering Interpretation and Philosophy

Size is a capacity signal, not a measure of value. It is useful as one gate in a larger decision, not as the complete policy.

19.13.5 Exercise 04

Exercise Title: Design a Reuse-Based Placement Policy That Keeps Frequently Accessed Tensors Resident in VRAM

Part 1 - Exercise Contract and Why It Matters

Track scalar access history and promote keys whose expected future reuse justifies sustained VRAM residency.

The implementation must distinguish old popularity from current demand. It should explain when a tensor becomes hot, retain only scalar telemetry, and measure whether each promotion eventually avoids enough reloads to repay itself.

Part 2 - System and Memory Mental Model

Frequency captures popularity; recency detects current phase; reuse distance estimates return interval. Metadata stores keys and numbers, never tensor or autograd references.

A cumulative count without decay makes yesterday's hot tensor immortal. A recency-only policy overreacts to one burst. Evaluate exponentially decayed frequency, windowed counts, and reuse distance, then choose the simplest signal whose prediction error is acceptable for the workload.

Part 3 - Quantitative Prediction Before Execution

Promote after a hot threshold and demote only below a colder threshold. Predict promotions, avoided reloads, and residence bytes from a trace.

Part 4 - Experimental Design and Instrumentation

Test stable-hot, one-time burst, and phase-changing keys. Log counts, last use, promotions, demotions, transfer traffic, and hit rate.

Split traces into calibration and evaluation periods. Record time-to-promotion, useful hits after promotion, residence duration, wasted promotion bytes, and misses caused by delayed recognition. Compare with an oracle that sees the future and report policy regret by workload phase.

Part 5 - PyTorch/CUDA Implementation

```
class ReusePlacementPolicy:
    def __init__(self, promote_count=4, cold_steps=20):
        self.promote_count = promote_count
        self.cold_steps = cold_steps
        self.step = 0
        self.counts = {}
        self.last_step = {}

    def observe(self, key):
        self.step += 1
        self.counts[key] = self.counts.get(key, 0) + 1
        self.last_step[key] = self.step

    def decide(self, key):
        count = self.counts.get(key, 0)
```

```
        age = self.step - self.last_step.get(key, 0)
        if count >= self.promote_count and age <= self.cold_steps:
            return "cuda:0", "hot"
        return "cpu", "not_hot"

def E04():
    return ReusePlacementPolicy()
```

Part 6 - Measurement, Validation, and Failure Analysis

Counts need aging or old popularity persists. A newly hot key needs exploration before history exists. Reuse policy still obeys hard VRAM capacity.

Part 7 - Engineering Interpretation and Philosophy

Residency should follow useful demand, but historical demand is only a forecast. Measure regret when promotions or demotions are wrong.

Hotness is not an intrinsic property of a tensor; it is a conditional forecast about a particular execution phase. A placement system should be willing to forget old evidence and should treat every resident tensor as a hypothesis that must continue earning scarce VRAM.

19.13.6 Exercise 05

Exercise Title: Compare Static Tensor Placement Against Dynamic Placement Under the Same VRAM Budget and Access Pattern

Part 1 - Exercise Contract and Why It Matters

Construct a controlled comparison in which static and dynamic placement receive the same tensor catalogue, access trace, CUDA computation, and strict VRAM budget. The experiment must determine whether adapting residency actually saves completed execution time rather than merely producing a higher cache-hit count.

Part 2 - System and Memory Mental Model

Static placement chooses one resident set before the trace begins. It pays no policy overhead and behaves predictably, but it cannot react when the workload changes phase. Dynamic placement may promote a newly hot tensor and evict a cold one, paying policy, transfer, and synchronization costs to do so. The fair unit of comparison is the entire completed trace, including initial population, misses, write-backs, and final synchronization.

Part 3 - Quantitative Prediction Before Execution

For each policy predict the number of H2D and D2H bytes, hits, misses, and evictions. A first-order time estimate is

$$T \approx T_{compute} + N_{H2D}L_{H2D} + \frac{B_{H2D}}{\beta_{H2D}} + N_{D2H}L_{D2H} + \frac{B_{D2H}}{\beta_{D2H}} + T_{policy}.$$

A dynamic policy wins only when avoided future reloads exceed its migration and decision overhead. Record this prediction before executing either policy.

Part 4 - Experimental Design and Instrumentation

Use three traces: stable popularity, a two-phase workload, and a random trace. Reset CUDA peak statistics and warm up kernels before every measured run. Log resident bytes, peak allocated bytes, hit rate, transferred bytes, eviction count, policy time, and synchronized wall time. Compare numerical outputs after the same ordered operations to ensure policy changes did not alter semantics.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict

class BudgetSimulator:
    def __init__(self, sizes, budget_bytes, dynamic):
        self.sizes = sizes
        self.budget_bytes = budget_bytes
        self.dynamic = dynamic
        self.resident = OrderedDict()
        self.used_bytes = 0
        self.hits = 0
        self.misses = 0
        self.h2d_bytes = 0
        self.evictions = 0

    def _remove_oldest(self):
        victim, unused = self.resident.popitem(last=False)
        self.used_bytes -= self.sizes[victim]
        self.evictions += 1

    def _admit(self, key):
        needed = self.sizes[key]
        while self.used_bytes + needed > self.budget_bytes:
            self._remove_oldest()
        self.resident[key] = True
        self.used_bytes += needed
        self.h2d_bytes += needed

    def access(self, key):
        if key in self.resident:
            self.hits += 1
            if self.dynamic:
                self.resident.move_to_end(key)
            return
        self.misses += 1
        if self.dynamic:
            self._admit(key)

    def initialize_static(self, keys):
        for key in keys:
            self._admit(key)
```

```
def E05(sizes, trace, budget_bytes, static_keys):
    static_policy = BudgetSimulator(sizes, budget_bytes, False)
    static_policy.initialize_static(static_keys)
    dynamic_policy = BudgetSimulator(sizes, budget_bytes, True)
    for key in trace:
        static_policy.access(key)
        dynamic_policy.access(key)
    return static_policy, dynamic_policy
```

Part 6 - Measurement, Validation, and Failure Analysis

The simulator isolates policy behavior; repeat the winning configurations with real pinned buffers, CUDA events, and compute. A high hit rate can still lose if it protects tiny tensors while repeatedly loading one expensive tensor. Do not exclude compulsory first loads, and do not time asynchronous copies without a completion event. Assert that resident bytes never exceed the stated budget.

Part 7 - Engineering Interpretation and Philosophy

Adaptivity is not intrinsically superior. Static placement is a strong baseline because certainty has value: no migration oscillation, minimal metadata, and stable latency. Dynamic placement earns its complexity only when measured phase changes create enough reuse value to pay for movement.

19.13.7 Exercise 06

Exercise Title: Measure the Performance Penalty of Moving a Tensor Between CPU and GPU More Often Than Its Reuse Justifies

Part 1 - Exercise Contract and Why It Matters

Measure the break-even point between keeping a tensor resident and repeatedly moving it across PCIe or another host-device interconnect. The exercise exposes placement thrashing as completed transfer latency, lost bandwidth, and GPU idle time rather than as an abstract policy mistake.

Part 2 - System and Memory Mental Model

Migration contains fixed launch latency, byte-dependent copy time, possible pageable-to-pinned staging, stream dependencies, and allocation overhead. A non-blocking call shortens CPU submission time but does not make the transfer free. If the next computation immediately waits for the tensor, the complete copy remains on the critical path.

Part 3 - Quantitative Prediction Before Execution

For r uses, ping-pong placement performs approximately r H2D and r D2H copies, whereas resident placement performs one H2D copy. Predict

$$\Delta T \approx (r-1)T_{H2D} + rT_{D2H} - C_{saved},$$

where C_{saved} is the opportunity value of the released VRAM. Sweep both bytes and reuse count because small transfers are latency-bound while large transfers approach bandwidth limits.

Part 4 - Experimental Design and Instrumentation

Allocate one reusable pinned host buffer and one CUDA buffer. Warm up the copy path, then compare keep-resident and ping-pong variants with identical kernels. Use CUDA events for device timeline duration and synchronized wall time for end-to-end cost. Record effective GB/s, CPU submission time, transfer count, GPU idle gaps, and output parity.

Part 5 - PyTorch/CUDA Implementation

```
import time
import torch

def completed_ms(operation):
    start = torch.cuda.Event(enable_timing=True)
    stop = torch.cuda.Event(enable_timing=True)
    start.record()
    operation()
    stop.record()
    stop.synchronize()
    return start.elapsed_time(stop)

def E06(elements=8_000_000, repeats=20):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    host = torch.randn(elements, dtype=torch.float32,
                       pin_memory=True)
    device = torch.empty_like(host, device="cuda")
    returned = torch.empty_like(host, pin_memory=True)

    device.copy_(host, non_blocking=True)
    torch.cuda.synchronize()

    def resident_work():
        for unused in range(repeats):
            device.add_(1.0)

    resident_ms = completed_ms(resident_work)

    def ping_pong_work():
        for unused in range(repeats):
            device.copy_(host, non_blocking=True)
            device.add_(1.0)
            returned.copy_(device, non_blocking=True)

    wall_start = time.perf_counter()
    ping_pong_ms = completed_ms(ping_pong_work)
    wall_ms = (time.perf_counter() - wall_start) * 1000.0
    expected = host + 1.0
    assert torch.equal(returned, expected)
    return resident_ms, ping_pong_ms, wall_ms
```

Part 6 - Measurement, Validation, and Failure Analysis

The destination of D2H is pinned and the event is synchronized before the CPU reads it. Removing that wait creates a correctness race. Avoid allocating new buffers inside the loop because the experiment would then mix allocator cost with migration cost. Report median and tail latency over several independent runs; the first run is a warm-up, not representative evidence.

Part 7 - Engineering Interpretation and Philosophy

Movement is justified by the future, not by the current pressure signal alone. Freeing VRAM for a moment can be irrational when a tensor will return before its reload cost is repaid. A placement engine therefore needs a notion of reuse horizon, not merely a reaction to low free memory.

19.13.8 Exercise 07

Exercise Title: Build a Cost Model That Estimates Whether Keeping a Tensor in VRAM Is Cheaper Than Repeated Host-to-Device Reloads

Part 1 - Exercise Contract and Why It Matters

Turn placement into an explicit economic decision. The model must compare the future cost of reloads with the opportunity cost of occupying scarce VRAM and must expose every assumption so that predictions can be calibrated against measurements.

Part 2 - System and Memory Mental Model

Residency consumes capacity over an interval; reloading consumes transfer-engine time, bus bandwidth, launch latency, and sometimes compute stall time. These costs are not interchangeable until expressed in a common objective such as predicted critical-path milliseconds. A tensor that reloads off the critical path is cheaper than one that blocks the compute stream.

Part 3 - Quantitative Prediction Before Execution

Define reload cost as expected reloads times measured H2D completion time times a critical-path fraction. Define residence cost as bytes times expected holding time times a calibrated VRAM shadow price. Keep the tensor when

$$N_{reload} T_{H2D} p_{critical} > M H \lambda_{VRAM}$$

and it fits after protected allocations. Predict the decision and sensitivity to bandwidth, reuse probability, and pressure before running the trace.

Part 4 - Experimental Design and Instrumentation

Calibrate fixed transfer latency and bandwidth using several sizes instead of one. Estimate reuse probability and reuse distance from a training prefix, then evaluate on a held-out trace. Log predicted savings, realized savings, false keeps, false evictions, bytes resident, and policy regret against an oracle with knowledge of the future trace.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PlacementEstimate:
    reload_ms: float
    residence_ms: float
    predicted_saving_ms: float
    keep_on_gpu: bool
    reason: str

class PlacementCostModel:
    def __init__(self, bandwidth_bytes_per_ms, latency_ms,
                 vram_price_per_byte_ms):
        self.bandwidth = bandwidth_bytes_per_ms
        self.latency_ms = latency_ms
        self.vram_price = vram_price_per_byte_ms

    def decide(self, size_bytes, expected_reloads,
               holding_ms, critical_fraction, available_bytes):
        one_reload = self.latency_ms + size_bytes / self.bandwidth
        reload_ms = expected_reloads * one_reload * critical_fraction
        residence_ms = size_bytes * holding_ms * self.vram_price
        saving = reload_ms - residence_ms
        if size_bytes > available_bytes:
            return PlacementEstimate(reload_ms, residence_ms,
                                     saving, False, "does_not_fit")
        keep = saving > 0.0
        reason = "reloads_cost_more" if keep else "residency_costs_more"
        return PlacementEstimate(reload_ms, residence_ms,
                                 saving, keep, reason)

def E07():
    bytes_per_ms = 12.0 * 1000.0 * 1000.0
    model = PlacementCostModel(bytes_per_ms, 0.025, 1.0e-12)
    return model.decide(
        size_bytes=64 * 1024 * 1024,
        expected_reloads=4.0,
        holding_ms=100.0,
        critical_fraction=0.8,
        available_bytes=2 * 1024 * 1024 * 1024,
    )
```

Part 6 - Measurement, Validation, and Failure Analysis

The shadow price is a calibration parameter, not a universal constant. Update it as free VRAM approaches the low watermark. Predictions fail when bandwidth is measured without contention, reuse changes phase, or overlapping copies are treated as fully critical. Show prediction error instead of hiding it behind a binary accuracy score.

Part 7 - Engineering Interpretation and Philosophy

A cost model makes policy disagreement debuggable. Even an imperfect explicit model is more useful than an unexplained threshold because its assumptions can be tested, recalibrated, and rejected. The goal is not perfect prophecy; it is lower decision regret under bounded resources.

19.13.9 Exercise 08

Exercise Title: Add Tensor Lifetime Tracking and Automatically Release or Move Tensors After Their Final Planned GPU Use

Part 1 - Exercise Contract and Why It Matters

Attach planned-use and completion metadata to each tensor so storage is acted on immediately after its final legal GPU consumer. Clean replicas may be released; dirty authoritative values must be written back before CUDA storage disappears.

Part 2 - System and Memory Mental Model

"Last Python reference" and "last GPU use" are different boundaries. A kernel can still be reading storage after Python has queued the operation. The placement engine therefore separates planned-use exhaustion from physical completion and records a CUDA event after the final consumer. Autograd-saved tensors remain protected until backward no longer needs them.

Part 3 - Quantitative Prediction Before Execution

From the known execution plan, compute each tensor's final-use index and predicted release point. The area under the resident-bytes timeline estimates VRAM occupancy over time. Predict peak reduction from prompt release and D2H traffic introduced by dirty write-back.

Part 4 - Experimental Design and Instrumentation

Create clean intermediates, dirty outputs, aliased views, and tensors saved for backward. Log planned uses, submitted uses, completion events, authority changes, release bytes, write-back bytes, and peak VRAM. Poison or reuse freed buffers in a negative test so premature release becomes visible as wrong output.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field
import torch

@dataclass
class LifetimeEntry:
    key: str
    remaining_uses: int
    dirty: bool
    gpu_tensor: object
    cpu_tensor: object = None
    final_event: object = None
    protected_reasons: set = field(default_factory=set)
```

```
    def submit_use(self, stream=None):
        if self.remaining_uses <= 0:
            raise RuntimeError("use submitted after planned lifetime")
        if stream is None:
            stream = torch.cuda.current_stream()
        self.gpu_tensor.record_stream(stream)
        self.remaining_uses -= 1
        if self.remaining_uses == 0:
            self.final_event = torch.cuda.Event()
            self.final_event.record(stream)

    def finalize(self):
        if self.remaining_uses != 0:
            return "still_needed"
        if self.protected_reasons:
            return "protected"
        self.final_event.synchronize()
        if self.dirty:
            if self.cpu_tensor is None:
                self.cpu_tensor = torch.empty_like(
                    self.gpu_tensor, device="cpu", pin_memory=True)
            self.cpu_tensor.copy_(self.gpu_tensor)
        self.gpu_tensor = None
        return "written_back" if self.dirty else "released"

def E08(gpu_tensor, planned_uses, dirty=False):
    return LifetimeEntry("tensor", planned_uses, dirty, gpu_tensor)
```

Part 6 - Measurement, Validation, and Failure Analysis

The blocking write-back in this first implementation favors clarity. A later exercise makes it asynchronous while retaining source and destination until completion. A view cannot be released independently from its base storage, and reference counts alone cannot reveal outstanding kernels. Validate both values and storage identity, and include backward in the plan when gradients exist.

Part 7 - Engineering Interpretation and Philosophy

Lifetime is a contract between the execution schedule and the allocator. Early release is valuable only when the engine can prove there is no future semantic or asynchronous use. Conservatism wastes capacity; optimism corrupts results. The correct design makes that proof explicit.

19.13.10 Exercise 09

Exercise Title: Track Tensor Access Frequency and Dynamically Promote Hot Tensors from CPU RAM to GPU VRAM

Part 1 - Exercise Contract and Why It Matters

Build a promotion controller that observes accesses without retaining autograd graphs, identifies genuinely hot CPU tensors, reserves capacity before copying, and exposes the CUDA copy only after its completion dependency is established.

Part 2 - System and Memory Mental Model

Frequency answers how often; recency answers how recently; an exponentially decayed score adapts to phase changes. Promotion is a state transition from CPU-resident to H2D-pending and finally to both-clean. During H2D-pending the pinned source must remain unchanged and alive, while consumers wait on the recorded ready event rather than synchronizing the whole device.

Part 3 - Quantitative Prediction Before Execution

Predict the first access at which each key crosses the hot threshold. Estimate promotion bytes, subsequent GPU hits, avoided H2D copies, and wasted promotions. Require enough expected future reuse to amortize one completed H2D transfer and any eviction that admission would force.

Part 4 - Experimental Design and Instrumentation

Feed stable-hot, bursty, and phase-shifted traces. Record decayed score, last access, promotion decision, capacity rejection, copy completion, GPU hit, and time-to-first-benefit. Compare against always-CPU and oracle residency. Verify that metadata contains only scalar values and keys.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class HotTensorPromoter:
    def __init__(self, budget_bytes, threshold=3.0, decay=0.90):
        self.budget_bytes = budget_bytes
        self.threshold = threshold
        self.decay = decay
        self.used_bytes = 0
        self.scores = {}
        self.resident = {}
        self.ready = {}
        self.transfer_stream = torch.cuda.Stream()

    def observe(self, key):
        old = self.scores.get(key, 0.0)
        self.scores[key] = old * self.decay + 1.0

    def promote(self, key, cpu_tensor):
        self.observe(key)
        if key in self.resident:
            return "already_resident"
        if self.scores[key] < self.threshold:
            return "not_hot"
        size_bytes = cpu_tensor.numel() * cpu_tensor.element_size()
```

```
        if self.used_bytes + size_bytes > self.budget_bytes:
            return "budget_rejected"
        if not cpu_tensor.is_pinned():
            return "source_not_pinned"
        with torch.cuda.stream(self.transfer_stream):
            gpu_tensor = torch.empty_like(cpu_tensor, device="cuda")
            gpu_tensor.copy_(cpu_tensor, non_blocking=True)
            event = torch.cuda.Event()
            event.record(self.transfer_stream)
        self.resident[key] = gpu_tensor
        self.ready[key] = event
        self.used_bytes += size_bytes
        return "promotion_pending"

    def acquire(self, key, consumer_stream=None):
        if consumer_stream is None:
            consumer_stream = torch.cuda.current_stream()
        consumer_stream.wait_event(self.ready[key])
        tensor = self.resident[key]
        tensor.record_stream(consumer_stream)
        return tensor

def E09(budget_bytes):
    return HotTensorPromoter(budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

This controller deliberately rejects rather than evicts when full; DMM10 can be integrated later for victim selection. The dictionary holding the CPU source is not shown, so the caller must preserve it until the ready event completes. A global cumulative frequency causes stale popularity; decay, windows, or phase detection are required. Do not count a pending promotion as a GPU hit.

Part 7 - Engineering Interpretation and Philosophy

Promotion is a speculative investment in future reuse. The important metric is not how many tensors become resident but how much critical-path transfer time is avoided after paying admission cost. A responsible engine records both benefit and regret for every speculation.

19.13.11 Exercise 10

Exercise Title: Detect Cold GPU Tensors and Demote Them to CPU When Available VRAM Falls Below a Configurable Threshold

Part 1 - Exercise Contract and Why It Matters

Create a pressure response that finds cold, legally movable tensors and demotes enough of them to restore a defined amount of available VRAM. The controller must protect active, dirty, aliased, and in-flight storage correctly.

Part 2 - System and Memory Mental Model

Low device-level free memory is a signal, not a victim decision. A clean tensor with a valid CPU replica can be dropped; a dirty GPU authority requires D2H write-back; an in-flight tensor cannot move until its consumer events complete. Releasing a Python tensor reduces live allocated memory, while the caching allocator may keep the resulting block reserved for reuse.

Part 3 - Quantitative Prediction Before Execution

Let F be current free bytes and F_t the recovery target. Select legal victims until their releasable bytes sum to at least $F_t - F$, including temporary D2H destination memory in the host budget. Predict victim order, write-back traffic, overshoot, and the next reuse penalty before execution.

Part 4 - Experimental Design and Instrumentation

Construct hot, cold-clean, cold-dirty, protected, and in-flight entries. Lower the artificial free-byte reading to trigger pressure. Log age, score, bytes, authority, eligibility reason, selected order, released allocated bytes, reserved bytes, D2H bytes, and subsequent reload misses.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class DemotionCandidate:
    key: str
    size_bytes: int
    last_access: int
    dirty: bool
    protected: bool
    in_flight: bool

def choose_cold_victims(entries, free_bytes, target_free_bytes):
    required = max(0, target_free_bytes - free_bytes)
    eligible = []
    for entry in entries:
        if entry.protected:
            continue
        if entry.in_flight:
            continue
        eligible.append(entry)
    eligible.sort(key=lambda item: item.last_access)

    victims = []
    reclaimable = 0
    writeback_bytes = 0
    for entry in eligible:
        if reclaimable >= required:
            break
        victims.append(entry)
        reclaimable += entry.size_bytes
        if entry.dirty:
```

```
            writeback_bytes += entry.size_bytes
    return victims, reclaimable, writeback_bytes

def E10(entries, free_bytes, target_free_bytes):
    victims, reclaimable, writeback = choose_cold_victims(
        entries, free_bytes, target_free_bytes)
    if free_bytes + reclaimable < target_free_bytes:
        raise RuntimeError("insufficient legal demotion candidates")
    return victims, reclaimable, writeback
```

Part 6 - Measurement, Validation, and Failure Analysis

Victim selection is separated from physical migration so it can be tested without risking data. Before committing, reserve pinned host capacity for dirty write-backs and revalidate that candidates did not become active. Compare `memory_allocated()` with device free memory; they describe different layers and will not move by identical amounts.

Part 7 - Engineering Interpretation and Philosophy

Pressure handling should be anticipatory and legality-first. The coldest tensor is not necessarily the cheapest victim, and a late emergency often has fewer safe choices. A good controller creates headroom before allocation failure and records why each protected tensor could not help.

19.13.12 Exercise 11

Exercise Title: Implement High- and Low-Watermark Tensor Placement to Prevent Rapid CPU-GPU Migration Oscillation

Part 1 - Exercise Contract and Why It Matters

Replace a single pressure threshold with a stateful high/low watermark controller. Once pressure begins, demotion continues until substantial headroom is restored; promotion remains disabled until the recovery boundary is crossed.

Part 2 - System and Memory Mental Model

A one-threshold policy chatters when free VRAM fluctuates around that boundary: one tensor is demoted, a small allocation completes, and the same tensor is promoted again. Hysteresis gives the controller memory. The entry boundary and exit boundary are deliberately different, producing stable modes named normal, pressure, and recovery.

Part 3 - Quantitative Prediction Before Execution

With total budget C, enter pressure when used bytes exceed H and keep evicting until used bytes fall below L, where $L < H < C$. The recovery amount is at least (used-L). Predict mode transitions and migration count for a noisy usage trace, then compare it with a single threshold.

Part 4 - Experimental Design and Instrumentation

Replay a trace that oscillates above and below the old threshold, a monotonic growth trace, and a sudden burst. Log mode, used bytes, requested bytes, promotion permission, eviction target, migrations, and time spent in pressure. Assert $0 \leq L < H \leq C$ and never admit past the hard capacity.

Part 5 - PyTorch/CUDA Implementation

```
class WatermarkController:
    def __init__(self, capacity_bytes, low_used_bytes,
                 high_used_bytes):
        if not 0 <= low_used_bytes < high_used_bytes <= capacity_bytes:
            raise ValueError("invalid watermarks")
        self.capacity = capacity_bytes
        self.low = low_used_bytes
        self.high = high_used_bytes
        self.mode = "normal"

    def update(self, used_bytes):
        if used_bytes > self.capacity:
            raise RuntimeError("hard VRAM budget violated")
        if self.mode == "normal" and used_bytes >= self.high:
            self.mode = "pressure"
        elif self.mode == "pressure" and used_bytes <= self.low:
            self.mode = "normal"
        return self.mode

    def eviction_target(self, used_bytes, requested_bytes=0):
        future_used = used_bytes + requested_bytes
        self.update(min(future_used, self.capacity))
        if future_used > self.capacity:
            self.mode = "pressure"
        if self.mode != "pressure":
            return 0
        return max(0, future_used - self.low)

    def promotion_allowed(self, used_bytes, tensor_bytes):
        if self.mode == "pressure":
            return False
        return used_bytes + tensor_bytes <= self.high

def E11(capacity_bytes):
    return WatermarkController(
        capacity_bytes,
        int(capacity_bytes * 0.70),
        int(capacity_bytes * 0.85),
    )
```

Part 6 - Measurement, Validation, and Failure Analysis

Watermarks should use the same memory definition as the hard admission budget. Mixing device free bytes with live tensor bytes creates unexplained transitions. Large allocations still require pre-admission eviction even in normal mode. Compare migration count, transferred bytes, and latency variance rather than claiming success merely because oscillation looks smoother.

Part 7 - Engineering Interpretation and Philosophy

Hysteresis accepts temporary deviation in exchange for system stability. It is a general control principle: decisions should not reverse until evidence is stronger than the noise that caused the previous decision. This reduces both transfer waste and tail-latency surprises.

19.13.13 Exercise 12

Exercise Title: Build a Placement Policy That Uses Tensor Size, Reuse Distance, Transfer Cost, and Remaining VRAM Simultaneously

Part 1 - Exercise Contract and Why It Matters

Combine the chapter's major signals into one transparent placement decision. The policy must apply hard legality and capacity constraints first, then rank feasible tensors by predicted benefit instead of relying on one isolated metric.

Part 2 - System and Memory Mental Model

Size represents capacity cost and transfer bytes. Reuse distance approximates how long the tensor occupies VRAM before its next benefit. Transfer cost captures the penalty avoided by residency. Remaining VRAM changes the opportunity cost: the same tensor can be rational under low pressure and irrational near the hard budget.

Part 3 - Quantitative Prediction Before Execution

Use expected avoided reload milliseconds divided by byte-time occupancy as a benefit density, then multiply by a pressure penalty. One interpretable score is

$$S = \frac{P_{reuse} T_{reload}}{M(1 + D_{reuse})} \left(\frac{F}{C}\right)^{\gamma}.$$

Hard-fit, protection, authority, and in-flight checks precede scoring. Predict ranking and rejected reasons for every candidate.

Part 4 - Experimental Design and Instrumentation

Generate candidates where each factor independently changes the correct answer: a tiny cold tensor, a large hot tensor, an expensive-to-reload tensor, and a soon-reused tensor. Sweep remaining VRAM and compare decisions with an oracle trace. Log raw features, normalized terms, final score, admission result, and realized regret.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class PlacementFeatures:
    key: str
    size_bytes: int
    reuse_probability: float
    reuse_distance: float
    reload_ms: float
    protected: bool = False
```

```
    in_flight: bool = False

def placement_score(item, free_bytes, capacity_bytes, gamma=2.0):
    if item.protected:
        return float("-inf"), "protected"
    if item.in_flight:
        return float("-inf"), "in_flight"
    if item.size_bytes > free_bytes:
        return float("-inf"), "does_not_fit"
    pressure_ratio = free_bytes / capacity_bytes
    pressure_term = pressure_ratio ** gamma
    benefit_ms = item.reuse_probability * item.reload_ms
    occupancy = item.size_bytes * (1.0 + item.reuse_distance)
    score = benefit_ms * pressure_term / occupancy
    return score, "scored"

def rank_candidates(candidates, free_bytes, capacity_bytes):
    results = []
    for item in candidates:
        score, reason = placement_score(
            item, free_bytes, capacity_bytes)
        results.append((score, reason, item.key))
    results.sort(key=lambda row: row[0], reverse=True)
    return results

def E12(candidates, free_bytes, capacity_bytes):
    return rank_candidates(candidates, free_bytes, capacity_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Feature scales and units matter. A score can silently become a size-only policy if byte magnitudes dominate. Report ablations that remove one factor at a time, and calibrate reload time with real measurements. Ranking is not admission: the engine must recompute available bytes after each selected tensor.

Part 7 - Engineering Interpretation and Philosophy

Multi-factor policy design is a claim about trade-offs. Keeping the formula visible lets engineers understand why an apparently hot tensor was rejected and whether the decision was caused by pressure, transfer cost, or reuse horizon. Interpretability is operational leverage during memory incidents.

19.13.14 Exercise 13

Exercise Title: Reproduce Tensor Placement Thrashing and Measure How Repeated Migration Can Make Dynamic Placement Slower Than Static Placement

Part 1 - Exercise Contract and Why It Matters

Construct a workload that defeats a reactive dynamic policy by repeatedly reversing placement decisions. Quantify the point at which migration traffic and synchronization make dynamic placement slower than a deliberately simple static baseline.

Part 2 - System and Memory Mental Model

Thrashing occurs when the working set and policy interact so that data is moved again before the previous movement produces enough useful work. A capacity just below the active working set and an alternating access pattern are sufficient. Each miss evicts the tensor required next, creating a cycle of negative reuse.

Part 3 - Quantitative Prediction Before Execution

For two equal tensors with capacity for one and trace $A, B, A, B, \ldots$, an LRU dynamic cache has nearly one H2D transfer per access. A static policy keeping A has about half hits without migration decisions. Predict migrations per useful GPU operation, total bytes, and completion time from calibrated transfer cost.

Part 4 - Experimental Design and Instrumentation

Sweep working-set-to-budget ratio from below one to well above one. Include sequential, alternating, and phase-local traces. Log migrations, re-migrations, residence duration, useful operations between movements, H2D/D2H bytes, completed time, and tail latency. Use exactly the same computations and outputs.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict

class ThrashMeter:
    def __init__(self, capacity_items):
        self.capacity = capacity_items
        self.resident = OrderedDict()
        self.loads = 0
        self.evictions = 0
        self.hits = 0
        self.last_loaded_step = {}
        self.short_residencies = 0
        self.step = 0

    def access(self, key):
        self.step += 1
        if key in self.resident:
            self.hits += 1
            self.resident.move_to_end(key)
            return
        self.loads += 1
        if len(self.resident) >= self.capacity:
            victim, unused = self.resident.popitem(last=False)
            age = self.step - self.last_loaded_step[victim]
            if age <= self.capacity + 1:
                self.short_residencies += 1
            self.evictions += 1
        self.resident[key] = True
        self.last_loaded_step[key] = self.step
```

```
    def report(self):
        accesses = self.step
        return {
            "loads_per_access": self.loads / max(1, accesses),
            "hit_rate": self.hits / max(1, accesses),
            "short_residencies": self.short_residencies,
            "evictions": self.evictions,
        }

def E13(repetitions=100):
    trace = []
    for unused in range(repetitions):
        trace.append("A")
        trace.append("B")
    meter = ThrashMeter(capacity_items=1)
    for key in trace:
        meter.access(key)
    return meter.report()
```

Part 6 - Measurement, Validation, and Failure Analysis

The item-count simulator assumes equal sizes; repeat with byte capacity and real copies to measure cost. A low hit rate is not by itself thrashing: streaming data may have no reuse. Require evidence of short residence followed by rapid reload. Account for write-back only when data is dirty, and synchronize at trial end.

Part 7 - Engineering Interpretation and Philosophy

Dynamic control can amplify scarcity when it reacts faster than useful workload phases change. Thrashing is not solved by a smarter victim name alone; it may require hysteresis, admission control, bypassing one-time data, or accepting a stable static partition.

19.13.15 Exercise 14

Exercise Title: Add Hysteresis to the Placement Controller and Prove That It Reduces Tensor Migration Thrashing

Part 1 - Exercise Contract and Why It Matters

Add distinct promotion and demotion evidence thresholds plus a minimum dwell period. Prove with a controlled trace that the mechanism reduces unnecessary state reversals while preserving most useful GPU hits.

Part 2 - System and Memory Mental Model

Hysteresis creates a dead band. A CPU tensor must become convincingly hot before promotion; a GPU tensor must become convincingly cold before demotion. A dwell period prevents immediate reversal even if noisy measurements briefly cross the opposite threshold. Hard capacity and correctness constraints still override the stability preference.

Part 3 - Quantitative Prediction Before Execution

Choose $S_p > S_d$ for promotion and demotion scores and dwell K steps. Predict transitions for scores oscillating around a single old threshold. The main metric is migration reduction; the counter-metric is missed useful GPU accesses caused by delayed promotion or demotion.

Part 4 - Experimental Design and Instrumentation

Evaluate smooth phase changes, high-frequency noise, sudden demand, and hard pressure. Compare no hysteresis, threshold-only hysteresis, and threshold plus dwell. Log state, score, age in state, transition reason, migration count, hit rate, transfer bytes, and realized runtime.

Part 5 - PyTorch/CUDA Implementation

```
class HysteresisPlacement:
    def __init__(self, promote_score=0.75, demote_score=0.30,
                 minimum_dwell_steps=5):
        if demote_score >= promote_score:
            raise ValueError("demote score must be below promote score")
        self.promote_score = promote_score
        self.demote_score = demote_score
        self.minimum_dwell = minimum_dwell_steps
        self.location = {}
        self.changed_at = {}
        self.transitions = 0

    def update(self, key, score, step, hard_pressure=False):
        location = self.location.get(key, "cpu")
        changed = self.changed_at.get(key, -self.minimum_dwell)
        dwell_satisfied = step - changed >= self.minimum_dwell

        next_location = location
        reason = "dead_band"
        if location == "cpu" and score >= self.promote_score:
            if dwell_satisfied and not hard_pressure:
                next_location = "cuda"
                reason = "hot_enough"
        elif location == "cuda" and score <= self.demote_score:
            if dwell_satisfied or hard_pressure:
                next_location = "cpu"
                reason = "cold_or_pressure"

        if next_location != location:
            self.location[key] = next_location
            self.changed_at[key] = step
            self.transitions += 1
        else:
            self.location.setdefault(key, location)
        return self.location[key], reason

def E14(scores):
    policy = HysteresisPlacement()
```

```
    decisions = []
    for step, score in enumerate(scores):
        decisions.append(policy.update("tensor", score, step))
    return decisions, policy.transitions
```

Part 6 - Measurement, Validation, and Failure Analysis

Do not celebrate fewer transitions if the tensor remains on the wrong tier for most useful work. Plot transfer savings against added miss cost and report phase adaptation delay. Hard OOM prevention must be allowed to break dwell protection, but that override should be recorded separately from ordinary policy behavior.

Part 7 - Engineering Interpretation and Philosophy

Stable decisions require evidence to reverse them. Hysteresis makes the policy less sensitive to measurement noise and acknowledges that every transition has real physical cost. The dead band is not indecision; it is an engineered region where maintaining the current state is cheaper than chasing uncertain benefit.

19.13.16 Exercise 15

Exercise Title: Perform Tensor Migration with Pinned CPU Buffers and Non-Blocking CUDA Transfers Without Breaking Correctness

Part 1 - Exercise Contract and Why It Matters

Implement H2D and D2H migrations that allow the CPU to continue while CUDA copies execute, yet never publish an incomplete destination or release a source too early. The result is a small transactional migration primitive.

Part 2 - System and Memory Mental Model

Pinned host memory permits DMA without first staging a pageable source. A non-blocking copy means submission can return before completion; authority does not transfer at that moment. The transaction retains source and destination, records a completion event on its transfer stream, and commits only after the event reports completion. D2H results are unreadable by the CPU before commit.

Part 3 - Quantitative Prediction Before Execution

Predict pinned allocation cost, CPU submission time, completed transfer time, and effective bandwidth. For M bytes, expected completed time is (L+M/B), while submission should be much smaller. Reuse buffers so the steady state excludes repeated pinned allocation overhead.

Part 4 - Experimental Design and Instrumentation

Test H2D and D2H independently over several sizes and dtypes. Verify a checksum only after commit. Include negative tests that mutate a pinned H2D source early or read a D2H destination early, but isolate them from production runs. Log transaction state, event readiness, source lifetime, and synchronized bandwidth.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass
import torch

@dataclass
class Migration:
    direction: str
    source: object
    destination: object
    stream: object
    completion: object
    state: str = "pending"

    def ready(self):
        return self.completion.query()

    def commit(self):
        self.completion.synchronize()
        self.state = "committed"
        return self.destination

class TensorMigrator:
    def __init__(self):
        self.stream = torch.cuda.Stream()

    def h2d(self, cpu_tensor):
        if not cpu_tensor.is_pinned():
            raise ValueError("H2D source must be pinned")
        with torch.cuda.stream(self.stream):
            destination = torch.empty_like(cpu_tensor, device="cuda")
            destination.copy_(cpu_tensor, non_blocking=True)
            completion = torch.cuda.Event()
            completion.record(self.stream)
        return Migration("h2d", cpu_tensor, destination,
                         self.stream, completion)

    def d2h(self, gpu_tensor):
        destination = torch.empty_like(
            gpu_tensor, device="cpu", pin_memory=True)
        with torch.cuda.stream(self.stream):
            destination.copy_(gpu_tensor, non_blocking=True)
            gpu_tensor.record_stream(self.stream)
            completion = torch.cuda.Event()
            completion.record(self.stream)
        return Migration("d2h", gpu_tensor, destination,
                         self.stream, completion)

def E15():
    if not torch.cuda.is_available():
```

```
        raise RuntimeError("CUDA is required")
    return TensorMigrator()
```

Part 6 - Measurement, Validation, and Failure Analysis

The transaction object itself preserves both buffers until commit. For H2D, a CUDA consumer must wait on the completion event and record its stream on the destination. For D2H, CPU code must call commit before reading. Pool pinned buffers in long-running systems because excessive page locking can harm host memory availability and allocation latency.

Part 7 - Engineering Interpretation and Philosophy

Asynchrony changes correctness from an immediate-value model into a happens- before model. The event is not merely a timing instrument; it is proof that a state transition may legally commit. Good asynchronous APIs make incomplete states visible and difficult to misuse.

19.13.17 Exercise 16

Exercise Title: Coordinate Dynamic Tensor Placement Across Multiple CUDA Streams and Protect In-Flight Tensor Storage from Premature Reuse

Part 1 - Exercise Contract and Why It Matters

Allow a tensor produced or migrated on one stream to be consumed by several other streams, then demote or release it only after all consumers finish. Avoid device-wide synchronization while preserving storage lifetime and ordering.

Part 2 - System and Memory Mental Model

Stream order is local. Operations on stream B do not automatically wait for a producer on stream A. A ready event publishes production completion. Each consumer waits on ready, records its own done event, and calls `record_stream()` so the caching allocator knows its storage is used on that side stream. Demotion waits on all done events before copying or releasing.

Part 3 - Quantitative Prediction Before Execution

Draw a dependency graph and count required edges: one ready event from producer to each consumer, then one completion dependency from every consumer to the demotion stream. Predict concurrency and critical path. A global synchronize adds dependencies to unrelated work and should be measurably slower.

Part 4 - Experimental Design and Instrumentation

Run two independent consumers after one H2D promotion. Compare global synchronization with event-only coordination. Use unequal kernel durations so a missing second completion wait becomes observable. Log streams, ready and done events, overlap, total completion time, and checksum. Stress allocator reuse by allocating a same-sized temporary immediately after release.

Part 5 - PyTorch/CUDA Implementation

```
import torch

class StreamSafeResident:
    def __init__(self, tensor, producer_stream):
        self.tensor = tensor
        self.ready = torch.cuda.Event()
        self.ready.record(producer_stream)
        self.consumer_events = []
        self.released = False

    def acquire(self, consumer_stream):
        if self.released:
            raise RuntimeError("resident storage already released")
        consumer_stream.wait_event(self.ready)
        self.tensor.record_stream(consumer_stream)
        return self.tensor

    def finish_consumer(self, consumer_stream):
        event = torch.cuda.Event()
        event.record(consumer_stream)
        self.consumer_events.append(event)

    def order_demotion(self, demotion_stream):
        for event in self.consumer_events:
            demotion_stream.wait_event(event)
        self.tensor.record_stream(demotion_stream)

    def release_after(self, demotion_stream):
        completion = torch.cuda.Event()
        completion.record(demotion_stream)
        completion.synchronize()
        self.tensor = None
        self.released = True

def E16(cpu_source):
    transfer = torch.cuda.Stream()
    with torch.cuda.stream(transfer):
        gpu = torch.empty_like(cpu_source, device="cuda")
        gpu.copy_(cpu_source, non_blocking=True)
        resident = StreamSafeResident(gpu, transfer)
    return resident
```

Part 6 - Measurement, Validation, and Failure Analysis

Calling `record_stream()` protects allocator reuse but does not create a data dependency; the explicit event wait is still required. Conversely, an event wait orders kernels but a placement manager that drops its last reference must still account for allocator lifetime. Register consumers before demotion selection so late acquisition cannot race with the release decision.

Part 7 - Engineering Interpretation and Philosophy

Multi-stream placement is resource ownership over a partial order. Launching a kernel is not evidence that its storage is free. The engine must know every outstanding reader or writer and express only the dependencies required for correctness. This preserves concurrency without gambling with memory.

19.13.18 Exercise 17

Exercise Title: Build a Memory-Budget Simulator That Predicts Tensor Residency Decisions Before Executing the Real CUDA Workload

Part 1 - Exercise Contract and Why It Matters

Build a deterministic, CUDA-free simulator that replays planned tensor accesses and predicts admissions, hits, evictions, traffic, and peak residency under a strict byte budget. Use it to reject impossible configurations before risking a real OOM.

Part 2 - System and Memory Mental Model

The simulator models policy-visible live tensors, not the entire CUDA allocator. Its budget therefore needs a safety reserve for CUDA context, workspaces, temporary activations, and non-managed allocations. Each access changes a logical state machine; transfers consume predicted time and bytes but allocate no real storage.

Part 3 - Quantitative Prediction Before Execution

For every trace step, predict used bytes before access, required admission bytes, victim bytes, used bytes after access, and transfer time. The core invariant is $0 \leq R_t \leq C_{managed}$. Estimate real peak as managed peak plus a separately measured unmanaged reserve and fragmentation margin.

Part 4 - Experimental Design and Instrumentation

Replay a captured real trace and a synthetic adversarial trace. Save every decision with a reason. Compare predicted H2D bytes, victim order, managed peak, and time against the real engine. Report residual error from overlap, allocator rounding, workspaces, and policy timing instead of forcing exact agreement.

Part 5 - PyTorch/CUDA Implementation

```
from collections import OrderedDict

class PlacementSimulator:
    def __init__(self, sizes, managed_budget, h2d_bytes_per_ms):
        self.sizes = sizes
        self.budget = managed_budget
        self.bandwidth = h2d_bytes_per_ms
        self.resident = OrderedDict()
        self.used = 0
        self.peak = 0
        self.h2d_bytes = 0
        self.events = []
```

```
    def access(self, step, key):
        if key in self.resident:
            self.resident.move_to_end(key)
            self.events.append((step, key, "hit", self.used))
            return
        needed = self.sizes[key]
        if needed > self.budget:
            raise RuntimeError("single tensor exceeds managed budget")
        while self.used + needed > self.budget:
            victim, unused = self.resident.popitem(last=False)
            self.used -= self.sizes[victim]
            self.events.append((step, victim, "evict", self.used))
        self.resident[key] = True
        self.used += needed
        self.h2d_bytes += needed
        self.peak = max(self.peak, self.used)
        self.events.append((step, key, "load", self.used))
        assert 0 <= self.used <= self.budget

    def report(self):
        return {
            "managed_peak_bytes": self.peak,
            "h2d_bytes": self.h2d_bytes,
            "predicted_h2d_ms": self.h2d_bytes / self.bandwidth,
            "events": self.events,
        }

def E17(sizes, trace, managed_budget, h2d_bytes_per_ms):
    simulator = PlacementSimulator(
        sizes, managed_budget, h2d_bytes_per_ms)
    for step, key in enumerate(trace):
        simulator.access(step, key)
    return simulator.report()
```

Part 6 - Measurement, Validation, and Failure Analysis

An LRU simulator is not a proof that the real allocator can satisfy a contiguous request. Add measured safety margins and validate near the boundary gradually. Do not confuse simulated tensor bytes with PyTorch reserved memory. A useful simulator is deliberately conservative and reports which unmodeled categories its reserve is intended to cover.

Part 7 - Engineering Interpretation and Philosophy

Simulation separates policy reasoning from hazardous execution. It gives the engine a chance to say “this plan cannot fit” before CUDA discovers that fact through failure. Prediction need not be perfect to be valuable; bounded and explainable error is enough to guide safe configuration.

19.13.19 Exercise 18

Exercise Title: Stress-Test the Placement Engine with Variable Tensor Sizes, Random Reuse Patterns, and Artificially Restricted VRAM

Part 1 - Exercise Contract and Why It Matters

Subject the engine to reproducible variable sizes, changing reuse distributions, dirty updates, protected intervals, and a managed budget far below physical VRAM. The test must discover invariant violations and performance collapse without intentionally destabilizing the whole device.

Part 2 - System and Memory Mental Model

Artificial restriction is safer and more repeatable than allocating until physical OOM. Variable sizes expose byte-accounting and fragmentation-sensitive choices; random reuse exposes stale prediction; dirty and in-flight states test correctness barriers. Stress is a distribution of cases, not one maximum tensor.

Part 3 - Quantitative Prediction Before Execution

Choose a seeded catalogue and compute whether every individual tensor fits the managed budget. Predict approximate working-set size, compulsory traffic, and pressure frequency. Define pass bounds before execution: zero wrong checksums, zero budget violations, bounded migration rate, and no unhandled allocation failure.

Part 4 - Experimental Design and Instrumentation

Run stable, bursty, alternating, and Zipf-like phases over multiple seeds. Keep sentinel values on authoritative copies and verify them after each completed migration. Record resident bytes, peak, admissions, demotions, dirty write-backs, rejected promotions, migrations per access, hit rate, latency percentiles, and policy decision time.

Part 5 - PyTorch/CUDA Implementation

```
import random
from collections import OrderedDict

class RestrictedBudgetStress:
    def __init__(self, sizes, budget_bytes):
        self.sizes = sizes
        self.budget = budget_bytes
        self.resident = OrderedDict()
        self.used = 0
        self.loads = 0
        self.evictions = 0

    def access(self, key):
        if key in self.resident:
            self.resident.move_to_end(key)
            return "hit"
        needed = self.sizes[key]
        if needed > self.budget:
```

```
            return "bypass_oversized"
        while self.used + needed > self.budget:
            victim, unused = self.resident.popitem(last=False)
            self.used -= self.sizes[victim]
            self.evictions += 1
        self.resident[key] = True
        self.used += needed
        self.loads += 1
        assert self.used <= self.budget
        return "load"

def E18(seed=17, tensor_count=100, steps=5000,
        budget_bytes=256 * 1024 * 1024):
    generator = random.Random(seed)
    sizes = {}
    for index in range(tensor_count):
        size_mib = generator.randint(1, 32)
        sizes[index] = size_mib * 1024 * 1024
    engine = RestrictedBudgetStress(sizes, budget_bytes)
    outcomes = {"hit": 0, "load": 0, "bypass_oversized": 0}
    for unused in range(steps):
        if generator.random() < 0.80:
            key = generator.randrange(max(1, tensor_count // 10))
        else:
            key = generator.randrange(tensor_count)
        outcome = engine.access(key)
        outcomes[outcome] += 1
    return outcomes, engine.loads, engine.evictions, engine.used
```

Part 6 - Measurement, Validation, and Failure Analysis

This first harness tests policy accounting; integrate real CUDA migration only after it passes. A fixed random seed is necessary but insufficient: preserve catalogue, trace, software versions, and hardware information. Minimize any failure trace to the shortest reproducible sequence, then inspect authority, events, and byte accounting at the first divergence.

Part 7 - Engineering Interpretation and Philosophy

Stress testing asks where assumptions cease to hold. Success is not surviving a large average workload; it is preserving invariants through rare combinations of pressure, timing, and reuse. Artificial budgets make those combinations repeatable and turn memory failure into a testable engineering object.

19.13.20 Exercise 19

Exercise Title: Build and Benchmark a PyTorch Dynamic Tensor Placement Engine That Maintains a Working Set Across RAM and VRAM Under a Strict Memory Budget

Part 1 - Exercise Contract and Why It Matters

Integrate accounting, policy, migration, events, authority, lifetime, and watermarks into one placement engine. The final system must keep a changing working set inside a hard managed-VRAM budget, preserve numerical correctness, and produce evidence explaining every promotion and demotion.

Part 2 - System and Memory Mental Model

Each logical tensor has one authoritative value and optional clean replicas. Its state may be CPU, H2D-pending, GPU, both-clean, GPU-dirty, D2H-pending, or released. Admission reserves bytes before CUDA allocation. Ready and consumer events define legality across streams. High/low watermarks provide headroom; reuse-cost scoring determines which legal tensor deserves residence.

Part 3 - Quantitative Prediction Before Execution

Set managed capacity below device free memory by explicit context, workspace, temporary, and fragmentation reserves. Predict peak managed bytes, transfer traffic, hit rate, critical-path transfer time, and decision overhead with the E17 simulator. State acceptance criteria: no budget violation, exact output parity, no use-before-ready, and better completed time than CPU-only or static placement on at least the workload class targeted by the policy.

Part 4 - Experimental Design and Instrumentation

Benchmark CPU-only, static-GPU, and dynamic variants on identical traces. Include stable locality, phase shifts, random reuse, and adversarial thrashing. Warm up, synchronize trial boundaries, repeat runs, and report medians and tails. Record state transitions, reasons, resident and pending bytes, allocated and reserved CUDA memory, H2D/D2H bytes, overlap, hits, evictions, policy time, and checksums.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field
from collections import OrderedDict
import torch

@dataclass
class TensorRecord:
    key: str
    cpu: object
    size_bytes: int
    gpu: object = None
    authority: str = "cpu"
    dirty: bool = False
    protected: set = field(default_factory=set)
    ready: object = None
    last_access: int = 0
    frequency: int = 0

class DynamicPlacementEngine:
    def __init__(self, budget_bytes, low_ratio=0.70,
                 high_ratio=0.85):
        self.budget = budget_bytes
```

```
        self.low = int(budget_bytes * low_ratio)

def E19(budget_bytes):
    if not torch.cuda.is_available():
        raise RuntimeError("CUDA is required")
    return DynamicPlacementEngine(budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

The compact reference engine uses blocking dirty demotion for an auditable baseline. A production version must register every consumer completion before demotion, use the E15 transaction for asynchronous write-back, count pending bytes, handle aliases by storage identity, and integrate autograd protection. Test admission rollback after allocation failure and never rely on `empty_cache()` as a substitute for live-tensor policy.

Part 7 - Engineering Interpretation and Philosophy

Dynamic placement is a small memory operating system inside the training or inference process. Its success comes from disciplined state, accounting, and ordering rather than clever eviction scores alone. The engine is trustworthy when it can defend three claims for every tensor: the newest value is known, all users are ordered, and the resource budget is never silently exceeded.

19.14 DMM12

Chapter Title: Dynamic Parameter Placement
Specialization: Dynamic Memory Management and CUDA Systems

19.14.1 Exercise 00

Exercise Title: Build a Precise Mental Model of Parameter Residency, Module Ownership, and Weight Movement Between CPU RAM and GPU VRAM

Part 1 - Exercise Contract and Why It Matters

Build a state model for parameters before writing an offloading engine. A parameter is not merely a tensor containing numbers: it is a registered member of an `nn.Module`, can be referenced by an optimizer, may be shared by several layers, and participates in autograd. The model must explain where the authoritative weight resides and who is allowed to move it.

The final contract must answer seven questions at every execution point: which logical parameter is being discussed, which module names refer to it, which storage contains the newest value, whether a CUDA copy is ready, which stream is still using it, whether a gradient exists, and what transition may happen next.

Part 2 - System and Memory Mental Model

Separate parameter identity from parameter storage. The Python `Parameter` object is what modules and optimizers reference; its data storage may change tiers. A single object may have multiple qualified names when weights are tied. A parameter can be CPU-only, H2D-pending, GPU-ready, GPU-dirty, D2H-pending, both-clean, protected-by-autograd, or released.

Module ownership is hierarchical rather than exclusive. A fully qualified parameter name identifies a path through a model, not necessarily a unique allocation. Buffers, optimizer states, gradients, and activations are separate memory categories and must not be hidden inside the parameter total. During training, moving a leaf parameter after forward can invalidate the graph expected by backward.

Part 3 - Quantitative Prediction Before Execution

For a dense parameter with shape dimensions d_i and element size s, predict bytes as $M = s \prod_i d_i$. Calculate logical bytes by name and unique bytes by parameter identity so tied weights are not counted twice. A promotion temporarily requires CPU source bytes, CUDA destination bytes, and possibly pinned staging bytes.

Estimate one reload as $T_{H2D} = L + M/B$. Keeping a group resident is rational when expected avoided reload time exceeds its VRAM opportunity cost and the group fits after workspace and activation reserves.

Part 4 - Experimental Design and Instrumentation

Create a model containing ordinary parameters, a tied embedding/output weight, a registered buffer, and frozen weights. Record every qualified name, object identity, storage identity, device, bytes, owner layer, gradient state, authority, pending event, and protected reason. Exercise clean promotion, layer execution, dirty training update, write-back, and a deliberately illegal demotion before backward.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class ParameterState:
    canonical_name: str
    owner_names: list
    size_bytes: int
    authority: str = "cpu"
    cpu_present: bool = True
    gpu_present: bool = False
    transfer_pending: bool = False
    dirty: bool = False
    protected_reasons: set = field(default_factory=set)

    def begin_h2d(self):
        if not self.cpu_present:
            raise RuntimeError("no CPU source for promotion")
        if self.transfer_pending:
            raise RuntimeError("another migration is already pending")
        self.transfer_pending = True

    def commit_h2d(self):
        if not self.transfer_pending:
            raise RuntimeError("no H2D migration to commit")
        self.gpu_present = True
        self.transfer_pending = False
        self.authority = "both_clean"

    def mark_gpu_updated(self):
        if not self.gpu_present:
            raise RuntimeError("GPU copy does not exist")
        self.authority = "gpu"
        self.dirty = True

def E00(name, owner_names, shape, element_size):
    elements = 1
    for dimension in shape:
        elements *= dimension
    return ParameterState(name, owner_names,
                          elements * element_size)
```

Part 6 - Measurement, Validation, and Failure Analysis

A device label cannot prove authority, readiness, or uniqueness. Calling `module.to()` replaces the placement of parameters and buffers together, while an optimizer may still own state tensors whose devices now disagree. Views and tied parameters make name-based byte sums incorrect. Validate object identity, unique storage, numerical checksums, and event completion after every transition.

Part 7 - Engineering Interpretation and Philosophy

Dynamic parameter placement is distributed ownership inside one Python process. The difficult problem is not copying bytes; it is preserving meaning while storage moves. A trustworthy engine can defend who owns the newest value, why a copy is safe to use, and why no future computation still needs the old tier.

19.14.2 Exercise 01

Exercise Title: Inspect Every PyTorch Parameter by Name, Shape, Dtype, Device, Element Count, and Memory Footprint

Part 1 - Exercise Contract and Why It Matters

Produce a complete parameter inventory that is safe to retain as telemetry. The report must reveal qualified names, tensor facts, trainability, aliases, and both logical and unique physical bytes without storing live Parameter objects.

Part 2 - System and Memory Mental Model

`named_parameters()` normally removes duplicate objects, which is useful for optimization but can hide tied ownership paths. Request duplicates when the installed PyTorch version supports it, then group names by object identity. Logical bytes equal element count times element size; unique bytes must be counted once per storage or parameter identity.

Part 3 - Quantitative Prediction Before Execution

Predict totals per dtype, device, and trainability class before running the inspector. For tied weights, predict that the by-name logical sum exceeds the unique sum. Compare parameter bytes with CUDA `memory_allocated()` only after separating buffers, gradients, context, and unrelated allocations.

Part 4 - Experimental Design and Instrumentation

Inspect a model before CUDA movement, after partial movement, and after gradient creation. Include frozen parameters and a tied weight. Save only strings, integers, booleans, shapes, and identities. Assert that every reported byte count is non-negative and that every object identity maps to a consistent shape and dtype.

Part 5 - PyTorch/CUDA Implementation

```
from collections import defaultdict

def parameter_rows(model):
    rows = []
    owners = defaultdict(list)
    iterator = model.named_parameters(remove_duplicate=False)
    for name, parameter in iterator:
        parameter_id = id(parameter)
        owners[parameter_id].append(name)
        row = {
            "name": name,
            "parameter_id": parameter_id,
```

```
            "shape": tuple(parameter.shape),
            "dtype": str(parameter.dtype),
            "device": str(parameter.device),
            "elements": parameter.numel(),
            "element_size": parameter.element_size(),
            "logical_bytes": parameter.numel()
            * parameter.element_size(),
            "requires_grad": parameter.requires_grad,
            "gradient_present": parameter.grad is not None,
        }
        rows.append(row)
    return rows, owners

def E01(model):
    rows, owners = parameter_rows(model)
    unique_bytes = {}
    logical_bytes_by_name = 0
    for row in rows:
        logical_bytes_by_name += row["logical_bytes"]
        parameter_id = row["parameter_id"]
        if parameter_id not in unique_bytes:
            unique_bytes[parameter_id] = row["logical_bytes"]
        row["owner_names"] = tuple(owners[parameter_id])
    unique_parameter_bytes = 0
    for size_bytes in unique_bytes.values():
        unique_parameter_bytes += size_bytes
    return {
        "parameters": rows,
        "logical_bytes_by_name": logical_bytes_by_name,
        "unique_parameter_bytes": unique_parameter_bytes,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Parameter identity detects ordinary tying, while unusual shared-storage views may require storage-pointer grouping. Quantized, sparse, meta, and sharded parameters need special accounting and should be marked rather than misreported. The explicit loops make every contribution to both totals visible.

Part 7 - Engineering Interpretation and Philosophy

An inventory is the accounting ledger from which placement policy borrows truth. If ownership or bytes are wrong at this stage, every later budget, eviction, and performance conclusion becomes numerically polished fiction.

19.14.3 Exercise 02

Exercise Title: Calculate the Exact VRAM Required by Model Parameters Before Moving the Model to CUDA

Part 1 - Exercise Contract and Why It Matters

Calculate parameter-only CUDA bytes before any model movement and distinguish that exact tensor payload from the larger amount a real process will consume. The estimator must handle tied parameters and mixed dtypes without guessing.

Part 2 - System and Memory Mental Model

Dense parameter payload is deterministic from shape and dtype. CUDA allocator rounding, module buffers, gradients, optimizer state, activations, workspaces, and context memory are additional categories. A training budget that includes only weights can be exact about the wrong scope and still OOM immediately.

Part 3 - Quantitative Prediction Before Execution

Compute

$$M_{parameters} = \sum_{p \in U} \text{numel}(p)\,\text{element_size}(p),$$

where U is the set of unique Parameter objects. Produce per-dtype and per-layer subtotals. For inference, add buffers and measured workspace reserve; for training, separately estimate gradients and optimizer states.

Part 4 - Experimental Design and Instrumentation

Reset CUDA peak statistics in a clean process, record the baseline after CUDA initialization, move the model, synchronize, and measure the delta. Compare the prediction with observed allocated and reserved bytes. Repeat for float32, float16, and a mixed-dtype model while keeping architecture constant.

Part 5 - PyTorch/CUDA Implementation

```
from collections import defaultdict

def exact_unique_parameter_bytes(model):
    seen = set()
    total_bytes = 0
    by_dtype = defaultdict(int)
    by_top_level_module = defaultdict(int)

    for name, parameter in model.named_parameters(
            remove_duplicate=False):
        parameter_id = id(parameter)
        if parameter_id in seen:
            continue
        seen.add(parameter_id)
        size_bytes = parameter.numel() * parameter.element_size()
        total_bytes += size_bytes
        by_dtype[str(parameter.dtype)] += size_bytes
        owner = name.split(".")[0]
        by_top_level_module[owner] += size_bytes

    return total_bytes, dict(by_dtype), dict(by_top_level_module)
```

```
def E02(model):
    total, by_dtype, by_module = exact_unique_parameter_bytes(model)
    return {
        "exact_parameter_bytes": total,
        "parameter_MiB": total / (1024.0 ** 2),
        "by_dtype": by_dtype,
        "by_top_level_module": by_module,
    }
```

Part 6 - Measurement, Validation, and Failure Analysis

Observed allocated memory can exceed the exact payload because CUDA allocations are rounded and the process already owns other tensors. Reserved memory is not parameter size. Conversely, a meta-device model has shapes but no materialized storage. State exactly which categories the estimate includes and never market parameter-only bytes as total training VRAM.

Part 7 - Engineering Interpretation and Philosophy

Exactness requires a boundary. This exercise teaches the useful discipline of saying "exact parameter payload" instead of "exact model memory." Honest scope makes estimates composable: weights, gradients, states, activations, and workspaces can later be added without double counting.

19.14.4 Exercise 03

Exercise Title: Move Selected Parameters Between CPU and GPU Without Moving the Entire nn.Module

Part 1 - Exercise Contract and Why It Matters

Move an explicit set of registered parameters while preserving their Parameter object identities and leaving unrelated weights untouched. Restrict the first implementation to inference or to movement before a training graph is built.

Part 2 - System and Memory Mental Model

`module.to()` recursively moves parameters and buffers, which is too broad for a placement engine. Replacing a Parameter object can break optimizer and shared-weight references. Changing its underlying data preserves the object but still changes device storage, so gradients and optimizer state require separate coordination.

Part 3 - Quantitative Prediction Before Execution

Before moving, predict selected unique bytes, H2D or D2H traffic, and peak bytes during the copy. Same-device selections should produce zero traffic. If two names identify the same Parameter, perform one physical movement and record both owners as satisfied.

Part 4 - Experimental Design and Instrumentation

Capture object IDs and checksums before movement. Move one layer, verify all other devices, execute a compatible computation, then move it back. Test tied weights and reject

movement while a protected autograd graph exists. Log reason, source, target, bytes, copied identities, and completion time.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def selected_parameter_objects(model, selected_names):
    selected_by_id = {}
    matched_names = set()
    for name, parameter in model.named_parameters(
            remove_duplicate=False):
        if name not in selected_names:
            continue
        matched_names.add(name)
        parameter_id = id(parameter)
        if parameter_id not in selected_by_id:
            selected_by_id[parameter_id] = (name, parameter)
    missing = set(selected_names)
    for name in matched_names:
        missing.discard(name)
    if missing:
        raise KeyError("unknown parameter names: " + str(sorted(missing)))
    selected = []
    for entry in selected_by_id.values():
        selected.append(entry)
    return selected

def move_selected_parameters(model, selected_names, target):
    moved = []
    selected = selected_parameter_objects(model, selected_names)
    with torch.no_grad():
        for name, parameter in selected:
            source = str(parameter.device)
            if source == str(torch.device(target)):
                moved.append((name, source, source, 0))
                continue
            bytes_moved = parameter.numel() * parameter.element_size()
            parameter.data = parameter.data.to(target)
            if parameter.grad is not None:
                parameter.grad = parameter.grad.to(target)
            moved.append((name, source, str(parameter.device),
                          bytes_moved))
    return moved

def E03(model, selected_names, target="cuda:0"):
    return move_selected_parameters(model, selected_names, target)
```

Part 6 - Measurement, Validation, and Failure Analysis

This explicit mutation is suitable for controlled education and inference, not for moving a leaf parameter between forward and backward. Optimizer state is not moved by this function and can later cause device mismatch. The missing-name check sees only one owner for tied parameters after deduplication, so a production registry should resolve every alias name to a canonical identity.

Part 7 - Engineering Interpretation and Philosophy

Selective movement reveals why dynamic placement is a systems feature rather than a convenience call. Preserving object identity protects ownership, but correct execution also requires coordination with gradients, optimizer state, buffers, inputs, and the lifetime of every graph that used the old storage.

19.14.5 Exercise 04

Exercise Title: Build a Parameter Registry That Tracks Device, Size, Layer Ownership, Access Count, and Last GPU Use

Part 1 - Exercise Contract and Why It Matters

Create the metadata control plane for dynamic placement. The registry must map every qualified name to one canonical parameter record, track scalar usage history, and avoid keeping accidental tensor or autograd references in logs.

Part 2 - System and Memory Mental Model

Names describe ownership paths; canonical identity describes the movable resource. One record can therefore contain several owner names. Current device is observable, while authority, pending migration, protection, and final GPU use are placement-engine states. Access count measures the past and is only a forecast of future reuse.

Part 3 - Quantitative Prediction Before Execution

Predict record count, alias count, total unique bytes, and per-layer ownership bytes. After replaying an access trace, predict access count, last-use step, reuse distance, and candidate hotness. Define whether a layer access increments all its parameters once or each actual low-level read.

Part 4 - Experimental Design and Instrumentation

Register a tied-weight model and assert that multiple names resolve to one canonical ID. Replay stable, bursty, and phase-changing layer traces. Log only scalar metadata and bounded event references needed for correctness. Verify that deleting the model is not prevented by the telemetry export.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass, field

@dataclass
class ParameterRecord:
    canonical_id: int
    owner_names: list
    shape: tuple
```

```
    dtype: str
    device: str
    size_bytes: int
    access_count: int = 0
    last_gpu_use: int = -1
    protected_reasons: set = field(default_factory=set)

class ParameterRegistry:
    def __init__(self, model):
        self.records = {}
        self.name_to_id = {}
        for name, parameter in model.named_parameters(
                remove_duplicate=False):
            canonical_id = id(parameter)
            self.name_to_id[name] = canonical_id
            if canonical_id not in self.records:
                self.records[canonical_id] = ParameterRecord(
                    canonical_id=canonical_id,
                    owner_names=[],
                    shape=tuple(parameter.shape),
                    dtype=str(parameter.dtype),
                    device=str(parameter.device),
                    size_bytes=parameter.numel()
                    * parameter.element_size(),
                )
            self.records[canonical_id].owner_names.append(name)

    def record_gpu_use(self, name, step):
        canonical_id = self.name_to_id[name]
        record = self.records[canonical_id]
        record.access_count += 1
        record.last_gpu_use = step

def E04(model):
    return ParameterRegistry(model)
```

Part 6 - Measurement, Validation, and Failure Analysis

The registry stores object IDs but not objects, so an ID could eventually be reused after model destruction. Scope the registry to one model lifetime. Refresh device state only at controlled transitions rather than trusting stale metadata. Tied parameters require one migration, whereas two independent parameters with equal values remain two resources.

Part 7 - Engineering Interpretation and Philosophy

A placement engine needs a stable vocabulary for discussing resources. The registry turns a changing module hierarchy into accountable identities and histories. Policy may be probabilistic, but identity and byte accounting cannot be.

19.14.6 Exercise 05

Exercise Title: Implement a Static Per-Layer Parameter Placement Map and Verify Forward Execution Across CPU and GPU Boundaries

Part 1 - Exercise Contract and Why It Matters

Assign every layer in a sequential model to an explicit device before inference, then move activations only at declared boundaries. The result is a reproducible baseline for later dynamic policies and a direct demonstration that parameter placement constrains activation placement.

Part 2 - System and Memory Mental Model

A PyTorch operator normally requires input, parameter, and relevant buffer to share a device. A static map such as layer 0 on CPU and layers 1–3 on CUDA therefore creates an activation transfer between layers 0 and 1. Consecutive layers on the same tier form a stage and avoid intermediate transfers.

Part 3 - Quantitative Prediction Before Execution

Sum unique parameter bytes per device. For every adjacent pair whose assigned devices differ, predict one activation transfer of N element_size bytes. Parameter fit alone is insufficient; reserve VRAM for the largest live activation and temporary kernel workspace.

Part 4 - Experimental Design and Instrumentation

Use one all-CPU map, one all-CUDA map, and at least two split points. Record parameter bytes, activation boundary bytes, device before each layer, transfer time, layer time, output checksum, and synchronized end-to-end latency. Compare all outputs against the all-CPU reference within dtype-appropriate tolerance.

Part 5 - PyTorch/CUDA Implementation

```
import torch

def apply_static_layer_map(layers, placement_map):
    for index, layer in enumerate(layers):
        if index not in placement_map:
            raise KeyError("missing device for layer " + str(index))
        layer.to(placement_map[index])

def execute_with_layer_map(layers, placement_map, inputs):
    activation = inputs
    trace = []
    for index, layer in enumerate(layers):
        target = torch.device(placement_map[index])
        source = activation.device
        copied = source != target
        if copied:
            activation = activation.to(target)
        activation = layer(activation)
        trace.append({
            "layer": index,
```

```
            "input_source": str(source),
            "execution_device": str(target),
            "activation_shape": tuple(activation.shape),
            "boundary_copy": copied,
        })
    return activation, trace

def E05(layers, placement_map, inputs):
    apply_static_layer_map(layers, placement_map)
    return execute_with_layer_map(layers, placement_map, inputs)
```

Part 6 - Measurement, Validation, and Failure Analysis

Moving only parameters while leaving BatchNorm buffers behind creates a hidden device mismatch; the static baseline moves each complete layer. Non-sequential models require a graph schedule rather than a simple loop. Synchronize trial boundaries because CUDA layer calls are asynchronous, and do not compare a CPU float32 output with an implicitly changed CUDA dtype.

Part 7 - Engineering Interpretation and Philosophy

Placement partitions an execution graph. A map that fits weights but causes an activation to cross the bus repeatedly can be slower than CPU execution. Good partitioning respects both state residency and the dataflow edges connecting stages.

19.14.7 Exercise 06

Exercise Title: Compare Whole-Model CUDA Residency Against Partial Parameter Residency Under the Same Inference Workload

Part 1 - Exercise Contract and Why It Matters

Benchmark two semantically identical inference systems: one with the entire model resident on CUDA and another with only selected layers resident. Measure the memory saved and the latency paid under the same requests and precision.

Part 2 - System and Memory Mental Model

Whole-model residency pays one initial weight transfer and maximizes reuse, but requires enough VRAM for every weight plus inference working memory. Partial residency lowers persistent parameter bytes while introducing parameter or activation transfers. Initial-load latency and steady-state latency are distinct deployment questions and must both be reported.

Part 3 - Quantitative Prediction Before Execution

Predict resident parameter bytes, boundary bytes per request, initial H2D bytes, and steady-state transfers for both variants. If R requests reuse the model, amortize initial load as T_{load}/R. State the expected break-even request count at which full residency repays its larger initial placement.

Part 4 - Experimental Design and Instrumentation

Clone one initialized model so weights are identical. Warm up kernels, reset peak statistics, and run fixed inputs in the same order. Measure cold start, median and tail request latency,

throughput, peak allocated VRAM, resident parameter bytes, H2D/D2H traffic, and output parity. Include batch-size sweeps.

Part 5 - PyTorch/CUDA Implementation

```
import copy
import time
import torch

def synchronized_inference(run_once, repetitions):
    if torch.cuda.is_available():
        torch.cuda.synchronize()
    started = time.perf_counter()
    output = None
    for unused in range(repetitions):
        output = run_once()
    if torch.cuda.is_available():
        torch.cuda.synchronize()
    elapsed = time.perf_counter() - started
    return output, elapsed

def E06(model, layers, placement_map, inputs, repetitions=20):
    full_model = copy.deepcopy(model).eval().to("cuda:0")
    partial_layers = copy.deepcopy(layers).eval()
    apply_static_layer_map(partial_layers, placement_map)

    def run_full_model():
        cuda_inputs = inputs.to("cuda:0")
        return full_model(cuda_inputs)

    def run_partial_model():
        output, unused_trace = execute_with_layer_map(
            partial_layers, placement_map, inputs)
        return output

    with torch.inference_mode():
        full_output, full_seconds = synchronized_inference(
            run_full_model, repetitions)
        partial_output, partial_seconds = synchronized_inference(
            run_partial_model, repetitions)
    comparison = torch.allclose(
        full_output.cpu(), partial_output.cpu(),
        rtol=1.0e-4, atol=1.0e-5)
    return full_seconds, partial_seconds, comparison
```

Part 6 - Measurement, Validation, and Failure Analysis

The helper functions from E05 must be available when this file is executed. Deep-copying a model requires enough host memory and may not preserve every custom external reference.

Measure each variant in a fresh process for the cleanest peak comparison. A partial model that accidentally recomputes or changes evaluation mode is not a placement comparison.

Part 7 - Engineering Interpretation and Philosophy

Memory optimization is a trade of space for movement and coordination. Partial residency is valuable when full residency is impossible or when VRAM has a more valuable competing use. When everything fits comfortably, deliberate movement must justify why it is better than simplicity.

19.14.8 Exercise 07

Exercise Title: Build a Size-Aware Parameter Placement Policy That Fits the Largest Useful Weight Set Inside a Fixed VRAM Budget

Part 1 - Exercise Contract and Why It Matters

Select a useful subset of parameter groups without exceeding a strict byte budget. Do not maximize bytes occupied; maximize declared utility subject to capacity, alias, protection, and indivisible-group constraints.

Part 2 - System and Memory Mental Model

Parameters should be grouped by the atomic unit required by execution, often a layer's weight and bias plus device buffers. Size is the cost, while usefulness can represent expected reuse, avoided transfer stall, or criticality. Shared parameters appear once even when several groups request them.

Part 3 - Quantitative Prediction Before Execution

This is a budgeted selection problem. A greedy benefit-per-byte ranking is interpretable but not always globally optimal. Predict selected groups, unique resident bytes, unused budget, and rejected utility. Compare greedy results with an exact small knapsack instance to expose the approximation.

Part 4 - Experimental Design and Instrumentation

Test equal-size, highly variable-size, shared-weight, and adversarial catalogues. Sweep budget from one group to full residency. Log group bytes, utility, density, aliases, selection order, cumulative unique bytes, and realized runtime benefit. Assert the budget after every admission.

Part 5 - PyTorch/CUDA Implementation

```
from dataclasses import dataclass

@dataclass
class ParameterGroupCandidate:
    name: str
    parameter_ids: tuple
    size_by_parameter: dict
    utility: float

def select_size_aware_groups(candidates, budget_bytes):
    ranked = []
```

```
    for candidate in candidates:
        group_bytes = 0
        for parameter_id in candidate.parameter_ids:
            group_bytes += candidate.size_by_parameter[parameter_id]
        density = candidate.utility / max(1, group_bytes)
        ranked.append((density, candidate))
    def density_value(item):
        return item[0]

    ranked.sort(key=density_value, reverse=True)

    selected = []
    resident_ids = set()
    used_bytes = 0
    for density, candidate in ranked:
        incremental_bytes = 0
        for parameter_id in candidate.parameter_ids:
            if parameter_id not in resident_ids:
                incremental_bytes += candidate.size_by_parameter[parameter_id]
        if used_bytes + incremental_bytes > budget_bytes:
            continue
        selected.append((candidate.name, density, incremental_bytes))
        used_bytes += incremental_bytes
        for parameter_id in candidate.parameter_ids:
            resident_ids.add(parameter_id)
        assert used_bytes <= budget_bytes
    return selected, used_bytes, resident_ids

def E07(candidates, budget_bytes):
    return select_size_aware_groups(candidates, budget_bytes)
```

Part 6 - Measurement, Validation, and Failure Analysis

Utility must be measured in a meaningful common unit. A density policy can fill VRAM with many small marginal groups while excluding one large critical group. Incremental bytes correctly account for sharing, but it also means group order changes cost. Reserve space for activations and pending transfers outside the parameter budget.

Part 7 - Engineering Interpretation and Philosophy

Capacity is not a target to fill; it is a constraint beneath a workload goal. The best resident set is the one that removes the most important bottleneck, not necessarily the set that leaves the fewest unused bytes.

19.14.9 Exercise 08

Exercise Title: Build a Reuse-Aware Placement Policy That Keeps Frequently Reused Parameters Resident on the GPU

Part 1 - Exercise Contract and Why It Matters

Track layer accesses and keep parameter groups resident when their predicted future reuse can repay promotion. Adapt to phase changes without allowing old popularity to occupy VRAM forever.

Part 2 - System and Memory Mental Model

Parameters in ordinary feed-forward inference are often used once per request but reused across requests. Recurrence, weight tying, mixture-of-experts routing, and iterative decoding create different reuse patterns. Frequency, recency, and reuse distance describe distinct aspects of this demand.

Part 3 - Quantitative Prediction Before Execution

Maintain a decayed score $S_t = \alpha S_{t-1} + 1$ on access and decay absent groups by phase. Promote only when expected avoided reloads times measured reload cost exceed admission and possible victim costs. Predict useful hits after each promotion and wasted bytes for promotions never reused.

Part 4 - Experimental Design and Instrumentation

Replay stable-hot, one-time burst, alternating-expert, and phase-shift traces. Compare cumulative count, sliding window, and exponential decay. Log score, last use, promotion threshold crossing, residence time, hits after promotion, eviction, transfer bytes, and regret against a future-aware oracle.

Part 5 - PyTorch/CUDA Implementation

```
class ReuseAwareParameterPolicy:
    def __init__(self, promote_score=3.0, demote_score=0.8,
                 decay=0.90):
        if demote_score >= promote_score:
            raise ValueError("demotion threshold must be lower")
        self.promote_score = promote_score
        self.demote_score = demote_score
        self.decay = decay
        self.scores = {}
        self.last_access = {}
        self.step = 0

    def begin_step(self):
        self.step += 1
        keys = list(self.scores.keys())
        for key in keys:
            self.scores[key] *= self.decay

    def observe(self, group_name):
        old_score = self.scores.get(group_name, 0.0)
        self.scores[group_name] = old_score + 1.0
        self.last_access[group_name] = self.step

    def action(self, group_name, currently_resident):
        score = self.scores.get(group_name, 0.0)
```

```
        if not currently_resident and score >= self.promote_score:
            return "promote", score
        if currently_resident and score <= self.demote_score:
            return "demote", score
        return "keep_state", score

```

Part 6 - Measurement, Validation, and Failure Analysis

Thresholds decide preference, not legality; hard fit and in-flight protection still apply. Decaying every registered group each step can be expensive for huge models, so production systems can compute lazy decay from timestamps. Evaluate whether delayed promotion misses the first expensive uses and whether slow decay causes phase-change thrashing.

Part 7 - Engineering Interpretation and Philosophy
